I Foreword and Preface

Foreword

Energy is central to addressing major challenges of the 21st Century, challenges like climate change, economic and social development, human well-being, sustainable development, and global security. In 2005, Prof. Bert Bolin, the founding Chair of the Intergovernmental Panel on Climate Change (IPCC), with other eminent scientists and policy-makers, identified that a comprehensive, science-based assessment of the global energy system was needed if these challenges were to be realistically addressed. The Global Energy Assessment (GEA) is the result of this shared vision.

Since the establishment of the GEA in 2006 by governing Council of the International Institute for Applied Systems Analysis (IIASA), 500 independent experts (about 300 authors and 200 anonymous reviewers) from academia, business, government, intergovernmental and non-governmental organizations from all the regions of the world have contributed to GEA in a process similar to that adopted by the IPCC.

The final GEA report examines: (a) the major global challenges and their linkages to energy; (b) the technologies and resources available for providing adequate, modern and affordable forms of energy; (c) the plausible structure of future energy systems most suited to addressing the century's challenges; and (d) the policies and measures, institutions and capacities needed to realize sustainable energy futures.

Undertaking such a massive assessment has required extraordinary leadership, intellectual input, support and coordination. Governance of the Assessment has been overseen by the GEA Council, led by two Co-Presidents, Ged Davis and José Goldemberg and comprising members of supporters and sponsors of the GEA, including international organizations, government agencies, corporations, and foundations and non-governmental organizations. Convening Lead Authors (CLAs) coordinated the 25 Chapters and the contributions of Lead and Contributing Authors. The GEA Executive Committee, led by two Co-Chairs, Thomas B. Johansson and Anand Patwardhan includes all CLAs. Review Editors were appointed by the GEA Council for each Chapter. They in turn appointed anonymous reviewers and guided the rigorous peer-review process.

Completion of GEA has involved dedication and sustained contributions from many colleagues around the world. Our thanks and gratitude go to: Leen Hordijk, the IIASA Director who initiated GEA at IIASA; Sten Nilsson, IIASA Acting Director and Deputy Director; and Detlof von Winterfeldt, the IIASA Director who provided personal and institutional support throughout. The resources and the encouragement they provided helped make GEA a reality. The GEA Organizing Committee and the GEA Council provided wise counsel and guidance throughout. Additionally the GEA Council solicited financial and in-kind resources without which GEA would not have been possible.

We are especially grateful for the contribution and support of the GEA Council, the Executive Committee, the Organizing Committee, the Secretariat, as well as the IIASA Council and management. As host organization for the GEA Secretariat, IIASA has provided substantial in-kind support to GEA over the past seven years.

The Co-Chairs Thomas B. Johansson and Anand Patwardhan of the GEA Executive Committee and the Associate Director, Luis Gomez-Echeverri, coordinated the work of multiple authors and provided intellectual leadership, the vision needed to conduct an assessment of this magnitude, and guidance consistent with the GEA Council resolutions.

It is a pleasure to acknowledge the contribution of the team of editors, Geoff Clarke, Esther Eidinow, Valerie Jones, Susan Guthridge-Gould, Karen Holmes, Gail Karlsson, Wendy Knerr, John Ormiston, Emily Schabacker, Misti Snow, Mark F. Speer, Jon Stacy, Linda Starke, Julia Stewart, Lloyd Timberlake, Michael Treadway, Thomas Woodhatch who patiently edited GEA manuscripts. Thanks to IIASA colleagues who worked with the GEA Secretariat – including Colin Adair, Brigitte Adamik, Marilyn Bernardo, Anita Brachtl, Claire Capate, Elisabeth Clemens, Katalin David, Susanne Deimbacher, Sanja Drinkovic, Linda Foith, Walter Foith, Amy Fox, Bill Godwin-Toby, Amnah Kasman, Martin Gugumuck, Margit Hegenbart, Anka James, Shari Jandl, Elizabeth Lewis, Monica Manchanda, Eri Nagai, Olivia Nilsson, Patrick Nussbaumer,

Sheila Poor, Leane Regan, Susan Riley, Michaela Rossini, Iain Stewart, Ingrid Teply-Baubinder, Mirjana Tomic, and Alicia Versteegh.

Finally we express our sincere gratitude to the GEA authors, whose knowledge and experience has made possible this unique and valuable volume. Behind these people are families who have generously foregone time such that GEA could be completed, we thank them also.

The publication of GEA in June 2012 and the importance of energy at Rio+20 is no coincidence. The UN General Assembly declared 2012 the year of "Sustainable Energy for All" and the UN Secretary General's office initiated a campaign for an Action Agenda to meet the world's energy challenges. The GEA shows that an energy transformation toward a sustainable future is possible with strong political commitment. It is our belief that this assessment will provide policy- and decision-makers around the world, with invaluable new knowledge to inform action and commitment towards achieving these goals and thereby resolving the 21st Century's greatest challenges.

Pavel Kabat
IIASA Director/CEO

Nebojsa Nakicenovic
GEA Director

Preface

Today the world of energy has many of the features established in the 20th century:

- Energy consumption grows on average at 2% per year, most of it (80%) originates in fossil fuels
- Energy growth is driven by population growth and economic growth, now predominantly in developing countries and high levels of consumption in the developed countries
- 3 billion people don't have access to basic energy services and have to cook with solid fuels

However, the present path of uninterrupted reliance on fossil fuels poses four challenges to sustainability:

- Soaring greenhouse gas emissions
- Decreasing energy security
- Air pollution at the local and regional levels with resulting health problems
- Lack of universal access to energy services

Most reviews of the energy system needed for the 21st century start with "business as usual" futures and then analyze the effectiveness of specific corrections of course. For many the preferred options are technological fixes such as such as carbon capture and storage (CCS), nuclear energy and even geo-engineering schemes. However, to achieve sustainable development all the needed attributes of energy services, that is availability, affordability, access, security, health, climate and environmental protection, must be met concurrently. The Global Energy Assessment (GEA) accepts this and is unashamedly normative, examining future energy pathways that point to new solutions. The aspirational goals in GEA are defined as:

- Stabilizing global climate change to 2°C above pre-industrial levels to be achieved in the 21st century
- Enhanced energy security by diversification and resilience of energy supply (particularly the dependence on imported oil),
- Eliminating household and ambient air pollution, and
- Universal access to modern energy services by 2030.

GEA's approach is the one adopted by policy planners and governments, that is to take a holistic view of the problems they faced, of which energy supply is only one of them. In such an approach externalities play a big role in determining choice among options. This is what governments do all the time, and is exemplified by the current debates on the future of nuclear energy, shale gas, the building of big dams or a large expansion of biofuels production. None of the preferred options can be established without an understanding of the wider policy agenda. For example, integrated urban planning leads to lower costs than a combination of non-integrated policies in building efficiency, compact layout and decentralized energy production.

The main purpose of GEA has been to establish a state-of-the-art assessment of the science of energy. This work examines not only the major challenges that all face in the 21st Century, and the importance of energy to each, but also the resources that we have available and the various technological options, the integrated nature of the energy system and the various enablers needed, such as policies and capacity development. Central to the integrated analysis

of the energy system has been a novel scenario exercise exploring some 40 pathways that satisfy simultaneously the normative social and environmental goals outlined above.

Without question a radical transformation of the present energy system will be required over the coming decades. Common to all pathways will be very strong efforts in energy efficiency improvement for buildings, industry and transportation, offering much-needed flexibility to the energy supply system. But in implementing efficiency options there will be a need to avoid continued lock-in to inefficient energy demand patterns and obsolescent technologies. we will see an increased share of renewables (biomass, hydro, wind, solar and geothermal), which could represent by 2050 over a half of the global energy supply. The foundation is being put in place. For example, half the world's new electric generating capacity added during 2008–10 was renewable, the majority in developing countries. Global 2010 renewable capacity, with additions of ~66 GW, is larger than nuclear power's global installed capacity. In the European Union electric capacity additions have been over 40% renewables in each year between 2006 and 2010, and in Denmark 30% of the electricity produced in 2010 was renewable. Even though China is still building coal plants, its 2010 net capacity additions were 38% renewables.

This will come at a cost, increasing the 2% of global GDP investment currently spent in the energy sector, especially in the next 20 years. However, this should not constrain the drive for universal access, which could be achieved by 2030 for as little as $40 billion per year, less than 3% of overall yearly investment. This would build on successful programs for energy access in a number of developing countries, such as Brazil, Mexico and South Africa. And results have been dramatic. In Brazil, during the ten years prior to September 2011 14 million people were connected to the electricity grid, at a cost of some 10 billion dollars.

Although the required transformation of the energy system is substantial, it is not without precedent. Last century between the 1920's and the 1970's oil replaced coal as the dominant energy source despite the immense available coal reserves. This occurred due to oil, as a liquid, being superior to coal in many respects, particularly for transportation. Similarly energy efficiency and renewables can be an easier way to solve energy security than producing fossil energy at higher costs that usually exacerbate environmental problems.

There are many combinations of energy resources, end-use, and supply technologies that can simultaneously address the multiple sustainability challenges. There will be an increased role of electricity and gases as energy carriers, co-utilization of biomass with fossil fuels in integrated systems, co-production of energy carriers, electricity, and chemicals, and, CCS.

All GEA energy pathways to a more sustainable future represent transformative change from today's energy systems. Large, early, and sustained investments are needed to finance this change, and can be in part achieved through new and innovative polices and institutional mechanisms that should reduce risks and increase the attractiveness of early, upfront investments, that have associated low long-term costs.

The GEA pathways that meet the sustainability goals generate substantial benefits across multiple economic and social objectives. This synergy is advantageous and important, given that measures which lead to local and national benefits, e.g. improved local and immediate health and environment conditions, support the local economy, may be more easily adopted than those measures that are put forward primarily on the grounds of goals that are global and long-term in nature, such as climate mitigation. An approach that emphasizes the local benefits of improved end-use efficiency and increased use of renewable energy would also help address global concerns.

Policies and incentive structures that promote R&D should be key areas for intervention. Rationalizing and reallocating subsidies, including subsidies to fossil fuels and nuclear energy can create new opportunities for investment. A major acceleration of publicly financed R&D and its reorientation towards energy efficiency and renewable energy

technologies is required. And to bring new technologies to market an integrated approach towards energy for sustainable development is needed; with policies in sectors such as industry, buildings, urbanization, transport, health, environment, climate, security, and others made mutually supportive.

The transition from coal to oil occurred without significant government regulations although subsidies played a role. However the transformation GEA envisages this century is more fundamental in character, and government policies are a key ingredient needed particularly in changing buildings codes, fuel efficiency standards for transportation and mandates for the introduction of renewables. A new found appreciation by policy-makers of the multiple benefits of sustainability options and their appropriate valuation will be critical for the transformation to occur.

The Global Energy Assessment's report establishes a benchmark for current understanding of the options for building a sustainable future for the energy system. But the Assessment consists more than just a report. Analytical tools have been developed to help translate the Assessment into actionable findings. Tools for decision making, that include global and regional scenarios, can be used to develop policy choices to address country-specific problems.

An important contribution to knowledge is the massive data base that is at the disposal of research and scientific community for their own use, and eventually analysis will be made available to the public at large.

Outreach has already started with the presentation of the early findings of GEA at the Vienna Energy Forum in June 2011. Importantly at that forum a Ministerial declaration, supported by the UNIDO leadership, endorsed the solutions offered by GEA, particularly:

- Ensure universal access to moderns forms of energy for all by 2030
- Reduce global energy intensity by 40% by 2030
- Increase the share of renewables 30% by 2030

These three objectives are reflected in the Action Agenda of the UN Secretary General's High-Level Group on "Sustainable Energy for All".

The aim going forward is to ensure the widest dissemination of GEA's work that is possible, including both national and regional policy dialogues.

This opportunity to layout a new approach to the design and implementation of sustainable energy pathways would not be possible without the extraordinary effort of the 500 or so contributors, be they authors from various disciplines and walks of life, reviewers, editors or members of the secretariat, executive team and council. We thank you all.

Ged Davis and José Goldemberg
GEA Co-Presidents

Key Findings

The Global Energy Challenge

Since before the Industrial Revolution, societies have relied on increasing supplies of energy to meet their need for goods and services. Major changes in current trends are required if future energy systems are to be affordable, safe, secure, and environmentally sound. There is an urgent need for a sustained and comprehensive strategy to help resolve the following challenges:

- *providing affordable energy services for the well-being of the 7 billion people today and the 9 billion people projected by 2050;*
- *improving living conditions and enhancing economic opportunities, particularly for the 3 billion people who cook with solid fuels today and the 1.4 billion people without access to electricity;*
- *increasing energy security for all nations, regions, and communities;*
- *reducing global energy systems greenhouse gas emissions to limit global warming to less than 2°C above pre-industrial levels;*
- *reducing indoor and outdoor air pollution from fuel combustion and its impacts on human health; and*
- *reducing the adverse effects and ancillary risks associated with some energy systems and to increase prosperity.*

Major transformations in energy systems are required to meet these challenges and to increase prosperity.

The Global Energy Assessment (GEA) assessed a broad range of resources, technologies and policy options and identified a number of 'pathways' through which energy systems could be transformed to simultaneously address all of the above challenges

These are the Key Findings:

1. Energy Systems can be Transformed to Support a Sustainable Future: the GEA analysis demonstrates that a sustainable future requires a transformation from today's energy systems to those with: *(i)* radical improvements in energy efficiency, especially in end use, and *(ii)* greater shares of renewable energies and advanced energy systems with carbon capture and storage (CCS) for both fossil fuels and biomass. The analysis ascertained that there are many ways to transform energy systems and many energy portfolio options. Large, early, and sustained investments, combined with supporting policies, are needed to implement and finance change. Many of the investment resources can be found through forward-thinking domestic and local policies and institutional mechanisms that can also support their effective delivery. Some investments are already being made in these options, and should be strengthened and widely applied through new and innovative mechanisms to create a major energy system transformation by 2050.

2. An Effective Transformation Requires Immediate Action: Long infrastructure lifetimes mean that it takes decades to change energy systems; so immediate action is needed to avoid lock-in of invested capital into existing energy systems and associated infrastructure that is not compatible with sustainability goals. For example, by 2050 almost three-quarters of the world population is projected to live in cities. The provision of services and livelihood opportunities to growing urban populations in the years to come presents a major opportunity for transforming energy systems and avoiding lock-in to energy supply and demand patterns that are counterproductive to sustainability goals.

3. Energy Efficiency is an Immediate and Effective Option: Efficiency improvement is proving to be the most cost-effective, near-term option with multiple benefits, such as reducing adverse environmental and health impacts, alleviating poverty, enhancing energy security and flexibility in selecting energy supply options, and creating employment and economic opportunities. Research shows that required improvements in energy efficiency particularly in end-use can be achieved quickly. For example:

- retrofitting buildings can reduce heating and cooling energy requirements by 50–90%;
- new buildings can be designed and built to very high energy performance levels, often using close to zero energy for heating and cooling;
- electrically-powered transportation reduces final energy use by more than a factor of three, as compared to gasoline-powered vehicles;
- a greater integration between spatial planning and travel that emphasizes shorter destinations and enhances opportunities for flexible and diverse choices of travel consolidating a system of collective, motorized, and non-motorized travel options offer major opportunities;
- through a combination of increased energy efficiency and increased use of renewable energy in the industry supply mix, it is possible to produce the increased industrial output needed in 2030 (95% increase over 2005) while maintaining the 2005 level of GHG emissions.

A portfolio of strong, carefully targeted policies is needed to promote energy efficient technologies and address, *inter alia*, direct and indirect costs, benefits, and any rebound effects.

4. Renewable Energies are Abundant, Widely Available, and Increasingly Cost-effective: The share of renewable energy in global primary energy could increase from the current 17% to between 30% to 75%, and in some regions exceed 90%, by 2050. If carefully developed, renewable energies can provide many benefits, including job creation, increased energy security, improved human health, environmental protection, and mitigation of climate change. The major challenges, both technological and economic, are:

- reducing costs through learning and scale-up;
- creating a flexible investment environment that provides the basis for scale-up and diffusion;
- integrating renewable energies into the energy system;
- enhancing research and development to ensure technological advances; and
- assuring the sustainability of the proposed renewable technologies.

While there remain sound economic and technical reasons for more centralized energy supplies, renewable energy technologies are also well-suited for off-grid, distributed energy supplies.

5. Major Changes in Fossil Energy Systems are Essential and Feasible: Transformation toward decarbonized and clean energy systems requires fundamental changes in fossil fuel use, which dominates the current energy landscape. This is feasible with known technologies.

- CO_2 capture and storage (CCS), which is beginning to be used, is key. Expanding CCS will require reducing its costs, supporting scale-up, assuring carbon storage integrity and environmental compatibility, and securing approval of storage sites.

- Growing roles for natural gas, the least carbon-intensive and cleanest fossil fuel, are feasible, including for shale gas, if related environmental issues are properly addressed.

- Co-processing of biomass and coal or natural gas with CCS, using known technologies, is important for co-producing electricity and low-carbon liquid fuels for transportation and for clean cooking. Adding CCS to such coproduction plants is less costly than for plants that make only electricity.

Strong policies, including effective pricing of greenhouse gas emissions, will be needed to fundamentally change the fossil energy system.

6. Universal Access to Modern Energy Carriers and Cleaner Cooking by 2030 is Possible: Universal access to electricity and cleaner cooking fuels and stoves can be achieved by 2030; however, this will require innovative institutions, national and local enabling mechanisms, and targeted policies, including appropriate subsidies and financing. The necessary technologies are available, but resources need to be directed to meet these goals. Universal access is necessary to alleviate poverty, enhance economic prosperity, promote social development, and improve human health and well-being. Enhancing access among poor people, especially poor women, is thus important for increasing their standard of living. Universal access to clean cooking technologies will substantially improve health, prevent millions of premature deaths, and lower household and ambient air pollution levels, as well as the emissions of climate-altering substances.

7. An Integrated Energy System Strategy is Essential: An integrated approach to energy system design for sustainable development is needed – one in which energy policies are coordinated with policies in sectors such as industry, buildings, urbanization, transport, food, health, environment, climate, security, and others, to make them mutually supportive. The use of appropriate policy instruments and institutions can help foster a rapid diffusion and scale-up of advanced technologies in all sectors to simultaneously meet the multiple societal challenges related to energy. The single most important area of action is efficiency improvement in all sectors. This enhances supply side flexibility, allowing the GEA challenges to be met without the need for technologies such as CCS and nuclear.

8. Energy Options for a Sustainable Future bring Substantial Multiple Benefits for Society: Combinations of resources, technologies, and polices that can simultaneously meet global sustainability goals also generate substantial and tangible near-term local and national economic, environmental, and social development benefits. These include, but are not limited to, improved local health and environment conditions, increased employment options, strengthened local economies through new business opportunities, productivity gains, improved social welfare and decreased poverty, more resilient infrastructure, and improved energy security. Synergistic strategies that focus on local and national benefits are more likely to be implemented than measures that are global and long-term in nature. Such an approach emphasizes the local benefits of improved end-use efficiency and increased use of renewable energy, and also helps manage energy-related global challenges. These benefits make the required energy transformations attractive from multiple policy perspectives and at multiple levels of governance.

9. Socio-Cultural Changes as well as Stable Rules and Regulations will be Required: Crucial issues in achieving transformational change toward sustainable future include non-technology drivers such as individual and public awareness, community and societal capacities to adapt to changes, institutions, policies, incentives, strategic spatial planning, social norms, rules and regulations of the marketplace, behavior of market actors, and societies' ability to introduce through the political and institutional systems measures to reflect externalities. Changes in cultures, lifestyles,

and values are also required. Effective strategies will need to be adopted and integrated into the fabric of national socio-cultural, political, developmental, and other contextual factors, including recognizing and providing support for the opportunities and needs of all nations and societies.

10. Policy, Regulations, and Stable Investment Regimes will be Essential: A portfolio of policies to enable rapid transformation of energy systems must provide the effective incentive structures and strong signals for the deployment at scale of energy-efficient technologies and energy supply options that contribute to the overall sustainable development. The GEA pathways indicate that global investments in combined energy efficiency and supply will need to increase to between US$1.7–2.2 trillion per year compared to present levels of about US$1.3 trillion per year (about 2% of current world gross domestic product) including end-use components. Policies should encourage integrated approaches across various sectors and promote the development of skills and institutional capacities to improve the investment climate. Examples include applying market-oriented regulations such as vehicle emissions standards and low carbon fuel standards and as well as renewable portfolio standards to accelerate the market penetration of clean energy technologies and fules. Reallocating energy subsidies, especially the large subsidies provided in industrialized countries to fossil fuels without CCS, and nuclear energy, and pricing or regulating GHG emissions and/or GHG-emitting technologies and fules can help support the initial deployment of new energy systems, both end-use and supply, and help make infrastructures energy efficient. Publicly financed research and development needs to accelerate and be reoriented toward energy efficiency, renewable energy and CCS. Current research and development efforts in these areas are grossly inadequate compared with the future potentials and needs.

* * * * *

The full GEA report is available for download in electronic form at www.globalenergyassessment.org. The website includes an interactive scenario database that documents the GEA pathways.

Introduction

Energy is essential for human development and energy systems are a crucial entry point for addressing the most pressing global challenges of the 21st century, including sustainable economic and social development, poverty eradication, adequate food production and food security, health for all, climate protection, conservation of ecosystems, peace and security. Yet, more than a decade into the 21st century, current energy systems do not meet these challenges.

A major transformation is therefore required to address these challenges and to avoid potentially catastrophic future consequences for human and planetary systems. The Global Energy Assessment (GEA) demonstrates that energy system change is the key for addressing and resolving these challenges. The GEA identifies strategies that could help resolve the multiple challenges simultaneously and bring multiple benefits. Their successful implementation requires determined, sustained and immediate action.

Transformative change in the energy system may not be internally generated; due to institutional inertia, incumbency and lack of capacity and agility of existing organizations to respond effectively to changing conditions. In such situations clear and consistent external policy signals may be required to initiate and sustain the transformative change needed to meet the sustainability challenges of the 21st century.

The industrial revolution catapulted humanity onto an explosive development path, whereby, reliance on muscle power and traditional biomass was replaced mostly by fossil fuels. In 2005, some 78% of global energy was based on fossil energy sources that provided abundant and ever cheaper energy services to more than half the people in the world. Figure SPM-1 shows this explosive growth of global primary energy with two clear development phases, the first

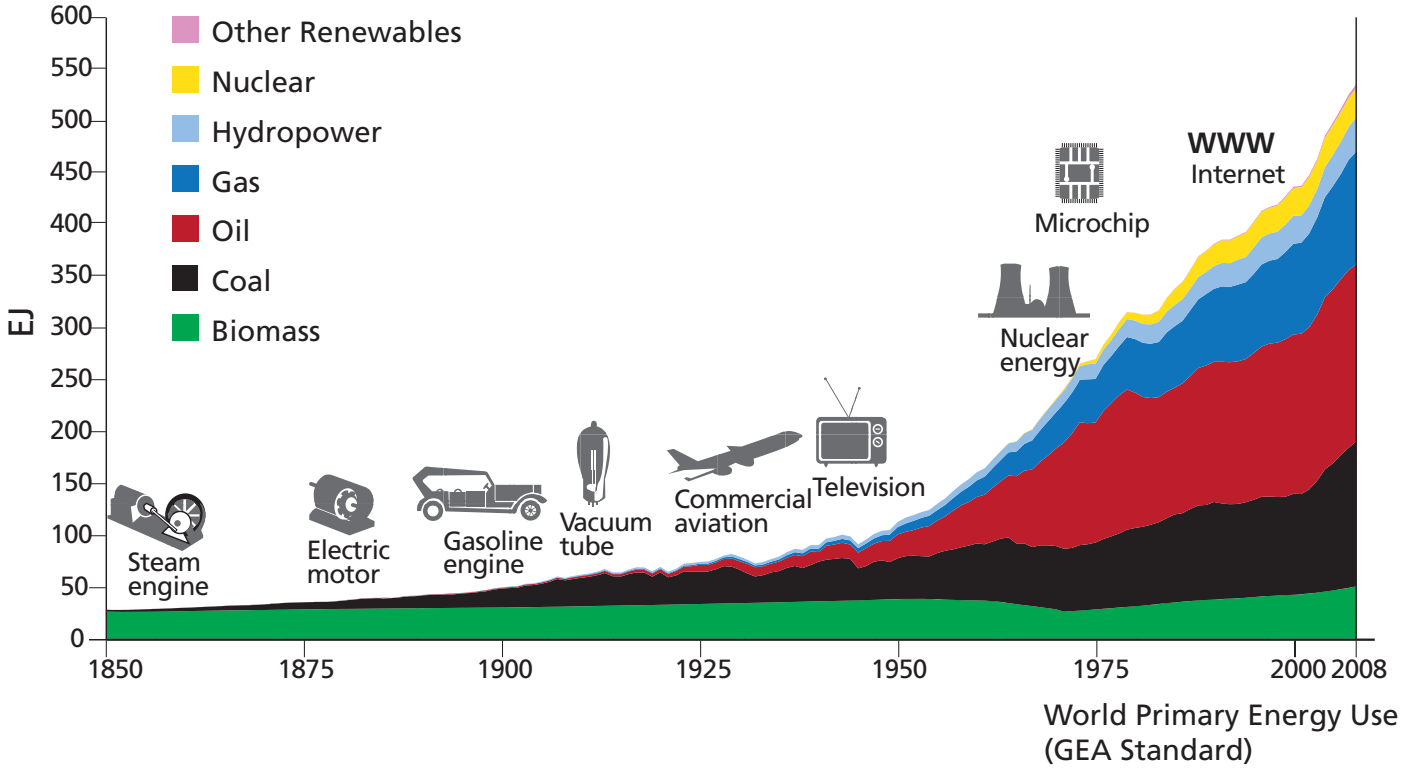

Figure SPM-1. | Evolution of primary energy shown as absolute contributions by different energy sources (EJ). Biomass refers to traditional biomass until the most recent decades, when modern biomass became more prevalent and now accounts for one-quarter of biomass energy. New renewables are discernible in the last few decades. Source: updated from Nakicenovic et al., 1998 and Grubler, 2008, see Chapter 1.[1]

characterized by a shift from reliance on traditional energy sources to coal and subsequently to oil and gas. Hydropower, biomass and nuclear energy during the past decades have a combined share of almost 22%. New renewables such as solar and wind are hardly discernible in the figure.

Despite this rapid increase in overall energy use, over three billion people still rely on solid fuels such as traditional biomass, waste, charcoal and coal for household cooking and heating. The resulting air pollution leads to over two million premature deaths per year, mostly of women and children. Furthermore, approximately 20% of the global population has no access to electricity. Addressing these challenges is essential for averting a future with high economic and social costs and adverse environmental impacts on all scales.

An energy system transformation is required to meet these challenges and bring prosperity and well-being to the 9 billion people expected by 2050. The encouraging news is that a beginning of such a transformation can be seen today in the rapidly growing investments in renewable energy sources, high-efficiency technologies, new infrastructures, near zero-energy buildings, electric mobility, 'smart' energy systems, advanced biomass stoves, and many other innovations. The policy challenge is to accelerate, amplify and help make the implementation of these changes possible, widespread and affordable. Initial experience suggests that many of these changes are affordable, although they may be capital intensive and require high upfront investments. However, in general they have lower long-term costs that offset many of the up-front added investment requirements. Many of these innovations also lead to benefits in other areas such as equity and poverty, economic development, energy security, improved health, climate change mitigation, and ecosystem protection.

This Summary for Policymakers expands on the GEA approach and the Key Findings. The Technical Summary provides further support for the key findings.

Goals Used in the Assessment and in the GEA Pathways Analysis

For many of the energy related challenges, different goals have been articulated by the global community, including, in many instances specific quantitative targets. Meeting these goals simultaneously has served as the generic framework for all assessments in the GEA. The GEA pathways illustrate how societies can reach global normative goals of welfare, security, health, and environmental protection outlined below simultaneously with feasible changes in energy systems.

The selection of indicators and the quantitative target levels summarized here is a normative exercise, and the level of ambition has, to the extent possible, been guided by agreements and aspirations expressed through, for example, the United Nations system's actions, resolutions, and from the scientific literature. This, of course, only refers to the necessary changes of the local and global energy systems; much more is required in other sectors of societies for overall sustainability to be realized.

In the GEA pathways analysis, global per capita gross domestic product (GDP) increases by 2% a year on average through 2050, mostly driven by growth in developing countries. This growth rate falls in the middle of existing projections. Global population size is projected to plateau at about 9 billion people by 2050. Energy systems must be able to ***deliver the required energy services*** to support these economic and demographic developments.

To avoid additional complexity, the GEA pathways assume one intermediate population growth pathway that is associated with uncertainty. Given that population growth has significant implications for future energy demand, however, it should be remembered that policies to provide more of the world's men and women the means to make responsible parental decisions (including safe contraception technologies) can significantly reduce the growth in population over the century as well as energy demand and CO_2 emissions. By increasing birth spacing, they would also bring benefits for maternal and child health.

Access to affordable modern energy carriers and end-use conversion devices to improve living conditions and enhancing opportunities for economic development for the 1.4 billion people without access to electricity and the 3 billion who still rely on solid and fossil fuels for cooking is a prerequisite for poverty alleviation and socioeconomic development.

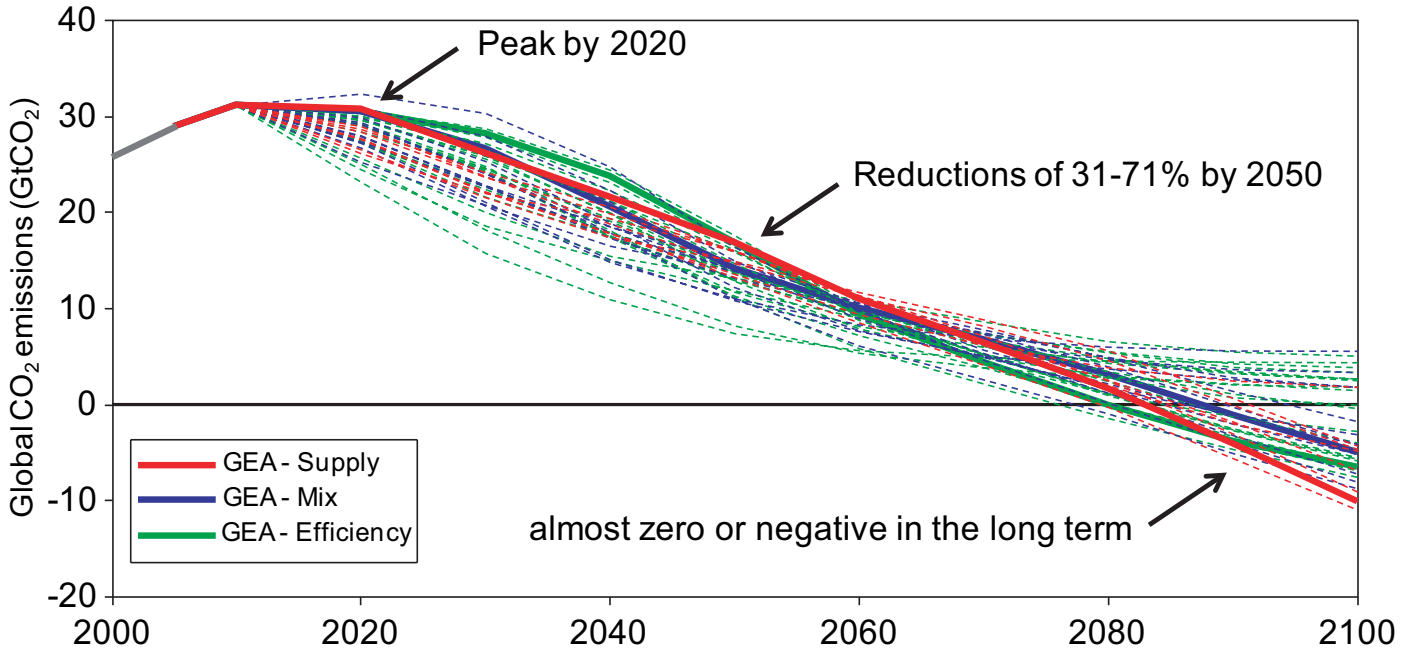

Figure SPM-2. | Development of global CO_2 emissions from energy and industrial sources to limit temperature change to below 2°C (with a success probability of >50%). Shown is that the emissions need to peak by around 2020 (or earlier) and decline toward zero during the following four to five decades. The later the peak occurs, the steeper the decline needs to be and higher the net "negative" emissions. The latter can be achieved through in the energy system through carbon dioxide capture and storage in conjunction with the use of sustainable biomass. Source: Chapter 17. For further details of the GEA pathways see the interactive web-based GEA scenario database hosted by IIASA: www.iiasa.ac.at/web-apps/ene/geadb.

Enhanced energy security for nations and regions is another key element of a sustainable future. Reduced global interdependence via reduced import/export balances, and increased diversity and resilience of energy supply have been adopted as key energy-related metrics. The targets for these goals were assessed ex-post through the GEA pathways analysis (Chapter 17), identifying the need for energy efficiency improvements and deployment of renewables to increase the share of domestic (national or regional) supply in primary energy by a factor of two and thus significantly decrease import dependency (by 2050). At the same time, the share of oil in global energy trade is reduced from the present 75% to below 40% and no other fuel assumes a similarly dominant position in the future.

The ***climate change mitigation*** goal is to contain the global mean temperature increase to less than 2°C above the preindustrial level, with a success probability of at least 50%. This implies global CO_2 emissions reductions from energy and industry to 30–70% of 2000 levels by 2050, and approaching almost zero or net negative emissions in the second half of the century (Figure SPM-2).

Health goals relating to energy systems include controlling household and ambient air pollution. Emissions reductions through the use of advanced fuels and end-use technologies (such as low-emissions biomass cookstoves) for household cooking and heating can significantly reduce human morbidity and mortality due to exposure to household air pollution, as well as help reduce ambient pollution. In the GEA pathways, this is assumed to occur for the vast majority of the world's households by 2030. Similarly, a majority of the world's population is also expected to meet the World Health Organization's (WHO) air quality guidelines (annual PM2.5 concentration < 10 μg/m^3 by 2030), while remaining populations are expected to stay well within the WHO Tier I-III levels (15–35 μg/m^3 by 2030). In addition, there needs to be a major expansion of occupational health legislation and enforcement in the energy sector.

Linkages between the energy system and the **environment** are at multiple levels and scales – from local to global. While the local environmental and ecological consequences of resource extraction, processing and energy conversion have been long recognized, attention is increasingly turning towards the growing evidence that humanity has reached a phase when anthropogenic pressures on Earth systems – the climate, oceans, fresh water, and the biosphere – risk irreversible disruption to biophysical processes on the planetary scale. The risk is that systems on Earth may then

Table SPM-1. | Global Burden of Disease, 2000 from Air Pollution and other Energy-related causes. These come from the Comparative Risk Assessment (CRA) published in 2004 by the World Health Organization (WHO). Estimates for 2005 in GEA for outdoor air pollution and household solid fuel use in Chapter 17 are substantially larger, but were not done for all risk pathways shown. Estimates for 2010 in the new CRA by WHO will be released in 2012 and will again include all pathways in a consistent framework.

	Total Premature Deaths – million	Percent of all Deaths	Percent of Global Burden in DALYs	Trend
Direct Effects [except where noted, 100% assigned to energy]				
Household Solid Fuel	1.6	2.9	2.6	Stable
Energy Systems Occupational*	0.2	0.4	0.5	Uncertain
Outdoor Air Pollution	0.8	1.4	0.8	Stable
Climate Change	0.15	0.3	0.4	Rising
Subtotal	2.8	5.0	4.3	
Indirect Effects (100% of each)				
Lead in Vehicle Fuel	0.19	0.3	0.7	Falling
Road Traffic Accidents	0.8	1.4	1.4	Rising
Physical Inactivity	1.9	3.4	1.3	Rising
Subtotal	2.9	5.1	3.4	
Total	5.7	10.1	7.7	

* One-third of global total assigned to energy systems.

Notes: These are not 100% of the totals for each, but represent the difference between what exists now and what might be achieved with feasible policy measures. Thus, for example, they do not assume the infeasible reduction to zero traffic accidents or air pollution levels.

Source: Chapter 4.

reach tipping points, resulting in non-linear, abrupt, and potentially irreversible change, such as destabilization of the Greenland ice sheet or tropical rainforest systems.

There are also a number of other concerns related to how energy systems are designed and operated. For example, activities need to be occupationally safe, a continuing concern as nano- and other new materials are used in energy systems. Other impacts such as oil spills, freshwater contamination and overuse, and releases of radioactive substances must be prevented (ideally) or contained. Waste products must be deposited in acceptable ways to avoid health and environmental impacts. These issues mostly influence local areas, and the regulations and their implementation are typically determined at the national level.

The world is undergoing severe and rapid change involving significant challenges. Although this situation poses a threat, it also offers a unique opportunity – a window of time in which to create a new, more sustainable, more equitable world, provided that the challenges can be addressed promptly and adequately. Energy is a pivotal area for actions to help address the challenges.

The interrelated world brought about by growth and globalization has increased the linkages among the major challenges of the 21st century. We do not have the luxury of being able to rank them in order of priority. As they are closely linked and interdependent, the task of addressing them simultaneously is imperative.

Energy offers a useful entry point into many of the challenges because of its immediate and direct connections with major social, economic, security and development goals of the day. Among many other challenges, energy systems are tightly linked to global economic activities, to freshwater and land resources for energy generation and food production, to biodiversity and air quality through emissions of particulate matter and precursors of tropospheric ozone, and to climate change. Most of all, access to affordable and cleaner energy carriers is a fundamental prerequisite for development, which is why the GEA places great emphasis on the need to integrate energy policy with social, economic, security, development, and environment policies.

Reaching the GEA goals simultaneously requires transformational changes to the energy system, in order to span a broad range of opportunities across urban to rural geographies, from developing to industrial countries, and in transboundary systems. The ingredients of this change are described in the following section.

Key Findings

The Global Energy Assessment (GEA) explored options to transform energy systems that simultaneously address all of the challenges above. A broad range of resources and technologies were assessed, as well as policy options that can be combined to create pathways[2] to energy for a sustainable future. These are the Key Findings:

1. Energy Systems can be Transformed to Support a Sustainable Future: *the GEA analysis demonstrates that a sustainable future requires a transformation from today's energy systems to those with: (i) radical improvements in energy efficiency, especially in end use, and (ii) greater shares of renewable energies and advanced energy systems with carbon capture and storage (CCS) for both fossil fuels and biomass. The analysis ascertained that there are many ways to transform energy systems and many energy portfolio options. Large, early, and sustained investments, combined with supporting policies, are needed to implement and finance change. Many of the investment resources can be found through forward-thinking domestic and local policies and institutional mechanisms that can also support their effective delivery. Some investments are already being made in these options, and should be strengthened and widely applied through new and innovative mechanisms to create a major energy system transformation by 2050.*

Humanity has the capacity, ingenuity, technologies and resources to create a better world. However, the lack of appropriate institutions, coordination mandates, political will and governance structures make the task difficult. Current decision making processes typically aim for short-term, quick results, which may lead to sub-optimal long-term outcomes. The GEA endeavors to make a compelling case for the adoption of a new set of approaches and policies that are essential, urgently required, and achievable.

The GEA highlights essential technology-related requirements for radical energy transformation:

- significantly larger investment in energy efficiency improvements especially end-use across all sectors, with a focus on new investments as well as major retrofits;
- rapid escalation of investments in renewable energies: hydropower, wind, solar energy, modern bioenergy, and geothermal, as well as the smart grids that enable more effective utilization of renewable energies;
- reaching universal access to modern forms of energy and cleaner cooking through micro-financing and subsidies;
- use of fossil fuels and bioenergy at the same facilities for the efficient co-production of multiple energy carriers and chemicals with full-scale deployment of carbon capture and storage; and
- on one extreme nuclear energy could make a significant contribution to global electricity generation, but on the other extreme, it could be phased out.

To meet humanity's need for energy services, comprehensive diffusion of energy and an increased contribution of energy efficiencies are required throughout the energy system – from energy collection and conversion to end use. Rapid diffusion of renewable energy technologies is the second but equally effective option for reaching multiple objectives. Conversion of primary energy to energy carriers such as electricity, hydrogen, liquid fuels and heat along with smart transmission and distribution systems are necessary elements of an energy system meeting sustainability objectives.

2 The GEA developed a range of alternative transformational pathways to explore how to achieve all global energy challenges simultaneously. The results of the GEA pathways are documented in detail at the interactive web-based GEA scenario database hosted by IIASA: www.iiasa.ac.at/web-apps/ene/geadb.

The GEA makes the case that energy system transformation requires an iterative and dynamic transformation of the policy and regulatory landscape, thereby fostering a buildup of skills and institutions that encourage innovation to thrive, create conditions for business to invest, and generate new jobs and livelihood opportunities.

A major finding of the GEA is that some energy options provide multiple benefits. This is particularly true of energy efficiency, renewables, and the coproduction of synthetic transportation fuels, cooking fuels, and electricity with co-gasification of coal and biomass with CCS, which offer advantages in terms of supporting all of the goals related to economic growth, jobs, energy security, local and regional environmental benefits, health, and climate change mitigation. All these advantages imply the creation of value in terms of sustainability. This value should be incorporated into the evaluation of these and other measures and in creating incentives for their use.

One implication of this is that nations and corporations can invest in efficiency and renewable energy for the reasons that are important to them, not just because of a global concern about, for example, climate change mitigation or energy security. But incentives for individual actors to invest in options with large societal values must be strong and effective.

The GEA explored 60 possible transformation pathways and found that 41 of them satisfy all the GEA goals simultaneously for the same level of economic development and demographic changes, including three groups of illustrative pathways that represent alternative evolutions of the energy system toward sustainable futures.[3] The pathways imply radically changed ways in which humanity uses energy, ranging from much more energy-efficient houses, mobility, products, and industrial processes to a different mix of energy supply – with a much larger proportion of renewable energy and fossil advanced fossil fuel technologies (see Figure SPM-3).

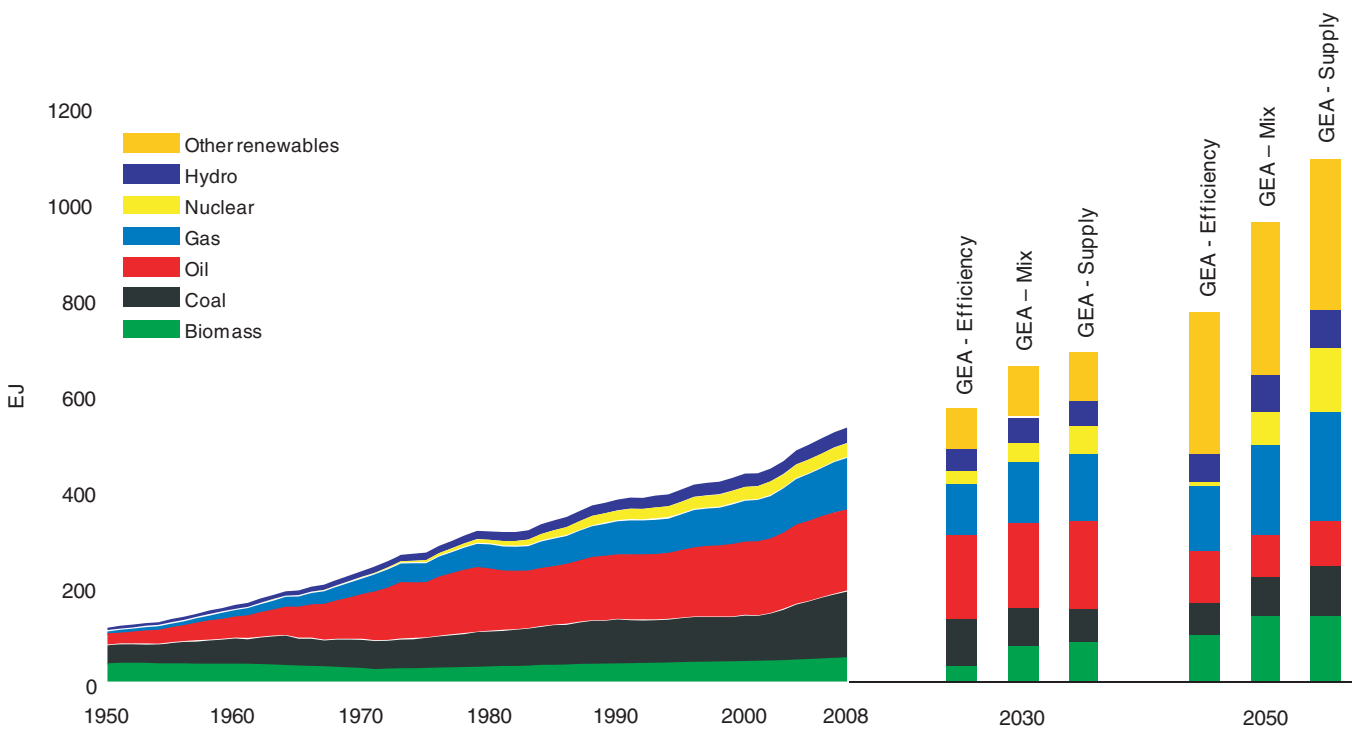

Figure SPM-3. | Development of primary energy to 2008 and in the three illustrative GEA pathways for the years 2030 and 2050. Source: based on Figures TS-24 and 17.13, Chapter 17. For further details of the GEA pathways see the interactive web-based GEA scenario database hosted by IIASA: www.iiasa.ac.at/web-apps/ene/geadb.

3 The pathways encompass eleven world regions, grouped into five GEA regions and energy sectors, including supply and demand, with a full range of associated social, economic, environmental and technological developments.

On the demand side, the three groups of GEA pathways pursue the energy efficiency options to a varying extent. On the supply side, the GEA pathways highlight the broad portfolio of technologies that will be needed to achieve the energy system transformation. Particularly important options are low-carbon energy from renewables, bioenergy, nuclear power, and CCS. In aggregate, at least a 60–80% share of global primary energy will need to come from zero-carbon options by 2050; the electricity sector in particular will need to be almost completely decarbonized by mid-century (low-carbon shares of 75–100%). Getting to that point requires major progress in several critical areas:

- Renewables: Strong renewable energy growth beginning immediately and reaching a global share of 30–75% of primary energy by 2050, with some regions experiencing in the high case almost a complete shift towards renewables by that time;

- Coal: A complete phase-out of coal power without CCS by 2050;

- Natural Gas: Natural gas acting as a bridging or transitional technology in the short to medium term and providing 'virtual' storage for intermittent renewables;

- Energy Storage: Rising requirement for storage technologies and 'virtual' systems (e.g., smart grids and demand-side management) to support system integration of intermittent wind and solar;

- Bioenergy: Strong bioenergy growth in the medium term from 45 EJ in 2005 to 80–140 EJ by 2050, including extensive use of agricultural residues and second-generation bioenergy to mitigate adverse impacts on land use and food production, and the co-processing of biomass with coal or natural gas with CCS to make low net GHG-emitting transportation fuels and or electricity;

- Nuclear: Nuclear energy as a choice, not a requirement. The GEA pathways illustrate that it is possible to meet all GEA goals even in the case of a nuclear phase-out. Nuclear energy can play an important role in the supply-side portfolio of some transition pathways; however, its prospects are particularly uncertain because of unresolved challenges surrounding its further deployment, as illustrated by the Fukushima accident and unresolved weapons proliferation risks;

- Carbon Capture and Storage: Fossil CCS as an optional bridging or transitional technology in the medium term unless there is high energy demand, in which case CCS may be essential. CCS technology offers one potentially relatively low-cost pathway to low carbon energy. CCS in conjunction with sustainable biomass is deployed in many pathways to achieve negative emissions and thus help achieve climate stabilization.

New policies would be needed to attract capital flows to predominantly upfront investments with low long-term costs but also low short-term rates of return.

The pathways indicate that the energy transformations need to be initiated without delay, gain momentum rapidly, and be sustained for decades. They will not occur on their own. They require the rapid introduction of policies and fundamental governance changes toward integrating global concerns, such as climate change, into local and national policy priorities, with an emphasis on energy options that contribute to addressing all these concerns simultaneously.

In sum, the GEA finds that there are possible combinations of energy resources and technologies that would enable societies to reach all the GEA goals simultaneously, provided that government interventions accommodate sufficiently strong incentives for rapid investments in energy end-use and supply technologies and systems.

2. An Effective Transformation Requires Immediate Action: *Long infrastructure lifetimes mean that it takes decades to change energy systems; so immediate action is needed to avoid lock-in of invested capital into energy systems and associated infrastructure that is not compatible with sustainability goals. For example, by 2050 almost three-quarters of the world population is projected to live in cities. The provision of services and livelihood opportunities to growing urban populations in the years to come presents a major opportunity for transforming energy systems and avoiding lock-in to energy supply and demand patterns that are counterproductive to sustainability goals.*

Given the longevity of the capital stock of energy systems and of the built environment, rates of change are slow and possible irreversibilities or 'lock-in' effects can have powerful long-lasting effects. Long-term transformations need to be initiated earlier rather than later. Therefore the time for action is *now.* Changes in current policies that are particularly critical in triggering longer-term transformations are technology, and urbanization.

Reflecting economic, social and environmental externalities in the market conditions is therefore a necessary first step to provide appropriate incentives for redirecting private sector investments. Such measures would include removal, or at least substantial reduction, of subsidies to fossil fuels without CCS and nuclear energy, stimulation of development and market entry of new renewable options, and emphasis on energy efficiency in all end-use sectors. According to the GEA pathway analysis, global energy systems investments need to increase to some US$1.7–2.2 trillion annually to 2050, with about US$300–550 billion of that being required for demand-side efficiency. This compares to about US$1 trillion supply-side investments and about $300 billion demand-side investments in energy components per year today. These investments correspond to about 2% of the world gross domestic product in 2005, and would be about 2–3% by 2050, posing a major financing challenge. New policies would be needed to attract such capital flows to predominantly upfront investments with low long-term costs but also low short-term rates of return.

Today about 3.5 billion people, about half the world population live in urban environments. Projections suggest that by 2050 an additional three billion people need to be integrated into the urban fabric. Housing, infrastructure, energy and transport services, and a better urban environment (especially urban air quality) are the key sustainability challenges for urban development.

Urban energy and sustainability policies can harness local decision-making and funding sources to achieve the largest leverage effects in the following areas:

- urban form and density (which are important macro-determinants of urban structures, activity patterns, and hence energy use, particularly for urban transport);
- the quality of the built environment (energy-efficient buildings in particular);
- urban transport policy (in particular the promotion of energy-efficient and 'eco-friendly' public transport and non-motorized mobility options); and
- improvements in urban energy systems through zero-energy building codes, cogeneration or waste-heat recycling schemes, where feasible.

There are important urban size and density thresholds that are useful guides for urban planning and policymaking. The literature review identified a robust density threshold of 50–150 inhabitants per hectare (5,000–15,000 people per square kilometer) below which urban energy use, particularly for transport, increases substantially and which should be avoided. There are also significant potential co-benefits between urban energy policies and environmental policies. However, they require more holistic policy approaches that integrate urban land use, transport, building, and energy policies with the more-traditional air pollution policy frameworks.

Policy coordination at an urban scale is as complex as potentially rewarding in sustainability terms. Institutional and policy learning needs to start early to trigger longer-term changes in urban form and infrastructures. A particular challenge is represented by small to medium sized cities (between 100,000 and 1 million inhabitants), as most urban growth is projected to occur in these centers, primarily in the developing world. In these smaller-scale cities, data and information to guide policy are largely absent, local resources to tackle development challenges are limited, and governance and institutional capacities are insufficient.

3. Energy Efficiency is an Immediate and Effective Option: *Efficiency improvement is proving to be the most cost-effective, near-term option with multiple benefits, such as reducing adverse environmental and health impacts, alleviating poverty, enhancing energy security and flexibility in selecting energy supply options, and creating employment*

and economic opportunities. Research shows that required improvements in energy efficiency particularly in end-use can be achieved quickly. For example:

- *retrofitting buildings can reduce heating and cooling energy requirements by 50–90%;*
- *new buildings can be designed and built to very high energy performance levels, often using close to zero energy for heating and cooling;*
- *electrically-powered transportation reduces final energy use by more than a factor of three, as compared to gasoline-powered vehicles;*
- *a greater integration between spatial planning and travel that emphasizes shorter destinations and enhances opportunities for flexible and diverse choices of travel consolidating a system of collective, motorized, and non-motorized travel options offers major opportunities;*
- *through a combination of increased enegry efficiency and increased use of renewable energy in the industry supply mix, it is possible to produce the increased industrial output needed in 2030 (95% increase over 2005) while maintaining the 2005 level of GHG emissions.*

A portfolio of strong, carefully targeted policies is needed to promote energy efficient technologies and address, inter alia, direct and indirect costs, benefits, and any rebound effects.

Progress in accelerating the rate of energy efficiency improvement worldwide is critical to an energy system for sustainability. Quickly improving energy efficiency through new investments and retrofits requires focused and aggressive policies that support rapid innovation through more stringent regulations of energy efficiency, fiscal incentives for new technologies, and pricing GHG emissions. Combined with higher energy prices, a culture of conservation among consumers and firms, and an increase in urban density societies can realize a dramatic increase in energy efficiency.

A major challenge is to resolve the issue of split incentives, that is, the situation where those who would be paying for efficiency improvements and other energy investments are more oriented toward short-term rates of return than to the long-term profitability of the investments and, likewise, they are rarely the beneficiaries of reduced energy costs and other public benefits.

Regulations are essential elements of energy policy portfolios to drive an energy transition. Standards for building codes, heating and cooling, appliances, fuel economy, and industrial energy management are one of the most effective policy tools for improving energy efficiency and should be adopted globally. These regulatory policies are most effective when combined with fiscal incentives and attention-attracting measures such as information, awareness, and public leadership programs.

The GEA analysis provides considerable evidence of the ability of such policy packages to deliver major change. However, the results from three decades of experiences with energy efficiency policies in industrial countries also show other effects.

These cost factors and rebound effects mean that subsidies to encourage acquisition of energy-efficient devices are unlikely, on their own, to cause the dramatic energy efficiency gains called for in the GEA analysis. For these gains to be realized, carefully targeted policies are needed. For example, strong efficiency regulations have proven effective. These are updated regularly and have incentives to reward manufacturers who push technology designs toward advanced efficiency by using electricity tariffs that reward efficiency investments and conservation.

In the buildings sector, new and existing technologies as well as non-technological opportunities represent a major opportunity for transformative change of energy use. Passive houses that reduce energy use for heating and cooling by 90% or more, for example, are already found in many countries. Increased investments in a more energy-efficient building shell are in part offset by lower or fully eliminated investments in heating/cooling systems, with energy costs for operation almost avoided, making these new options very attractive. Passive house performance is possible also

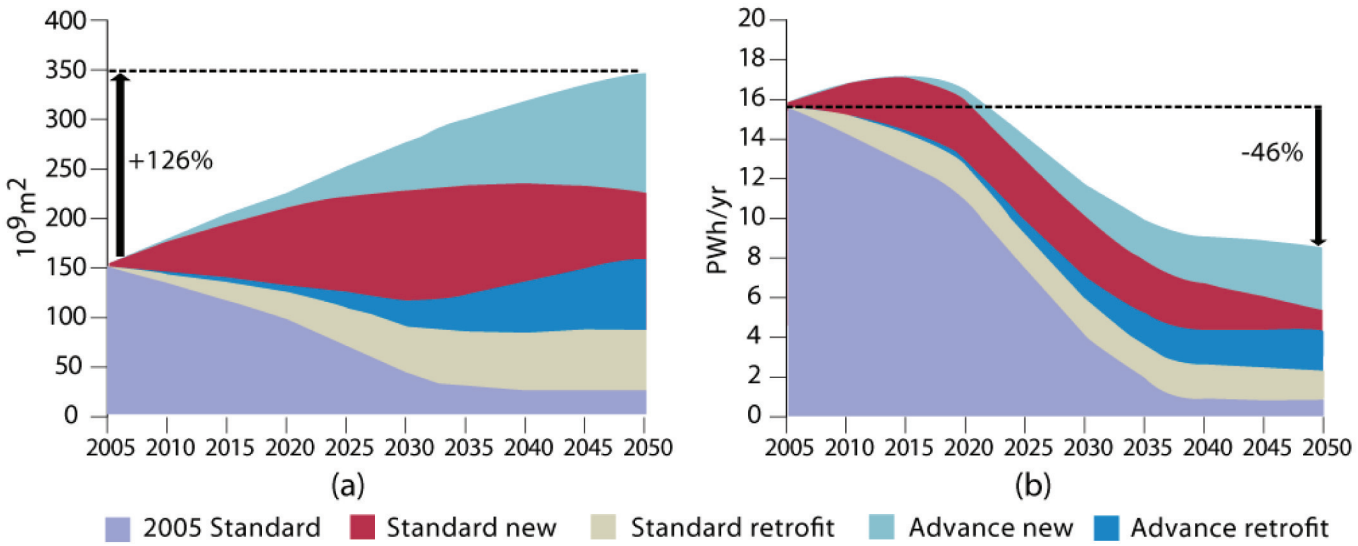

Figure SPM-4. | Global final thermal energy use in buildings (a) and global floor area (b) in the state-of-the-art scenario (corresponding approximately to the "GEA-Efficiency" group of pathways), 2005–2050. Source: Chapter 10.

Key: Explanations of efficiency categories: standard: today's stock; new: new buildings built to today's building code or anticipated new building codes (without additional policies); advance new: new buildings built to today's state-of-the-art performance levels; retrofit: assumes some efficiency gains, typically 35%; advanced retrofit: retrofit built to state-of-the-art levels.

for existing buildings, if it is included as a performance goal when major renovations are done. Energy Plus houses, delivering net energy to the grid over a year, have been constructed even in high latitudes. Building-integrated solar photovoltaics can contribute to meeting the electricity demand in buildings, especially in single-family homes, and solar water heaters can cover all or part of the heat required for hot water demand. However, requiring buildings to be zero-energy or net-energy suppliers may not be the lowest-cost or most sustainable approach in addressing the multiple GEA goals and typically may not be possible, depending on location.

Analysis carried out under the GEA pathway framework demonstrates that a reduction of global final energy use for heating and cooling of about 46% is possible by 2050 compared with 2005 through full use of today's best practices in design, construction, and building operation technology and know-how. This can be obtained even while increasing amenities and comfort and simultaneously accommodating an increase in global floor area of over 126% (Figure SPM-4).

There is, however, a significant risk of lock-in. If stringent building codes are not introduced universally and energy retrofits accelerate but are not subject to state-of-the-art efficiency levels, substantial energy use and corresponding GHG emissions can be 'locked-in' for many decades. This could lead to a 33% increase in global energy use for buildings by 2050 instead of a decrease of 46% (Figure SPM-5).

Wide adoption of the state-of-the-art in the buildings sector would not only contribute significantly to meeting the GEA's multiple goals, such developments would also deliver a wide spectrum of other benefits. A review of quantified multiple benefits showed that productivity gains through reduced incidence of infections from exposure to indoor air pollution score particularly high in industrial countries. Other benefits included increases in productivity, energy security, indoor air quality and health, social welfare, real estate values, and employment. The approximately US$57 trillion cumulative energy cost savings until 2050 in avoided heating and cooling energy costs alone substantially exceeds the estimated US$15 trillion investments that are needed to realize this pathway. The value of the additional benefits has also been shown to be substantial, often exceeding the energy cost savings. In several cases the multiple benefits are so significant, and coincide with other important policy agendas (such as improved energy security, employment, poverty alleviation, competitiveness), that they provide easier and more attractive entry points for local policymaking than climate change or other environmental agendas.

Influencing energy use in the transport sector involves affecting transport needs, infrastructure, and modes, as well as vehicle energy efficiency. Policies for urbanization will have a large impact on transport needs, infrastructure, and

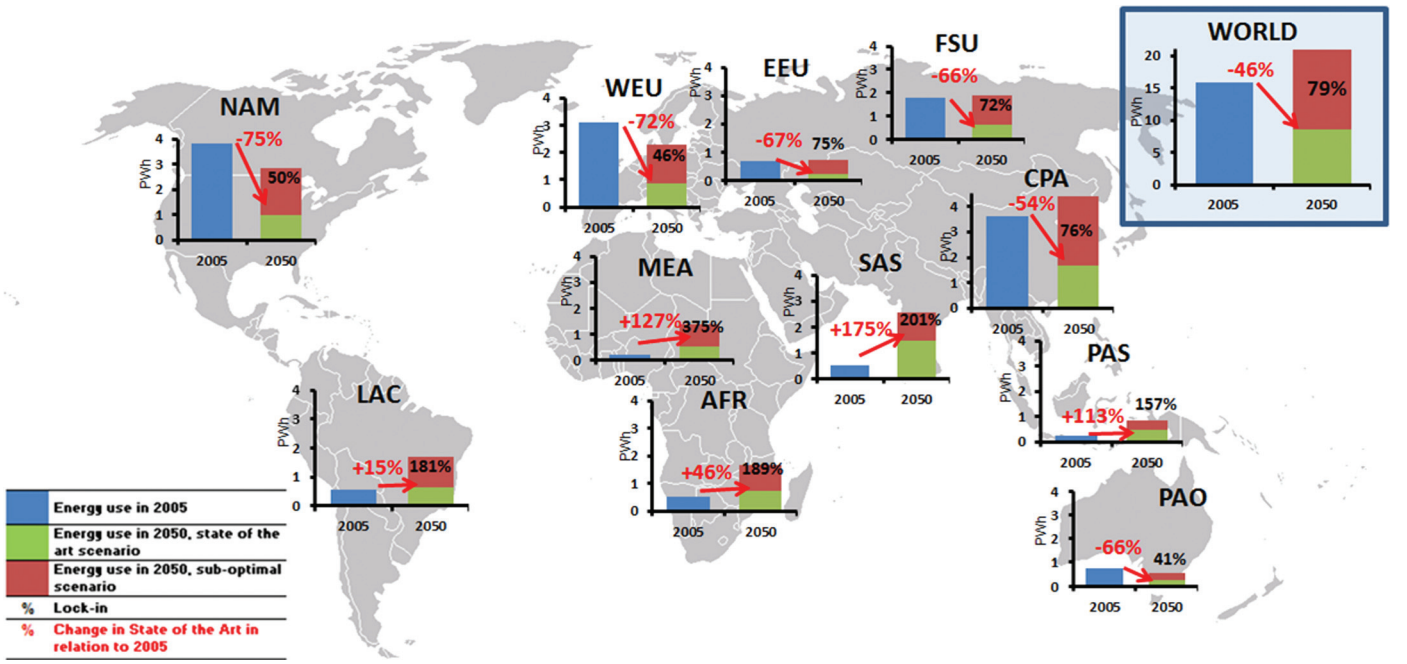

Figure SPM-5. | Final building heating and cooling energy demand scenarios until 2050: state-of-the-art (~corresponding roughly to the GEA-Efficiency set of pathways) and sub-optimal (~corresponding roughly to the GEA-Supply set of pathways scenarios, with the lock-in risk (difference). Note: Green bars, indicated by red arrows and numbers, represent the opportunities through the state-of-the-art scenario, while the red bars with black numbers show the size of the lock-in risk (difference between the two scenarios). Percent figures are relative to 2005 values. Source: Chapter 10.

the viability of different transport modes on the local scale. Both the decision to travel and the choice of how to travel affect fuel consumption. With a focus on urban road transport, a transition to sustainable transport can follow the framework known as 'avoid-shift-improve'. This considers three major principles under which diverse policy instruments are grouped, with interventions assuming different emphasis in industrial and developing countries. They need to focus on technological options, ('improve'), not only with respect to climate mitigation but also with respect to local environmental conditions and social concerns. The other two components – modal shift and avoiding travel influence the level of activity and structural components that link transport to carbon emissions.

A major transformation of transportation is possible over the next 30–40 years and will require improving vehicle designs, infrastructure, fuels and behavior. In the short term improving overall sector energy efficiency, introducing alternative low-carbon fuels and electricity, enhancing the diversification, quantity and quality of public modes of transport is necessary. Medium term goals require reducing travel distances within cities by implementing compact urban design that improves accessibility to jobs and services and facilitates use of non-motorized modes, and replacing and adopting vehicle and engine design (for trucks, airplanes, rail, and ships) following the best available technological opportunities for increasing efficiency and societal acceptability.

Transport policy goals for urbanization and equity include the adoption of measures for increasing accessibility and the affordable provision of urban mobility services and infrastructure that facilitates the widespread use of non-motorized options Cities can be planned to be more compact with less urban sprawl and a greater mix of land uses and strategic siting of local markets to improve logistics and reduces the distances that passengers and goods need to travel. Urban form and street design and layout can facilitate walking, cycling, and their integration within a network of public transport modes. Employers in many sectors can enhance the job-housing balance of employees through their decisions on where to be located and can provide incentives for replacing some non-essential journeys for work purposes with the use of information technologies and communication.

Modal share could move to modes that are less energy-intensive, both for passenger and freight transport. In cities, a combination of push and pull measures through traffic demand management can induce shifts from cars to public transit and cycling and can realize multiple social and health benefits. In particular, non-motorized transportation could be promoted everywhere as there is wide agreement about its benefits to transportation and people's health. Parking

policies and extensive car pooling and car sharing, combined with information technology options can become key policies to reduce the use of cars. Efficient road capacity utilization, energy use and infrastructure costs for different modes could be considered when transport choices are made.

There are still many opportunities to improve conventional vehicle technologies. The combination of introducing incremental efficiency technologies, increasing the efficiency of converting the fuel energy to work by improving drive train efficiency, and recapturing energy losses and reducing loads (weight, rolling, air resistance, and accessory loads) on the vehicle has the potential to approximately double the fuel efficiency of 'new' light-duty vehicles from 7.5 liters per 100 km in 2010 to 3.0 liters per 100 km by 2050.

The emergence of electric drive technologies such as plug-in hybrid electric vehicles allows for zero tailpipe emissions for low driving ranges, up to around 50 kilometers in urban conditions. All-electric battery vehicles can achieve a very high efficiency (more than 90%, four times the efficiency of an internal combustion engine vehicle but excluding the generation and transmission of the electricity), but they have a low driving range and short battery life. If existing fuel saving and hybrid technologies are deployed on a broad scale, fleet-average specific fuel savings of a factor of two can be obtained in the next decade.

The aggregate energy intensity in the industrial sector in different countries has shown steady declines due to improvements in energy efficiency and a change in the structure of the industrial output. In the EU-27, for instance, the final energy use by industry has remained almost constant (13.4 EJ) at 1990 levels; 30% of the reduction in energy intensity is due to structural changes, with the remainder due to energy efficiency improvements.

In different industrial sectors, adopting the best achievable technology can result in savings of 10–30% below the current average. An analysis of cost-cutting measures in 2005 indicated energy savings potentials of 2.2 EJ for motors and 3.3 EJ for steam systems. The economic payback period for these measures ranges from less than nine months to four years. A systematic analysis of materials and energy flows indicates significant potential for process integration, heat pumps, and cogeneration.

Nevertheless, such a transformation has multiple benefits. Improved energy efficiency in industry results in significant energy productivity gains as a result, for example, in improved motor systems; compressed air systems; ventilation, heat recovery, and air conditioning systems; and improvements in comfort and the working environment through better lighting, thermal comfort, and reduced indoor air pollution from improved ventilation systems, and, in turn, improved productivity boosts corporate competitiveness.

4. Renewable Energies are Abundant, Widely Available, and Increasingly Cost-effective: *The share of renewable energy in global primary energy could increase from the current 17% to between 30% to 75%, and in some regions exceed 90%, by 2050. If carefully developed, renewable energies can provide many benefits, including job creation, increased energy security, improved human health, environmental protection, and mitigation of climate change. The major challenges, both technological and economic, are:*

- *reducing costs through learning and scale-up;*
- *creating a flexible investment environment that provides the basis for scale-up and diffusion;*
- *integrating renewable energies into the energy system;*
- *enhancing research and development to ensure technological advances; and*
- *assuring the sustainability of the proposed renewable technologies.*

While there remain sound economic and technical reasons for more centralized energy supplies, renewable energy technologies are also well-suited for off-grid, distributed energy supplies.

The GEA pathways show that renewable energies can exceed 90% of projected energy demand for specific regions. The GEA pathways analysis indicates that a significant increase in renewable energy supplies is technically feasible and necessary in order to meet the GEA goals.

Table SPM-2. | Renewable energy flows, potential, and utilization in EJ of energy inputs provided by nature.[a]

	Primary Energy 2005[b] [EJ]	Direct Input 2005 [EJ]	Technical potential [EJ/yr]	Annual flows [EJ/yr]
Biomass, MSW, etc.	46.3	46.3	160–270	2200
Geothermal	0.78	2.3	810–1545	1500
Hydro	30.1	11.7	50–60	200
Solar	0.39	0.5	62,000–280,000	3,900,000
Wind	1.1	1.3	1250–2250	110,000
Ocean	-	-	3240–10,500	1,000,000

[a] The data are direct energy-input data, not primary energy substitution equivalent shown in the first column. Considering technology-specific conversion factors greatly reduces the output potentials. For example, the technical 3150 EJ/yr of ocean energy in ocean thermal energy conversion (OTEC) would result in an electricity output of about 100 EJ/yr.

[b] Calculated using the GEA substitution method (see Chapter 1, Appendix 1.A.3).

Figure SPM-6. | Renewable power capacity and generation (excluding large hydro) as a percentage of global capacity and generation, respectively, and their rates of change also in percent; 2004–2010. Source: UNEP and BNEF, 2011, see Chapter 11.[4]

The resource base is sufficient to provide full coverage of human energy demand at several times the present level and potentially more than 10 times this level (see Table SPM-2). Starting in 2007 renewable power generating capacity has grown fast in the world (see Figure SPM-6), and is now over 30% of total capacity expansion, excluding large scale hydropower. Figure SPM-7 shows a regional breakdown of the investments.

4 **UNEP and BNEF, 2011:** *Global Trends in Renewable Energy Investment 2011: Analysis of Trends and Issues in the Financing of Renewable Energy*. United Nations Environment Programme (UNEP), Nairobi, Kenya and Bloomberg New Energy Finance (BNEF), London, UK.

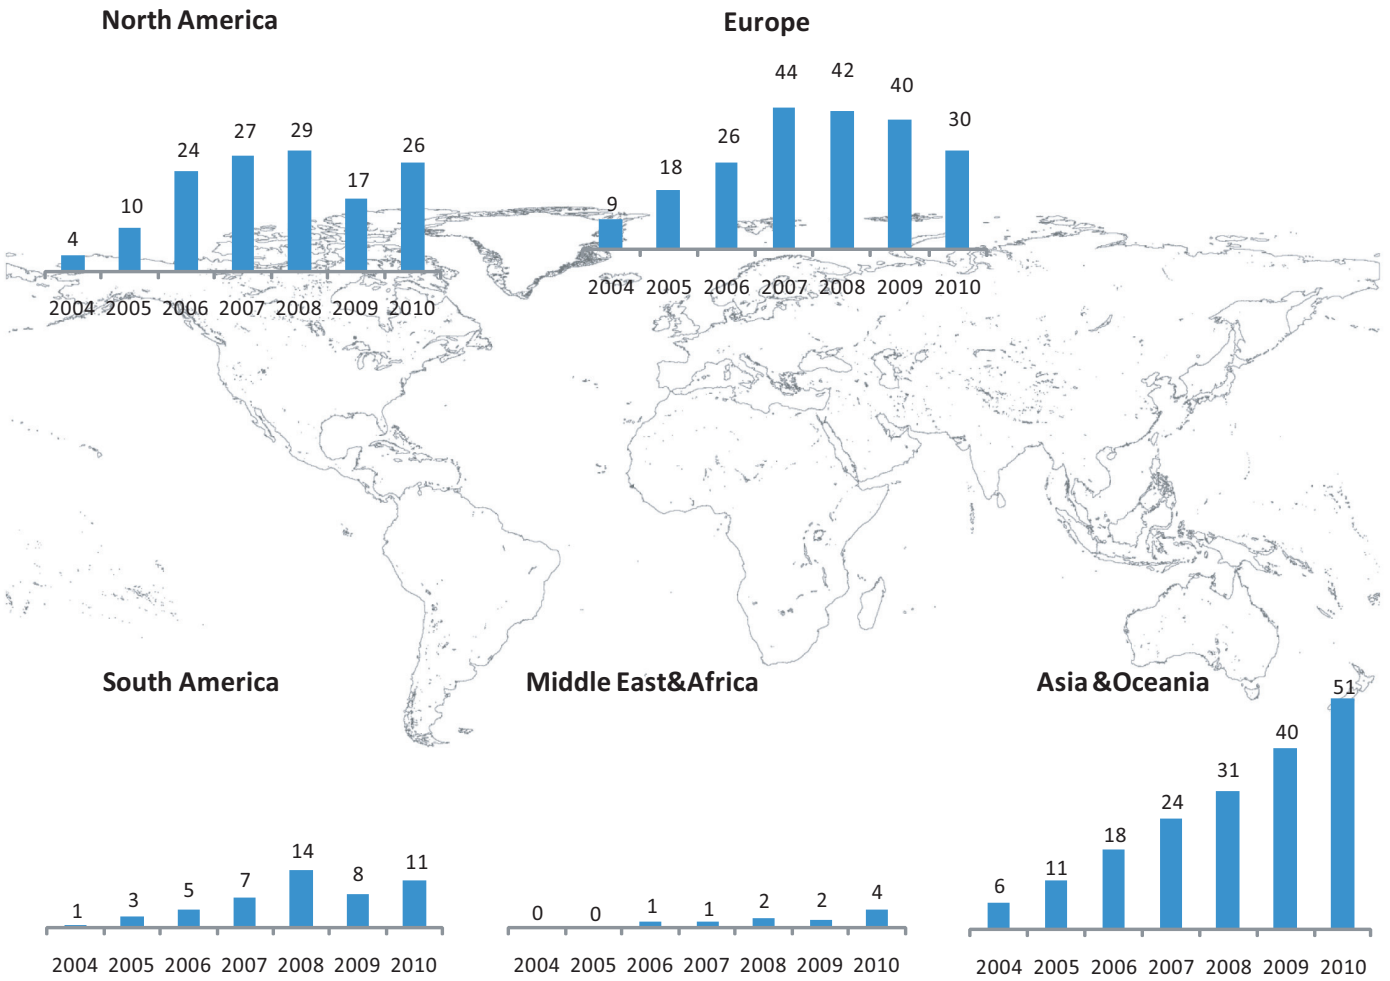

Figure SPM-7. | New financial investments in renewable energy, by region, 2004–2010 (US$$_{2005}$bn). New investment volume adjusts for reinvested equity; total values include estimates for undisclosed deals. This comparison does not include small-scale distributed energy projects or large-scale hydropower investments. Source: Chapter 11.

The rapid expansion in renewables, which has largely taken place in only a few countries, has usually been supported by incentives of different types or driven by quota requirements. Especially successful have been the feed-in tariffs used in the majority of EU countries, China, and elsewhere. Global investments in 2009 were slightly lower as a result of the financial crises (although with less reduction than for most other energy technologies), and in 2010 they rebounded. Both wind and solar PV electricity are nowadays cost-competitive in some markets and are projected to become so in many markets in the next 5–10 years without any public subsidy. However, renewables face resistance due to lock-in to conventional energies and substantial market barriers in the majority of markets.

The intermittent and variable generation of wind, solar and wave power must be handled within an electricity system that was not designed to accommodate it, and in which traditional base load-power from nuclear, geothermal and fossil power stations with restricted flexibility limit the system's ability to follow load variations. Energy systems have historically been designed to handle loads that vary over seconds, days, weeks, and years with high reliability. These systems are becoming increasingly able to accommodate increased quantities of variable generation through use of so-called smart systems with advanced sensing and control capabilities. With support from accurate and timely load forecasting, capacity management, and overall intelligent load and demand-side management, experience has shown that at least 20%, perhaps up to 50%, of variable renewable generation can be accommodated in most existing systems at low costs and that it is feasible to accommodate additional intermittent generation with additional investment in grid flexibility, low capital cost fuel-based generation, storage, and demand-side management (smart grids).

Safe and reliable improvements of interconnections between nations and across geographical regions will facilitate the compensation due to fluctuations in electricity generation from rapidly increasing shares of variable renewable energies in the system. Wind and solar PV and most hydrokinetic or ocean thermal technologies offer the unique additional attribute of virtually complete elimination of additional water requirements for power generation. Other renewable options, including bio-based options, geothermal, concentrating solar, and hydropower on a life-cycle basis, still require water for cooling of a steam turbine or are associated with large amounts of evaporation.

The development of high-voltage direct current (HVDC) transmission cables may allow the use of remote resources of wind and solar at costs projected to be affordable. Such cables have been installed for many years in sub-marine and on-shore locations, and demand is increasing (in the North Sea, for example). This is significant, as some of the best renewable energy resources are located far from load centers. In conjunction with energy storage at the generation location, such transmission cables can be used to provide base load electricity supply.

The GEA pathways analysis indicates that a significant increase in renewable energy supplies is technically feasible and necessary in order to meet the GEA objectives.

5. Major Changes in Fossil Energy Systems are Essential and Feasible: *Transformation toward decarbonized and clean energy systems requires fundamental changes in fossil fuel use, which dominates the current energy landscape. This is feasible with known technologies.*

- *CO_2 capture and storage (CCS), which is beginning to be used, is key. Expanding CCS will require reducing its costs, supporting scale-up, assuring carbon storage integrity and environmental compatibility, and securing approval of storage sites.*
- *Growing roles for natural gas, the least carbon-intensive and cleanest fossil fuel, are feasible, including for shale gas, if related environmental issues are properly addressed.*
- *Co-processing of biomass and coal or natural gas with CCS, using known technologies, is important for co-producing electricity and low-carbon liquid fuels for transportation and for clean cooking. Adding CCS to such coproduction plants is less costly than for plants that make only electricity.*

Strong policies, including effective pricing of greenhouse gas emissions, will be needed to fundamentally change the fossil energy system.

Table SPM-3. | Fossil and uranium reserves, resources, and occurrences.[a]

	Historical production through 2005 [EJ]	Production 2005 [EJ]	Reserves [EJ]	Resources [EJ]	Additional occurrences [EJ]
Conventional oil	6069	147.9	4900–7610	4170–6150	
Unconventional oil	513	20.2	3750–5600	11,280–14,800	> 40,000
Conventional gas	3087	89.8	5000–7100	7200–8900	
Unconventional gas	113	9.6	20,100–67,100	40,200–121,900	> 1,000,000
Coal	6712	123.8	17,300–21,000	291,000–435,000	
Conventional uranium[b]	1218	24.7	2400	7400	
Unconventional uranium	34	n.a.		7100	> 2,600,000

[a] The data reflect the ranges found in the literature; the distinction between reserves and resources is based on current (exploration and production) technology and market conditions. Resource data are not cumulative and do not include reserves.

[b] Reserves, resources, and occurrences of uranium are based on a once-through fuel cycle operation. Closed fuel cycles and breeding technology would increase the uranium resource dimension 50–60 fold. Thorium-based fuel cycles would enlarge the fissile-resource base further.

Source: Chapter 7.

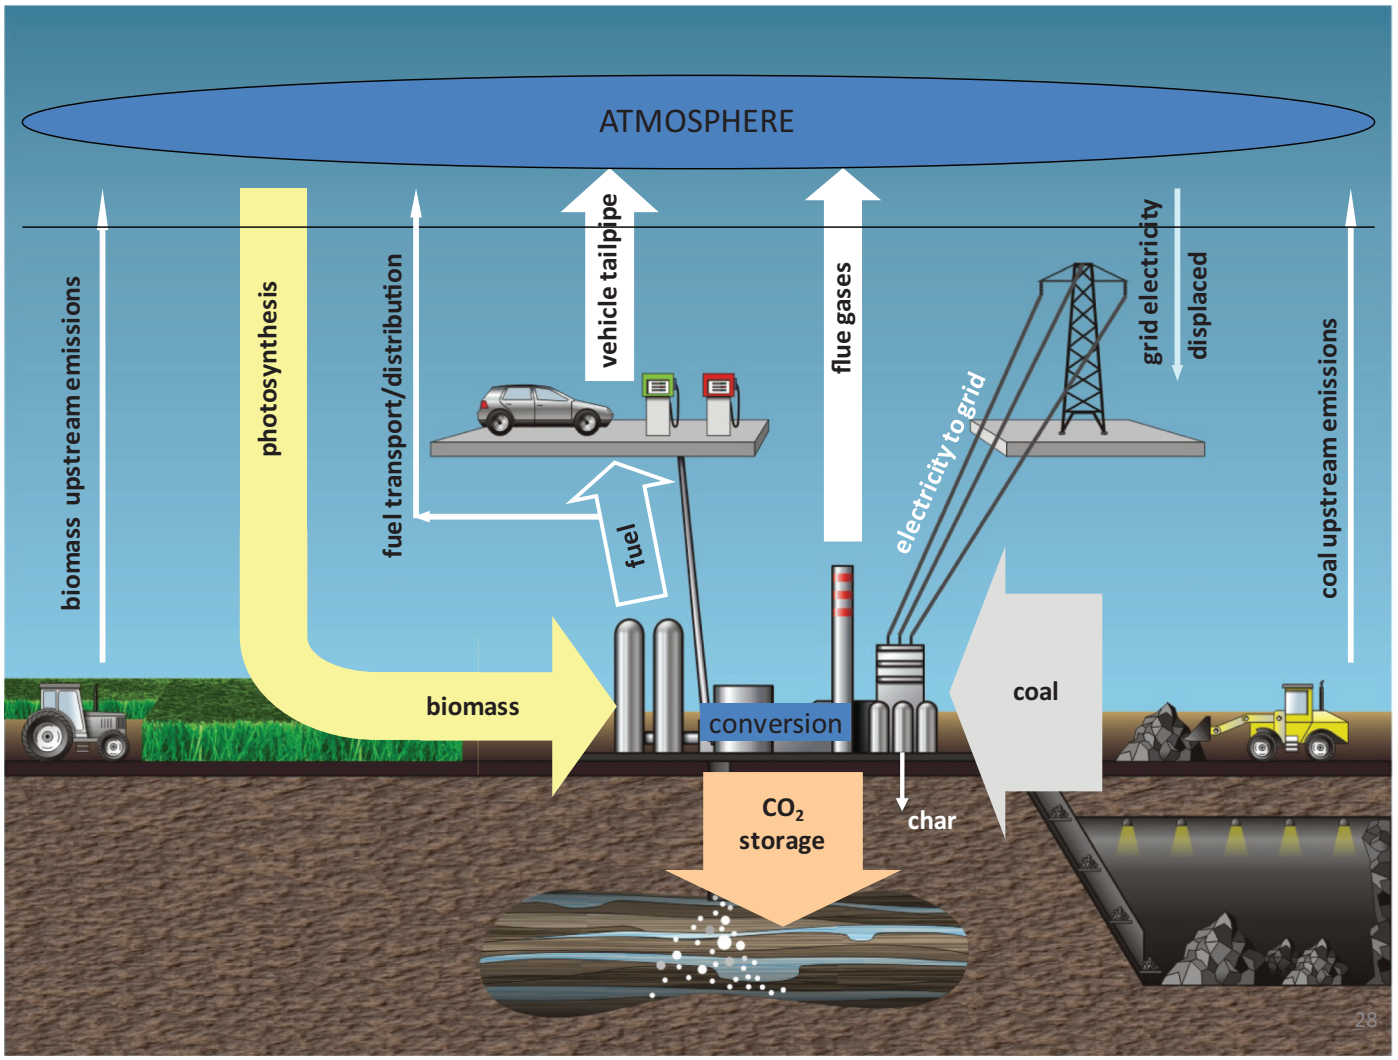

Figure SPM-8. | Carbon flows for conversion of coal and biomass to liquid fuels and electricity. For this system, when biomass is approximately 30% of the feedstock input (on a higher heating value basis), the net fuel cycle GHG emissions associated with the produced liquid fuels and electricity would be less than 10% of the emissions for the displaced fossil energy. Source: Larson et al., 2010, see Chapter 12.[5]

Continued use of coal and other fossil fuels in a carbon-constrained world requires strategies that deal with this reality. For industrial and developing countries, these strategies would differ in the short term but converge in the long term. For developing countries, the emphasis could be on increasing access to energy services based on clean energy carriers, building new manufacturing and energy infrastructures that anticipate the evolution to low-carbon energy systems, and exploiting the rapid growth in these infrastructures to facilitate introduction of the advanced energy technologies needed to meet sustainability goals. In industrial countries, where energy infrastructures are largely already in place, a high priority could be overhauling existing coal power plant sites to add additional capabilities (such as co-production of power and fuels) and CCS. Simply switching from coal to natural gas power generation without CCS will not achieve the needed carbon emission reductions.

Among the technologies that use fossil fuels, co-production strategies using coal plus biomass and CCS have the greatest ability to address all the major energy-related societal challenges. In the long term, hydrogen made from fossil fuels with CCS is an energy option, but infrastructure challenges are likely to limit this option in the near

5 **Larson, E. D., G. Fiorese, G. Liu, R. H. Williams, T. G. Kreutz and S. Consonni, 2010:** Co-production of Decarbonized Synfuels and Electricity from Coal + Biomass with CO_2 Capture and Storage: an Illinois Case Study. *Energy – Environmental Science*, **3**(1):28–42.

term. Co-production with CCS of electricity and carbon-based synthetic transportation fuels such as gasoline, diesel and jet fuel represent low-cost approaches for simultaneously greatly reducing carbon emissions for both electricity and transportation fuels and providing multiple benefits (Figure SPM 8): enhancing energy supply security, providing transportation fuels that are less polluting than petroleum-derived fuels in terms of conventional air pollutants, providing super-clean synthetic cooking fuels as alternatives to cooking with biomass and coal (critically important for developing countries), and greatly reducing the severe health damage costs due to air pollution from conventional coal power plants.

No technological breakthroughs are needed to get started with co-production strategies, but there are formidable institutional hurdles created by the need to manage two disparate feedstock supply chains (for coal and biomass) and provide simultaneously three products (liquid fuels, electricity, and CO_2) serving three different commodity markets.

6. Universal Access to Modern Energy Carriers and Cleaner Cooking by 2030 is Possible: *Universal access to electricity and cleaner cooking fuels and stoves can be achieved by 2030; however, this will require innovative institutions, national and local enabling mechanisms, and targeted policies, including appropriate subsidies and financing. The necessary technologies are available, but resources need to be directed to meet these goals. Universal access is necessary to alleviate poverty, enhance economic prosperity, promote social development, and improve human health and well-being. Enhancing access among poor people, especially poor women, is thus important for increasing their standard of living. Universal access to clean cooking technologies will substantially improve health, prevent millions of premature deaths, and lower household and ambient air pollution levels, as well as the emissions of climate-altering substances.*

Access to affordable modern energy carriers and cleaner cooking, improves well-being and enables people to alleviate poverty and expand their local economies. Enhanced access to modern energy carriers and cleaner cooking can become an effective tool for improving health for example, by reducing air pollution and can also help combat hunger by increasing food productivity and reducing post-harvest losses. Modern energy carriers and end-use conversion devices could improve education and school attendance by providing better lighting, heating, and cooling services. Electrifying rural health centers enables medical services to be provided at night, medicines to be preserved and more-advanced medical equipment to be used. Reduction of the proportional cost of energy services, particularly for rural poor people who spend a significant part of their time and disposable income on energy, is also important. This can liberate financial and human, especially women's, resources for other important activities or expenses, such as education, purchasing more and better-quality food, and expanding income-generating activities.

Several challenges exist to improving access to modern forms of energy and cleaner cooking. These include low income levels, unequal income distribution, inequitable distribution of modern forms of energy, a lack of financial resources to build the necessary infrastructure, weak institutional and legal frameworks, and a lack of political commitment to scaling up access. Even among households that have physical access to electricity and modern fuels, a lack of affordability and unreliable supplies limit their ability to use these resources, particularly for productive purposes. In addition to access to modern forms of energy, there must be access to end-use devices that provide the desired energy services. Those who can afford modern energy carriers may still not be able to afford the upfront costs of connections or the conversion technology or equipment that makes that energy useful.

While the scale of the challenge is tremendous, access to energy for all, electricity for all, and modern fuels or stoves for all by 2030 is achievable. This will require global investments of US$36–41 billion annually – a small fraction of total energy infrastructural investments required by 2030. It is expected that as households with public sector support gain access to modern energy and end-use devices and start earning incomes, their standard of living and ability to pay for the energy services utilized would successively expand.

Between 1990 and 2008 almost two billion people gained access to electricity, more than the corresponding population increase of 1.4 billion people over that time period (see Figure SPM-9). By 2030, the 1.4 billion people currently without access to electricity plus the projected population increase to 2030 of 1.5 billion people need to be connected to meet the GEA goal on electricity access (see Figure SPM-10). To achieve this, a multitrack approach is needed, combing grid extension with microgrids and household systems. Grid extension is currently the lowest cost per kWh delivered and also the preferred delivery form by most customers because of the capacity to deliver larger quantities of power for

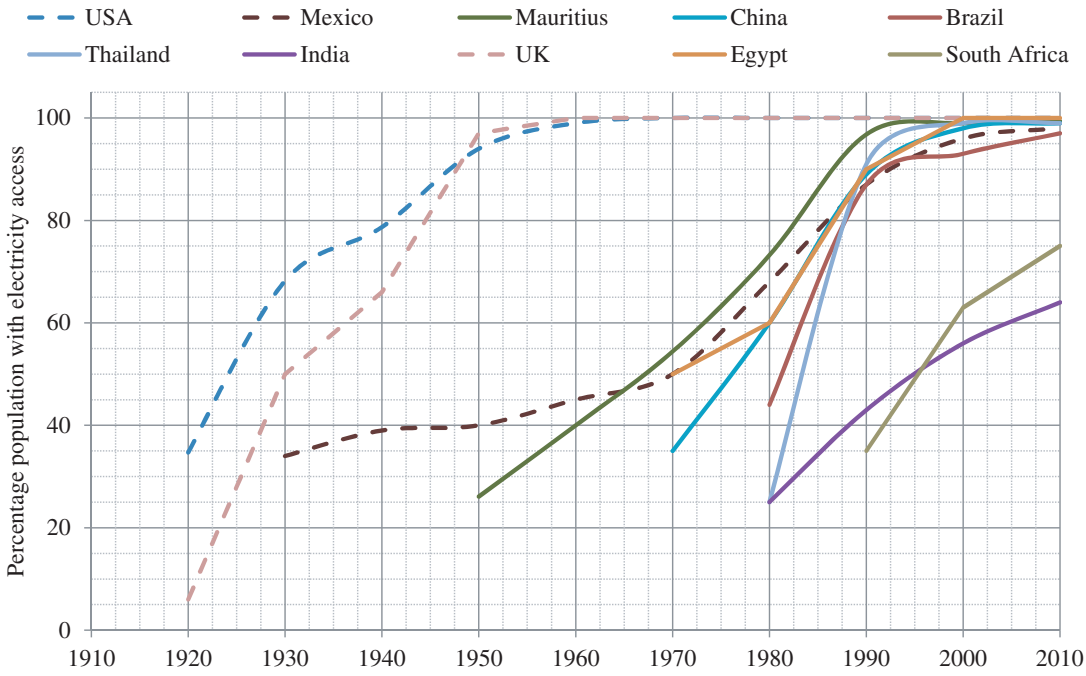

Figure SPM-9. | Historical experience with household electrification in select countries. Source: Chapter 19.

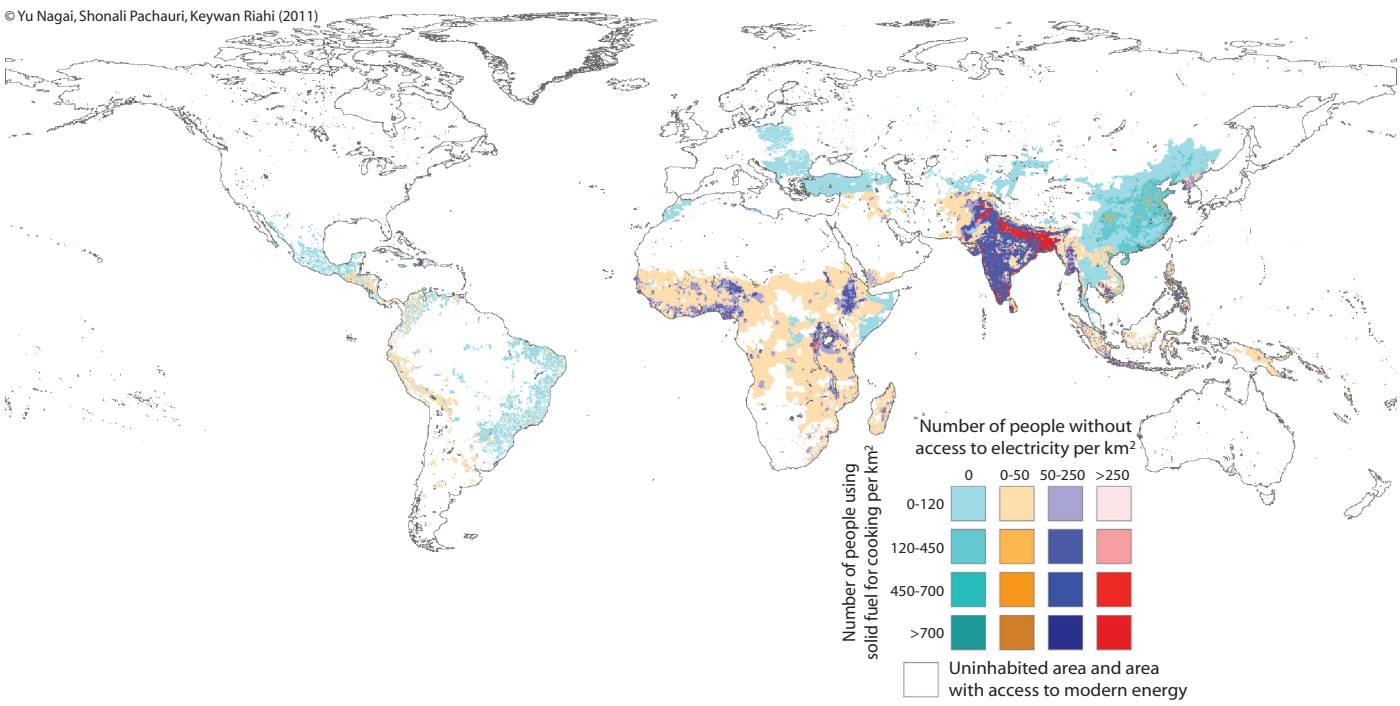

Figure SPM-10. | Density of population lacking access to modern energy carriers in 2005. Colored areas show people per km² without access to electricity and those that use solid fuels for cooking, e.g., dark blue and red areas show where people do not have access to electricity and cook predominately using solid fuels. Source: Chapters 17 and 19.

productive purposes. For many remote populations grid extension by 2030 will be highly unlikely and microgrids offer an alternative, based on local renewable energies or imported fossil fuels. An interesting approach to providing modern energy and development in remote villages is the multifunctional platform beginning to gain hold in West Africa. Household electrification is expanding rapidly in some countries, based on solar PV that are financed by micro-credits that has been done without increasing household expenses for energy (replacing candles and kerosene).

About 3 billion people rely entirely, or to a large degree, on traditional biomass or coal for cooking and heating. This number has not changed appreciably over the last decades, particularly among households in rural areas. Indeed, more people rely on these fuels today than any time in human history. Improving the cooking experience for these populations will require access to cleaner liquid or gaseous fuels, especially biogas, liquid petroleum gas (LPG), and ethanol, or alternatively access to advanced biomass stoves with efficiency and pollutants emissions similar to those of gas stoves. Transitioning to such fuels or stoves is not likely to have negative implications for climatic change. This is because transitioning to modern fuels (even in the case that these are fossil based) will displace large quantities of traditional biomass use. Current technologies that use traditional biomass are a factor 4–5 times less efficient than cooking with modern fuels such as LPG, and are associated with significant emissions of non-CO_2 Kyoto gases (e.g., CH_4, N_2O) and aerosols (e.g., BC, OC) due to incomplete combustion.

Providing universal and affordable access to electricity and cleaner cooking is possible if timely and adequate policies are put in place. Overall, and on the basis of successful experiences of increasing access to modern energy, no single approach can be recommended above the others. What is clear, however, is that the current institutional arrangements and policies have met with mixed success, at best. Reforms are needed, at global and country level, to strengthen the feasibility of energy projects for poor people, expand the range of players involved, open up the regulatory system, and allow for innovation. In the specific case of access to cleaner cooking, fuel subsidies alone will be neither sufficient nor cost-effective in terms of achieving ambitious energy access objectives (see Figure SPM-11). Financial mechanisms, such as micro-credit, will need to complement subsidies to make critical end-use devices such as cleaner cookstoves affordable for poor people.

A paradigm shift is needed in the approach to energy planning and policy implementation in order to facilitate access to modern forms of energy and cleaner cooking. Current supply-side approaches that simply take as their starting point the provision of electricity, petroleum, or gas, or of equipment of a particular type (solar technology, improved cookstoves, biogas, and other forms of bioenergy) are unable to reap the full potential of social and economic improvements that

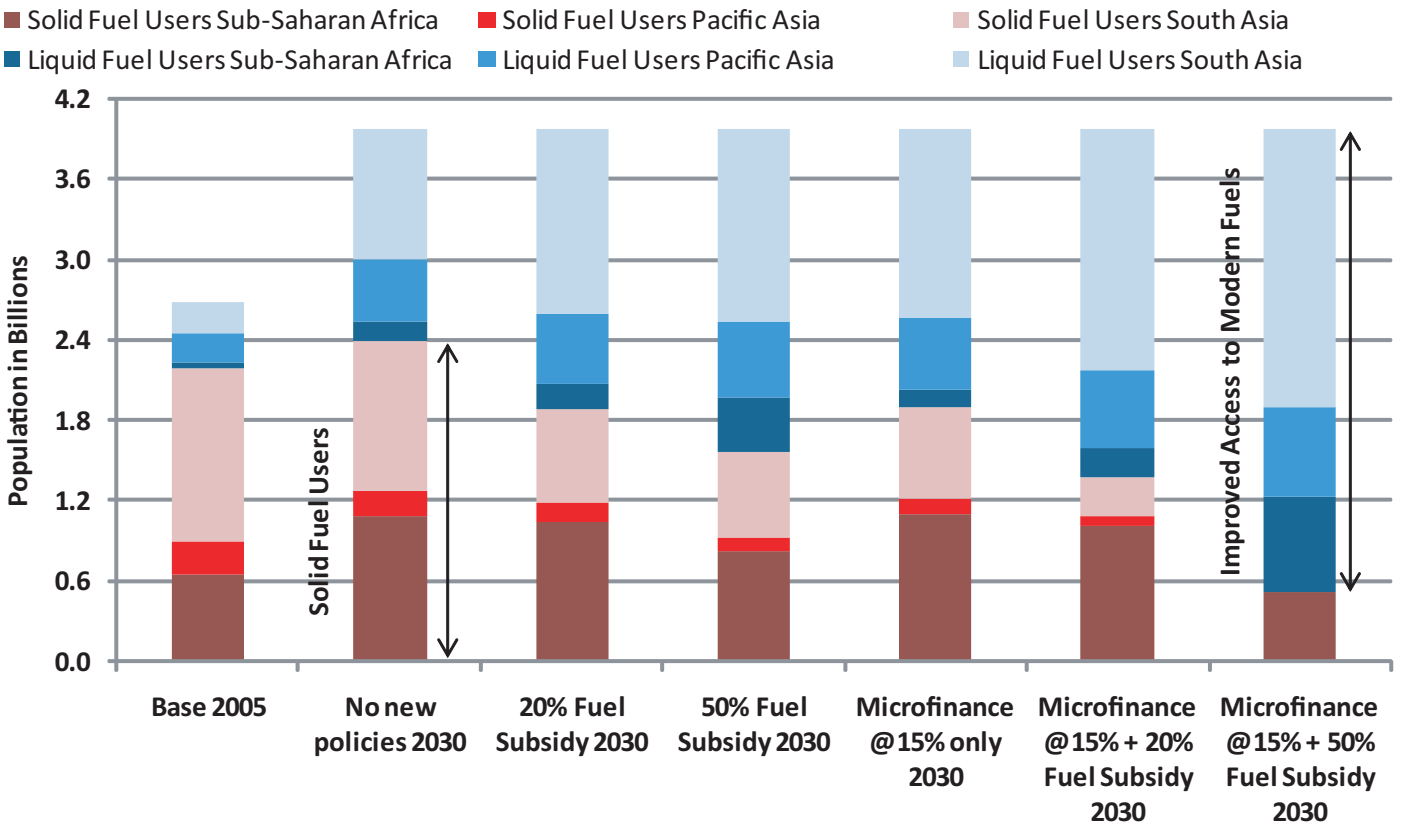

Figure SPM-11. | Impact of alternative policy scenarios on access to cleaner cooking fuels in three developing regions. Subsidies are relative to consumer price levels and are additional to existing subsidies. Source: Chapter 17.

follow from improved energy access and cleaner cooking. Leveraging funding and access to capital from public and private sources – for needed investments at the macro level and, at the micro level, for meeting costs for low-income households – is crucial in efforts to expand access to energy services for the poorest people. Creative financing mechanisms and transparent cost and price structures will be critical to achieving the required scale-up and quick roll-out of solutions to improve access.

Policy recommendations in the form of general ideas or guidelines are provided below. Regional and national contexts should be considered in defining strategies, instruments, and measures.

- A better understanding and a clearer diagnosis of the structure and functioning of energy systems, along with the needs (energy services) to be supplied, is needed. It has often been absent in the discussion of proposals and the role of public policies. Good policies need good diagnoses. Support and funds for diagnosis and information should be part of the strategies.

- Subsidies are generally justified as a response to inequality and social expectations in energy provision. However, their net effect can be positive or negative depending on the intended goals of the subsidy, and the way a subsidy is implemented. An effective tariff and subsidy regime has to be transparent and minimize administrative costs to avoid gaming of the system and to maximize the benefits that accrue to the intended recipients. Subsidies to energy should be complemented with funds toward solving the first-cost capital financing problem since up-front costs of equipment are, usually, the key barrier.

- Financing mechanisms are needed for every scale of energy intervention. Mobilizing affordable and genuine international, regional, national, and local funds is crucial.

- Energy access policy is part of a wider development policy and should be aligned with other sector policies and objectives. If these policies are misaligned, they can reduce the effectiveness of any given policy. Policy misalignments can occur when different energy policies work at cross-purposes or when government priorities that could benefit from an effective energy policy are not aligned. In particular, there is a need to link rural and peri-urban energy supply more closely with rural development. This would shift the focus from minimal household supply to a more comprehensive approach to energy that includes productive activities and other welfare-enhancing uses of energy. Ideally, the linkages between energy and other policy priorities, such as health, education, gender equality and poverty alleviation, should be recognized explicitly and local solutions that address these needs be encouraged and supported.

- Capacity development is needed, especially for the design and implementation of public policies oriented to poor people.

7. An Integrated Energy System Strategy is Essential: *An integrated approach to energy system design for sustainable development is needed – one in which energy policies are coordinated with policies in sectors such as industry, buildings, urbanization, transport, food, health, environment, climate, security, and others, to make them mutually supportive. The use of appropriate policy instruments and institutions can help foster a rapid diffusion and scale-up of advanced technologies in all sectors to simultaneously meet the multiple societal challenges related to energy. The single most important area of action is efficiency improvement in all sectors. This enhances supply side flexibility, allowing the GEA challenges to be met without the need for technologies such as CCS and nuclear.*

Energy-focused policies must be coordinated and integrated with policies addressing socioeconomic development and environmental protection in other sectors. Effective policy portfolios will require a combination of instruments, including regulatory frameworks and investment policies, as well as measures for strengthening capacity development, which stimulate innovation.

The main conclusion from the GEA pathways analysis is that energy efficiency improvements are the most important option to increase the flexibility of regional and sectoral energy end use and supply systems. In pathways with high rates of efficiency improvements, it was possible to achieve the GEA normative goals under any of the assumed supply portfolio restrictions and even without including nuclear energy and CCS technologies.

Energy systems differ between regions, between major economies, and between developing and industrial countries. Approaches to the necessary transitions to create energy systems for a sustainable future therefore vary, and policies that work successfully in one region may fail in another. Nevertheless, there are lessons to be learned from shared experiences. The evolution of energy systems will depend on how well technologies are implemented and how well policies are instituted to bring about the required changes.

Prevailing market and institutional structures in the energy sector have a significant influence on investments in different end-use and supply-side options. In countries with well-developed energy markets, spot-market energy trading is common and long-term contracts are becoming less frequent; and it is now more difficult to ensure long-term returns on large-scale investments. This is the main impediment to financing of large capital-intensive energy-supply projects.

Governments must recognize that policies promoting competition in the electricity sector must also prevent the short-term exercise of market power that results in unjustified excessive profits for some producers and speculators as well as price volatility for consumers, requiring continued regulation and public sector involvement in energy system planning and long-term contracting.

A regulatory framework is essential as it facilitates the creation and modernization of physical infrastructure and capital investments in energy end-use and supply systems. It is also necessary for economic development and poverty reduction.

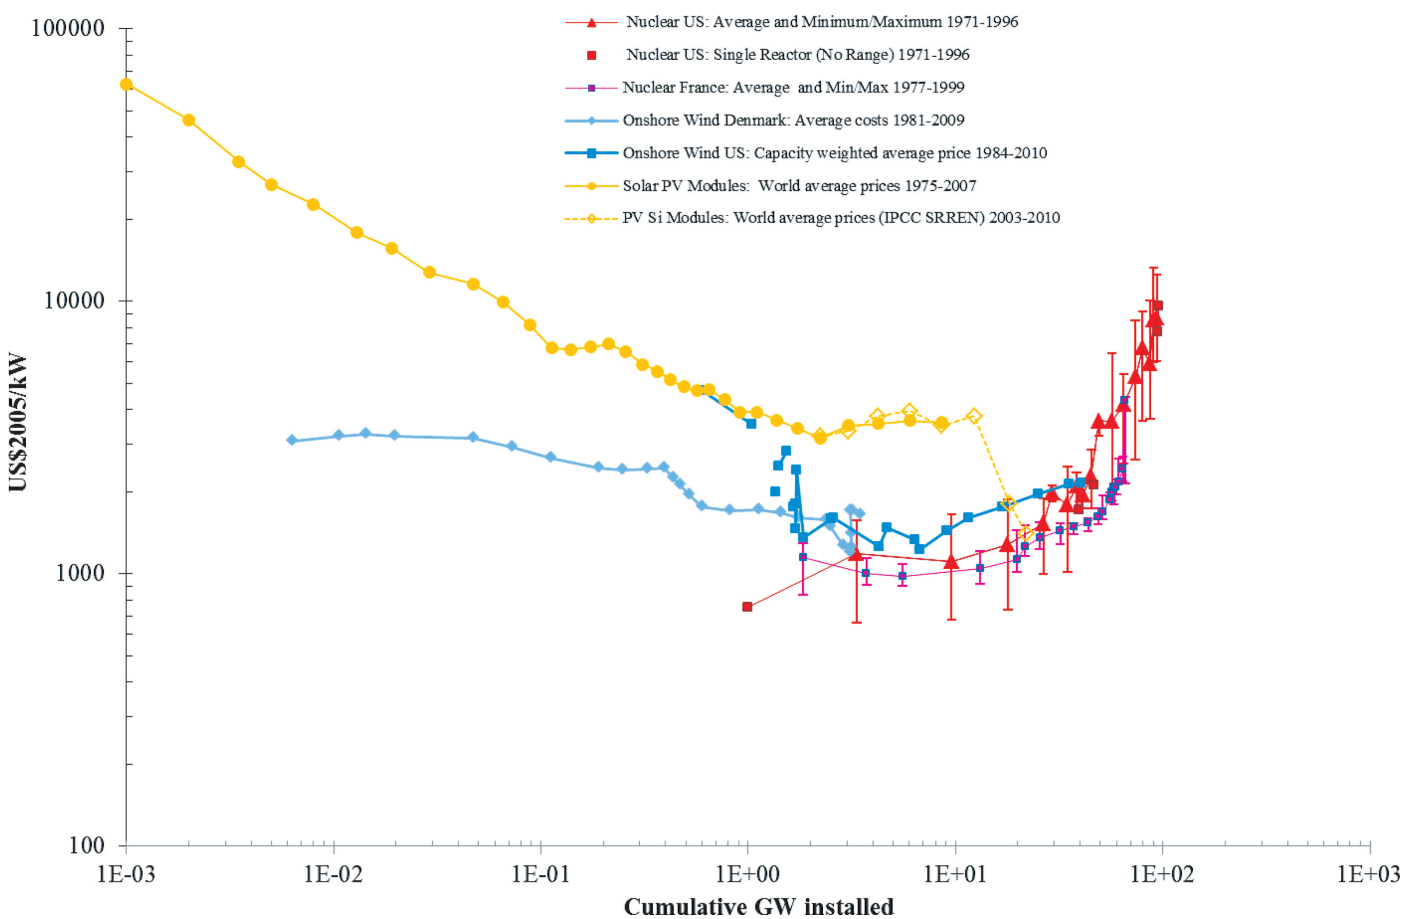

Figure SPM-12. | Cost trends of selected non-fossil energy technologies (US$2005/kW installed capacity) versus cumulative deployment (cumulative GW installed) Chapter 24 data have been updated with most recent cost trends (2010) available in the literature for PV Si Modules and US onshore wind turbines. Note that the summary illustrates comparative cost trends only and is not suitable for direct economic comparison of different energy technologies due to important differences between the economics of technology components (e.g. PV modules versus total systems installed), cost versus price data, and also differences in load factors across technologies (e.g., nuclear's electricity output per kW installed is three to four times larger than that of PV or wind turbine systems). Source: Chapter 24.

Success will depend on the implementation of robust public and private partnerships that can achieve unprecedented cooperation and integration between and among the public and private sectors, civil society, and academia.

A multiplicity of policies is required to address the potential impacts of the energy system on human health and the environment. A mix of regulations, information programs, and subsidies are needed, for example, to stimulate the rapid adoption of household energy-using devices that have virtually zero indoor emissions. Ambient air quality requires regulations on emissions from fuel combustion. Similarly, regional air quality must be protected by technology and emissions regulations or by direct emissions pricing.

Policies to foster energy from biomass should seek to minimize the trade-offs between biomass for food and biomass for fuel by encouraging the use of biomass residues and sustainable feedstocks as well as efficient conversion processes. Many developing countries import all or most of their current liquid fuels (in the form of oil and diesel) at increasingly higher costs and have at the same time large areas that are off-grid.

Greenhouse gas pricing policies will be essential in shifting energy systems toward low-carbon emission technologies, fuels, and activities. While there is disagreement on which pricing method is best – carbon taxes or cap and trade – the two approaches can be designed so that their effects are quite similar. The price certainty of a carbon tax can be approximated with cap and trade by setting a price floor and ceiling for permit prices. The revenues generated by a carbon tax can also be obtained by auctioning permits in the cap and trade approach

It is important to complement GHG pricing with a portfolio of other regulatory and market mechanisms. This is because different instruments are more effective in different sectors, geographic and cultural regions, as well as for different options. For instance, due to the magnitude and diversity of market barriers prevailing in the building sector, different regulatory and market-based instruments and their packages needed to be tailored to overcome specific barriers.

Strategic alliances and strong coordination among various policy fields will be able to lead to the realization of a larger share of technological potential by improving the economics of efficiency investments through the addition of further benefits to cost-efficiency considerations, such as security, employment, social welfare, and regional development. For example, policies for urban planning that encourage high density development with investments in public transport are likely to lead to lower long-term energy demand. Similarly, policies for renewable energy technologies could emphasize positive spillover effects on new venture and job creation. By actively seeking opportunities for such cross-sectoral integration; the required changes in the energy system may be accelerated. For example, a shift to clean cooking may be regarded as much a required change in the energy system, as an intervention to improve maternal and child health.

8. Energy Options for a Sustainable Future bring Substantial, Multiple Benefits for Society: *Combinations of resources, technologies, and polices that can simultaneously meet global sustainability goals also generate substantial economic, environmental, and social development benefits. These include, but are not limited to, improved local health and environment conditions, increased employment options, strengthened local economies through new business opportunities, productivity gains, improved social welfare and decreased poverty, more resilient infrastructure, and improved energy security. Synergistic strategies that focus on local and national benefits are more likely to be implemented than measures that are global and long-term in nature. Such an approach emphasizes the local benefits of improved end-use efficiency and increased use of renewable energy, and also helps manage energy-related global challenges. These benefits make the required energy transformations attractive from multiple policy perpectives and at multiple levels of governance.*

The energy systems illustrated by the GEA pathways meet the sustainability goals by design while generating substantial economic, environmental, and social benefits. For example, achieving near-term pollution and health objectives is furthered by investing in the same energy technologies that would be used to limit climate change. Policies to control emissions of greenhouse gases, or to increase access to cleaner cooking fuels could, in turn, bring significant improvements in pollution related health impacts. For example as the GEA pathways indicate, a saving of 20 million disability adjusted life years (DALYs) from outdoor air pollution and more than 24 million DALYs from household air

pollution. In addition, universal access to electricity and cleaner cooking fuels opens up opportunities for education, for income generating activities, and significantly improved well-being.

This synergy is crucial and advantageous, given that measures which lead to local and national benefits (e.g., improved health and environment) may be more easily adopted than those measures that are put forward solely on the grounds of global goals. Many energy efficiency and renewable energy options enjoy such synergies and generate benefits across multiple objectives. Some of these advantages can be so substantial for certain investments and measures that they may offer more attractive entry points into policymaking than the climate or social targets alone. This is particularly the case where benefits are local rather than global. Seeking local benefits and receiving global benefits as a bonus is very attractive, and this is often the case for investments in energy efficiency and renewable sources of energy.

Therefore, even if some of these multiple benefits cannot be easily monetized, identifying and considering them explicitly may be important for decision-making. Cost-effectiveness (or cost-benefit) analyses evaluating energy options may fare differently when multiple benefits are considered.

The enhancement of end-use efficiency in buildings, transport and industry offers many examples of benefits across multiple environmental, social, and economic objectives:

- *inter alia* improved social welfare as a result of very high efficiency and thus very low fuel-cost buildings;
- reduced need for public funds spent on energy price subsidies for people living in poverty; health benefits through significantly reduced indoor and outdoor air pollution, often translating into commendable productivity gains;
- productivity gains and general improvements in operational efficiency in industry translate into strengthened competitiveness; and
- enhancing efficiency by increasing the rate of building retrofits can in addition be a source of employment and know-how.

Other benefits that are difficult to quantify include improved comfort and well-being, reduced congestion, new business opportunities, and better and more durable capital stock.

Rapid decarbonization of the energy system for climate protection also reduces the need for subsidies presently given to carbon-intensive petroleum products and coal. Subsidies for these fuels amount to approximately US$132–240 billion per year, and only 15% of this total is spent directly towards those with limited access to clean energy. However, GHG mitigation in the GEA pathways would, at the same time, reduce consumption of carbon-intensive fossil fuels, leading to a reduction in the need for subsidies for petroleum products and coal in the order of US$70–130 billion per year by 2050 compared to today.

Whether an impact is a benefit or a liability depends on the baseline and specific local situation. For example, while LPG causes major environmental and climate impacts in itself, it still has major advantages in many areas when it replaces traditional biomass as a fuel. Thus a unique novelty of the analysis is that it provides a new, additional framework for a well-founded assessment for individual decisions to choose among various energy alternatives, which complement financial appraisals. For example, in regions where access to modern forms of energy is a major energy policy goal, evaluations of "energy security" will play an essential role in ranking the different options available at comparable costs. In other areas, access or employment may be key secondary objectives of energy policy and these can play an important role in additional prioritization of options with comparable local costs.

There is a broad array of different benefits in the spectrum of policy target areas, which represent many potential entry points into policy-making. However, some options can have a wider range of multiple benefits than others, in particular renewable energies and improved energy end-use efficiency.

9. Socio-Cultural Changes as well as Stable Rules and Regulations will be Required: *Crucial issues in achieving transformational change toward sustainable future include non-technology drivers such as individual and public awareness, community and societal capacities to adapt to changes, institutions, policies, incentives, strategic spatial planning, social norms, rules and regulations of the marketplace, behavior of market actors, and societies' ability to introduce through the political and institutional system, measures to reflect externalities. Changes in cultures, lifestyles, and values are also required. Effective strategies will need to be adopted and integrated into the fabric of national socio-cultural, political, developmental, and other contextual factors, including recognizing and providing support for the opportunities and needs of all nations and societies.*

The complexity, magnitude, and speed of the changes envisaged in this transformation will necessitate a major shift in the way that societies analyze and define the concept of 'capacities' and the way in which they go about the important task of developing these capacities to meet the challenges of energy transitions. Different from some of the linear approaches to capacity development and to technology transfer and deployment used today, which often fail to appreciate the complexity of change processes, the concept of capacity development advanced by the GEA is intimately linked to the energy transitions perspective based on multilayered processes of system change.

In these processes, special attention is paid to the informal institutions that arise out of historically shaped habits, practices, and vested interests of players in the system already in place and to the tendency for path dependence, where past choices constrain present options. They are given special attention because they constitute potential impediments to needed change. In the transitions perspective, both learning and unlearning such habits, practices, and norms in the course of change are important.

Traditional habits, practices, and norms also shape the styles of communication in societies. Evidence shows that the more successful change processes take place in environments that tend to move away from top-down communication and consultation to more active and continuous dialogue practices. Capacity development has an important role to play in building mechanisms of support and capacities for interactive feedback, flexibility, and adaptive management and change. And because these traditional habits, practices, and norms are embedded in a broader social context, building capacities for dialogue at the local level is essential.

Market development and the role of feedback and flexibility at the local and project level are also essential in support of the diffusion of new energy technologies, but they are usually ignored in the design of capacity building initiatives. Also important is the need to build and strengthen capacities for local manufacture, repair, and distribution of new energy-related technologies, whether related to improved cookstoves, solar home systems, or other forms of early energy access initiatives, or to the introduction of more modern and decentralized forms of energy. Successful examples of energy technology development and diffusion also point to the need to develop and strengthen local research capacities, participating in collaborative research and development efforts and coordinating across sectors and disciplines.

But these new and emerging forms of knowledge networking, coupled with new and innovative forms of finance and technology research collaboration and development, require new and enhanced capacities for effective participation on the international level that many countries, particularly developing ones, do not have or are not well developed today. The increasingly complex and fast-paced world of energy and climate change finance is a good example of an area where present capacities fall far short of the need. The recent climate change negotiations alone have generated pledges of fast-start finance up to 2012 of some US$30 billion and promises to work collaboratively so that this funding can grow to some US$100 billion by 2020.

This is only a small part of the overall investment projections needed to meet the high growth in energy demand – some US$1.7–2.2 trillion per year are needed to 2050. The world of energy finance has always been a large and complex market. The difference today is that it is becoming even more complex, with new and innovative instruments of finance, including the carbon market, and with countries demanding more attention to the need to develop, introduce, and diffuse new technologies. Under these conditions, a multi-goal approach can both speed the diffusion of new energy technologies as well as stimulate the development and energy transition processes in developing countries.

10. Policies, Regulations, and Stable Investment Regimes will be Essential: *A portfolio of policies to enable rapid transformation of energy systems must provide the effective incentive structures and strong signals for the deployment at scale of energy-efficient technologies and energy supply options that contribute to the overall sustainable development. The GEA pathways indicate that global investments in combined energy efficiency and supply will need to increase to between US$1.7–2.2 trillion per year compared to present levels of about US$1.3 trillion per year (about 2% of current world gross domestic product) including end-use components. Policies should encourage integrated approaches across various sectors and promote the development of skills and institutional capacities to improve the investment climate. Examples include applying market-oriented regulations such as vehicle emissions standards and low carbon fuel standards and as well as renewable portfolio standards to accelerate the market penetration of clean energy technologies and fuels. Reallocating energy subsidies, especially the large subsidies provided in industrialized countries to fossil fuels without CCS, and nuclear energy, and pricing or regulating GHG emissions and/or GHG-emitting technologies and fuels can help support the initial deployment of new energy systems, both end-use and supply, and help make infrastructures energy efficient. Publicly financed research and development needs to accelerate and be reoriented toward energy efficiency, renewable energy and CCS. Current research and development efforts in these areas are grossly inadequate compared with the future potentials and needs.*

The GEA analysis has identified pronounced asymmetries in current incentive structures for the development, early deployment, and the widespread diffusion of energy end-use and supply technologies that need rebalancing. Current technology policy frameworks are also often fragmented and contradictory instead of integrated and aligned. Nowhere is this more apparent that in the continued subsidies for fossil fuels that amount to close to US$500 billion and are in direct contradiction with policy initiatives that promote increasing energy end-use efficiency and deployment of renewables. This assessment has also identified a marked mismatch between the critical needs for vastly improved energy efficiency and the under-representation of energy efficiency in publicly funded energy research and development and deployment (RD&D) and incentives for early market deployment of new technologies which are presently characterized by a distinct supply-side over-emphasis.

A first, even if incomplete, assessment of the entire global investments into energy technologies – both supply and demand-side technologies – across different innovation stages suggests RD&D investments of some US$50 billion, market formation investments (which rely on directed public policy support) of some US$150 billion, and an estimated range of US$1–5 trillion investments in mature energy supply and end-use technologies (technology diffusion). The GEA pathways estimate the current annual energy investments at about US$1.3 trillion per year. The difference to the estimated range up to US$5 trillion is related mostly to the magnitude of demand-side investments that is not included in the pathways. Demand-side investments are of critical importance, particularly because the lifetimes of end-use technologies can be considerably shorter than those on the supply side. Demand-side investments might thus play an important role in achieving pervasive and rapid improvements in the energy system.

Major developing economies have become significant players in global energy technology RD&D, with public- and private-sector investments approaching some US$20 billion – in other words, almost half of global innovation investments – which are significantly above OECD public-sector energy RD&D investments (US$13 billion).

Policies now need to move toward a more integrated approach, stimulating simultaneously the development as well as the adoption of efficient and cleaner energy technologies and measures. RD&D initiatives without simultaneous incentives for consumers to adopt the outcomes of innovation efforts risk not only being ineffective but also precluding the market feedbacks and learning that are critical for continued improvements in technologies.

Another area of near-term technology policy focus is the domain of enhancing the international cooperation in energy technology research and development as well as in the domains of technology standards. Through dynamic standard setting and international harmonization, predictable and long-term signals are provided to innovation players and markets. Ambitious efficiency standards are of particular urgency for long-lived capital assets such as buildings. Other end-use technologies such as vehicles or appliances turn over much more quickly, offering the possibility of more gradually phased in technology standards as long as clear long-term signals are provided.

Table SPM-4. | Energy investments needed between 2010 and 2050 to achieve GEA sustainability goals and illustrative policy mechanisms for mobilizing financial resources. GEA pathways indicate that global investments in combined energy efficiency and supply have to increase to about US$1.7–2.2 trillion per year compared with the present level of some US$1.3 trillion (2% of current gross world product). Given projected economic growth, this would be an approximately constant fraction of GDP in 2050.

Times	Investment (billions of US$/year)		Policy mechanisms			
		2010–2050	Regulation, standards	Externality pricing	Carefully designed subsidies	Capacity building
Efficiency	n.a.[a]	290–800[b]	*Essential* (elimination of less efficient technologies every few years)	*Essential* (cannot achieve dramatic efficiency gains without prices that reflect full costs)	*Complement* (ineffective without price regulation, multiple instruments possible)[c]	*Essential* (expertise needed for new technologies)
Nuclear	5–40[d]	15–210	*Essential* (waste disposal regulation and, of fuel cycle, to prevent proliferation)	*Uncertain* (GHG pricing helps nuclear but prices reflecting nuclear risks would hurt)	*Uncertain* (has been important in the past, but with GHG pricing perhaps not needed)	*Desired* (need to correct the loss of expertise of recent decades)[e]
Renewables	190	260–1010	*Complement* (feed-in tariff and renewable portfolio standards can complement GHG pricing)	*Essential* (GHG pricing is key to rapid development of renewables)	*Complement* (tax credits for R&D or production can complement GHG pricing)	*Essential* (expertise needed for new technologies)
CCS	<1	0–64	*Essential* (CCS requirement for all new coal plants and phase-in with existing)	*Essential* (GHG pricing is essential, but even this is unlikely to suffice in near term)	*Complement* (would help with first plants while GHG price is still low)	*Desired* (expertise needed for new technologies)[e]
Infrastructure[f]	260	310–500	*Essential* (security regulation critical for some aspects of reliability)	*Uncertain* (neutral effect)	*Essential* (customers must pay for reliability levels they value)	*Essential* (expertise needed for new technologies)
Access to electricity and cleaner Cooking[g]	n.a.	36–41	*Essential* (ensure standardization but must not hinder development)	*Uncertain* (could reduce access by increasing costs of fossil fuel products)	*Essential* (grants for grid, micro-financing for appliances, subsidies for clean cookstoves)	*Essential* (create enabling environment: technical, legal, institutional, financial)

[a] Global investments into efficiency improvements for the year 2010 are not available. Note, however, that the best-guess estimate from Chapter 24 for investments into energy components of demand-side devices is by comparison about US$300 billion per year. This includes, for example, investments into the engines in cars, boilers in building heating systems, and compressors, fans, and heating elements in large household appliances. Uncertainty range is between US$100 billion and US$700 billion annually for investments in components. Accounting for the full investment costs of end-use devices would increase demand-side investments by about an order of magnitude.

[b] Estimate includes efficiency investments at the margin only and is thus an underestimate compared with demand-side investments into energy components given for 2010 (see note a).

[c] Efficiency improvements typically require a basket of financing tools in addition to subsidies, including, for example, low- or no-interest loans or, in general, access to capital and financing, guarantee funds, third-party financing, pay-as-you-save schemes, or feebates as well as information and educational instruments such as labeling, disclosure and certification mandates and programs, training and education, and information campaigns.

[d] Lower-bound estimate includes only traditional deployment investments in about 2 GW capacity additions in 2010. Upper-bound estimate includes, in addition, investments for plants under construction, fuel reprocessing, and estimated costs for capacity lifetime extensions.

[e] Note the large range of required investments for CCS and nuclear in 2010–2050. Depending on the social and political acceptability of these options, capacity building may become essential for achieving the high estimate of future investments.

[f] Overall electricity grid investments, including investments for operations and capacity reserves, back-up capacity, and power storage.

[g] Annual costs for almost universal access by 2030 (including electricity grid connections and fuel subsidies for cleaner cooking fuels).

Some of the policies for energy for sustainability described above simply involve an improvement of existing policies, such as better management of the electricity sector or more responsible use of fossil fuel resource rents. But the dominant message of the GEA is that the global energy system must be rapidly modified and expanded to provide energy access to those who have none, and must quickly transform to an energy system more supportive of sustainable development. This transition will require considerable investments over the coming decades. Table SPM-4 indicates the necessary investments to achieve this as estimated by the GEA, and links these to the types of policies needed. It also assesses these policies in terms of their necessity and their ability to complement or substitute for each other. Although

considerable, these investment levels can be compared to estimates of global fossil fuel subsidy levels on the order of US$500 billion a year, of which an estimated US$100 billion goes to producers.

Table SPM-4 compares the costs and policies for different technology options to those of promoting energy access. Different types of technologies and objectives will require different combinations of policy mechanisms to attract the necessary investments. Thus, the Table identifies 'essential' policy mechanisms that must be included for a specific option to achieve the rapid energy system transformation, 'desired' policy mechanisms that would help but are not a necessary condition, 'uncertain' policy mechanisms in which the outcome will depend on the policy emphasis and thus might favor or disfavor a specific option, and policies that are inadequate on their own but could 'complement' other essential policies.

GEA findings indicate that global investments in combined energy efficiency and supplies have to increase to about US$1.7–2.2 trillion per year compared with the present level of some US$1.3 trillion (2% of current gross world product). Given projected economic growth, this would be an approximately constant fraction of GDP in 2050.

For some objectives, such as energy access, future investment needs are comparatively modest. However, a variety of different policy mechanisms – including subsidies and regulation as well as capacity building programs – need to be in place. Regulations and standards are also essential for almost all other options listed in the Table, while externality pricing might be necessary for capital-intensive technologies to achieve rapid deployment (such as a carbon tax to promote diffusion of renewables, CCS, or efficiency). The GEA estimates that the investment requirements to transform energy systems are in the range of US$1.7–2.2 trillion per year through 2020. Capital requirements for energy infrastructure are only a small part of the overall investment projections, but among the highest priorities of the options listed. A multi-goal approach can both speed the diffusion of new energy technologies as well as stimulate the development and energy transition processes in developing countries.

Increasing investments in the energy system as depicted by the GEA pathways requires the careful consideration of a wide portfolio of policies in order to create the necessary financial incentives, adequate institutions to promote and support them, and innovative financial instruments to facilitate them The portfolio needs to include regulations and technology standards in sectors with, for example, relatively low price elasticity in combination with externality pricing to avoid rebound effects, as well as targeted subsidies to promote specific 'no-regret' options while addressing affordability. In addition, focus needs to be given to capacity development to create an enabling technical, institutional, legal, and financial environment to complement traditional deployment policies (particularly in the developing world).

In sum, the GEA finds that attainment of a sustainable future for all is predicated on resolving energy challenges. This requires the creation of market conditions, via government interventions, that invite and stimulate investments in energy options that provide incentives for rapid investments in energy end-use and supply technologies and systems.

1 Introduction

Energy is essential for human development and energy systems are a crucial entry point for addressing the most pressing global challenges of the 21st century, including sustainable economic, and social development, poverty eradication, adequate food production and food security, health for all, climate protection, conservation of ecosystems, peace, and security. Yet, more than a decade into the 21st century, current energy systems do not meet these challenges.

In this context, two considerations are important. The first is the capacity and agility of the players within the energy system to seize opportunities in response to these challenges. The second is the response capacity of the energy system itself, as the investments are long-term and tend to follow standard financial patterns, mainly avoiding risks and price instabilities. This traditional approach does not embrace the transformation needed to respond properly to the economic, environmental, and social sustainability challenges of the 21st century.

A major transformation is required to address these challenges and to avoid potentially catastrophic consequences for human and planetary systems. The GEA identifies strategies that could help resolve the multiple challenges simultaneously and bring multiple benefits. Their successful implementation requires determined, sustained, and immediate action.

The industrial revolution catapulted humanity onto an explosive development path, whereby reliance on muscle power and traditional biomass was replaced mostly by fossil fuels. In 2005, approximately 78% of global energy was based on fossil energy sources that provided abundant and ever cheaper energy services to more than half the world's population. Figure TS-1 shows two clear development phases in this explosive growth of global primary energy: the first characterized by a shift from reliance on traditional energy sources to coal and subsequently to oil and gas. During the past decades, hydropower, biomass, and nuclear energy have a combined share of almost 12%, while new renewables, such as solar and wind, are hardly discernible in Figure TS-1. These major transitions are also illustrated in Figure TS-2, which shows the shares of global primary energy and their changes over the period from 1850 to 2008. The dominance of biomass in the 1800s was overtaken by coal in the first half of the 20th century, giving way to oil around 1970. Oil still retains the largest share of global primary energy.[2]

Despite this rapid increase in overall energy use, over three billion people still rely on solid fuels such as traditional biomass, waste,

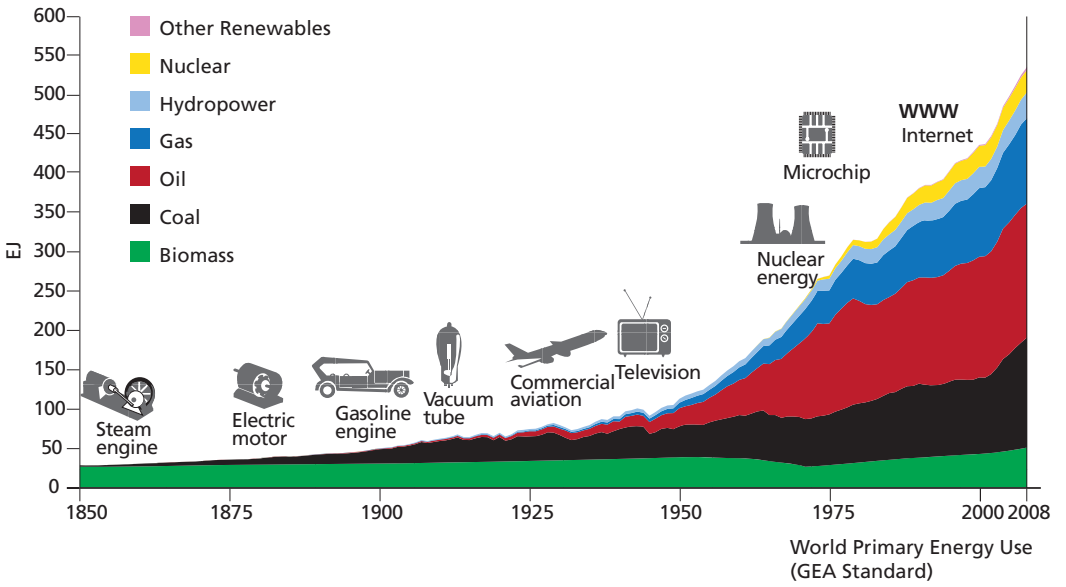

Figure TS-1 | Evolution of primary energy shown as absolute contributions by different energy sources (EJ). Biomass refers to traditional biomass until the most recent decades, when modern biomass became more prevalent and now accounts for one-quarter of biomass energy. New renewables have emerged in the last few decades. Source: updated from Nakicenovic et al., 1998 and Grubler, 2008, see Chapter 1.[1]

charcoal, and coal for household cooking and heating. The resulting air pollution leads to over two million premature deaths per year, mostly of women and children. Furthermore, approximately 20% of the global population has no access to electricity, making it difficult for children to study after sunset and impossible, for example, to keep vaccines cold, provide mechanical energy for agriculture and irrigation, and power the most simple machines for manufacturing and commerce. This situation undermines economic development and energy security, and causes indoor and outdoor air pollution and climate change. Addressing these challenges is essential to averting a future with high economic and social costs and adverse environmental impacts on all scales.

An energy system transformation is required to meet these challenges and bring prosperity and well-being to the nine billion people expected by 2050. The encouraging news is that the beginnings of such a transformation can be seen today, in the rapidly growing investments in renewable energy sources, high-efficiency technologies, new infrastructure, near zero-energy buildings, electric mobility, 'smart' energy systems, advanced biomass stoves, and many other innovations. The policy challenge is to accelerate, amplify, and help make the implementation of these changes possible, widespread, and affordable. Initial experience suggests that many of these changes are affordable, although they may be capital intensive and require high upfront investments. However, in general, they have lower long-term costs that offset many of the upfront added-investment requirements. Many of these innovations also lead to benefits in other areas such as equity and poverty, economic development, energy security, improved health, climate change mitigation, and ecosystem protection.

Grubler, A., 2008: Energy transitions. In *Encyclopedia of Earth*. C. J. Cleveland (ed.), Environmental Information Coalition, National Council for Science and the Environment, Washington, DC.

At the same time, the beginning of this grand transformation is, to a large extent, obscured by business-as-usual (BAU) thinking and behavior. Also, it tends to be blocked by current decision-making processes, institutions, consumption patterns, capital vintages, interests, and investment patterns that show a lock-in to old development pathways. However, there are excellent examples in many countries of transformational changes showing the opportunities available. The transition from the 'pervasive old' to the 'emerging new' will require continuous and major enhancements in awareness, knowledge, and skills, as well as new institutions, policies, and strategies.

GEA shows that while the local, regional, and global challenges, and their demands on energy systems, are enormous, they can all be met in a timely manner, effectively, and simultaneously – if societies want to do so. The assessment shows that a transformation toward energy systems supportive of sustainable development is possible. However, it will require decision makers to approach energy systems in an innovative and integrated way, to significantly strengthen their efforts domestically, and to coordinate their activities internationally.

GEA explored 60 alternative energy transformation pathways toward a sustainable future that simultaneously satisfy all the normative social and scientifically based environmental goals: continued economic development, universal access to modern energy carriers, climate and environment protection, improved human health, and better energy security.

The 60 pathways were grouped into three different approaches toward achieving the normative goals: GEA-Supply, GEA-Mix, and GEA-Efficiency. They were selected to represent three alternative evolutions of the energy system toward a sustainable future (details are in Section TS-4). A major conclusion is that many of these pathways satisfy all the GEA goals (see Sections TS-2.6 and TS-4).

This Technical Summary synthesizes and integrates the main findings from the individual chapters in the GEA report. It is structured as follows. Section TS-2 outlines the magnitude and orientation of the energy system change that is required, and forms the basis for specific goals expressed in terms of qualitative and quantitative indicators. Section TS-3 presents the building blocks of the transformation, such as energy resources, energy end-use and supply technologies, infrastructures, and systems. Section TS-4 describes the energy pathways for sustainable development and their implications. Section TS-5 presents policy tools and interventions to implement energy pathways that deliver on the goals for sustainable development.

2 The Need for Change

This section summarizes the major global challenges of the 21st century that require actions on energy systems in order to be resolved. GEA has developed energy-related indicators of sustainability that are discussed

in this section, and used in Section TS-4 in the development of pathways toward a sustainable future.

2.1 Economic and Population Growth[4]

Energy access is fundamental to the growth and development of modern economies. Energy use is rising rapidly, driven by worldwide population growth, increased economic prosperity, an expanding middle class, and the lifestyles of the richest 1–2 billion people, as well as by the burgeoning use of ever more energy-intensive technologies in homes and workplaces around the world. This explosive growth in energy use is illustrated in TS-1. Even as the total energy use has increased rapidly, there is wide variation on a per capita basis (up to a factor of 10) in the final energy use among major world regions (see Figure TS-3).

On an individual basis, this variation is of the same order of magnitude as the disparity in global income distribution. Particularly striking on the regional level is how the sectoral shares in final energy vary from about equal percentage allocations at the higher levels of energy use to almost all energy being used in the residential (and commercial) sector at the lowest levels – meaning that almost no energy services are available to support production and development.

Several historic shifts are likely to fundamentally alter the global economy over the coming decades. First, as developing nations move from poverty to relative affluence, there will be a shift from agriculture to more energy-intensive commercial enterprises. Greater affluence has historically also been associated with an increase in meat consumption and other protein-rich diets, which multiply the stresses on the global environment due to the elevated need for water and land and increased greenhouse gas (GHG) emissions.

Currently, the process of industrialization is energy-intensive, as it requires high levels for material transformations. Rising incomes are expected to generate higher demands for private transport as well as for space and water heating, space cooling, and power-hungry household appliances. Demand for freight transport also implies increasing demand for energy transport services. It is unclear to what extent these demands are subject to saturation at higher income levels.

Second, for the first time in human history half the world population now lives in cities, and this urban fraction is growing faster than the overall population growth. The largest and fastest-growing urban centers are found in the world's poorer regions, where lack of energy access is most prevalent.

Access to affordable and sustainable energy services is fundamental to human development and economic growth. Economies lacking proper access to modern forms of energy (particularly electricity and other forms of mechanical energy for productive purposes, and also cleaner household combustion) cannot develop and contribute to improvements in well-being.

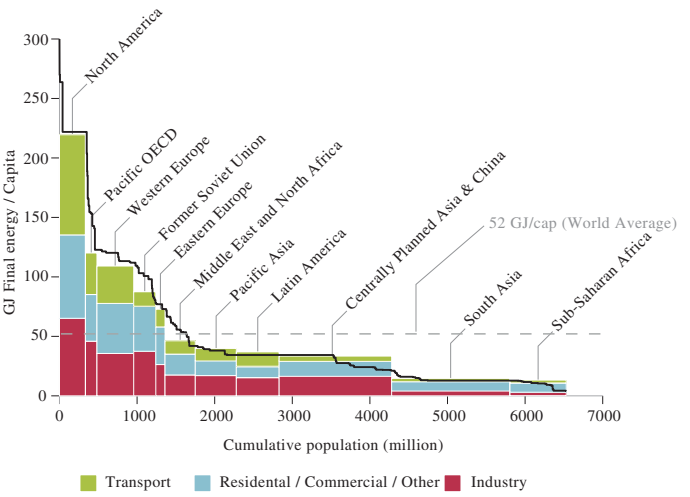

Figure TS-3 | Final energy (GJ) per capita versus cumulative population for 11 world regions sorted by declining per capita energy use (with final energy use disaggregated by sector and total, color bars) and final energy per capita for 137 countries in 2005 (black, solid line). Dashed horizontal line shows the average final energy per capita, which indicates that approximately 1.5 billion people are above and 5.5 billion below that level. Source: Chapters 1 and 19.

Energy for sustainable development must concurrently meet, without compromise, all dimensions of energy service requirements. These include availability, affordability, accessibility, security, health, climate, and environmental protection. The approach in GEA focuses on the energy options that deliver benefits for many, if not all, of these dimensions to avoid costly lock-in effects from a focus on a single dimension.

Being a multiplier of consumption, population growth remains a major driver of global impacts. Given the absolute limits of the planet, as illustrated by the need to limit concentrations of climate-altering pollutants, reductions in population growth trends can provide valuable additional decades to help resolve energy and other problems before reaching planetary limits. There is no coercion implied here, as studies show that hundreds of millions of women wish to control their family size but do not have access to modern contraceptive technologies. Models show, for example, that by providing such services, CO_2 emissions from energy use could be reduced by 30% in 2100 over what is otherwise projected. Providing reproductive health services to these women is also an equity issue – all women, not just those in rich countries, ought to have access to such services. It is also an important health issue, as spacing births, which, along with reducing the total number of births, is an effect of giving women access to contraception, has major benefits for child and maternal health.

2.2 Energy Access, Poverty, and Development[5]

Poverty is the most critical social challenge that faces developing and industrialized countries globally. Approximately three billion people live

4 Section TS-2.1 is based on Chapter 6.

5 Section TS-2.2 is based on Chapters 2 and 19.

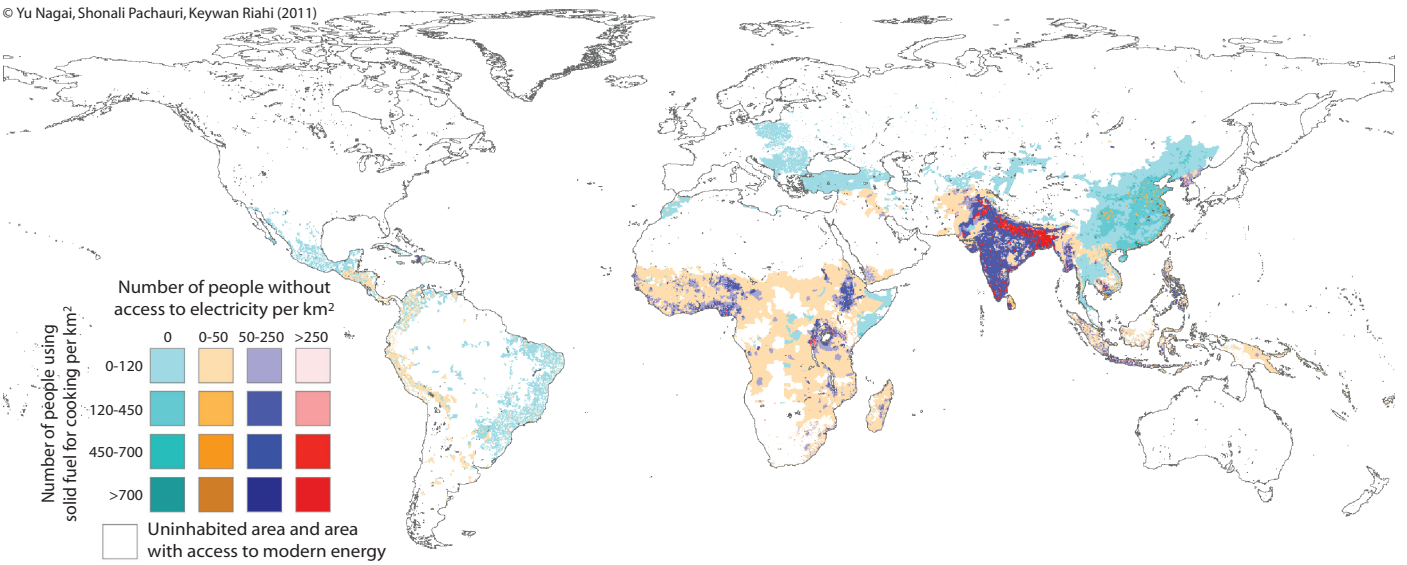

Figure TS-4 | Density of population lacking access to modern energy carriers in 2005. Colored areas show people per km² without access to electricity and those that use solid fuels for cooking, e.g., dark blue and red areas show where people do not have access to electricity and cook predominately using solid fuels. Source: Chapters 17 and 19.

on less than US$2 a day, with about 1.4 billion living in extreme poverty, on less than US$1.25 a day. The number of people with no access to electricity is 1.4 billion. Around 2.7 billion people rely on traditional biomass, such as fuel wood, charcoal, and agricultural residues (including animal dung), for cooking and heating, and another 400 million cook and/or heat with coal, making a total of around three billion people who rely on solid fuels for cooking and heating (see Figure TS-4).

Providing access to modern energy carriers and end-use conversion devices, such as cleaner cookstoves, is a major step to enable people living in poverty to improve their lives and reach the United Nations Millennium Development Goals and beyond.

Enhanced access to electricity, fuels and cleaner cooking systems can be an effective tool for improving health, for example by reducing air pollution, and can combat extreme hunger by increasing food productivity and reducing post-harvest losses. The energy technologies needed are relatively affordable, can often be produced locally, and in many cases do not require large-scale centralized energy supply options or costly infrastructure. Modern energy carriers, such as electricity and cleaner burning fuels, and end-use conversion devices can also improve education and school attendance by providing better energy services, such as lighting, heating, and cooling services. Electrifying rural health centers enables medical services to be provided at night, medicines to be preserved, and more-advanced medical equipment to be used.

Modern carriers and end-use conversion devices also encourage investments in capital goods that use electricity, which, in turn, allows the establishment of advanced agro-processing industries in rural areas, such as sugar production, milk cooling, grain milling, and food preservation. Processing will help make more food edible for longer, keep more money in local communities if the processing is done locally, and, in some cases, help farmers retain control of sales. These not only enhance rural incomes through increased sales and better prices, they also increase food production, and thereby contribute to reducing extreme hunger. Enhancing access among poor people, especially poor women, Is thus important for increasing their standard of living. Reducing the proportional cost of energy services is also important, particularly for the rural poor, who spend a significant part of their time and disposable income on energy. This can liberate financial and human resources for other important activities or expenses, such as education, purchasing more and better-quality food, and expanding income-generating activities.

2.3 Energy Security[6]

Energy security, that is, the uninterrupted provision of vital energy services, is critical for every nation. For many industrial countries, the key energy security challenges are dependence on imported fossil fuels and reliability of infrastructure. Many emerging economies have additional vulnerabilities, such as insufficient power generation capacity, high energy intensity, and rapid demand growth. In many low-income countries, multiple vulnerabilities of energy systems overlap, making them especially insecure.

Oil is at the center of contemporary energy-security concerns for most nations, regions, and communities. Oil products provide over 90% of transport energy in almost all countries. Thus, disruptions of oil supplies may have catastrophic effects, not only on personal mobility, but also on food production and distribution, medical care, national security, manufacturing, and other vital functions of modern societies. At the same time, conventional oil resources are increasingly concentrated in just a few

6 Section TS-2.3 is based on Chapter 5.

regions. The concerns over political stability affecting resource extraction and transport add to uncertainty. Moreover, the global production capacity of conventional oil is widely perceived as limited (see Section TS-3.1.1). Furthermore, the demand for transport fuels is steadily rising, especially rapidly in emerging Asian economies. Thus, for most countries, an ever higher share of their oil, or even all of it, must be imported. More than three billion people live in countries that import more than 75% of the oil and petroleum products they use (see Figure TS-5). An additional 1.7 billion people living in countries with limited domestic oil resources (including China) are likely to experience similarly high levels of import dependence in the coming decades.

The increasing concentration of conventional oil production, and the rapidly shifting global demand patterns, make some analysts and politicians fear a 'scramble for energy' or even 'resource wars'. These factors result in rising and volatile oil prices that affect all economies, especially low-income countries, almost all of which import over 80% of their oil supplies. The costs of energy imports (primarily oil products) exceed 20% of the export earnings in 35 countries that together are home to 2.5 billion people.

Import dependence is also common in countries that extensively use natural gas. Almost 650 million people live in countries that import over 75% of their gas. Most of these countries rely on a very limited number of gas suppliers (in many cases just one) and import routes. The risks of supply disruptions and price fluctuations are often the most serious energy security issues in such countries. The potential of recent shale gas technology developments to alleviate these concerns is at present uncertain.

Electricity systems in many low- and middle-income countries have inadequate generation capacity, low diversity of generation options, and low reliability of transmission and distribution systems. In over two-thirds of low-income countries, electricity supply is interrupted for at least one hour each day. Over 700 million people live in countries that derive a significant proportion of their electricity from only one or two major dams. Hydroelectric power production may also become insecure due to increased stress on global water supplies through increased population,

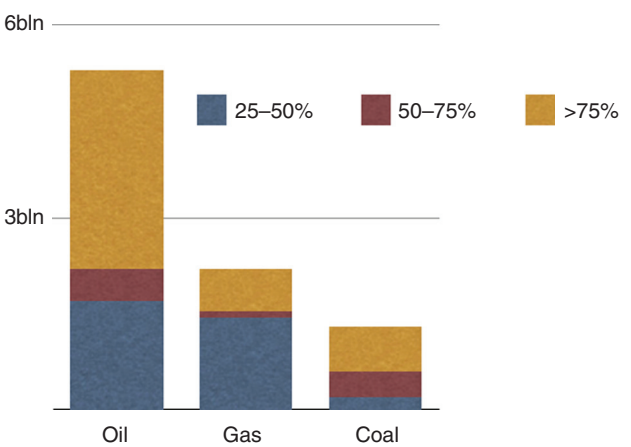

Figure TS-5 | Number of people in countries that are dependent on imported oil, gas and coal. Source: data from Chapter 5.

agriculture, energy production, and climate change, which may affect seasonal water availability.

Many countries using nuclear power are experiencing an aging of the reactor fleet and workforce, as well as problems obtaining the capital and technologies to renew or expand nuclear programs. Twenty-one out of 29 countries with nuclear power plants have not started to build a new reactor in the last 20 years, and in 19 of these countries the average age of nuclear power plants is over 25 years. Large-scale enrichment, reactor manufacturing, and reprocessing technologies are currently concentrated in just a few countries (see Figure 5.5 in Chapter 5). The spread of enrichment or reprocessing to a larger number of countries is opposed by concerns over nuclear weapons proliferation – one of the main controversies – and the risks and costs associated with nuclear energy.

Another energy security issue is 'demand security'. Vital energy export revenues play a major part in the economies of some 15–20 mainly low- or middle-income countries. In many cases these revenues are not expected to last for more than one generation, and in several cases they may cease in less than a decade. In addition, poor energy-exporting nations are at a high risk of the 'resource curse': economic and political instability eventually affecting human development and security. The present economic and social importance of energy export revenues should be recognized in international arrangements, while diversifying the economies of countries excessively dependent on energy exports is also a high priority in dealing with 'demand security'.

2.4 Environment[7]

Linkages between the energy system and the environment are seen on multiple levels and scales – from local to global. While the local environmental and ecological consequences of resource extraction, processing, and energy conversion have been long recognized, attention is increasingly turning toward the growing evidence that humanity has reached a phase when anthropogenic pressures on Earth systems – the climate, oceans, freshwater, and the biosphere – risk irreversible disruption to biophysical processes on the planetary scale. The risk is that systems on Earth may then reach tipping points, resulting in non-linear, abrupt, and potentially irreversible change, such as destabilization of the Greenland ice sheet or tropical rainforest systems.

The challenges are illustrated in Figure TS-6, showing planetary boundaries for nine Earth system processes, which together define a safe operating space for humanity (indicated by the green area), within which human development stands a good chance of proceeding without large-scale deleterious change. Estimates indicate that the safe levels are being approached or, in some cases, transgressed. Energy systems contribute to humanity's approach to many of the planetary boundaries,

7 Section TS-2.4 is based on Chapters 3 and 17.

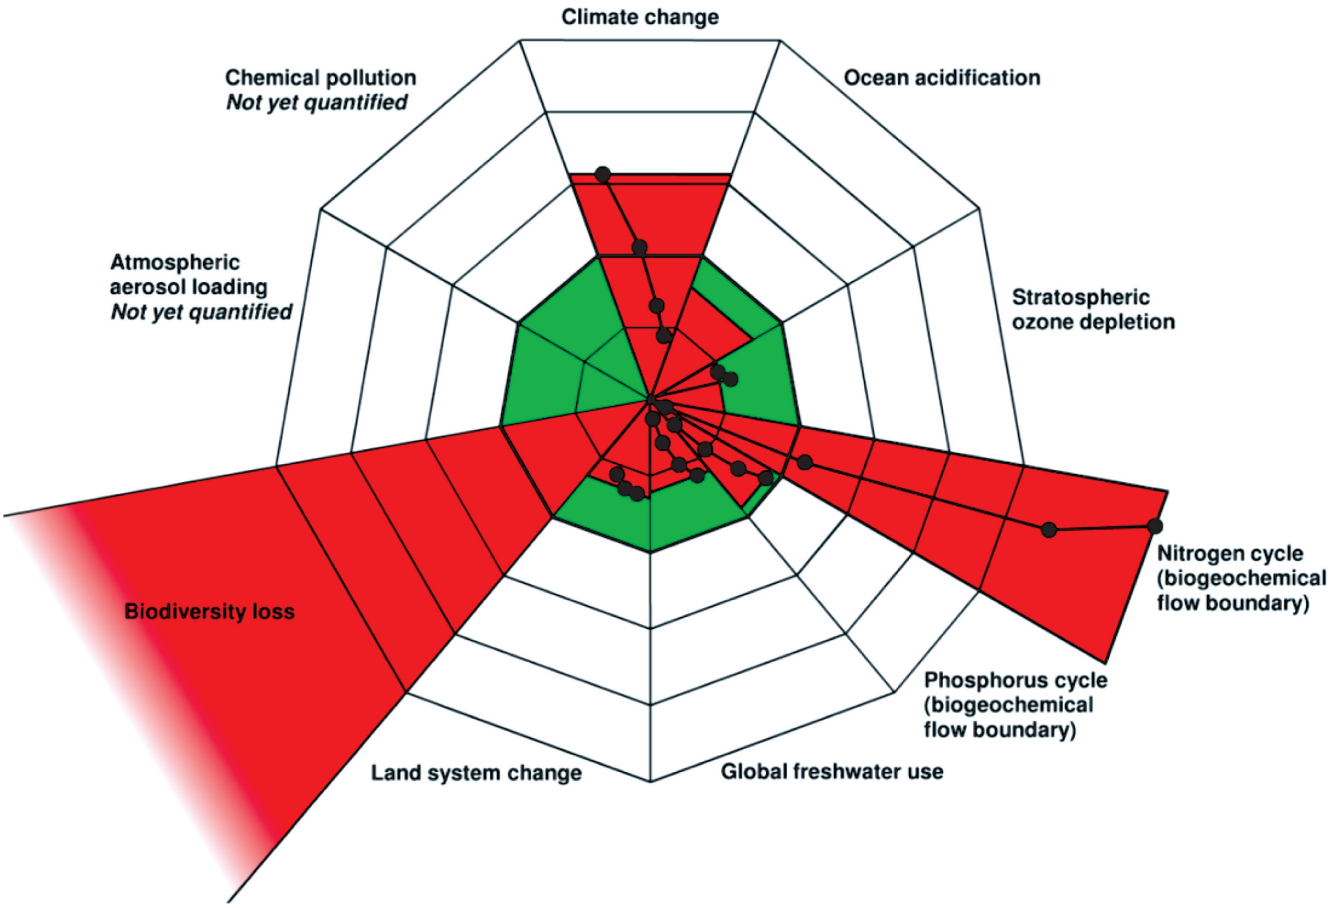

Figure TS-6 | Current global state of the world for the 10 proposed planetary boundaries. The green area denotes a "safe operating space" for human development, and red indicates the current position for each boundary process. The dots indicate evolution by decade from the 1950s. Source: Chapter 3.

and in particular climate change, aerosol loading, ocean acidification, biodiversity loss, chemical pollution, land system change, the nitrogen cycle, and fresh water use.

In 2005, energy supply and use contributed around 80% of CO_2 emissions and 30% of methane emissions (Chapter 1), as well as large fractions of other substances, such as black carbon, organic carbon, and aerosols that can either warm or cool the atmosphere, depending on their composition. Energy systems are furthermore tightly linked to land and freshwater use through dependence on water and land resources for energy generation. They are also linked to ecosystem services and air quality through emissions of particulate matter and atmospheric pollutants, such as nitrogen and sulfur oxides, and precursors of tropospheric ozone that can lead to acidification, eutrophication, and reduced net primary productivity. Consequently, the energy system has a critical part to play in achieving global sustainability.

One of the areas of concern most influenced by energy systems is climate change. Threats to agriculture, biodiversity, ecosystems, water supply in some areas and floods in others, sea levels, and many other environmental aspects will continue to worsen unless climate change is curbed significantly. Moreover, degradation of land, biodiversity, and freshwater resources, which are closely related to energy generation and use, has accelerated climate change. In response to this challenge, the global community decided to take actions to limit anthropogenic warming to less than 2°C above pre-industrialized levels (UNFCC, Decision 1/CP.16). This stabilization target is the normative goal adopted by GEA and is reflected in all pathways toward a more sustainable future (see Section TS-4). GEA recognizes however, that even a 2°C target may lead to large adverse effects, including risks of reaching tipping points, thus highlighting the need for an even more ambitious target.

Limiting global temperature increase to less than 2°C above pre-industrial levels (with a probability of greater than 50%) requires rapid reductions of global CO_2 emissions from the energy sector with a peak around 2020 and a decline thereafter to 30–70% below 2000 emissions levels by 2050, finally reaching almost zero or even negative CO_2 emissions in the second half of the century (see Figure TS-7). Given that even a 2°C target will likely lead to significant impacts, assuring only a 50% chance of success is a rather low bar to set. A higher probability of meeting the 2°C target, or a lower temperature-increase target, would require higher emission reductions by 2050 and beyond. In particular, the later

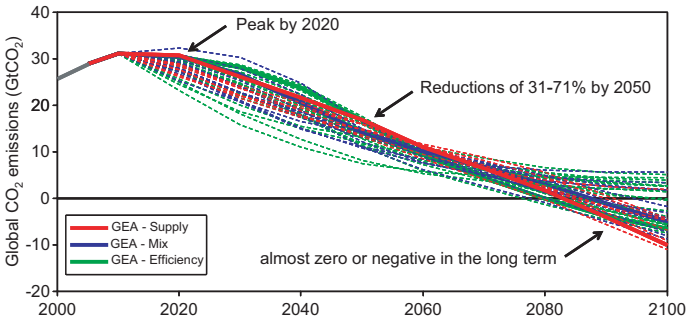

Figure TS-7 | Development of global CO_2 emissions from energy and industrial sources to limit temperature change to below 2°C (with a probability of >50%). Shown is that the emissions need to peak by around 2020 (or earlier) and decline toward zero during the following four to five decades. The later the peak occurs, the steeper the decline needs to be and higher the net 'negative' emissions. The latter can be achieved in the energy system through CCS in conjunction with the use of sustainable biomass. Source: Chapter 17. For further details of the GEA pathways see the interactive web-based GEA scenario database hosted by IIASA: www.iiasa.ac.at/web-apps/ene/geadb.

the emissions peak, the higher the need for net 'negative' emissions in the second half of the century, for example, by using biomass together with carbon capture and storage (CCS) (see Section TS-3.3.2.2).

Reducing emissions of both long-lived GHGs, such as CO_2, and short-lived climate forcers, such as ozone precursors and black carbon (both emitted, for example, from the combustion of diesel fuel and household biomass fuel), is essential. Reducing short-lived climate forcers is critical to slow the rate of near-term climate change and provides a far greater likelihood of achieving the 2°C target when coupled with aggressive measures to also bring down long-lived GHG emissions.

The focus on planetary-scale impacts does not reduce the importance of addressing local and regional environmental and ecological impacts. Atmospheric pollutants may limit the net primary productivity of ecosystems, and lead to the acidification and eutrophication of land and seascapes. Land is affected through loss or damage to ecosystems from land-use change and contamination from energy-related waste arising from activities such as mining, drilling, and the transport of fossil fuels. In addition, disaster mitigation systems need to be continually developed and implemented to avert energy-related environmental disasters, for example, from nuclear accidents, oil rig explosions, oil tanker spills, flooding from hydroelectric dam bursts, and so on.

Differences in energy provisioning systems around the world cause variability in the environmental challenges. Reducing such problems requires policy implementation targeted at the most threatening environmental effects specific to a nation and region. Problems may arise when the impacts considered a priority at the regional scale differs from those at the global scale.

In such situations, international cooperative approaches may be required to provide economic and social infrastructural support to address both national and regionally perceived priorities, and more internationally driven concerns over environmental threats and the ability to remain within the safe operating limits of planetary boundaries.

2.5 Health[8]

Energy systems are currently responsible for a large proportion of the global burden of disease, which is in the order of five million premature deaths annually from air pollution and other energy-related causes and more than 8% of all ill health (lost healthy life years from both morbidity and premature mortality) (see Table TS-1).

Air pollution from incomplete combustion of fuels and biomass burning is a major contributor to ill health. As cooking fuel is the greatest source of household indoor air pollution, and a significant source of outdoor pollution, access to cleaner cooking (see Section TS-2.2) would provide significant improvement. Outdoor air pollution in both urban and rural areas accounted for 2.7 million premature deaths globally in 2005, while about 2.2 million premature deaths are estimated to occur annually from exposure to indoor air pollution in developing countries, mainly among women, the elderly, and young children. Other sources of outdoor air pollution include the transportation sector, industry, power plants, and space conditioning.

Occupational health impacts, particularly from harvesting/mining and processing biomass and coal, are currently the next most important impact on health from energy systems. Miners are exposed to collapsing mine shafts, fire and explosion risks, toxic gases (carbon monoxide), lung-damaging dusts (coal and silica), and hot work environments, as well as injury and ergonomics hazards. Oil and gas workers face injury risks, particularly during drilling, emergency situations, and work on offshore platforms, as well as exposure to toxic materials at refineries.

Unlike biomass and fossil fuels, nuclear power systems are not a significant source of routine health impacts, although they often garner considerable public and policy concern. Average radiation doses to workers in nuclear power industries have generally declined over the past two decades. For nuclear power facilities, as with large hydroelectric facilities, the major health risks lie mostly with high-consequence but low-probability accidents.

Climate change is beginning to have an important impact on health, causing an estimated 150,000 premature deaths in 2000, with more than 90% of these occurring among the poorest populations in the world. Both the direct health burden and the share of climate change impacts due to energy systems are expected to rise under current projections of GHG emissions and changing background health conditions in vulnerable populations. By 2010, this impact may have doubled.

8 Section TS-2.5 is based on Chapter 4.

Table TS-1 | Global burden of disease in 2000 from air pollution and other energy-related causes. These come from the Comparative Risk Assessment (CRA) published in 2004 by the World Health Organisation. GEA estimates for 2005 of outdoor air pollution and household solid fuel use in Chapter 17 are substantially larger, but were not done for all CRA risk pathways shown. Estimates for 2010 in the new CRA will be released in 2012 and will again include all pathways in a consistent framework.

	Total Premature Deaths – million	Percent of all Deaths	Percent of Global Burden in DALYs	Trend
Direct Effects [except where noted, 100% assigned to energy]				
Household Solid Fuel	1.6	2.9	2.6	Stable
Energy Systems Occupational*	0.2	0.4	0.5	Uncertain
Outdoor Air Pollution	0.8	1.4	0.8	Stable
Climate Change	0.15	0.3	0.4	Rising
Subtotal	2.8	5.0	4.3	
Indirect Effects (100% of each)				
Lead in vehicle Fuel	0.19	0.3	0.7	Falling
Road Traffic Accidents	0.8	1.4	1.4	Rising
Physical Inactivity	1.9	3.4	1.3	Rising
Subtotal	2.9	5.1	3.4	
Total	5.7	10.1	7.7	

* One-third of global total assigned to energy systems.

Notes: These are not 100% of the totals for each, but represent the difference between what exists now and what might be achieved with feasible policy measures. Thus, for example, they do not assume the infeasible reduction to zero traffic accidents or air pollution levels. DALYS = disability adjusted life years.

2.6 Goals Used in the Assessment and in the GEA Pathways Analysis

For many of the energy-related challenges different goals have been articulated by the global community, in many instances including specific quantitative targets. This sub-section summarizes the concrete goals in major areas that require changes to energy systems, based on Section TS-2. Meeting these goals simultaneously has served as the generic framework for all assessments in GEA. The GEA pathways, described and elaborated in Section TS-4, illustrate how societies can reach the global normative goals of welfare, security, health, and environmental protection outlined below, simultaneously with feasible changes in energy systems.

The selection of indicators and quantitative target levels summarized here is a normative exercise, and the level of ambition has, to the extent possible, been guided by agreements and aspirations expressed through, for example, the United Nations system's actions and resolutions, and from the scientific literature. This, of course, only refers to the necessary changes of the local and global energy systems; much more is required in other sectors of societies for overall sustainability to be realized.

In the GEA pathways analysis, the global per capita gross domestic product (GDP) increases on average by 2% per year through 2050, mostly driven by growth in developing countries. This growth rate declines in the middle of existing projections. Global population size is projected to plateau at about nine billion people by 2050. Energy systems must be able to ***deliver the required energy services*** to support these economic and demographic developments.

Universal access to affordable modern energy carriers and end-use conversion (especially electricity and cleaner cooking)[9] by 2030 for the 1.4 billion people without access to electricity and the three billion people who still rely on solid and fossil fuels for cooking is a prerequisite for poverty alleviation and socioeconomic development.

Enhanced energy security for nations and regions is another key element of a sustainable future. Reduced global interdependence via reduced import/export balances and increased diversity and resilience of energy supply have been adopted as key energy-related metrics. The targets for these goals were assessed ex-post through the GEA pathways analysis (Chapter 17), identifying the need for energy efficiency improvements and deployment of renewables to increase the share of domestic (national or regional) supply in primary energy by a factor of two, and thus significantly decrease import dependency (by 2050). At the same time, the share of oil in global energy trade is reduced from the present 75% to below 40% and no other fuel assumes a similarly dominant position in the future.

9 See Chapter 2.2.

The ***climate change mitigation*** goal is to, at a minimum, contain the global mean temperature increase to less than 2°C above the pre-industrial level, with a probability of at least 50%. This implies global CO_2 emissions reductions from energy and industry to 30–70% of 2000 levels by 2050, and approaching almost zero or net negative emissions in the second half of the century.

Health and environment goals include controlling household and ambient air pollution, ocean acidification, and deforestation. Emissions reductions through the use of advanced fuels and end-use technologies for household cooking and heating can significantly reduce human morbidity and mortality due to exposure to household air pollution, as well as help reduce ambient pollution. In the GEA pathways, this is assumed to occur for the vast majority of the world's households by 2030. Similarly, a majority of the world's population is also expected to meet WHO air-quality guidelines (annual PM2.5 concentration[10] <10 µg/m^3), while the remaining population is expected to stay well within the WHO Tier I-III levels (15–35 µg/m^3) by 2030. In addition, there needs to be a major expansion of occupational health legislation and enforcement in the energy sector.

There are also a number of other concerns related to how energy systems are designed and operated. For example, activities need to be occupationally safe, a continuing concern as nano-technologies and other new materials are used in energy systems. Other impacts such as oil spills, freshwater contamination and overuse, and releases of radioactive substances must be prevented (ideally) or contained. Waste products must be deposited in acceptable ways to avoid health and environmental impacts. These issues mostly influence local areas, and the regulations and their implementation are typically determined at the national level. The analysis of indicators and pathways to sustainability in Section TS-4 assumes that such concerns and impacts are under control.

Reaching these goals simultaneously requires transformational changes to the energy system in order to span a broad range of opportunities across urban to rural geographies, from developing to industrial countries, and in transboundary systems. The ingredients of this change are described in the Section TS-3.

3 Options for Resources and Technologies

This section assesses the building blocks that can be used for transforming energy systems toward a sustainable future, including the available resources, whether fossil fuels, fissile material, or renewable energy flows. It assesses technology options on the demand and supply sides and concludes with some insights from a comparative evaluation of options. We begin with a brief description of current global and regional energy systems.

The ultimate purpose of energy systems is to deliver energy that either directly or indirectly provides goods and services to meet people's needs and aspirations. The *energy system* includes all steps in the chain – from primary energy resources to energy services (see Figure TS-8). The *energy sector* refers to the steps in the chain, from the extraction of primary energy resources through to the delivery of final energy carriers for use in end-use technologies that produce energy services or goods. In economic terms, the energy sector includes those businesses responsible for the different steps in this chain.

It is important to define that, for GEA purposes, energy services refer to illumination, information and communication, transport and mobility of people and goods, hot water, thermal comfort, cooking, refrigeration, and mechanical power. Electricity and kerosene are examples of energy carriers, not energy services. All goods and services are provided using energy and thus have energy embedded in them; however, they are not energy services *per se*.

The supply side of energy systems consists of energy resources and the technologies that convert them into energy carriers for final use. Increased demand for improved energy services, mostly in developing countries, and driven in part by population growth and socioeconomic development, is inevitable. Meeting the increased global demand will require a transformation of current energy supply systems (as well as of conversion and end-use systems, as previously described) globally. Such a transformation is not a new phenomenon. Figure TS-1 shows how the relative role of different sources has varied during the growth of global primary energy over the decades. The first transition was from biomass to coal, followed by the transition from coal to oil, which currently remains the largest source of primary energy, although natural gas is steadily increasing its share.

The energy supply situation in 2005 is illustrated by Figure TS-9. Fossil fuels dominate in all regions of the world, with oil having the largest share in the Organisation for Economic Co-operation and Development (OECD), Countries the Middle East and Africa (MAF), and Latin America and the Caribbean (LAC), while coal dominates in Asia and natural gas in Eastern Europe and the Former Soviet Union (REF).

The distribution of primary sources of energy in 2005 shows fossil fuels contributing over 78%, renewables (including large hydro) over 16%, and nuclear over 5% (Figures TS-9 and TS-10). In 2009, fossil fuels were used in 68% of electricity generation, hydropower contributed 16%, nuclear 13.5%, and other renewables contributed 2.6% (see Figure TS-17).

10 PM2.5 refers to particulate matter less than 2.5 micrometers in size.

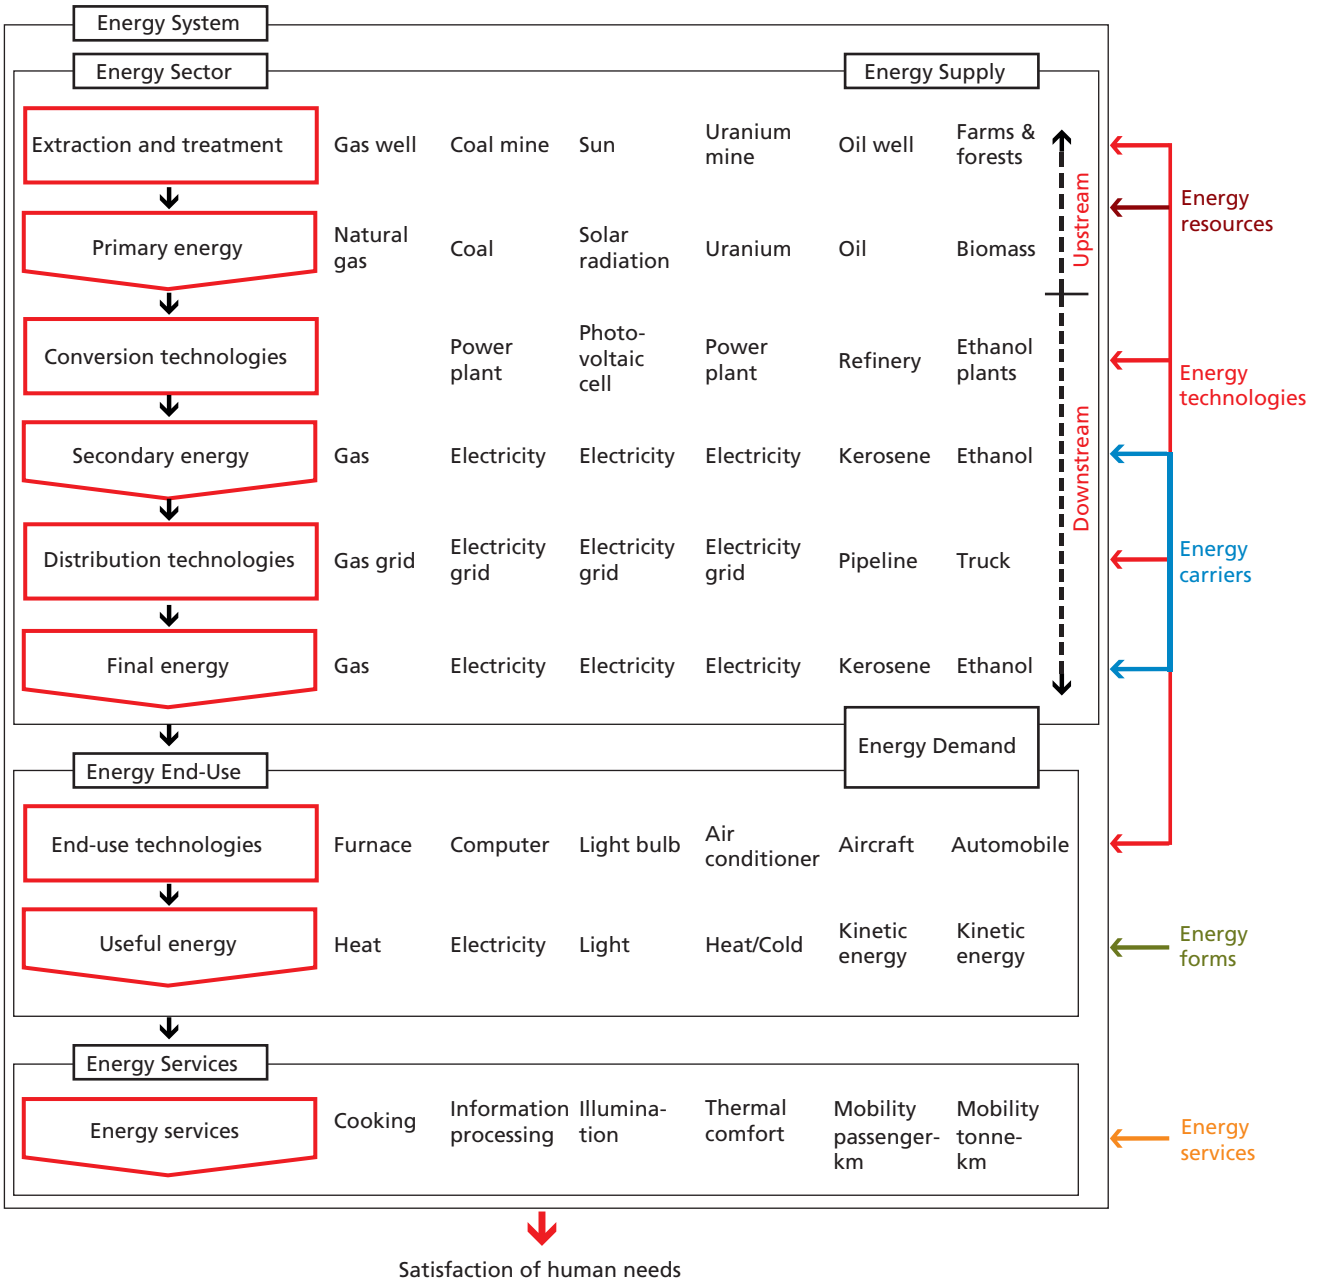

Figure TS-8 | Schematic diagram of the energy system with some illustrative examples of the energy sector, energy end-use, and energy services. The energy sector includes energy extraction, treatment, conversion, and distribution of final energy. The list is not exhaustive and the links shown between stages are not 'fixed'; for example, natural gas can also be used to generate electricity, and coal is not used exclusively for electricity generation. Source: adapted from Nakicenovic et al., 1996b; see Chapter 1.[11]

3.1 Energy Resources

An energy resource is the first step in the energy services supply chain. Provision of energy carriers is largely ignorant of the particular resource that supplies them, but the infrastructure, supply, and demand technologies, and fuels along the delivery chain, often depend highly on a

11 **Nakicenovic, N., A. Grubler, H. Ishitani, T. Johansson, G. Marland, J. R. Moreira and H.-H. Rogner, 1996b:** Energy primer. Figure TS-9 | World primary energy (by source), final energy (by energy carrier), useful energy (by sector/type of energy service), and electricity generated by different energy sources for 2005, World and five GEA regions.[12] Primary, final, and useful energy in EJ and electricity in TWh and EJ; feedstocks are included. Note: circle areas are proportional to electricity generated, but electricity graphs are not to the same scale as those for other energy forms; 1 TWh = 0.0036 EJ. Source: Chapter 1.

particular type of resource. The availability and costs of bringing energy resources to the point of end-use are key determinants of affordable and accessible energy carriers.

The availability of energy resources *per se* poses no inherent limitation to meeting the rapidly growing global energy demand as long as adequate upstream investments are forthcoming for exhaustible resources in exploration, production technology, and capacity and, by analogy, for renewables in conversion technologies. However, exploitation of sufficient energy resources will require major investments and is not without significant environmental and other consequences.

12 The five GEA regions consist of OECD90, which includes the UNFCCC Annex I countries; REF, which includes Eastern Europe and the Former Soviet Union; Asia, which excludes Asian OECD countries; MAF consisting of the Middle East and Africa; and LAC, which includes Latin America and the Caribbean.

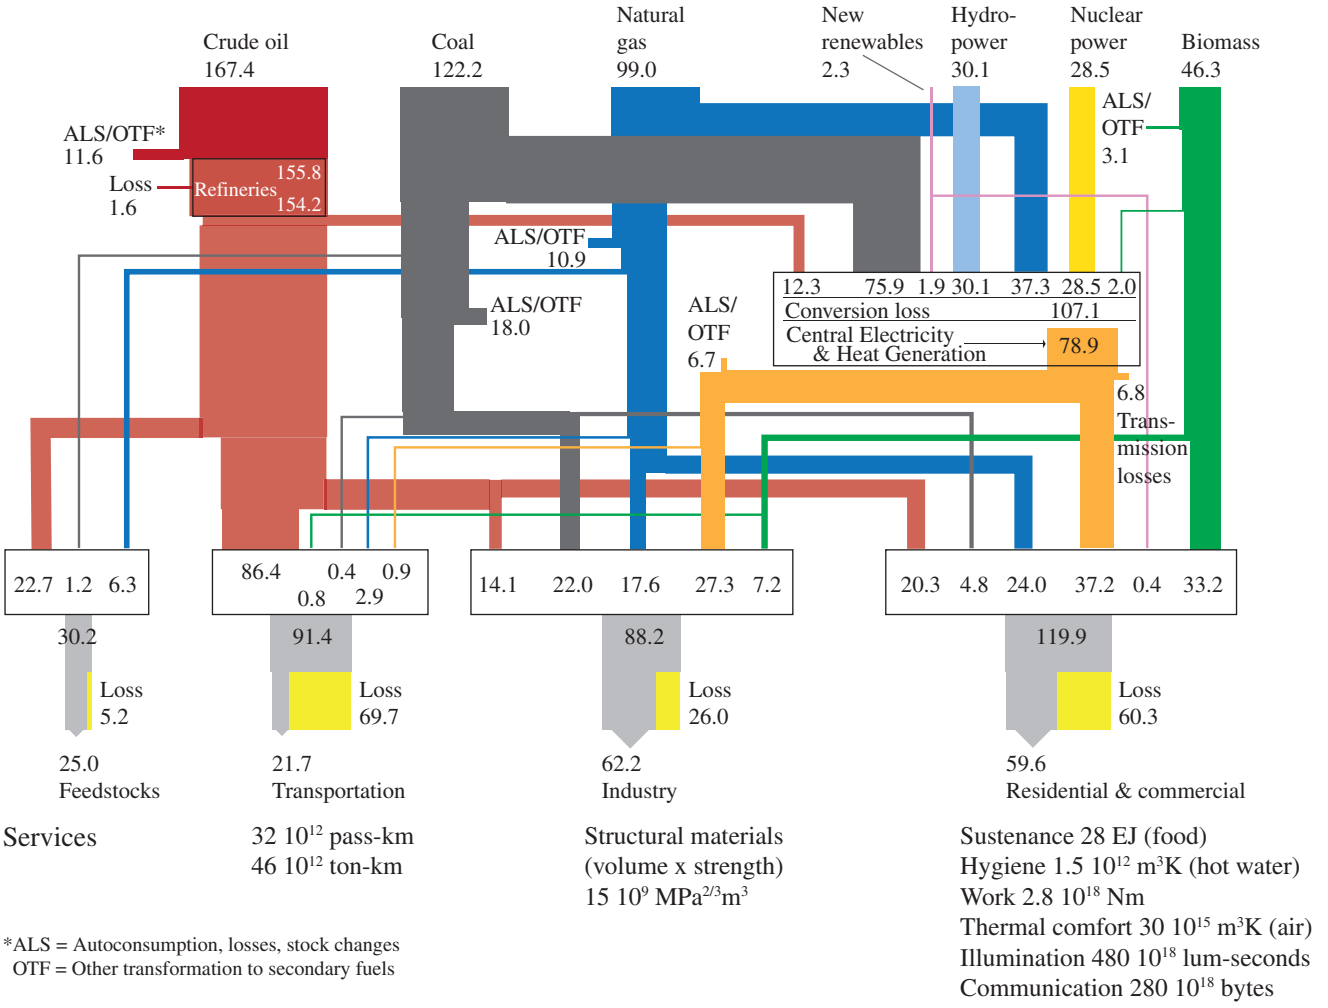

Figure TS-10 | Global energy flows (in EJ) from primary to useful energy by primary resource input, energy carrier (fuels), and end-use sector applications in 2005. Source: data from IEA, 2007a; 2007b (corrected for GEA primary energy accounting standard) and Cullen and Allwood, 2010, see Chapter 1.[13]

3.1.1 Hydrocarbons and Fissile Resources[14]

Hydrocarbons and fissile materials are plentiful in the Earth's crust, yet they are finite. The extent of ultimately recoverable oil, natural gas, coal, or uranium has been subject to numerous reviews, and there are wide ranges of estimates in the literature (see Table TS-2). For example, figures between 4900 and 13,700 exajoules (EJ) for conventional oil reserves and resources have caused continued debate and controversy. Such large ranges can be the result of varying boundaries of what is included in the analysis of a finite stock of an exhaustible resource (e.g., conventional oil only, or conventional oil plus unconventional occurrences such as oil shale, tar sands, and extra-heavy oils). Uranium resources are a function of the level of uranium ore concentrations in the source rocks considered technically and economically extractable over the long run as well as the prospects of tapping into the vast amounts in sea water.

Oil production from difficult-to-access areas or from unconventional resources is not only more energy-intensive, it is also technologically and environmentally more challenging. Production from tar sands, shale oil, and gas, or the deep-sea production of conventional oil and gas, raise further environmental risks – ranging from oil spillages, ground- and freshwater contamination, and GHG emissions, to the release of toxic materials and radioactivity. A significant fraction of the energy gained needs to be reinvested into the extraction of the next unit, adding to already higher exploration and production costs.

14 Section TS-3.1.1 is based on Chapter 7.

Table TS-2 | Fossil and uranium reserves, resources, and occurrences.[a]

	Historical production through 2005	Production 2005	Reserves	Resources	Additional occurrences
	[EJ]	[EJ]	[EJ]	[EJ]	[EJ]
Conventional oil	6069	147.9	4900–7610	4170–6150	
Unconventional oil	513	20.2	3750–5600	11,280–14,800	>40,000
Conventional gas	3087	89.8	5000–7100	7200–8900	
Unconventional gas	113	9.6	20,100–67,100	40,200–121,900	>1,000,000
Coal	6712	123.8	17,300–21,000	291,000–435,000	
Conventional uranium[b]	1218	24.7	2400	7400	
Unconventional uranium	34	n.a.		7100	>2,600,000

[a] The data reflect the ranges found in the literature; the distinction between reserves and resources is based on current (exploration and production) technology and market conditions. Resource data are not cumulative and do not include reserves.

[b] Reserves, resources, and occurrences of uranium are based on a once-through fuel cycle operation. Closed fuel cycles and breeding technology would increase the uranium resource dimension 50–60 fold. Thorium-based fuel cycles would enlarge the fissile-resource base further.

Source: Chapter 7

Historically, technology change and knowledge accumulation have largely counterbalanced otherwise dwindling resource availabilities or steadily rising production costs (in real terms). They extended the exploration and production frontiers, which, to date, have allowed the exploitation of all finite energy resources to grow. The questions now are whether technology advances will be able to sustain growing levels of finite resource extraction, and what the necessary stimulating market conditions will be.

Resources first need to be identified and delineated before the technical and economic feasibility of their extraction can be determined. But having identified resources in the ground does not guarantee either that they can be technically recovered or their economic viability in the marketplace. The viability is determined by the demand for a resource (by the energy service-to-resource chain), the price it can obtain over time, and the technological capability to extract the resource efficiently.

Thus, timely aboveground investment in exploration and production capacities is essential in unlocking belowground resources. Private-sector investment is governed by expected future market and price developments, while public-sector investment competes with other development objectives. At least 10 years can elapse between investment in new production capacities and the actual start of deliveries, especially for the development of unconventional resources. Until new large-scale capacities come online, uncertainty and price volatility will prevail.

Nuclear fuel reserves are sufficient for approximately 100 years of consumption at today's production rates (see Table TS-2). The resources are much larger and, if uranium in seawater is included, practically sufficient for much longer, even with an expansion of global nuclear capacity.

There appears to be a consensus that there are sufficient fossil (for oil, see Figure TS-11) and fissile energy resources to fuel global energy needs for many decades. There is much less consensus as to their actual future availability in the marketplace. This availability is dependent on the balance between a variety of constraining and enabling factors. For example, the factors that can reduce the accessible stocks and flows from them include:

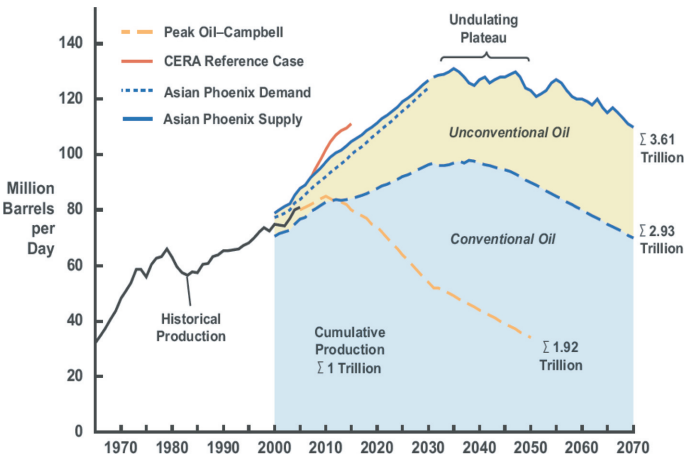

Figure TS-11 | The figure shows future oil production projections, comparing an undulating plateau with a peak oil projection. The Campbell peak oil projections is from Campbell (see Chapter 7) and is shown together with more optimistic projections of increased use of conventional oil resources as well as the use of unconventional oil resources. Source: Witze, 2007; see Chapter 7.[15]

- smaller and smaller deposits in harsher and harsher environments, leading to rising exploration, production, and marketing costs;
- excessive environmental burdens;

15 **Witze, A., 2007:** Energy: That's oil folks…, *Nature*, **445**: 14–17.

Table TS-3 | Renewable energy flows, potential, and utilization in EJ of energy inputs provided by nature.[a]

	Primary Energy 2005[b] [EJ]	Utilization 2005 [EJ]	Technical potential [EJ/yr]	Annual flows [EJ/yr]
Biomass, MSW, etc.	46.3	46.3	160–270	2200
Geothermal	0.78	2.3	810–1545	1500
Hydro	30.1	11.7	50–60	200
Solar	0.39	0.5	62,000–280,000	3,900,000
Wind	1.1	1.3	1250–2250	110,000
Ocean	-	–	3240–10,500	1,000,000

[a] The data are energy-input data, not output. Considering technology-specific conversion factors greatly reduces the output potentials. For example, the technical 3150 EJ/yr of ocean energy in ocean thermal energy conversion (OTEC) would result in an electricity output of about 100 EJ/yr.

[b] Calculated using the GEA substitution method (see Chapter 1, Appendix 1.A.3).

- diminishing energy ratios;
- low rate of technological advances; and
- public intolerance of accident risks.

On the other hand, demand, high prices (plus associated investments), innovation, and technology change tend to increase stock sizes and flow rates. The question is: which combinations of these forces acting in opposite directions are going to govern fuels production in the mid to long term? It is likely that, due to the constraints, only a fraction of these resources may ever be produced.

In conclusion:

- Hydrocarbon resources are huge compared with conceivable future energy needs, but realizing any significant proportion of these available resources will require major investments and is not without significant consequences.
- Development of these resources and potentials is subject to many constraints, but not by a constraint on physical availability.
- The peak of oil and other fossil fuels is not caused by the lack of resources, but rather by other changes, such as the transformation toward sustainable futures and perhaps insufficient investments in the supply chains.

3.1.2 Renewable Energy Flows[16]

Renewable energy resources comprise the harvesting of naturally occurring energy flows. While these flows are abundant (see Table TS-3) and far exceed (by orders of magnitude) the highest future energy demand imagined for global energy needs, the challenge lies in developing adequate technologies to manage the often low or varying energy densities and supply intermittencies and to convert them into usable energy carriers or utilize them for meeting energy demands.

Solar radiation reaching the Earth's surface amounts to 3.9 million EJ/yr and, as such, is almost 8000 times larger than the annual global energy needs of some 500 EJ. Accounting for cloud coverage and empirical irradiance data, the local availability of solar energy is 633,000 EJ. The energy carried by wind flows is estimated at about 110,000 EJ/yr, and the energy in the water cycle amounts to more than 500,000 EJ/yr, of which 200 EJ/yr could theoretically be harnessed for hydroelectricity. Net primary biomass production is approximately 2400 EJ/yr, which after deducting the needs for food and animal feed, leaves, in theory, some 1330 EJ/yr for energy purposes. The global geothermal energy stored in the Earth's crust up to a depth of 5000 meters is estimated at 140,000 EJ/yr, with the annual rate of heat flow to the surface of about 1500 EJ/yr. Oceans are the largest solar energy collectors on Earth, absorbing on average some one million EJ/yr.

The amounts of these gigantic annual energy flows that can be technically and economically utilized are significantly lower, however. Renewables, except for biomass, convert resource flows directly into electricity or heat. Their technical potentials are limited by factors such as geographical orientation, terrain, or proximity of water, while their economic potentials are a direct function of the performance characteristics of their conversion technologies within a specific local market setting. The data shown in Table TS-3 are the energy input potentials provided by nature.

3.2 Energy End-Use

The sectoral and regional distributions of per capita final energy use are shown in Figure TS-2. Globally, of a total final energy use in 2005 of

16 Section TS-3.1.2 is based on Chapters 7 and 11.

330 EJ, three sectors dominate – buildings (residential and public/commercial) is the largest sector with 34% (112 EJ), followed by transport at 28% (91 EJ), and industry with 27% (88 EJ). The relative shares of these sectors vary somewhat by region, with high-income countries having greater shares of residential, commercial, public, and transportation energy use, while residential and industrial sectors dominate the energy use in low-income countries. Therefore, this section reviews the options for enhancing efficiency in the industry, transportation, and buildings sectors.

3.2.1 Industry[17]

As noted, the industrial sector accounted for about 27% (88 EJ) of global final energy use in 2005. The production of materials – chemicals, iron and steel, non-metallic minerals (including cement), non-ferrous metals, paper and pulp, and mining – accounts for about 70% of global industrial final energy use. The final energy use of 88 EJ in 2005 excludes the energy use in coke ovens and blast furnaces, and feedstock energy use for petrochemicals. The addition of the energy inputs for these subsectors results in a final energy use of 115 EJ in 2005.

There has been a geographic shift in primary materials production, with developing countries accounting for the majority of production capacity. China and India have high growth rates in the production of energy-intensive materials like cement, fertilizers, and steel (12–20% per year after 2000). In other economies, the demand for materials is seen to grow initially with income and then stabilizes. For example, in industrial countries per capita use seems to reach saturation at about 400–500 kilograms for cement and about 500 kilograms for steel.

The aggregate energy intensity in the industrial sector in different countries has shown steady declines due to improvements in energy efficiency and a change in the structure of the industrial output. In the EU-27, for example, the final energy use by industry has remained almost constant (13.4 EJ) at 1990 levels despite output growth; 30% of the reduction in energy intensity is due to structural changes, with the remainder due to energy efficiency improvements.

In different industrial sectors, adopting the best achievable technology can result in savings of 10–30% below the current average costs. An analysis of cost-cutting measures in 2005 indicated energy savings potentials of 2.2 EJ for motors and 3.3 EJ for steam systems. The economic payback period for these measures ranges from less than nine months to four years. A systematic analysis of materials and energy flows indicates significant potential savings for process integration, heat pumps, and cogeneration.

An exergy analysis (the second law of thermodynamics) reveals that the overall global industry efficiency is only 30%. Clearly, there are major energy efficiency improvements possible through research and development (R&D) in next-generation processes. The effective use of demand-side management can be facilitated by a combination of mandated measures and market strategies. To level the playing field for energy efficiency, a paradigm shift is required – with a focus on energy services, not energy supply *per se*. This requires a reorientation of energy supply, distribution companies, and energy equipment manufacturing companies.

Nevertheless, such a transformation has multiple benefits. Improved energy efficiency in industry results in significant energy productivity gains, for example, in improved motor systems; compressed air systems; ventilation, heat recovery, and air conditioning systems; and improvements in comfort and working environments through better lighting, thermal comfort, and reduced indoor air pollution from improved ventilation systems, and, in turn, improved productivity boosts corporate competitiveness.

Policies and capacity development to capture the opportunities are needed globally. New business models are also needed and are being deployed to deliver a transformation that shifts the focus to energy services. For example, energy service companies (ESCOs) are already a multibillion dollar market per year globally, and substantial new business opportunities await progressive enterprises and innovative technological and business initiatives.

A frozen efficiency scenario based on today's technologies (close to the GEA counterfactual pathway, see Section TS-4) has been constructed for industry between 2005 and 2030, which implies a demand for final energy of 225 EJ in 2030. This involves an increase of the industrial energy output in terms of manufacturing value added of 95% over the 2005 value. Owing to normal efficiency improvements from new technology designs over time, the BAU scenario results in a final energy demand being reduced from 225 EJ to 175 EJ in 2030.

An aggressive energy-efficient scenario (consistent with the GEA-Efficiency pathway, see Section TS-4) can result in a significant reduction in the energy intensity of the industrial sector. Such a scenario for 2030 has been constructed with the same increase in the manufacturing value added and only a 17% increase in final energy demand (to a total final energy demand for industry of 135 EJ) (see Figure TS-12.)

For existing industries, measures include developing capacity for systems assessment for motors, steam systems, and pinch analysis; sharing and documentation of best practices, benchmarks, and roadmaps for different industry segments; and enabling access to low-interest finance. A new energy management standard, ISO50001, for energy management in companies has been developed by the International Organization for Standardization. It will allow industries to systematically monitor and track energy efficiency improvements. To significantly improve energy efficiency, a paradigm shift is required – with a focus on energy services, not on energy supply *per se*. This requires a reorientation and new

17 Section TS-3.2.1 is based on Chapter 8.

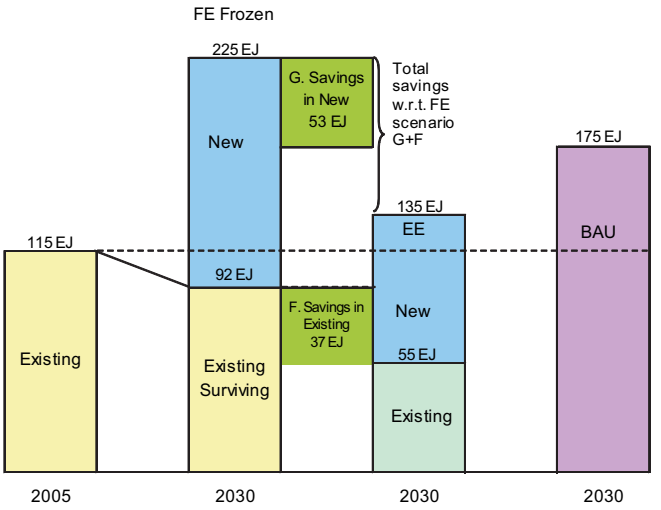

Figure TS-12 | Energy use in industry in 2005 and scenarios based on frozen efficiency and business-as-usual (BAU) scenarios for 2030 for an increase of manufacturing value added by 2030 of 95% over the 2005 level. The BAU and efficiency scenarios are consistent with GEA pathways. The surviving plants in 2030 from 2005 are subject to energy efficiency improvements (37 EJ) reducing their energy use from 92 EJ in 2005 to 55 EJ in 2030. Savings in the new capacity brings the frozen efficiency number from 225 – 92 = 133 EJ in 2005 to 80 EJ in 2030. Source: Chapter 8.

business models for energy supply, distribution companies, and energy equipment manufacturing companies.

Renewables currently account for 9% of the final energy use of industry (10 EJ in 2005). If an aggressive renewables strategy results in an increase in renewable energy supply to 23% in 2030 (23 EJ), it is possible to have a scenario of near-zero growth in GHG emissions in the industrial sector. Further reductions in overall energy use and emissions would be possible by dematerialization, redesign of products, and materials recycling.

Future industrial growth to 2030 is possible with net zero growth in GHG emissions provided there is a reorientation of the energy sector to focus on energy services, renewable energies (Chapter 11), and low-carbon fossil fuel use (Chapters 12 and 13).

3.2.2 Transport[18]

The transportation sector is responsible for approximately 28% (91 EJ) of global final energy demand. Road transport accounts for more than 70% of that total and 95% of transport energy comes from oil-based fuels. A major transformation of transportation is possible over the next 30–40 years and will require improving vehicle designs, infrastructure, fuels, and behavior. In the short term, improving overall sector energy efficiency, introducing alternative low-carbon fuels and electricity, and enhancing the diversification, quantity, and quality of public modes of transport is necessary. Medium-term goals require reducing travel distances within cities by implementing compact urban design that improves accessibility to jobs and services and facilitates use of non-motorized modes, and replacing and adopting vehicle and engine design (for trucks, airplanes, rail, and ships) following the best-available technological opportunities for increasing efficiency and societal acceptability.

Transport policy goals for urbanization and equity include the adoption of measures for increasing accessibility and the affordable provision of urban mobility services and infrastructure that facilitates the widespread use of non-motorized options. Cities can be planned to be more compact with less urban sprawl and a greater mix of land uses and strategic siting of local markets to improve logistics and reduce the distances that passengers and goods need to travel. Urban form and street design and layout can facilitate walking, cycling, and their integration within a network of public transport modes. Employers in many sectors can enhance the job–housing balance of employees through their decisions on where to locate and can provide incentives for replacing some non-essential journeys for work purposes with the use of information technologies and communication.

Modal shares could move to modes that are less energy-intensive, both for passenger and freight transport. In cities, a combination of push-and-pull measures through traffic-demand management can induce shifts from cars to public transit and cycling and can realize multiple social and health benefits. In particular, non-motorized transportation could be promoted everywhere as there is wide agreement about its benefits to transportation and people's health. Parking policies and extensive car pooling and car sharing, combined with information technology options, can become key policies to reduce the use of cars. Efficient road-capacity utilization, energy use, and infrastructure costs for different modes could be considered when transport choices are made (see Figure TS-13).

Life cycle analyses (LCA), together with social and environmental impact assessments, are useful tools to compare different technologies. Significant uncertainties need to be addressed with respect to LCA system boundaries and modeling assumptions – especially in the case of biofuels and land use – and to future unknown technological advances. Hybrid electric vehicles (HEVs) can improve fuel economy by 7–50% over comparable conventional gasoline vehicles, depending on the precise technology used and on driving conditions (although comparable modern diesel engines can be equally fuel-efficient). Plug-in hybrid electric vehicles (PHEVs) allow for zero tailpipe emissions for low driving ranges, such as around 50 km in urban conditions. All-electric battery vehicles (BEVs) can achieve a very high efficiency (more than 90%, four times the efficiency of an internal combustion engine vehicle, but excluding the generation and transmission of the electricity), but they have a short driving range and battery life. Charging times are also, at present, significantly longer than fueling time for liquids. Consequently, BEVs have limited market penetration at present. If existing fuel saving

18 Section TS-3.2.2 is based on Chapters 9 and 17.

D)	Fuel	Fossil	Fossil	Food	Fossil	Food	Electricity	Electricity

*Lower values correspond to Austrian busses, upper values correspond to diesel busses in Mexico city before introduction of BRT system.

Key:

A) Values are indicative for European and Asian cities and can vary significantly across cities, world regions, and particular situations. For example, BRT capacity can more than double with a second lane. Suburban rails in India can transport up to 100,000 passengers per hour.

B) Energy intensity in MJ per passenger km. SUVs can exceed depicted values for cars. Energy values for bus in the US are generally higher due to low ridership. While BRT systems have similar energy efficiencies as normal busses, they provide signficant systemic energy savings via modal shift, small bus substitution, and reduction in parallel traffic. BRT systems can also be converted from oil based fuels to renewable based electricity and hydrogen.

C) Estimated infrastructure costs in euros per passenger kilometer are highest for subway systems and heavy rail. Costs for bus system can be significantly lower than for individual motorized transport. Infrastructure costs for non-motorized transport are very cost competitive and can realize significant social benefits.

D) Dominant fuels are given for each mode.

Figure TS-13 | Comparative corridor capacity (people per hour), energy intensity per passenger kilometer (MJ/p-km), infrastructure cost (€/p-km), and main source of energy. Source: modified from Breithaupt, 2010; see Chapter 9.[19]

and hybrid technologies are deployed on a broad scale, fleet-average specific fuel savings of a factor of two can be obtained in the next decade (Figure 9.41, Chapter 9).

Increasing the performance of high-energy density batteries for PHEVs could lead to higher market penetration of BEVs. Hydrogen fuel cell vehicles (FCVs) could alleviate the dependence on oil and reduce emissions significantly. For HEVs and FCVs, the emissions are determined by the mode of production of hydrogen and electricity. Further technological advances and/or cost reductions would be required in fuel cells, hydrogen storage, hydrogen or electricity production with low- or zero-carbon emissions, and batteries, including charging time. Substantial and sustained government support is required to reduce costs further and to build up the required infrastructure.

There are still many opportunities to improve conventional technologies. The combination of introducing incremental efficiency technologies, increasing the efficiency of converting the fuel energy to work by improving drivetrain efficiency, and recapturing energy losses and reducing loads (weight, rolling, air resistance, and accessory loads) on the vehicle has the potential to approximately double the fuel efficiency of 'new' light-duty vehicles from 7.5 liters per 100 km in 2010 to 3.0 liters per 100 km by 2050 (Figure 9.41, Chapter 9).

19 **Breithaupt, M., 2010:** *Low-carbon Land Transport Options towards Reducing Climate Impacts and Achieving Co-benefits*. Presented at the Fifth Regional Environmentally Sustainable Transport (EST) Forum in Asia, 23–25 August 2010, Bangkok, Thailand.

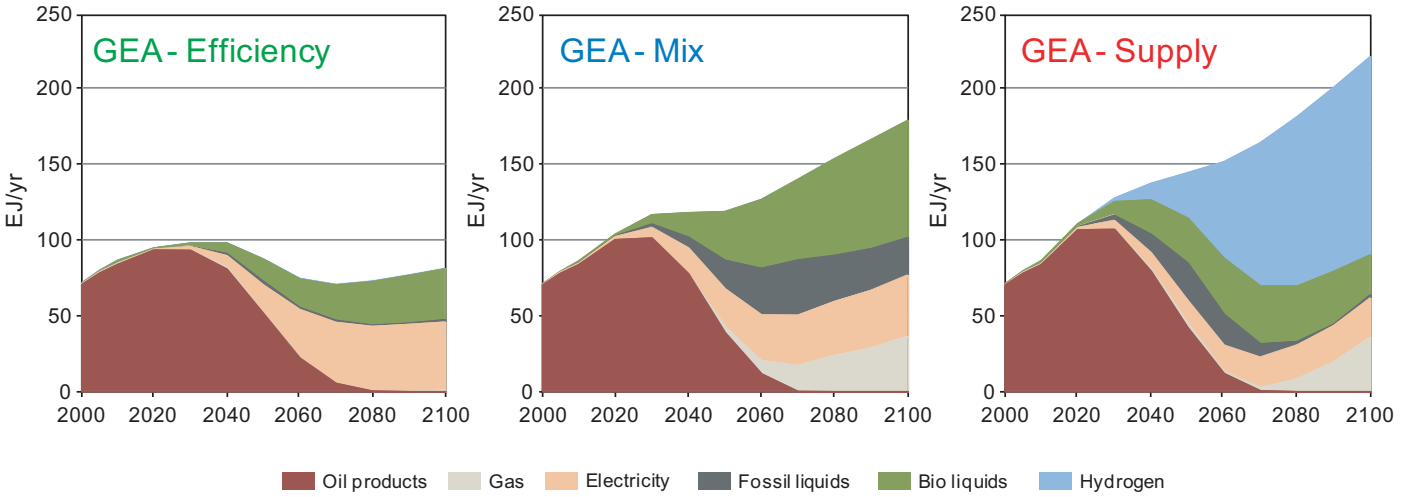

Figure TS-14 | Illustrative examples of fuel use in the transport sector for three GEA pathways. GEA-Supply features a strong technology push for new advanced technologies such as hydrogen, GEA-Efficiency features a strong reliance on regulation to reduce transport energy demand in combination with hybrid electric/biofuel technologies, and GEA-Mix features a co-evolution of both strategies, leading to regionally diverse transport systems. Source: Chapter 17 pathways and the GEA online database. For further details of the GEA pathways see the interactive web-based GEA scenario database hosted by IIASA: www.iiasa.ac.at/web-apps/ene/geadb.

Fuel economy standards have been effective in reducing fuel consumption and therefore could be adopted worldwide. The overall effectiveness of standards can be significantly enhanced if combined with fiscal incentives and consumer information. Taxes on vehicle purchase, registration, use, and motor fuels, as well as road and parking pricing policies, are important determinants of vehicle energy use and emissions.

Aviation transportation presents unique challenges owing to the requirement for very high density fuels. Studies indicate that fuel efficiency of aviation can be improved by 40–50% by 2050 through a variety of means, including technology, operation, and management of air traffic. As aviation's growth rate is projected to be the highest of the transport sub-sectors, such efficiency improvements will not be enough to keep overall energy use in the sector from increasing; thus, alternative low-carbon, high energy-density fuels will play a crucial role in decarbonizing emissions from aviation.

In the maritime sector, a combination of technical measures could reduce total energy use by 4–20% in older ships and 5–30% in new ships by applying state-of-the-art knowledge, such as hull and propeller design and maintenance. Reducing the speed at which a ship operates brings significant benefits in terms of lower energy use. For example, cutting a ship's speed from 26 to 23 knots can yield a 30% fuel saving.

GEA explored three distinctly different pathways for the transport sector (Figure TS-14), all of which satisfied the goals adopted for the GEA analysis (Section TS-4). In all pathways conventional oil is essentially phased out shortly after 2050. In the GEA-Efficiency pathway, electricity and biofuels dominate, while in GEA-Supply, hydrogen plays a large role. In GEA-Mix, natural gas and fossil/biofuel liquids are also being used. The conclusion is that there are many combinations of energy carriers that would be able to fuel the transport sector.

3.2.3 Buildings[20]

Buildings are integrated systems that encompass and deliver multiple energy services and that require holistic approaches to achieve substantial reductions in energy demand and associated benefits. The sector, and activities in buildings themselves, are responsible for approximately 34% (112 EJ) of global final energy demand, with three-quarters of this amount for thermal purposes. Several energy-related problems in buildings (such as poor indoor air quality or inadequate indoor temperatures) affect the health and productivity of residents significantly.

New and existing technologies, as well as non-technological opportunities, represent a major opportunity for transformative change of energy use in buildings. Passive houses that reduce energy use for heating and cooling by 90% or more, for example, are already found in many countries. Increased investments in a more energy-efficient building shell are in part offset by lower or fully eliminated investments in heating/cooling systems, with energy costs for operation almost avoided, making these new options very attractive. Passive-house performance is also possible for existing buildings, if it is included as a performance goal when major renovations are done. Energy Plus houses, delivering net energy to the

20 Section TS-3.2.3 is based on Chapter 10.

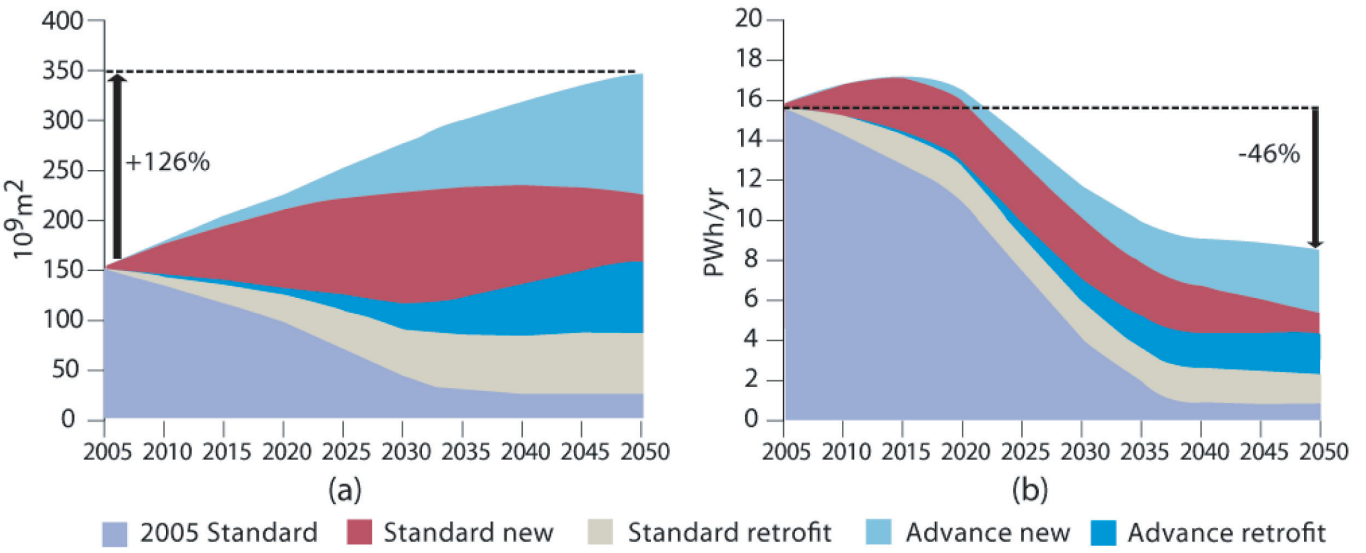

Figure TS-15 | Global final thermal energy use in buildings (a) and global floor area (b) in the state-of-the-art scenario (corresponding approximately to the 'GEA-Efficiency' group of pathways), 2005–2050. Source: Chapter 10.

Key: Explanations of efficiency categories: standard, today's stock; new, new buildings built to today's building code or anticipated new building codes (without additional policies); advance new, new buildings built to today's state-of-the-art performance levels; retrofit, assumes some efficiency gains, typically 35%; advanced retrofit, retrofit built to state-of-the-art levels.

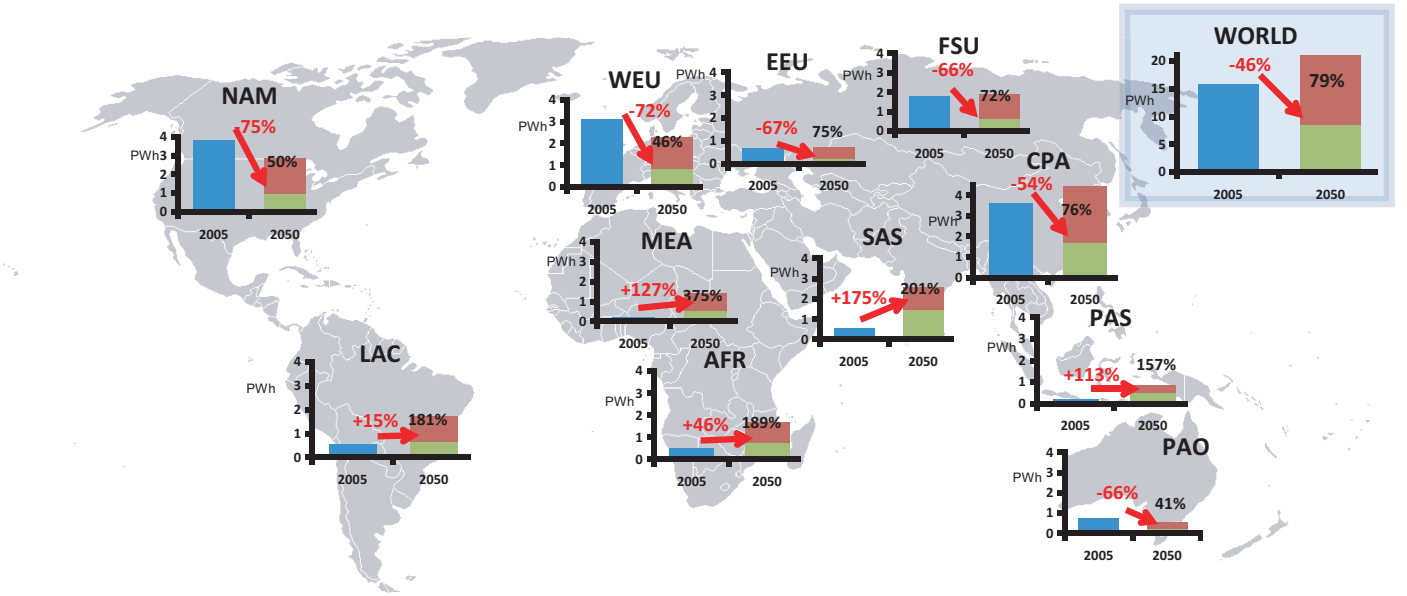

Figure TS-16 | Final building heating and cooling energy demand scenarios until 2050: state-of-the-art (~corresponding to the GEA-Efficiency set of pathways) and sub-optimal (~corresponding to the GEA-Supply set of pathways scenarios), with the lock-in risk (difference). Note: Green bars, indicated by red arrows and numbers, represent the opportunities through the state-of-the-art scenario, while the red bars with black numbers show the size of the lock-in risk (difference between the two scenarios). Percent figures are relative to 2005 values. Source: Chapter 10.

grid over a year, have been constructed even in high latitudes. Building-integrated solar photovoltaics (PVs) can contribute to meeting the electricity demand in buildings, especially in single-family homes, and solar water heaters can cover all or part of the heat required for hot water demand. However, requiring buildings to be zero-energy or net-energy suppliers may not be the lowest cost or most sustainable approach in addressing the multiple GEA goals, and sometimes may not be possible, depending on location.

Analysis carried out under the GEA pathway framework demonstrates that a reduction of global final energy use for heating and cooling of about 46% by 2050 compared with 2005 is possible through the full use

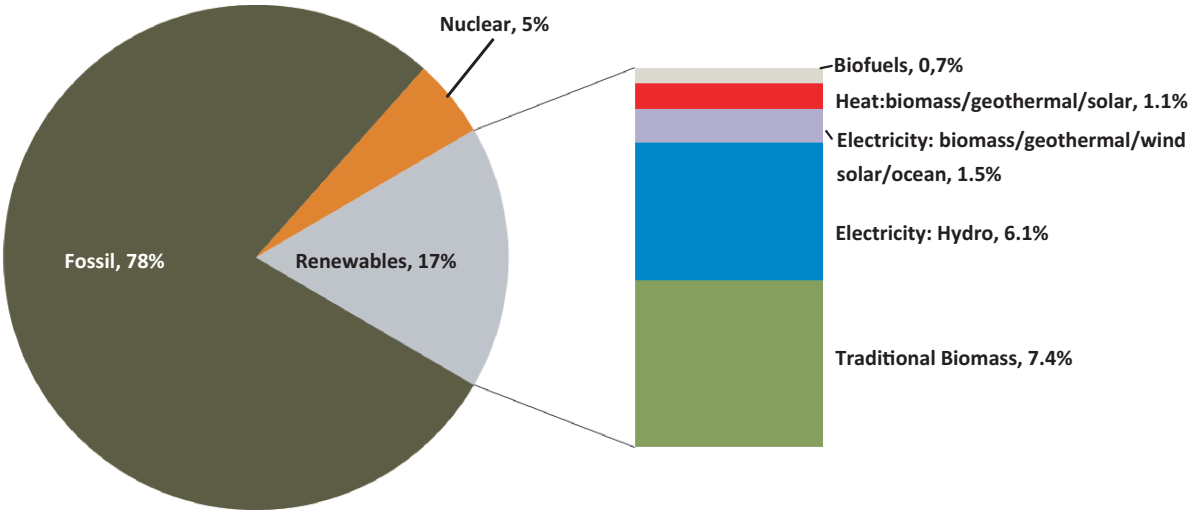

Figure TS-17 | Renewable share of primary energy use, 2009 (528 EJ). Source: Chapter 11.

of today's best practices in design, construction, and building operation technology and know-how. This can be obtained even while increasing amenities and comfort and simultaneously accommodating an increase in floor space of over 126% (see Figure TS-15.)

However, there is a significant risk of lock-in. If stringent building codes are not introduced universally and energy retrofits accelerate but are not subject to state-of-the-art efficiency levels, substantial energy use and corresponding GHG emissions can be 'locked in' for many decades. This could lead to a 33% increase in global energy use for buildings by 2050 instead of a decrease of 46% (see Figure TS-16).

Wide adoption of the state-of-the-art in the buildings sector would not only contribute significantly to meeting GEA's multiple goals, but such developments would also deliver a wide spectrum of other benefits. A review of quantified multiple benefits showed that productivity gains through reduced incidence of infections from exposure to indoor air pollution score particularly high. Other benefits included increases in productivity, energy security, indoor air quality and health, social welfare, real estate values, and employment. The approximately US$57 trillion cumulative energy-cost savings until 2050 in avoided heating and cooling energy costs alone substantially exceeds the estimated US$15 trillion investments that are needed to realize this pathway. The value of the additional benefits has also been shown to be substantial, often exceeding the energy cost savings. In several cases the multiple benefits are so significant and coincide with other important policy agendas (such as improved energy security, employment, poverty alleviation, competitiveness) that they provide easier and more attractive entry points for local policymaking than climate change or other environmental agendas.

A transition to a very low energy-use level for buildings requires a shift in the focus of energy-sector investment from the supply side to an integrated system solution and services perspective, as well as the innovation and cultivation of new business models.

A broad portfolio of approaches is available and has been increasingly applied worldwide to capture the cost-effective efficiency potentials. Owing to the large number and diversity of market barriers, single instruments such as a carbon pricing will not unlock the large efficiency potentials. Policy portfolios tailored to different target groups and a specific set of barriers are needed. Nevertheless, deep reductions in building-energy use will not be possible without ambitious and strictly enforced performance standards, including building codes for new construction and renovation as well as appliance standards.

3.3 Energy Supply

3.3.1 Renewable Energy[21]

The potential to provide electricity, heat, and transport fuels to deliver all energy services from renewable energies is huge. The resource base is more than sufficient to provide full coverage of human energy demand at several times the present level and potentially more than 10 times this level.

In 2009, renewable energy sources contributed about 17% of world primary energy use, mainly through traditional biomass (7.4%) and large hydropower (6.1%), while the share from solar, wind, modern biomass, geothermal, and ocean energy was 3.3% (see Figure TS-17).

Many examples exist of hydropower plants, geothermal power plants, and biomass combustion for heat and for combined heat and power

21 Section TS-3.3.1 is based on Chapter 11.

(CHP) that have been fully competitive with fossil fuels for decades. In select locations, and for specific markets (such as remote locations), wind and solar (or hybrid systems) have also provided least-cost, highly reliable energy supplies. In broader markets, starting from an initially very low level, very rapid growth of wind and solar technologies has occurred in the last decade, strongly stimulated by public policies. Wind energy has grown globally by more than 25% per year for more than 15 years and solar PV by more than 50% per year for around 10 years. Costs have dropped by 50–90% on a dollar per megawatt-hour basis over the past decades, and they continue to decline rapidly. Technologies such as solar water heaters and wind farms on good sites are nowadays competitive with conventional energy technologies on standard economic terms (without including any external costs and benefits). An overview of the present status and future potential of renewable energy options is presented in Table TS-4.

The rapid expansion in renewables, which largely has taken place in only a few countries, has usually been supported by different types of incentives or driven by quota requirements. The feed-in tariffs (FITs) used in the majority of EU countries, China, and elsewhere have been especially successful. Global investments in 2009 were slightly lower as a result of the financial crises (although with less reduction than for most other energy technologies) (see Figure TS-18); however, they rebounded in 2010. Both wind and solar PV electricity are already

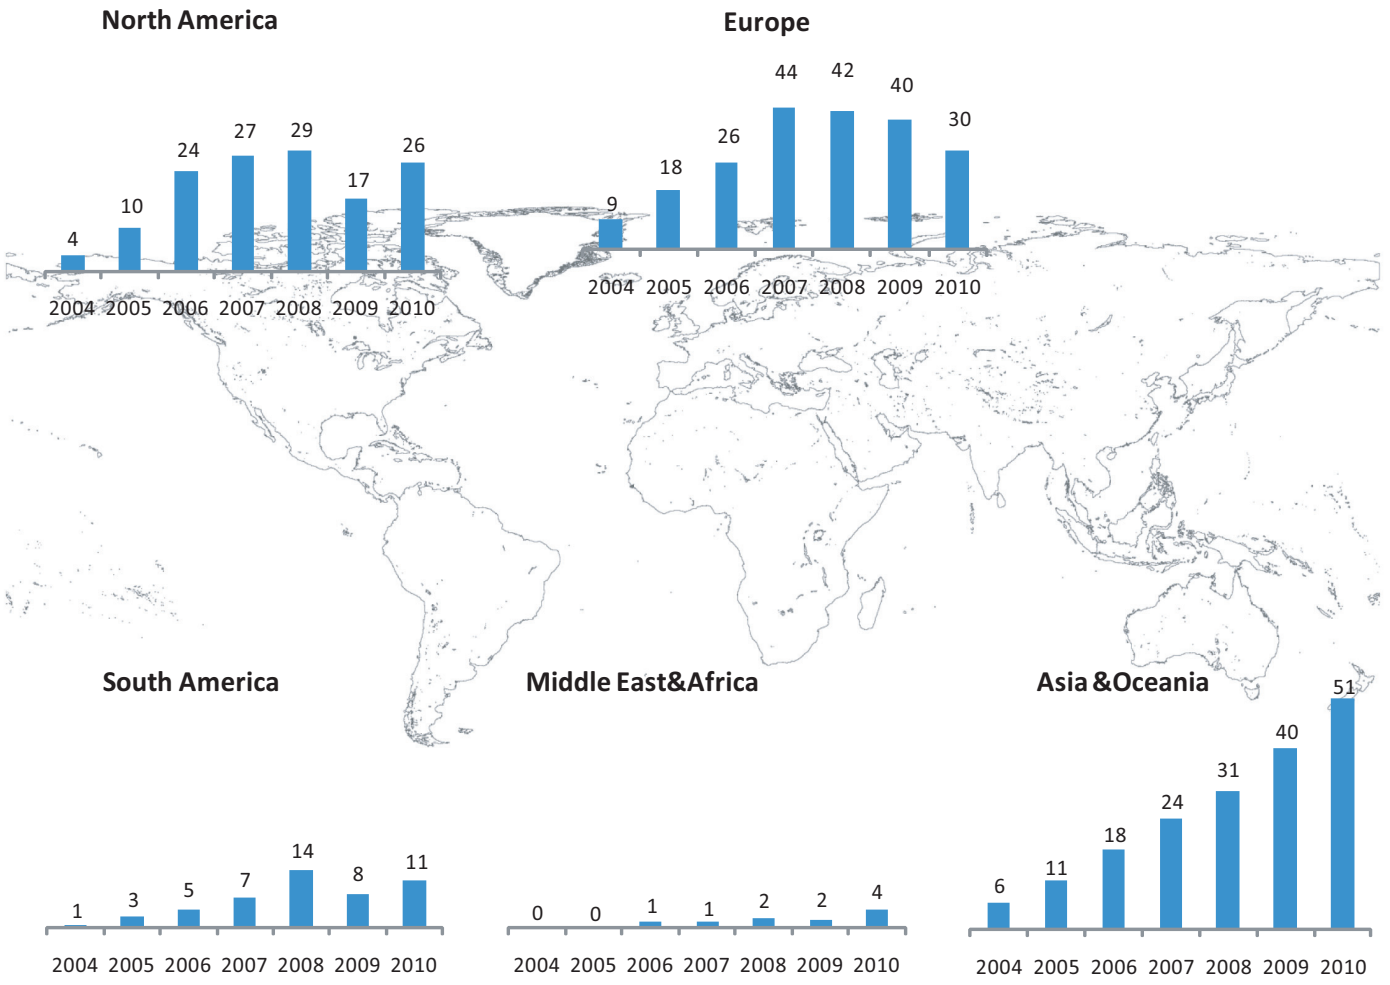

Figure TS-18 | New financial investments in renewable energy, by region, 2004–2010 (billion $US_{2005}$$). New investment volume adjusted for reinvested equity; total values include estimates for undisclosed deals. This comparison does not include small-scale distributed energy projects or large-scale hydropower investments. Source: Chapter 11.

cost-competitive in some markets and are projected to become so in many more markets in the next 5–10 years without being favored by public policy. However, renewables face resistance due to lock-in to conventional energies and substantial market barriers in the majority of markets.

Renewable power capacity additions now represent more than one-third of all global power capacity additions (see Figure TS-19). While substantial on an annual basis, with a very large total installed capacity, renewables remain a relatively small contributor to global energy supply.

The intermittent and variable generation of wind, solar, and wave power must be handled within an electricity system that was not designed to accommodate it, and in which traditional base load-power from nuclear, geothermal, and fossil power stations with restricted flexibility limit the system's ability to follow load variations. Energy systems have historically been designed to handle loads that vary over seconds, days, weeks, and years with high reliability. These systems are becoming increasingly able to accommodate increased quantities of variable generation through use of so-called smart systems with advanced sensing and control capabilities. With support from accurate and timely load forecasting, capacity management, and overall intelligent load and demand-side management, experience has shown that at least 20%, and perhaps up to 50%, of variable renewable generation can be accommodated in most existing systems at low costs, and that it is feasible to accommodate additional intermittent generation with additional investment in grid flexibility, low capital cost fuel-based generation, storage, and demand-side management (smart grids).

Intelligent improvement and increase of interconnection between states and across geographic regions will help maintain and increase reliability of energy systems in an environment with rapidly increasing shares of variable renewable energies in the system. Wind and solar PV, and most hydrokinetic or ocean thermal technologies, offer the unique additional attribute of virtually complete elimination of additional water requirements for power generation. Other renewable options, including bio-based options, geothermal, concentrating solar, and hydropower on

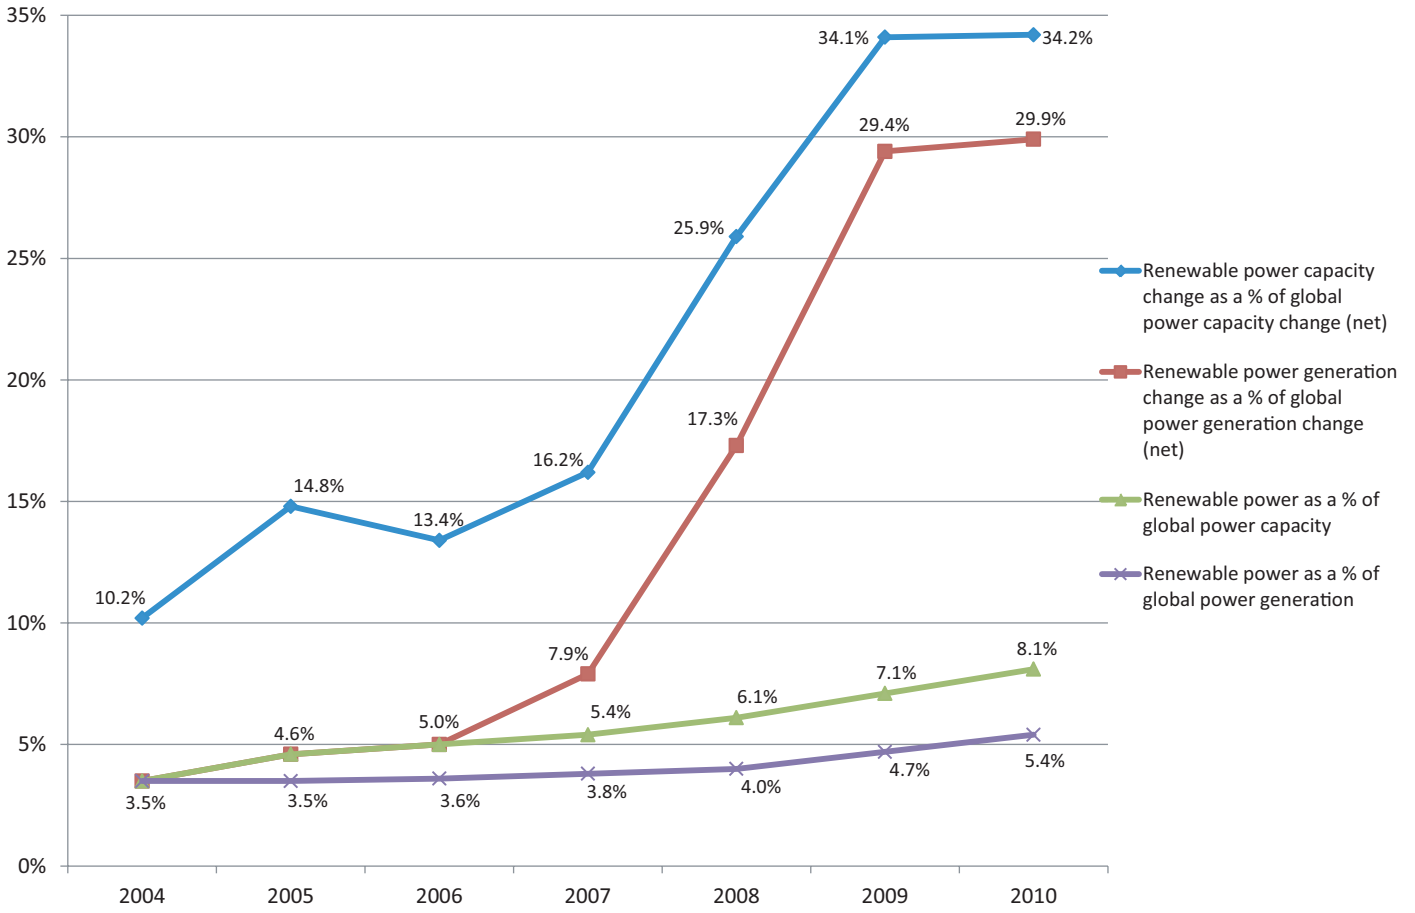

Figure TS-19 | Renewable power capacity (excluding large hydro) and generation as a percentage of global capacity and generation, respectively, and their rates of change also in percent; 2004–2010 Source: UNEP and BNEF, 2011; see Chapter 11.[22]

a life-cycle basis, still require water for cooling a steam turbine or are associated with large amounts of evaporation.

The development of high-voltage direct current transmission cables may allow the use of remote resources of wind and solar at costs projected to be affordable. Such cables have been installed for many years in sub-marine and on-shore locations, and demand is increasing (in the North Sea, for example). This is significant, as some of the best renewable energy resources are located far from load centers. In conjunction with energy storage at the generation location, such transmission cables can be used to provide base load electricity supply.

The GEA pathways show that renewable energies can meet up to 100% of projected energy demand for specific regions. The GEA pathways analysis indicates that a significant increase in renewable energy supplies from 17% of global primary energy use in 2009 up to 30–75% and would result in multiple benefits.

22 **UNEP and BNEF, 2011:** *Global Trends in Renewable Energy Investment 2011: Analysis of Trends and Issues in the Financing of Renewable Energy*. United Nations Environment Programme (UNEP), Nairobi, Kenya and Bloomberg New Energy Finance (BNEF), London, UK.

3.3.2 Fossil Energy Systems[23]

This section has two parts. The first part covers new opportunities in the conversion of fossil fuels to liquid energy carriers and electricity. Co-utilization of coal and biomass is highlighted in conjunction with CCS, which is the subject of the second part.

3.3.2.1 Fuels, Heat, and Electricity from Fossil Resources

A radical transformation of the fossil energy landscape is feasible for simultaneously meeting the multiple sustainability goals of wider access to modern energy carriers, reduced air pollution, enhanced energy security, and major GHG emissions reductions. The essential technology-related requirements for this transformation are continued enhancement of unit energy conversion efficiencies, the development of CO_2 capture and storage, use of both fossil and renewable energy in the same facilities, and efficient co-production of multiple energy carriers at the same facilities.

23 Section TS-3.3.2.1 is based on Chapter 12.

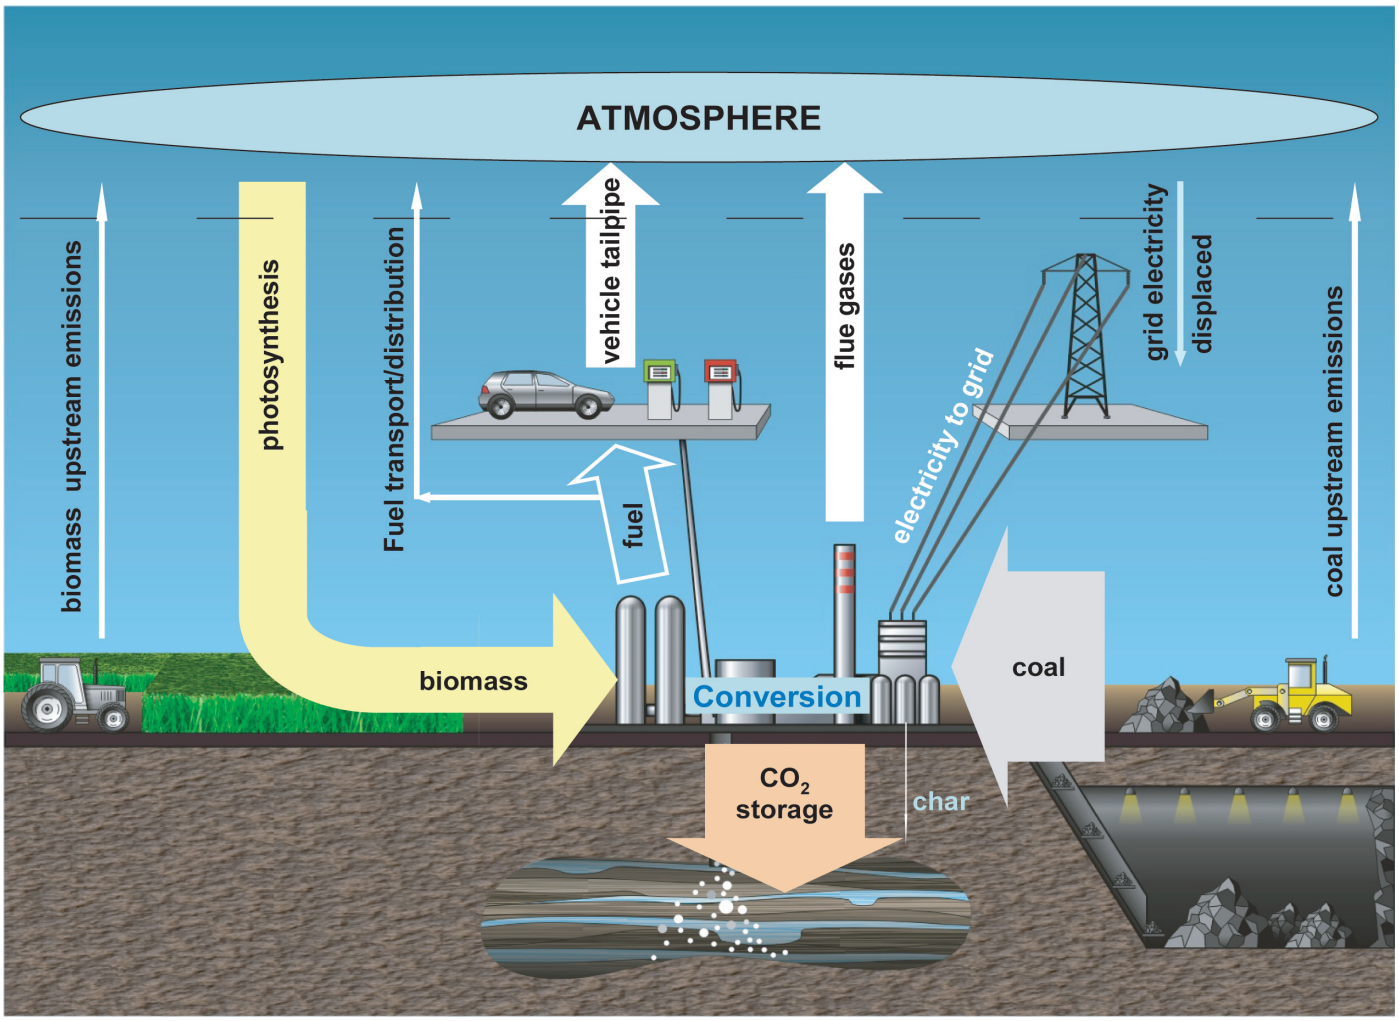

Figure TS-20 | Carbon flows for conversion of coal and biomass to liquid fuels and electricity. When biomass is approximately 30% of the feedstock input (on a higher heating value basis), the net fuel cycle GHG emissions associated with the produced liquid fuels and electricity would be less than 10% of the emissions for the displaced fossil energy. Source: Chapter 12.[24]

For developing and industrial countries alike, fossil fuels – which will dominate energy use for decades to come – must be used judiciously by designing energy systems for which the quality of energy supply is well matched to that required and also by exploiting other opportunities for realizing high efficiencies. Continued use of coal and other fossil fuels in a carbon-constrained world will increase the requirement for CO_2 capture and storage.

Since developing and industrial countries have different energy priorities, strategies for fossil energy development will vary in the short term, but they must converge in the long term. In developing countries, the emphasis could be on increasing access to energy services based on cleaner energy carriers, building new manufacturing and energy infrastructures that anticipate the evolution to low-carbon energy systems, and exploiting the rapid growth in these infrastructures to facilitate introduction of the advanced energy technologies needed to meet sustainability goals.

In industrial countries, where energy infrastructures are largely already in place, a high priority could be overhauling existing coal power plant sites to add additional capabilities (such as co-production of electricity and liquid transport fuels) and CCS. (Simply switching from coal to natural gas power generation without CCS will not achieve the needed carbon emission reductions.)

Among the technologies that use fossil fuels, only co-production and co-processing strategies using biomass with fossil fuel and with CCS have the ability to achieve deep reductions in CO_2 through 'net negative' emissions. These technologies could begin to be deployed in the 2015–2020 time frame as nearly all of their components are already in commercial use. In the long term, hydrogen made from fossil fuels with CCS is a decarbonization energy option, but infrastructure challenges are likely to limit this option in the near term.

24 **Larson, E. D., G. Fiorese, G. Liu, R. H. Williams, T. G. Kreutz and S. Consonni, 2010:** Co-production of Decarbonized Synfuels and Electricity from Coal + Biomass with CO_2 Capture and Storage: an Illinois Case Study. *Energy & Environmental Science*, **3**(1):28–42.

Co-production with CCS represents a low-cost approach for simultaneously greatly reducing carbon emissions for both electricity and transportation fuels (such as gasoline, diesel, and jet fuel), enhancing energy supply security, providing transportation fuels that are less polluting than petroleum-derived fuels in terms of conventional air pollutants, providing clean synthetic cooking fuels as alternatives to cooking with biomass and coal (critically important for developing countries), and greatly reducing the severe health-damage costs due to air pollution from conventional coal power plants.

Co-processing biomass with coal or natural gas in co-production systems requires, at most, half as much biomass to provide low-carbon transport fuels compared with advanced fuels made only from biomass such as cellulosic ethanol. Co-production also represents a promising approach for gaining early market experience with CCS (because CO_2 capture is less costly than for stand-alone power plants) and can serve as a bridge to enabling CCS as a routine activity for biomass energy (with corresponding negative GHG emissions) after 2030 (see Figure TS-20).

No technological breakthroughs are needed to get started with co-production strategies, but there are formidable institutional hurdles created by the need to manage two disparate feedstock supply chains (for a fossil fuel and biomass) and simultaneously provide three products (liquid fuels, electricity, and CO_2) serving three different commodity markets.

Creative public policies that promote the needed changes in the fossil fuel landscape would include the setting of a price on GHG emissions, more stringent regulations on air pollution, performance-based support for the early deployment of promising technology, and an emphasis on cost reduction through accelerated learning. These actions would need to be supported by international collaboration and intellectual and financial assistance from industrial to developing countries for technology adoption and technological and institutional capacity building.

3.3.2.2 Carbon Capture and Storage[25]

Over the past decade there has been a remarkable increase in interest and investment in CCS. In 2011, 280 projects were in various stages of development, and governments have committed billions of dollars for R&D, scale-up, and deployment. Considering full life-cycle emissions, CCS technology can reduce CO_2 emissions from fossil fuel combustion from stationary sources by about 65–85%. CCS is applicable to many of these sources, including the power generation and industrial sectors. Applying CCS with bioenergy would open up a route to achieving negative emissions.

Although the technology for CCS is available today, significant improvements are needed to support its widespread deployment. CCS involves the integration of four elements: CO_2 capture (separation and compression of CO_2), transportation to a storage location, and isolation from the atmosphere by pumping the CO_2 into appropriate saline aquifers, oil and gas reservoirs, and coal beds with effective seals that keep it safely and securely trapped underground.

Successful experiences with five ongoing projects (Weyburn-Midale, La Barge, In Salah, Sleipner, Snøhvit) demonstrate that, at least on a limited scale, CCS appears to be safe and effective for reducing emissions. Moreover, relevant experience from nearly 40 years of CO_2 utilization for enhanced oil recovery, currently at the aggregate rate of 40 Mt/yr, also shows that CO_2 can safely be pumped and retained underground.

Significant scale-up will be needed to achieve large reductions in CO_2 emissions through CCS. A five- to ten-fold scale-up in the size of individual projects is needed to capture and store emissions from a typical coal-fired power plant. A thousand-fold scale-up in CCS would be needed to reduce emissions by billions of tonnes per year.

Worldwide storage capacity estimations are improving, but more experience is needed. Estimates for oil and gas reservoirs are about 1000 billion tonnes (Gt) CO_2, saline aquifers are estimated to have a capacity ranging from about 4000 to 23,000 Gt, and coal beds have about 200 Gt. However, there is still considerable debate about how much sequestration capacity actually exists, particularly in saline aquifers. Research, geological assessments, and – most important – commercial-scale demonstration projects will be needed to improve confidence in capacity estimates.

Added costs and reduced energy efficiencies are associated with CCS. Costs for CCS are estimated to be from below US$30 to above US$200 per tonne of CO_2 avoided, depending on the type of fuel, the capture technology, and the assumptions about the baseline technology. And they would increase the cost of stand-alone power generation by 50–100%. Capital costs and parasitic energy requirements of 15–30% are the major cost drivers. Further R&D could help reduce costs and energy requirements. In addition, pursuing electricity generation via co-production with transportation fuels could also reduce costs for generating decarbonized electricity from coal (as described in Chapter 12).

Early CCS demonstration projects are likely to cost much more than projected long-term costs, but there are opportunities to keep costs down for demonstration by coupling to existing sources of low-cost CO_2 (e.g., coal-to-chemicals or fuels facilities in China) and/or to storage of anthropogenic CO_2 via enhanced oil recovery (as currently practiced in a large-scale CO_2 storage project in Canada).

Access to capital for large-scale deployment could be a major factor limiting the widespread use of CCS. Owing to the added costs, CCS will not take place without strong incentives to limit CO_2 emissions. Certainty about the policy and regulatory regimes will be crucial for obtaining access to capital to build these multibillion dollar projects.

25 Section TS-3.3.2.2 is based on Chapter 13.

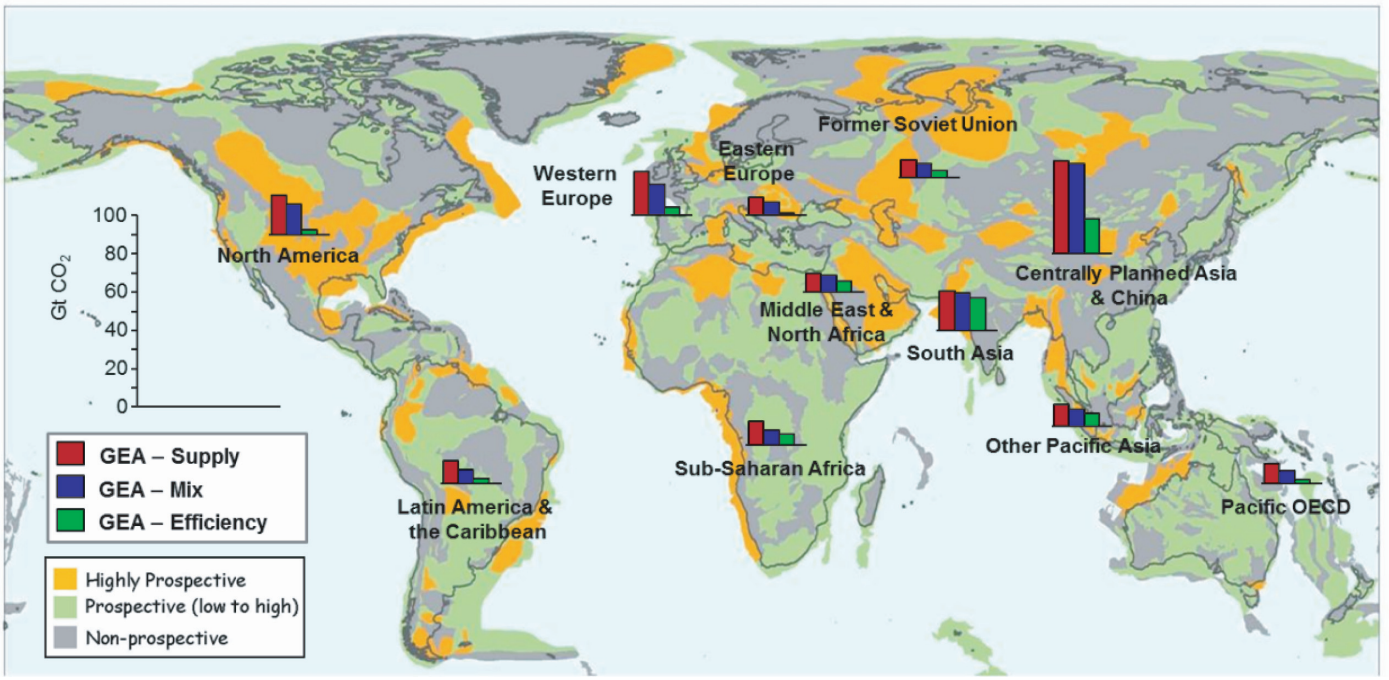

Figure TS-21 | Global map showing prospective geological carbon storage areas (Bradshaw and Dance, 2005)[26] superimposed on the estimated CO_2 storage requirements from CCS across the three illustrative GEA pathways (Chapter 17). Storage requirements in the illustrative GEA pathways are below 250 $GtCO_2$ by 2050, and below 1300 $GtCO_2$ by 2100. This is significantly less compared to the global geological CO_2 storage capacity, which includes saline aquifers ranging from about 4000 to 23,000 $GtCO_2$, and oil and gas reservoirs of about 1000 $GtCO_2$ (Chapter 13). For further details of the GEA pathways see the interactive web-based GEA scenario database hosted by IIASA: www.iiasa.ac.at/web-apps/ene/geadb.

To manage the environmental risks of CCS, clear and sufficient regulations are needed and enforced to ensure due diligence over the lifecycle of the project – particularly siting decisions, operating guidelines, monitoring, and closure of a storage facility.

Social, economic, policy, and political factors may limit deployment of CCS if not adequately addressed. Critical issues include ownership of underground pore space, long-term liability and stewardship, GHG accounting approaches, and verification and regulatory oversight regimes. Government support to lower barriers for early deployment is needed to encourage private-sector adoption. Developing countries will need support for getting access to technologies, lowering the cost of CCS, developing workforce capacity, and training regulators for permitting, monitoring, and oversight. CCS combined with biomass gasification has negative emissions, which are likely to be needed to achieve atmospheric stabilization of CO_2 and may provide an additional incentive for CCS adoption.

The assessment of future pathways suggests an overall requirement of CCS of up to 250 $GtCO_2$ of cumulative captured emissions by 2050. This is much less than the estimated storage capacity (see Figure TS-21).

26 **Bradshaw, J. and T. Dance, 2005:** Mapping geological storage prospectivity of CO2 for the world's sedimentary basins and regional source to sink matching. *Proceedings of the 7th International Conference on Greenhouse Gas Control Technologies*.

3.3.3 Nuclear Energy[27]

The share of nuclear energy, currently 14% of world electricity, has declined in recent years. Nevertheless, there are 441 nuclear power reactors in the world with 374 GWe of generating capacity, and another 65 under construction, of which 45 have been launched in the past five years, 27 of them in China. New grid connections peaked at 30 GW/yr in the mid-1980s, and the last decade has witnessed a decline to an average of 3 GWe/yr in new nuclear capacity and 1 GWe/yr of retirements for a net increase of 2 GWe/yr. Increases in the capacity factors of existing units have, to a degree, compensated for a slower increase in installed capacity. Efforts are being made to extend the lives of existing plants and to encourage the construction of new ones with government loan guarantees, caps on liability for the consequences of accidents, and other subsidies, and thereby sustain, and even increase by a few percent, the share of nuclear energy in a growing global electric power sector. This is the most that the International Atomic Energy Agency believes is achievable by 2050, based on its review of national plans.

Although the momentum of global nuclear power expansion slowed considerably in recent decades, there are important differences between nations and regions. In OECD countries, home of 83% of global installed nuclear capacity, very little construction is under way. Costs per unit remain high, and may even be increasing in Western Europe and North

27 Section TS-3.3.3 is based on Chapter 14.

America, which together account for 63% of global capacity. Among the reasons for cost increases in the 1980s and 1990s were increased stringency in safety requirements and construction delays in the United States after the Three Mile Island accident (see Figure TS-23). These factors can be expected to play a role again for some time after the accident at Japan's Fukushima Daiichi nuclear power plant in 2011. Costs are lower in East Asia and Russia, where most of the new construction is underway. There has been concern in China, however, about the availability of qualified workers and the adequacy of regulatory oversight. After the Fukushima accident, Germany, Italy, Switzerland, and Japan have decided, or announced plans, to scale back nuclear energy, and the United States, European Union, Japan and China announced comprehensive safety reviews.

Many developing countries have aspirations to build their first nuclear power plant, but a large fraction do not have the funds and currently have grid capacities that are too small to manage the large unit sizes of the currently available nuclear power plants. There is currently interest in the nuclear energy establishments of the developed countries, but in smaller reactors whose costs may be reduced through mass production.

Although over the past decades many proposals have been made for improving reactor safety and strengthening the barriers blocking the misuse of nuclear energy technologies for weapons purposes, it is still not clear how these problems will be dealt with. Most importantly, it has been understood since the end of World War II that the nonproliferation regime would be greatly strengthened if enrichment and plutonium were placed under international or multinational control. Plutonium separation and recycle persists in some countries, however, despite the fact that it is unlikely to be economic for the foreseeable future. Also countries continue to build national enrichment plants that could be misused to produce highly enriched uranium for weapons. Consequently, unless problems associated with proliferation and safety are effectively addressed, nuclear energy may not be a preferred climate change mitigation option even though it has low carbon emissions – other low-carbon electric power supply options may be more attractive.

Uncertainty characterizes the long-term role of nuclear energy in the GEA pathways. As with other energy technologies, it is an option, not a necessity, to meet future energy needs in a climate-friendly way. As discussed later, the scenarios in GEA demonstrate it is possible to meet all the GEA goals, including the climate goals, without nuclear power, even in the case of high demand scenarios. At the same time, in some scenarios with higher energy demand, it plays a large role in the energy mix. The resulting nuclear installed capacity in the scenarios ranges between 75 and 1850 GWe by 2050 with the lower bound resulting in a complete phase-out in the second half of the century. This uncertainty in the future of nuclear energy results from uncertainties in its future cost and public concerns about reactor safety, the proliferation of weapons-grade fissile materials, and the absence of arrangements in most countries for final disposal of spent fuel and/or the radioactive waste from spent-fuel reprocessing and plutonium recycle. Note that the high end of the above range is higher than the high projection put forward by the IAEA, based on the high ends of national projections before the Fukushima accident in 2011. In the past, nuclear growth has been far below the IAEA's high projection – and, until 2000, even below its low projections.

We have not considered nuclear fusion separately in the scenarios, given that fusion power is not likely to become a commercial energy option before the middle of the century at the earliest and would compete most directly with fission. However, pure fusion would have significant advantages relative to fission with regard to safety, proliferation resistance, and radioactive waste. Fusion–fission hybrids would not have these advantages.

3.4 Energy Systems[28]

The mechanisms by which energy is supplied to the final consumer are critical to the success of global and local economies. For the complex and diverse energy supply system to operate smoothly, many sources of energy – and their conversion to forms that can be delivered for use by consumers, from households to industry and commercial businesses – must operate in harmony within stable markets. Without the smooth operation of this complex interwoven system, the global economy cannot function (Chapter 15.1).

Energy supply systems differ between regions, between major economies, and between developing and industrial countries. Approaches to the necessary transitions[29] to create energy systems for a sustainable future therefore vary, and policies that work successfully in one region may fail in another. Nevertheless, there are lessons to be learned from shared experiences. The evolution of energy systems will depend on how well technologies are implemented and how well policies are instituted to bring about these changes.

Sustainable conversion from energy sources to energy carriers and efficient transmission and distribution for end-uses is crucial. This places particular emphasis on energy carriers such as electricity, hydrogen, heat, natural gas, biogas, and liquid fuels. All are key to transporting energy from more-remote production locations to growing urban population centers. Marketplaces will determine how much of each is used in any geographic region and when and how rapidly that use occurs.

As noted earlier, industry accounts for 27% of global final energy use, residential and public/commercial buildings use 34%, transport uses 28%, and agriculture/feedstocks/other uses account for 11%. Electricity

28 Section TS-3.4 is based on Chapters 15.

29 Transitions are covered more generally in Section TS-3.4.1 and in Chapters 16, 24, and 25.

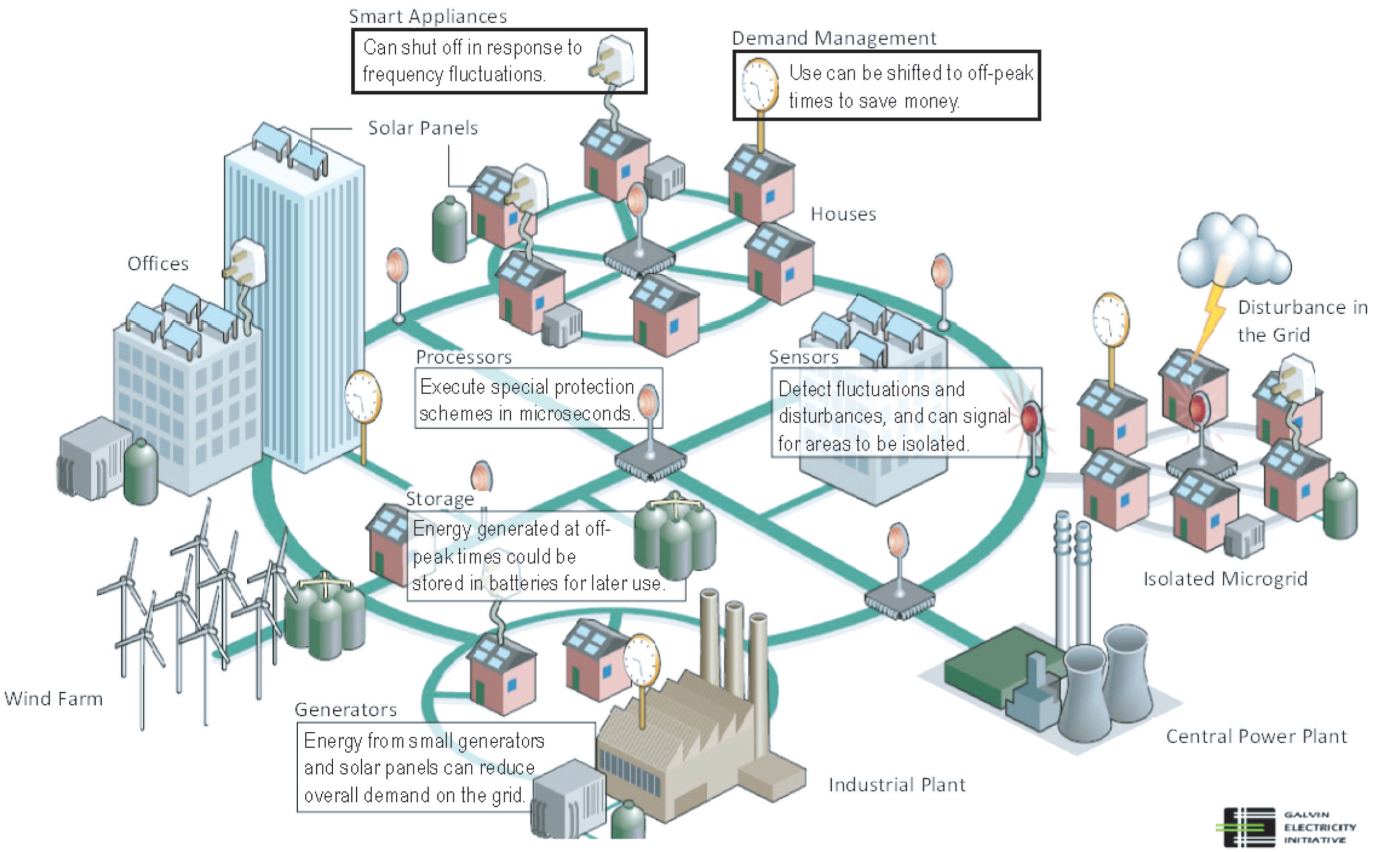

Figure TS-22 | Example of a smart grid, a network of integrated microgrids that can monitor and heal itself. Source: Amin, 2008; see Chapter 15.[30]

generation accounts for over one-third of the world's primary energy demand, with an average conversion efficiency of only around 36% (ranging from up to 90% for large hydro to less than 15% in some very old coal-fired power stations). Over half of all electricity generated is used in buildings, a category that includes households, services, and the public sector. More importantly, 40% of primary energy use results in heat, and much of this is wasted. Using more heat from thermal and geothermal power stations for industrial processes, district-heating schemes, and so on, would increase the overall efficiency of energy use (Chapter 15.2.1).

Providing integrated and affordable energy storage systems for modern energy carriers is essential. This is perhaps the largest and most perplexing part of the energy systems for a sustainable future that is needed for future economic security since costs are relatively high; pumped hydro storage being the lowest storage cost where feasible.

The entire energy grid for each energy source, from conversion to end-use, must be optimized into 'smart grids' using a digital system that continuously communicates between source and end-use and that integrates all energy carriers and their transmission and distribution systems (see Figure TS-22).

The potential of competitive electricity markets to most efficiently match energy supply and demand is a proven principle that is at the heart of the industrial world's economic system. Based on that success, it is rapidly becoming the standard for economic systems around the world.

In countries with well-developed energy markets, spot-market energy trading has been introduced and long-term contracts are becoming less frequent. The result for countries that supply energy is generally negative, and it is now more difficult to ensure long-term returns on large-scale investments. This is a threat to the financing of large capital-intensive energy supply projects.

Effective approaches to improving energy systems will be led by the private sector – but it is essential that there be a stable governance framework, facilitation of physical infrastructure, capital investments, and the social cohesion necessary for economic development and poverty reduction. Success will depend on the implementation of robust global public/private partnerships that can achieve unprecedented cooperation and integration between governments, between businesses, and between governments and businesses. This needs to happen rapidly to achieve energy systems for a sustainable future envisioned in the GEA goals.

30 **Amin, M., 2008:** Interview with Massoud, Amin, "Upgrading the Grid". *Nature*, **454**: 570–573.

Crucial to improved energy systems to meet rapidly changing needs is the urgent requirement to boost development and investment in advanced systems (Chapter 15, Sections 15.7.5, 15.8.5, and 15.9). The lag time between research and large-scale commercial deployment is long, yet funding for energy system R&D and demonstrations has been declining for 20 years. This trend must be reversed and involves enhanced cooperation among and between private and public sectors.

3.4.1 Transitions in Energy Systems[31]

The beginning of transformative change may be seen in a number of innovations and experiments in the energy sector. These experiments include technology-driven innovations in generation and end-use; system-level innovations that could reconfigure existing systems; and business-model innovations centered on energy service delivery. Experiments in generation include hybrid systems, where combining multiple primary energy sources help address issues such as intermittency. Experiments in end-use include technology options for the simultaneous delivery of multiple energy services, or even energy and non-energy services. System-level experiments include innovations in storage, distributed generation, and the facilitation of energy efficiency by effectively monetizing savings in energy use and the creation of new intermediaries such as ESCOs. In some of these experiments, technology can lead to changing relationships between players or changing roles for players; for example, the process of consumers becoming producers as seen in small-scale biogas projects.

To generate a base of innovations and effectively support those that show promise, understanding of the dynamics of technology transitions is essential. The transitions literature suggests that large-scale, transformative change in technology systems involves a hierarchy of changes from experiments to niches to technology regimes, with linkages across different scales.

3.4.2 Opportunities in System Integration

It is important to focus energy-related solutions on providing the energy services needed rather than on energy supply *per se*. Examples include telecommuting and electronic/IT services (such as e-banking) that replace the need for many routine car trips, or a relaxation of summer dress codes in offices (saving the energy used for air conditioning).

Measures to improve efficiency on the end-use side of the energy chain typically save more primary energy and associated pollution than measures on the supply side. This is because 1 kilowatt-hour (kWh) saved on the end-use side can often reduce 2–3 kWh worth of primary energy use and associated emissions. The GEA pathways assessment (Section TS-4) concludes that strategies focusing more on improved energy efficiency are by and large associated with lower costs for reaching the GEA goals than those focusing more on supply-side options.

GEA also finds that end-use-focused solutions reduce the risk that sustainability goals become unattainable. They increase the chances for multiple benefits, including improved local and indoor air pollution, and thus result in significant health gains, reduced congestion, reduced poverty, productivity gains, increased comfort and well-being, potential energy security improvements, new business opportunities, and sometimes enhanced employment opportunities.

The efficiency of end-use devices is also important when providing energy access. Lowest-cost devises, sometimes second-hand, can lock poor populations into using much more energy than needed; conversely, if efficient basic devices or appliances are also subsidized when providing access, consumers will be able to afford a higher level of energy services.

While individual system-, process-, and component-level efficiencies have improved significantly over the last few decades, the major opportunities for reducing energy intensity of economic activities lie in system optimization strategies rather than a focus on single components.

In industry, major advances have been achieved in process efficiency, with relatively fewer potentials remaining for such improvements. Still, most markets and policymakers tend to focus on individual system components (e.g., motors and drives, compressors, pumps, and boilers) with improvement potentials of 2–5%, while systems have much more impressive improvement potentials: 20% or more for motor systems and 10% or more for steam and process-heating systems.

Another way to reduce energy use in industry is to use fewer materials, as 70% of industrial energy use goes into the production of materials. A focus on increasing the rates of product reuse, renovation, remanufacture, and recycling has significant potential.

In buildings, novel approaches focusing on holistic methods that involve integrated design principles have been known to achieve as much as 90% energy reductions for heating and cooling purposes compared with standard practices (Section TS-3.2.3). Small-scale CHP has attracted interest for large buildings, and with the cost declines of PV, even if currently more expensive than grid electricity, the prospect of not being dependent on grid electricity has emerged. However, for feasibility, economic, and environmental reasons, requiring buildings to be zero-energy or net-energy suppliers is not likely to be the lowest cost or most sustainable approach in eliminating fossil fuel use, and is sometimes even impossible.

Energy use in densely built and populated areas, up to hundreds of watts per square meter (W/m^2) land area, typically significantly exceeds

31 Section TS-3.4.1 is based on Chapter 16.

annual average local renewable energy flows (typically below 1 W/m^2). Therefore net zero-energy buildings are only feasible in low-density areas and in building types with low power or heat loads. High-rise or commercial buildings with high energy use, such as hospitals, cannot meet their entire energy demand through building-integrated renewable energy sources.

It is typically single-family or low-rise, lower-density multifamily residential neighborhoods that can become zero net-energy users for their residential energy needs (excluding transportation). Therefore, care needs to be exercised that zero-energy housing mandates do not incentivize further urban sprawl that leads to more automobile dependence and a growth in transport energy use, as efficient public transport systems are not economical in low-density urban areas.

Rather than aiming for buildings that use zero fossil fuel energy as quickly as possible, an economically sustainable energy strategy would implement a combination of the following: reduced demand for energy; use of available waste heat from industrial, commercial, or decentralized electricity production; on-site generation of heat and electricity; and off-site supply of electricity. Many forms of off-site renewable energy are less expensive than on-site PV generation of electricity and are thus able to achieve more mitigation and sustainable energy supply per unit of expenditure. At the same time, PV costs are expected to become competitive for grid-connected small consumers in major grid markets during this decade. Furthermore, PV must compete against the retail rather than the wholesale cost of electricity produced off-site. On-site production of electricity also improves overall system reliability by relieving transmission bottlenecks within urban demand centers. All of these steps point to the importance of policy integration.

3.5 Evaluating Options

The previous sub-sections describe various supply-side and end-use technologies, as well as the primary energy sources and their availability, and the changes taking place in the entire energy system. A number of

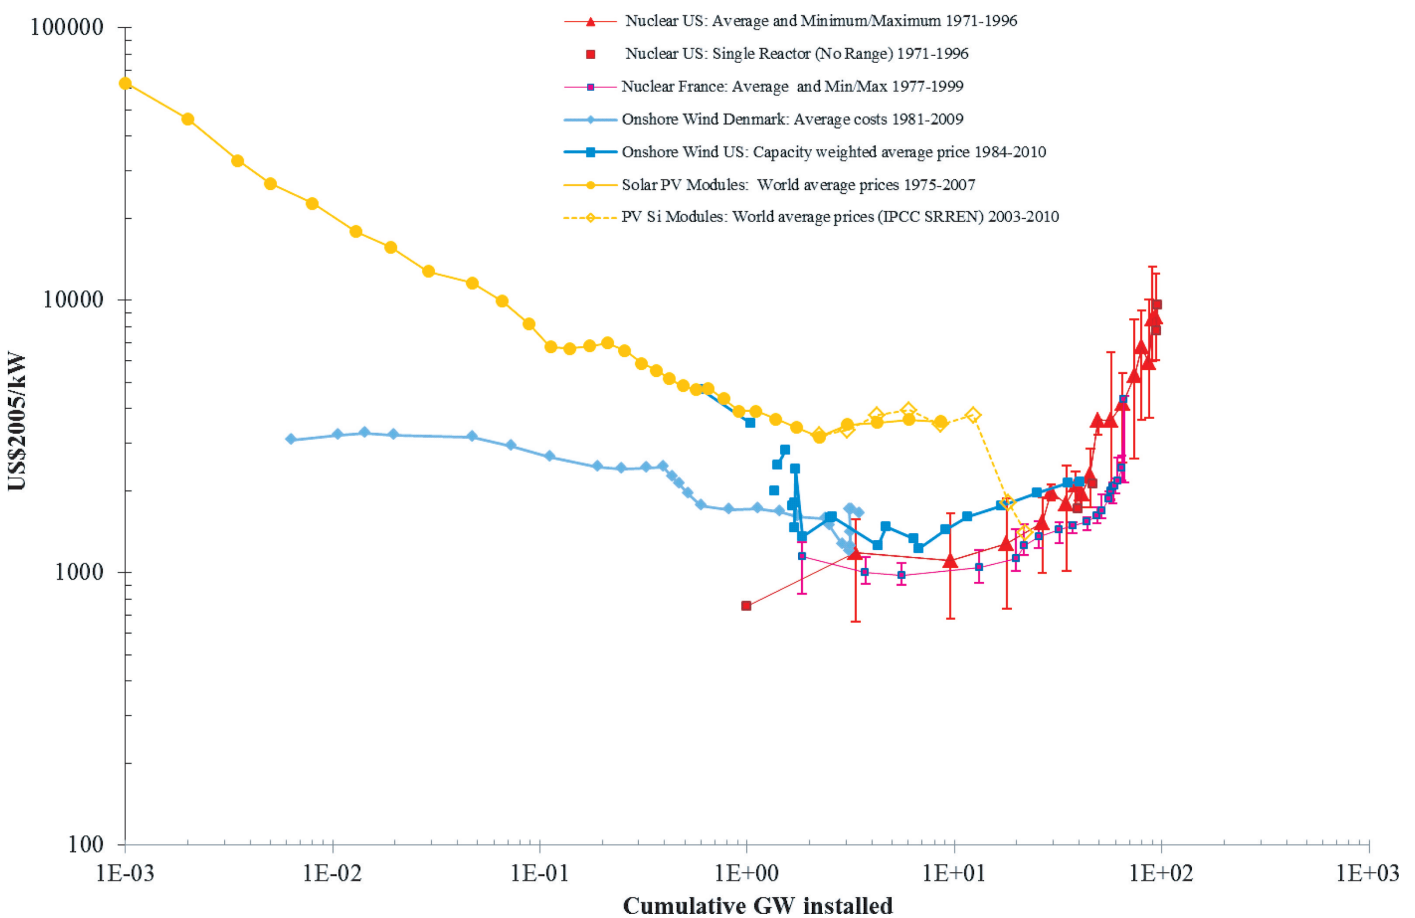

Figure TS-23 | Cost trends of selected non-fossil energy technologies (US2005$/kW installed capacity) versus cumulative deployment (cumulative GW installed) Chapter 24 data have been updated with the most recent cost trends (2010) available in the literature for PV Si Modules and US onshore wind turbines. Note that the summary illustrates comparative cost trends only and is not suitable for a direct economic comparison of different energy technologies due to important differences between the economics of technology components (e.g., PV modules versus total systems installed), cost versus price data, and also differences in load factors across technologies (e.g., nuclear's electricity output per kW installed is three to four times larger than that of PV or wind turbine systems). Source: Chapter 24.

attributes of these options need to be considered while evaluating their feasibility, appropriateness, and attractiveness. These include costs, benefits, environmental outcomes, and trade-offs across multiple objectives.

3.5.1 Costs and Environmental Performance of Options

Costs of Non-fossil Energy Supply Options

Figure TS-23 shows cost trends of selected non-fossil energy technologies. Despite a wide range in experiences of cost trend across technologies, two important observations stand out. First, there is a marked contrast between nuclear technologies, showing persistent cost escalations, versus the other non-fossil technologies, which generally show declining costs/prices with accumulated market deployment experience. Second, improvement trends are highly variable across technologies and also over time. For some technologies (e.g., wind in the United States and Europe) historical cost improvements were temporarily reversed after the year 2003–2004, suggesting possible effects of ambitious demand-pull policies in face of manufacturing capacity constraints and rising profit margins that (along with rising commodity and raw material prices) have led to cost escalations in renewable energy technologies as well.

Greenhouse Gas Emissions

One of the goals in the GEA analysis is to reduce emissions of GHGs. Tables TS-5 and TS-6 present the specific emissions per kWh for different technologies. Data are all life-cycle emissions of the major gases converted to CO_2 equivalent per GJ. The lowest emissions from renewables are from run-of-the-river hydropower, followed by hydro (reservoir), which displays a large variation depending on biological material in the reservoir, solar PV, wind, biomass, and geothermal. Nuclear energy has lower emissions than fossil-based generation, even if CCS is applied.

Combining fossil fuels with CCS reduces emissions significantly, although they are still significantly higher than renewables and nuclear. Combined use of fossil fuel and biomass with CCS can offer electricity and fuels with no net or negative emissions. As photosynthesis removes CO_2 from of the atmosphere, this results in negative emissions – that is, removal and storage of CO_2 when the biomass fuel is combined with CCS, which returns the CO_2 molecules to the ground (Table TS-7).

Quantifying emissions for electricity co-produced with liquid fuels (or for liquid fuels co-produced with electricity) is complicated by the issue of how to apportion emissions between the different products. The approach adopted here is to assign a percentage reduction (or increase) in emissions equal to the emission for the complete co-production system divided by emissions for a reference system consisting of separate conventional fossil fuel technologies (without CCS) that collectively produce the same amount of fuels and electricity.

Table TS-5 | Life-cycle emissions of GHGs for electricity generation. These numbers include direct emissions at the power plant and associated emissions upstream and downstream of the plant. The numbers here must be regarded as approximate as they depend on many assumptions, including the composition of the present energy systems.

Type	Conversion scheme	g CO_2-eq per kWh_e	
		w/o CCS	with CCS
Renewables	Solar photovoltaic[a]	16	
	Wind[b]	8	
	Hydro (reservoir)[c]	2–48	
	Hydro (run-of-river)	1–18	
	Geothermal[d]	~100	
	Biomass-IGCC[e]	25	–776
Fossil	Sub-critical coal[f]	896	187
	Super-critical coal[f]	831	171
	Coal-IGCC[g] Coal+biomass in coproduction with transportation fuels[h]	787–833 750	126–162 71
	NGCC[i] Natural gas + biomass in co-production with transportation fuels[h]	421 448	110 87
Nuclear	LWR, once-through fuel cycle[j]	38 ± 27	

CCS = carbon capture and storage; CO_2-eq = carbon dioxide equivalents; HT = high-temperature; IGCC = integrated gasification combined cycle; LWR = light water reactor; MWh = megawatt-hour; and NGCC = natural gas combined cycle.

a) For an in-plane irradiation of 1700 kWh/m^2 and a value of 10 g CO_2-eq per kWh_e or even less, see Chapter 11, Section 11.6.

b) Data from ExternE, vol 6, 1995.

c) Chapter 11, Section 11.3 gives estimates on emissions from hydropower.

d) High temperature brine, Chapter 11, Section 11.4. Note: emissions are very variable between existing geothermal power plants.

e) As-received biomass moisture content is 15% by weight (see Chapter 12, Table 12.1). This assumes zero emissions associated with indirect land-use change, as would be the case with utilization of most biomass residues or biomass grown on abandoned cropland.f) From Chapter 12, Table 12.6.

g) From Chapter 12, Table 12.7.

h) With co-production, how the life-cycle emissions for the system are allocated to each product is arbitrary. In Chapter 12 a Greenhouse Gas Emissions Index (GHGI) for co-production is defined as the system life-cycle emissions divided by life-cycle emissions for a reference system producing the same amount of electricity and transportation fuels. The reference system makes electricity in a supercritical coal-fired plant with CO_2 vented and transportation fuels from petroleum. The emissions rates given in this table are calculated as GHGI × (831 kgCO_2eq/kWh), where the GHGI values are from Table 12.27. The GHGI values will change with the fraction of fuel input to co-production that is biomass. For the systems in this table, biomass accounts for 29% of the higher heating value fuel input for the coal+biomass system and 34% for the natural gas+biomass system.

i) From Chapter 12, Table 12.8.

j) From Chapter 14.

Table TS-6 | Life-cycle emissions of GHGs for different liquid fuel supply technologies. Note: ILUC: Indirect Land Use Change; GHGI: Greenhouse Gas Index; CTL: Coal to Fischer-Tropsch liquid fuels; BTL: biomass to Fischer-Tropsch liquid fuels.

	Without ILUC	With ILUC	Source
	$kgCO_2$-eq/GJ LHV

GTL with CCS	82		
CO-PRODUCTION OF LIQUID FUELS AND ELECTRICITY (electricity is a major co-product)			
CTL with CCS*	64		Chapter 12, Table 12.22
Coal+biomass to FTL with CCS*	8.5		
Natural gas+biomass to FTL with CCS*	9.6		Chapter 12, Table 12.27

* The emissions estimates for these systems are from Chapter 12, based on the GHG emissions index (GHGI), defined in Table 12.15, note (c). The emissions rates in this table are calculated as GHGI × Z, where the GHGI values are taken from Chapter 12 and Z is the lifecycle GHG emissions for petroleum-derived fuels that would be displaced by the fuels produced from coal, gas, and/or biomass.

a) Chapter 11 (Fig. 11.20) gives range from 73 to 210 for corn ethanol (without ILUC).

b) Chapter 11 (Fig. 11.20) gives 19 (without ILUC)

c) Chapter 11 (Fig. 11.20) gives 23 $kgCO^2$-eq/GJ w/o ILUC

3.5.2 Multiple Benefits

The GEA pathways that meet the sustainability goals also generate substantial economic and social benefits. For example, achieving society's near-term pollution and health objectives is greatly furthered by investing in the same energy technologies that would be used to limit climate change. Increased stringency of air pollution policies globally and increased access to cleaner cooking fuels would bring significant improvements in pollution-related health impacts as compared to currently planned air-quality legislations and access trends, with a saving of 20 million disability adjusted life years (DALYs) from outdoor air pollution and more than 24 million DALYs from household air pollution.

This synergy is advantageous and important, given that measures which lead to local and national benefits, for example, improved health and environment, may be more easily adopted than those measures that are put forward solely on the grounds of global goals. Many energy efficiency and renewable energy options enjoy such synergies and generate

Table TS-7 | Synthesis and taxonomy of multiple benefits related to sustainable energy options. The options are discussed in the different rows, while the policy goal where the multiple benefits occur is covered in the different columns. The first five columns summarize how the various options discussed contribute to (or occasionally compromise) reaching the multiple objectives of GEA. The remaining three columns identify further multiple benefits and impacts. The table focuses on the more sustainable sub-options within the rows, and acknowledges if there are major differences in the particular impact among the sub-options (such as with and without CCS). It is important to recognize, however, that this is a synthesis table and thus cannot be fully comprehensive.

Sustainable Energy Options	Access	Energy Security	Health	Environment	Climate Change (mitigation and adaptation)	Development and Economic benefits, poverty alleviation	Risks of large accidents	Employment (local)
Efficiency								
Industry	–	Energy import need reductions due to saved energy; a robust industry makes for stronger social and defense systems	Reduced health impacts from lower regional industrial and energy-related air pollution	Reduced energy-related emissions from saved energy; lower industrial pollution from material efficiency & recycling	Lower CO_2 emissions due to saved energy; lower non-CO_2 GHG emissions due to process/material efficiency	Productivity gains and increased competitiveness; For all end-use sectors: New business opportunities for efficiency implementation, e.g. ESCOs, Reduced investment needs in supply thus more funds for development	Lower risk of industrial accidents from more efficient, safer and fewer processes; Gains through displaced risky generation	New jobs in efficiency implementation, ESCOs, equipment production
Transport	Better and more equitable access to mobility services	Alternative fuels: Shift to non-oil dependent economy; lower oil consumption for efficiency, modal shift and non-motorized mobility	Health gains from lower urban air pollution; lower mortality and morbidity from reduced accidents	Significant improvement in urban air quality due to reduced specific emissions and transport volumes	Lower GHG emissions due to efficiency gains, alternative fuels, non-motorized and alternative mobility	Reduced economic damages from congestion; better access to economic activities; economic savings through lower transport costs due to efficiency and alternative mobility; more time for productive activity from improved mobility	Lower risk for oil spills due to lower oil consumption and trade	Local employment gains for public transport
Buildings (residential, public and services)	Access to higher energy service levels from same budget and production capacity through efficiency	Reduced needs for imports due to saved energy; more resilient energy systems from building-integrated distributed generation	Clean/efficient cooking; lower respiratory infectious morbidity in well-ventilated buildings; reduced noise exposure	Reduced energy-related emissions from saved energy; both local and regional	Reduced GHG emissions: CO_2 from saved energy, non-CO_2 from less cooling; more climate and heat resilience: adaptation gains	Increased social welfare: More disposable income through saved energy costs; potentially eliminated poverty; Reduced needs for tariff subsidies; productivity gains from reduced illnesses in well-ventilated buildings; increased value for real estate	Gains if energy savings are large enough to displace risky power generation	Large net local employment benefits, especially for retrofits; high employment intensity of energy savings' through efficiency
Systems and grids								
Advanced electricity and gas systems (possibly hydrogen in future)	Inexpensive and more linked systems provide easier access; Distributed generation provides access where needed	Smart systems provide redundancy through rapid deployment of energy, and enhanced use of alternatives. Microgrids offer autonomy, stability, flexibility	Smart systems are more efficient, reducing air pollution from sources	Smart systems reduce overall need for energy with less environmental impact; Can assimilate large amounts of variable renewable energy source (RES)	More efficient, use less energy and produce fewer GHGs	ICT, smart systems, microgrids, and distributed generation increase efficiency and productivity by providing stability and instant flexibility; Smart systems are less expensive and thus more ubiquitous.	Faster, more reliable and redundant systems reduce accident risks	Distributed generation and smart systems mean mostly local jobs
Supply								

Oil (with and without CCS)	Oil products such as kerosene and LPG provide clean solutions to the access to cleaner cooking goal, and would reduce GHG emissions from the cooking	Dependence from producers in politically unstable regions; control of oil sources as demonstrated cause of armed conflicts	Health benefits if cleaner fuels replace traditional biomass use	Lower indoor and local pollution if cleaner oil-based fuels replace traditional biomass	Lower black carbon emissions if cleaner oil-based fuels replace traditional biomass; with CCS: reduced CO_2 emissions for large point-sources	Major income source for many oil-rich countries; with CCS can provide low GHG energy source for many places and uses. Its price volatility can impact the economies; and affects mobility affordability	Risk of spills in the extraction and transport of oil and oil products	Mostly low labor intensity of extraction and use; mostly centralized
Coal (with and without CCS and biomass)	Can provide the fuels for access to cleaner cooking in many countries; provided technology routes such as analyzed in Chapter 12	Coal and biomass are geographically rather equally available; can be imported easily	Health impacts through mining and burning-related emissions need to be addressed along the lines in Chapter 12	Potential major landscape impacts from mining. Large particulate and other emissions, including radioactive; damages through mining, may be difficult to avoid	Highest specific emissions without CCS; with biomass co-gasification CCS enables CO_2-free power; and can even have negative emissions	With high oil prices low C electricity can be provided at costs that are much lower than for power-only plants with CCS via coal/biomass co-production with CCS systems that simultaneously offer low C fuels at lower costs than biofuels.	Risk of coal mine accidents, although not large mortalities; for CCS: risk of leakage	If the primary future role of coal is shifted from the present focus on generating electricity to co-production of liquid fuels and electricity with CCS from coal + biomass, there would be significant new industries associated with making these liquid fuels that would replace oil imports
Natural gas	Provides access to more energy services if available locally	Might reduce reliance on other imported energy if available locally; more equally distributed than oil	Little or no impact due to relatively perfect combustion	Lower emissions than other fossil fuels	High GHG emissions prices needed to induce CCS for power-only systems, a challenge that can be greatly mitigated if instead electricity and synfuels are co-produced with CCS; CH_4 emissions can be controlled	Can provide low-cost energy needs for economic development in regions where available; cleaner with CCS, the added cost of CCS can be mitigated in a world of high oil prices by making synthetic fuels + electricity instead of just electricity	Risks of gas leaks from storage and pipelines and exposures	Low labor intensity of extraction and use
Nuclear	Can provide the energy for access in countries with insufficient local energy sources	More ubiquitously available/importable than many other sources. Major security risks from facilitating nuclear-weapon proliferation	Large health benefits in comparison with fossil and traditional biomass energy	Occasional radioactive releases from whole fuel cycle; radioactive waste challenges	Much lower emissions of CO_2 than fossil-fueled power plants on a life-cycle basis	Can provide the energy for development in regions where insufficient local resources are available; though at what cost depends on many factors	Risk of large releases of radioactivity; risks from facilitating nuclear-weapon proliferation	Low employment intensity; centralized employment

Sustainable Energy Options	Access	Energy Security	Health	Environment	Climate Change (mitigation and adaptation)	Development and Economic benefits, poverty alleviation	Risks of large accidents	Employment (local)
Renewables								
Solar (CSP and PV)	PV: Provides interim power source until full access to grid is provided; Thermal: provides some hot water. Can be self-made	Security gains through reduced energy and fuel import needs	Improved health due to lower emissions and pollution	Reduced emissions from fossil fuels and resources depletion; lifecycle environmental impact for PV	Limited life-cycle GHG	Most distributed energy source: can provide the energy right where needed; High cost of solar electric technology, but no fuel expenditures once equipment is installed; low cost (potentially self-made) for solar thermal; new industrial opportunities	Risk reductions through avoided conventional risky generation	More employment intensive than large-scale power generation, but many related jobs can be 'exported'
Wind	Better access to electricity through local/regional power generation	Security gains through reduced energy import needs	Improved health due to lower emissions, pollution	Reduced emissions from fossil fuels, but noise and visual impacts; some ecological impacts	Limited life-cycle GHG emissions	Most competitive RES-E technology and thus can provide affordable power; new industrial opportunities; eliminated fuel costs: no fuel import costs eliminate price volatility	Risk reductions through avoided conventional risky generation	More employment intensive than large-scale power generation, but many related jobs can be 'exported'
Hydro	Better access to electricity through local power generation (e.g., small hydro)	Security gains through reduced energy import needs	Improved health due to lower emissions, pollution	Reduced emissions from fossil fuels, but large hydro has serious environment and social liabilities	Limited life-cycle GHG emissions	Large hydro is the most ubiquitous large RES, can provide significant energy for development in many countries. Can be very affordable; can help in flood regulation; new recreational space creation	Risk of dam break and catastrophic flooding for large hydro	Can be employment intensive, part of jobs created are local
Biomass (with and without CCS)	If biomass is used primarily to make synthetic transportation fuels via gasification, LPG which can be used as a clean cooking fuel will be an inevitable byproduct, and much lower cooking fuel use rate via LPG compared to burning biomass implies that the LPG could go a long way in meeting cooking fuel needs even if providing transportation fuel is the main objective. This is discussed in Chapter 12	Security gains through reduced energy import needs; biomass can be ubiquitously available and easily imported, land use competition issues can be avoided with adequate zoning as done in Brazil	Traditional biomass burning can have very high indoor pollution and related health toll	Like any agricultural crop, needs to be sustainably produced to avoid deforestation and other major environmental impacts; risk of ecological damages through monocultures, which can be avoided with adequate environmental legislation such as fauna corridors and maintenance of local native forest.	Variable life-cycle GHG emissions; needs to be consciously minimized. *With CCS it can provide one of the few opportunities for negative GHG emissions*	Presently provides the most ubiquitous source of energy for the poorest, but with large impacts when not produced in a sustainable way; If sustainably produced, can fuel development in many regions, but potential competition with food production and thus impact on food prices	Risk reductions through avoided conventional risky generation	Very employment intensive if sustainably produced, most jobs created are local

benefits across multiple objectives. Some of these benefits can be so substantial for certain investments/measures that they may offer more attractive entry points into policymaking than climate or social targets. This is particularly the case where benefits are local rather than global. Seeking local benefits and receiving global benefits as a bonus is very attractive, and this is often the case for investments in energy efficiency and renewable sources of energy.

Therefore, even if some of these multiple benefits cannot be easily monetized, identifying and considering them explicitly may be important for decision making. Cost-effectiveness (or cost–benefit) analyses evaluating sustainable energy options may fare differently when several benefits are combined into one investment evaluation.

The enhancement of end-use efficiency in buildings, transport, and industry offers many examples of benefits across multiple social and economic objectives. Among the most important ones are: improved social welfare, including alleviated or eliminated poverty as a result of very high efficiency and thus very low fuel-cost buildings; reduced need for public funds spent on energy price subsidies or social relief for poor people; and health benefits through significantly reduced indoor and outdoor air pollution, often translating into commendable productivity gains. Productivity gains and general improvements in operational efficiency in industry translate into improved competitiveness. Improving efficiency by increasing the rate of building retrofits can be a source of employment generation. Other benefits that are non-quantifiable or difficult to account for include improved comfort and well-being, reduced congestion, new business opportunities, and improved and more durable capital stock.

Other economic benefits of rapidly decarbonizing the energy system are the reduced need for subsidies into carbon-intensive petroleum products and coal. At present, subsidies for these fuels amount to approximately US$132–240 billion per year[32] (Chapter 17). Only 15% of this total is spent directly toward poor people who have limited access to clean energy. As noted in Section TS-5.2.1, subsidies to poor people must be increased in order to achieve universal access. GHG mitigation in the GEA pathways would, however, at the same time reduce consumption of carbon-intensive fossil fuels by the rest of the population, leading to a reduction in the need for subsidies for oil products and coal in the order of US$70–130 billion per year by 2050 compared to today.

A review of the co-benefits related to the discussions in this assessment, that is, selected key routes through which the various sustainable energy options described earlier in this section and in Chapters 7–15 of the report contribute to different policy goals, is presented in Table TS-7. The purpose is to summarize the main routes of impacts through which the various options affect the multiple objectives set out in GEA, as well as to identify further benefits. However, whether an impact is a benefit or a liability depends on the baseline and local situation: for example, while liquid petroleum gas (LPG) has major environmental and climate impacts in itself, it still has major advantages in many areas when it replaces traditional biomass burning. Thus, a key novelty of Table TS-7 is that it provides a new, additional framework for a well-founded assessment for individual choices among various energy alternatives that complements the financial appraisals. For example, in jurisdictions where access to modern forms of energy is a major energy policy goal, evaluations in the 'energy security' column may play a key role in ranking the different options available at comparable costs. In other areas, access or employment may be key secondary objectives of energy policy and these may play the chief role in additional prioritization of options with comparable local costs. The evaluations Table TS-7 are qualitative and, due to the challenges of comparing very different types of effects, are indicative only.

Table TS-7 demonstrates that there is a very broad array of different benefits in a large spectrum of policy target areas, representing many potential entry points into policymaking. However, some options can have a wider range of co-benefits than others, such as improved efficiency, system solutions, and some renewables, such as biomass with CCS and fossil fuel/biomass co-processing with CCS. The lowest levels of co-benefits arise from nuclear power and fossil-fuel related options, even with CCS. There are less-marked differences among the options with regard to policy goals, such as energy security: most of the sustainability options discussed in this report have positive impacts on security. In contrast, others, such as poverty and access, are harder to contribute to: it is mainly renewable forms of energy that can significantly contribute to these goals. Improved efficiency, at the same time, has positive impacts on almost all policy goal areas and often has the broadest range and largest co-benefits.

3.5.3 Trade-offs and Constraints[33]

Changes in food and energy use will not only have substantial environmental impacts, they will also influence each other in many ways. At the same time, the production of food and energy and their dependence on water resources will be affected by global environmental change, including climate change.

Population growth and economic growth are major factors contributing to increased demand for land and water. In addition, growth in incomes is strongly correlated with increased consumption of animal-derived food (meat, milk, eggs). This combination will increase pressure on land and water resources if not counteracted by environmentally sound land- or water-saving innovations.

Sustainability issues arising from competition and synergies between the future production of bioenergy and food are highly important in this context, but they can be avoided with adequate policies, as discussed in

32 'Tax-inclusive' subsidies are higher at a little below US$500 billion.

33 Section TS-3.5.3 is based on Chapter 20.

Chapter 20. The global bioenergy potential from dedicated energy crops, considering sustainability constraints (such as maintenance of forests, areas with high biodiversity value, or protected areas) as well as food demand and feed demand of livestock, was estimated to be 44–133 EJ/yr in 2050. Substantially higher or lower levels could also be possible, as there are large uncertainties with respect to many important factors: land and water availability; feedbacks between food, livestock, and energy systems (in particular, future crop yields and feeding efficiency of livestock); and climate change.

Food prices are a concern, particularly in poorer areas of the world. They are influenced by many factors, including temperature and precipitation, pest attacks, and oil and fertilizer prices. There is a concern that major bioenergy crop expansion would become a significant factor, but there are studies, as mentioned in Chapter 20, that show different points of view. The potential indicated above takes such concerns into consideration. However, land allocation for different purposes will have to be monitored and managed carefully, as free competition between food, bioenergy, and other markets (e.g., fiber) could lead to swings in agricultural prices and supply. Adequate policies for introducing bioenergy plantations could avoid adverse social, economic, and ecological effects, while best-practice examples suggest that bioenergy plantations could be highly beneficial in terms of sustainability if based on sound strategies. Monitoring, managing, and enforcing adequate policies are required to ensure sustainability of bioenergy production. Adequate land and water-use environmental zoning and planning should be implemented to consider specific environmental conditions of each region.

Policies that support biofuels expansion should carefully evaluate the price and related food-security implications of scenarios relevant to the situation in each country. They should ensure sustainable production for any agricultural product and give priority to the diversification of technologies and fuels, while identifying different options for the future, based on adequate environmental zoning, and sustainable policies, as well as considering the overall impacts of each fuel. This must occur through public policies that govern and regulate markets and stimulate efficient technologies. These policies include biofuels sustainability based, for example, on certification schemes adequate for each country

The impact of climate change on land use systems is, at present, rather imperfectly understood. In subtropical and tropical regions, changes in climate and the rainfall regime may change the agricultural suitability of a region significantly. Temperature change may require the migration of some crops and agricultural areas to regions with a more temperate climate or higher levels of soil moisture and rainfall. In general, crop productivity in the tropics may decline even with a 1–2°C increase in local temperature. This would also have significant impacts on renewable energy resources, for example cloud cover, rainfall, and wind speed.

Multiple uses of water – for human consumption, hydro and thermal power generation, manufacturing, agriculture, water security, bioenergy, and so on – are feasible and associated with environmental, social, and strategic aspects, as well as with potential trade-offs. Competition between food and energy crops may not always be over 'the same water'. Depending on the type of feedstock, it is possible to cultivate adequate bioenergy crops in areas where conventional food production is not feasible due to, for example, water constraints – that is, the 'water footprints' are of a different character.

3.5.4 Rethinking Consumption[34]

The well-being of the 'final consumer' drives the production of goods and services and consequent energy service demand. Is a lifestyle that has high throughput of energy and materials globally sustainable in the long run? The literature on ecological footprints shows the unsustainability of ever-growing consumption in a growth path led by economic well-being. Studies offer the potential to get life-cycle approaches into a decision-making context and open up the possibility of a diversification of the policy portfolio.

The growing constraints on people's time as they pursue economic well-being have led people to buy appliances that save labor but use more energy. Walking, cycling, jogging, and natural green spaces are being taken over by energy-guzzling health clubs and the like, and by highly irrigated green spaces, while small traditional retail stores are being replaced by high energy using air-conditioned shopping malls. A convergence in the high level of energy service demands across various cultures, geographies, and income classes is the dominant trend.

Technology, income levels, and lifestyles are causing important changes in both direct and indirect energy requirements of households. While energy efficiency through technological improvement is helping, energy use and GDP growth have not really been decoupled in many countries. Lifestyle changes are essential to realize the full benefits of the technical potential.

In the short term, for incremental changes it is advantageous to consider consumers as shoppers and purchasers in a marketplace. By controlling information, education, and so on, what people buy can be influenced to achieve the desired outcome. In the medium term, an approach that relies on human well-being in terms of sustainable development, on Millennium Development Goal indicators, and on the triple bottom line (with more emphasis toward environmentalism) can have a moderate dampening effect on energy use.

In the longer term, an ecological footprint index and the criterion of 'sufficiency' provide promising policy options in individualistic liberal

34 Section TS-5.4.4 is based on Chapter 21.

societies for increasing sustainability in the energy system and motivating the adoption of a new value system. A human well-being indicator needs to evolve beyond GDP and the Human Development Index to reflect responsible individual and community behavior, sufficiency, happiness, and social ecosystem balance. Transformational change in the social fabric that places individual and community actions in the proper context has a role to play in reaching a low-energy path.

Despite health alerts and religious taboos, meat consumption has increased due to the aggressive marketing strategies of producers and distributors, creating an association between wealthy people's diet and meat consumption. There is a lack of awareness that a reduction in per capita meat consumption, especially in industrial countries, could reduce numerous health risks as well as global energy use and GHG emissions.

Education systems in modern societies can promote the virtues of going beyond classical humanistic contents of individual freedom and dignity and instead emphasize more collective aspects. The role of the state is to ensure adoption of a rights-based policy line that can make the duty to 'do no harm' a global right that matches the right to not be harmed. Governance that evolves organically can shape the course of action that involves the state and various communities such as non-government organizations, corporations, communities, civil society, and religious institutions.

Formal, informal, ethical, public, and mass media systems of education could generate social values that redefine modernism through more cultural diversity and local specificities instead of homogenization. Responsible individual and community behavior that justifies sufficiency in liberal societies needs broader and faster dissemination through investments in various institutions.

4 GEA Transformational pathways[35]

GEA explored 60 alternative pathways of energy transformations toward a sustainable future that simultaneously satisfy all its normative social and environmental goals of continued economic development, universal access to modern energy carriers, climate and environment protection, improved human health, and higher energy security (see Section TS-2.6).

The pathways were divided into three different groups, called GEA-Supply, GEA-Mix, and GEA-Efficiency, representing three alternative evolutions of the energy system toward sustainable futures. The pathways within each group portray multiple sensitivity analyses about the 'robustness' of the three different approaches in mastering the transformational changes needed to reach more sustainable futures. Of the 60 pathways explored, 41 clearly simultaneously fulfilled all the normative goals – indicating that such futures are reachable from a resource, technology, and economic point of view.

For such a transformation to be achieved, the pathways presume that political commitment, the availability of necessary financing (coming forward in response to the right market signals), and technological learning and diffusion occur pervasively throughout the world. Achieving the goals assumed in GEA generates significant benefits. Realizing these benefits requires governments to provide market conditions that ensure appropriate investments are mobilized (see Section TS-5). Thus, planning for a future energy system requires going beyond pure economic costs and needs to factor in salient environmental and social externalities. Thus, the 41 pathways jointly indicate the plausibility of transformative changes if the externalities and benefits related to the GEA sustainability goals are appropriately accounted for.

Together, these 41 transformational pathways integrate the conclusions of individual GEA chapters on major challenges and options into a consistent framework of scenario analysis. The analysis included a narrative that constituted the initial platform for the three alternative sets of quantitative pathways, which were developed by two different integrated assessment modeling frameworks (MESSAGE and IMAGE).

The energy transformations captured by the pathways encompass 11 world regions, grouped into five GEA regions. They also include various energy sectors, including supply and demand, with a full range of associated social, economic, environmental, and technological developments. They result in radically changed ways in which humanity uses energy, ranging from much more energy-efficient houses, mobility, products, and industrial processes to a different mix of energy supply – with a much larger proportion of renewable energy and advanced fossil fuel technologies.

The pathways indicate that the energy transformations need to be initiated without delay, gain momentum rapidly, and be sustained for decades. They will not occur on their own. In fact, the pathways imply a significant departure from recent trends. Serious policy commitments are therefore required. Furthermore, it would require the rapid introduction of policies and fundamental governance changes toward integrating global concerns, such as climate change, into local and national policy priorities, with an emphasis on energy options that contribute to addressing all these concerns simultaneously.

Although energy transformations in the pathways are fundamental and rapid, they are not historically unprecedented. In the past, energy systems have experienced similar, or even more profound, transformations – for example, when coal replaced biomass in the 19th century, or when electricity was introduced in the first half of the 20th century. More recently, a number of countries have rapidly shifted from coal to natural gas. Transformational changes closer to the consumer,

35 Section TS-4 is based on Chapter 17.

such as the replacement of horse carriages by automobiles, occurred within three decades in many parts of the world. The need for sustained transformation is, however, new and unprecedented on the global scale.

The GEA pathways are based on the assumption that the advanced technologies known today, often commercially unviable under current market conditions, would be improved through vigorous R&D and deployment to achieve cost reductions and better technical performance through economies of scale and through learning by using and by doing. Various combinations of resources, technologies, and policies are incorporated across the different pathways. While there is some flexibility in the choice of specific policy mechanisms, achieving all the GEA normative goals simultaneously is an extremely ambitious task.

For each of the three groups of pathways, one 'illustrative' case has been chosen that captures the salient characteristics of the group. The illustrative pathways are not necessarily the average or median of the set, but rather pathways that capture the overall characteristics of the respective group. They depict salient branching points for change and policy implementation. The characteristics differ significantly and depend on choices about technologies, infrastructures, behaviors, and lifestyles, as well as on future priorities on supply and demand-side policies. These choices have, in turn, widespread implications for technology availability and scale-up, institutional and capacity requirements, and financing needs.

The main distinguishing dimensions of the three illustrative GEA pathways are as follows:

- *Demand versus supply focus.* While the assessment shows that a combination of supply-side and demand-side measures is needed to transform the energy system, emphasis on either side is an important point of divergence, as exemplified by GEA-Supply compared to GEA-Efficiency. A critical factor is thus how much the changes in demand for energy services together with demand-side efficiency measures can reduce the amount of energy required to provide mobility, housing, and industrial services. This dimension is one of the main distinguishing characteristics and motivates the naming of the three illustrative pathways.

- *Global dominance of certain energy options versus regional and technological diversity.* Once technological change is initiated in a particular direction, it becomes increasingly difficult to alter its course. Whether the transformation of the future energy system follows a globally more uniform or diverse path thus has important implications, given irreversibility, 'lock-in', and the path dependency of the system. GEA-Efficiency and GEA-Supply pathways depict worlds with global dominance of certain demand and supply options, while GEA-Mix pathways are characterized by higher levels of regional diversity.

- *Incremental versus radical new solutions.* Given that the GEA sustainability objectives are ambitious, the transformational changes to realize them need to be introduced rapidly across all GEA pathways. For instance, all pathways feature decreasing shares of carbon-intensive supply options. The pathways differ, however, with respect to the emergence of new solutions. Some rely more heavily on today's advanced options (such as efficiency and renewables in GEA-Efficiency) and infrastructures (such as biofuels in GEA-Mix), while others depict futures with more radical developments (such as hydrogen or CCS in GEA-Supply).

The transformation can be achieved from different levels of energy demand as well as through alternative combinations of primary energy resources (see Box TS-1 and Figure TS-24).

4.1 Requirements for Achieving the Transformation

Despite the flexibility and choices available across the pathways regarding the direction and dynamics of the energy system transformations, also a large number of robust characteristics are common to all pathways. These commonalities are summarized below. They illustrate the magnitude of energy system changes that would need to be introduced to reach the GEA sustainability objectives.

Improvements to at least the historical rate of change in energy intensity are necessary to reduce the risk that the sustainability objectives become unreachable. Further improvements in energy intensity, entailing aggressive efforts to improve end-use efficiency, increase the flexibility of supply and improve the overall cost-effectiveness of the energy system transformation (see Box TS-2). 'Negawatts' provide more choices at lower costs than 'Megawatts'.[36]

A broad portfolio of supply-side options, focusing on low-carbon energy from renewables, bioenergy, nuclear power, and CCS, was explored, achieving at least a 60–80% share of zero-carbon options in primary energy by 2050. These include:

- Strong renewable energy growth beginning immediately and reaching between 165–650 EJ of primary energy by 2050. This corresponds to a global share of 30–75% of primary energy with some regions experiencing, in the high case, almost a complete shift toward renewables by 2050.

- Rising requirement for storage technologies and 'virtual' systems (e.g., smart grids and demand-side management) to support system integration of intermittent wind and solar.

36 Amory Lovins is well known for highlighting the need for achieving high energy efficiencies through "Negawatts rather than Megawatts".
Lovins, A.B., 1990: The Negawatt Revolution, *Across the Board*, **27**(9) 23–29. http://www.thewindway.us/pdf/E90–20_NegawattRevolution.pdf.

Box TS-1 | The three groups of GEA pathways

All GEA pathways share common socioeconomic assumptions, including demographic and economic developments. They differ radically in the structure of the future energy systems.

GEA-Efficiency pathways emphasize efficiency. The global pace of energy intensity improvements thus double compared to the long-term historical average. For example, this implies that in the buildings sector, efficiency would be improved by a factor of four by 2050. This would require measures and policies to achieve the rapid adoption of best-available technology throughout the energy system, for example, to, retrofit existing plants, enhance recycling, improve life-cycle product design in the industry sector; reduce energy demand through aggressive efficiency standards, including electrification, a shift to public transport, and reduction of demand for private mobility. Emphasis in GEA-Efficiency is thus on demand-side R&D and solutions to limit energy demand for services. This results in a primary energy demand level in 2050 of 700 EJ, compared to the level of 490 EJ in 2005.

GEA-Efficiency also relies on increasing renewable energy, approaching 75% of primary energy by 2050, and further increasing its contribution to about 90% by the end of the century. Figure TS-24 shows the illustrative efficiency pathway with various sensitivity analyses, indicating the changes by 2050. In some of the efficiency pathways nuclear power is assumed to be phased out over the lifetime of existing capacities, whereas CCS provides an optional bridge for the medium-term transition toward renewables. In the illustrative pathway, coal use declines immediately while the oil peak is reached before 2030. Unconventional oil resources thus remain largely untapped, given the GEA environmental objectives to reduce GHG and air pollutant emissions. Natural gas contribution remains at about current levels as it is the least carbon-intensive of all fossil sources. In contrast, the role of renewables increases across all pathways.

GEA-Supply features a major focus on the rapid up-scaling of all supply-side options. A more modest emphasis on efficiency leads to energy intensity improvement rates roughly comparable to historical experience. Primary energy demand in the illustrative Supply pathway reaches about 1050 EJ in 2050. Massive up-scaling of energy supply R&D and deployment investments lead to new infrastructures and fuels (such as hydrogen and electric vehicles in the transportation sector). Renewables contribute about half of primary energy by the middle of the century. The GEA-Supply pathways show similar levels of expansion for renewables as those in the GEA-Efficiency pathways. As a result of relatively higher levels of energy demand, the share of renewables is, however, comparatively smaller in the GEA-Supply pathways. Further implications of the relatively higher energy demand is that fossil CCS is becoming an essential building block in the medium term to decarbonize the remaining fossil share of the supply system. In the long term, the contribution of fossil CCS declines as the transition toward zero-carbon options progresses. New nuclear power plants gain significant market share after 2030 in some of the supply pathways. This presupposes that issues related to weapons proliferation, nuclear waste, and other inherent risks of nuclear energy are satisfactorily resolved. However, supply pathways also include nuclear phase-out cases that imply vigorous increases of alternative energy sources given the relatively high energy demand. This is possible; however, it was not possible to formulate a GEA-Supply pathway without the CCS technology, indicating that CCS is a must with such high levels of demand for fossil fuels (Figure TS-24). In principle, fossil fuels can either be used with CCS at high demand levels or the energy demand level can be reduced to meet GHG emission reduction goals, as in GEA-Efficiency.

GEA-Mix pathways are intermediate with respect to many scenario characteristics, such as efficiency focus and the up-scaling of advanced and cleaner supply-side technologies discussed in Section TS-4. The primary energy demand level reaches 920 EJ in 2050. The main emphasis is on diversity of energy supply and technology portfolios, thus enhancing system resilience against innovation failures or technology shocks. Furthermore, large differences in regional implementation strategies reflect local choices and resource endowments. This results in the co-evolution of multiple fuels, particularly in the transport sector, where, for example, second-generation bio-liquids, fossil/bio-liquids with CCS, and electricity gain importance in different regions.

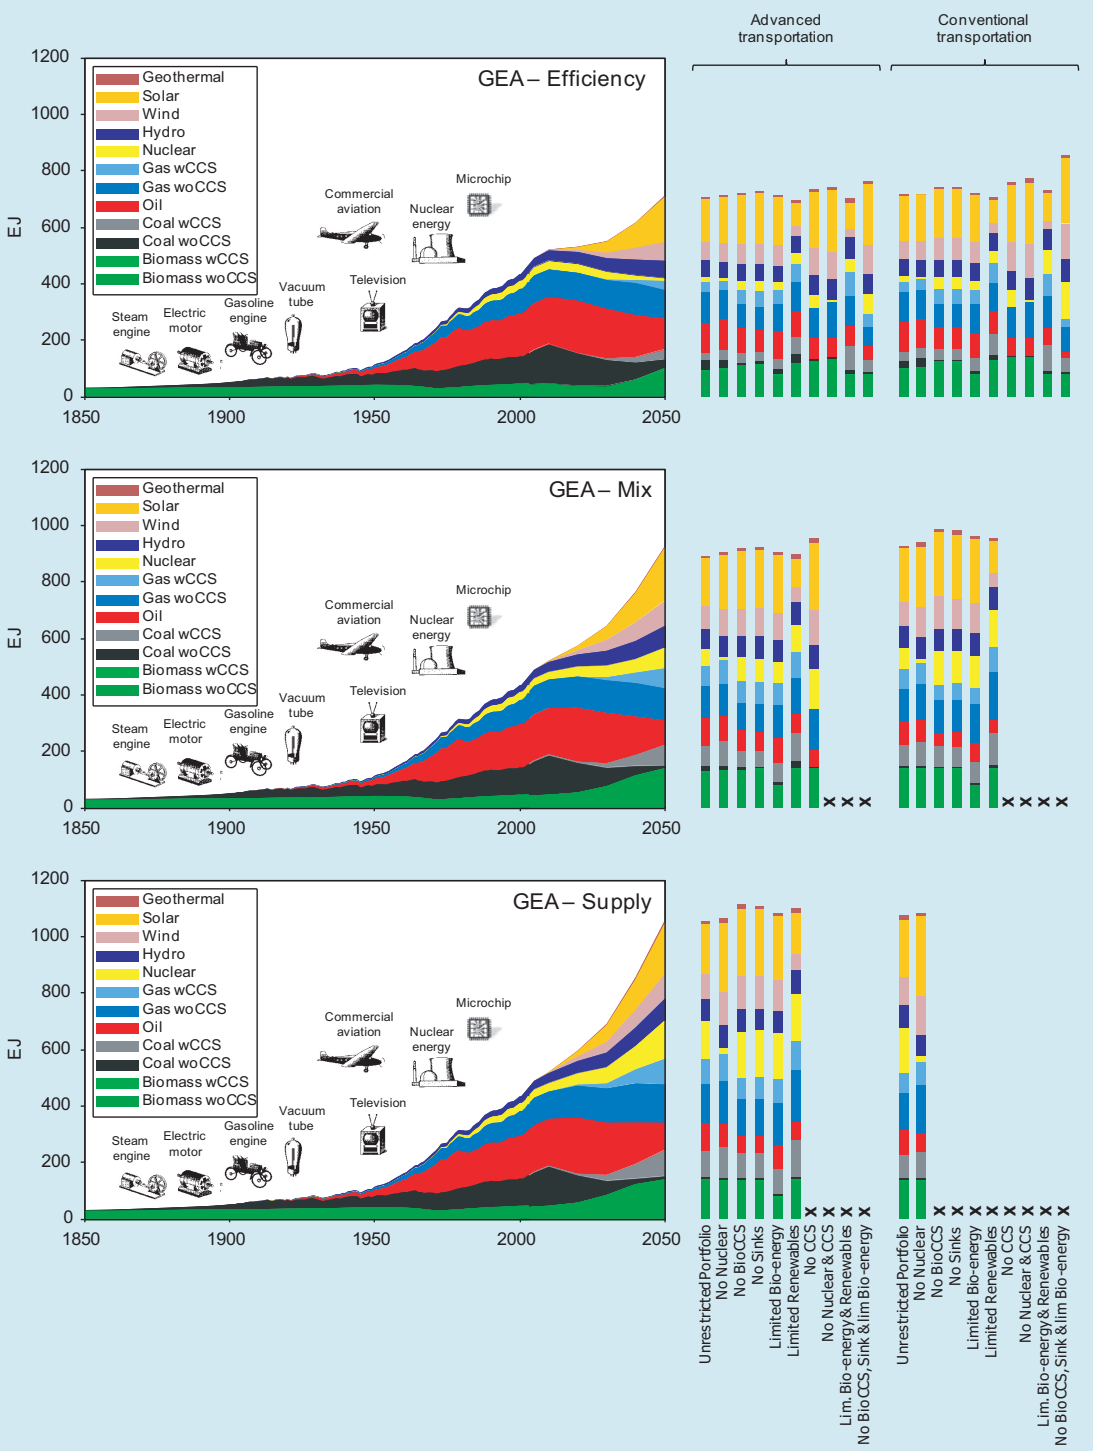

Figure TS-24 | Development of primary energy in the three sets of GEA pathways. Left-hand panels show the three illustrative GEA pathways, and right-hand bars give the 2050 primary energy mix of all 60 pathways explored. Conventional transportation refers to pathways that assume the continuation of a predominantly liquid-based transportation system, whereas advanced transportation refers to pathways that allow for fundamental changes in infrastructures – for example, high penetration of electric vehicles or other major breakthroughs in transportation technology such as hydrogen fuel cells. Pathways marked 'x' indicated the 19 cases where, under the specific combination of assumptions, the GEA normative goals could not be reached. For further details of the GEA pathways see the interactive web-based GEA scenario database hosted by IIASA: www.iiasa.ac.at/web-apps/ene/geadb.

- Strong bioenergy growth in the medium term from 45 EJ in 2005 to 80–140 EJ by 2050 (including extensive use of agricultural residues and second-generation bioenergy to mitigate adverse impacts on land use and food production).

- Nuclear power plays an important role in some of the pathways, while others assess the consequences of a nuclear phase-out. They illustrate that it is possible to meet the GEA normative goals even with a nuclear phase-out. The GEA-Efficiency pathways provide more flexibility in these cases. The range of nuclear in the GEA pathways is similar to the ranges found in other studies in the peer-reviewed scenario literature. In some GEA-Supply pathways, nuclear energy's contribution grows to 1850 GWe installed capacity, which is well above the IAEA's high projection of 1228 GWe. In the past, nuclear growth has been far below the IAEA's high projection – and, until 2000, even below the low projections. The nuclear contribution, however, is particularly uncertain across the pathways because of unresolved challenges surrounding its further deployment due to weapons proliferation risks and especially in the aftermath of Fukushima.

- Fossil CCS as an optional bridging or transitional technology in the medium term, unless there is high energy demand, in which case cumulative storage from CCS of up to 250 $GtCO_2$ by 2050 may be needed. In the pathways, it is a bridging technology that helps offset the gap between the need to vigorously decarbonize the energy system and the time needed to diffuse low-carbon options across the pathways. In the long term, CCS in conjunction with sustainable biomass is deployed in many pathways to achieve negative emissions and thus help achieve climate stabilization.

Vigorous decarbonization in the electricity sector leads to low-carbon shares in total generation of 75–100% by 2050, while coal power without CCS is phased out. Natural gas acts as a bridging or transitional technology in the short to medium term and provides 'virtual' storage for intermittent renewables.

The availability of energy resources by itself does not limit deployment on an aggregated global scale, but it may pose important constraints regionally, particularly in Asia, where energy demand is expected to grow rapidly.

Global energy systems investments need to increase to some US$1.7–2.2 trillion annually during the coming decades, with about US$300–550 billion of that being required for demand-side efficiency. This compares to about US$1 trillion supply-side investments and about $300 billion demand-side investments (energy components) per year currently. These investments correspond to about 2% of the world GDP in 2005, and would be about 2–3% by 2050, posing a major financing challenge. New policies would be needed to attract such capital flows to predominantly upfront investments with low long-term costs, but also low short-term rates of return.

4.2 Meeting Multiple Objectives

Universal access to electricity and cleaner cooking fuels requires the rapid shift from the use of traditional biomass to modern, cleaner, flexible energy carriers, and cleaner cooking appliances. This is achievable by 2030 provided that investments of US$36–41 billion per year are secured (half of which would be needed in Africa). About half of the investments would be required for a transition to modern fuels and stoves for cooking and the other half for electrifying rural populations.

Pollution control measures across all sectors need to be tightened beyond present and planned legislation so that the majority of the world population meets the WHO air-quality guideline (annual PM2.5 concentration <10 $\mu g/m^3$ by 2030), while the remaining population stays well within the WHO Tier I-III levels (15–35 $\mu g/m^3$ by 2030). This would lead to total annual air pollution control costs of about US$200–350 billion by 2030. The ancillary benefits of climate mitigation policies enacted in the pathways reduce the overall pollution control costs by about 50–65%.

Limiting global temperature increase to less than 2°C over pre-industrial levels (with a probability of >50%) is achieved in the pathways through rapid reductions of global CO_2 emissions from the energy sector, peaking around 2020 and declining thereafter to 30–70% below 2000 emissions levels by 2050, ultimately reaching almost zero or even 'net' negative CO_2 emissions in the second half of the century.

Enhanced energy security across world regions is achieved in the pathways by limiting dependence on imported energy and by increasing the diversity and resilience of energy systems. A focus on energy efficiency improvement and renewable deployment across pathways increases the share of domestic (national or regional) supply by a factor of two and thus significantly decreases import dependency. At the same time, the share of oil in global energy trade is reduced from the present 75% to below 40% and no other fuel assumes a similarly dominant position in the future.

5 Policy Tools and Areas of Action[37]

The previous sections describe the need for transformative change in the energy system (Section TS-2.6) and the different combinations of supply side and end-use technologies that could enable this need to be met in a timely and adequate fashion (Section TS-4). As noted in Section TS-4, a number of such different combinations meet the normative goals of access, security, climate protection, and health. These combinations are very different in terms of the magnitude and

37 Section TS-5 is based on Chapter 22–25 and specific policy discussions in Chapters 8–10 and 11–15, and 17.

Box TS-2 | Flexibility of Supply

The pathways explore a wide range of future energy transformations that are consistent with the GEA sustainability goals. Some of them explore future developments in which selected supply-side options were either limited or excluded completely. These pathways focus on overall questions of the 'feasibility' of such limitations and their economic and resource implications. In sum, 60 pathways were explored and 41 were found to be compatible with the GEA sustainability goals. They constitute a wide portfolio of sensitivity analyses regarding the nature and direction of future energy transformations.

The main conclusion from the GEA pathways analysis is that energy efficiency improvements are the single most important option to increase the flexibility of supply and the structure of the regional and sectoral energy systems. With high rates of efficiency improvements in GEA-Efficiency, it was possible to achieve the GEA normative goals under any of the assumed portfolio restrictions. Only in the GEA-Efficiency pathways was it possible to do so in the absence of both nuclear energy and CCS.

GEA-Supply, with high energy demands, requires the rapid and simultaneous growth of many advanced technologies, resulting in reduced flexibility on the supply side. Some more critical options are needed in all GEA-Supply pathways, such as bioenergy, non-combustible renewables (i.e., hydropower, intermittent renewables, and geothermal), and CCS. Excluding, or limiting, these options renders the high demand pathways infeasible. Nevertheless, the high demand pathways explore feasible energy transformations with limitations of some options, such as nuclear energy, as shown in Figure TS-25.

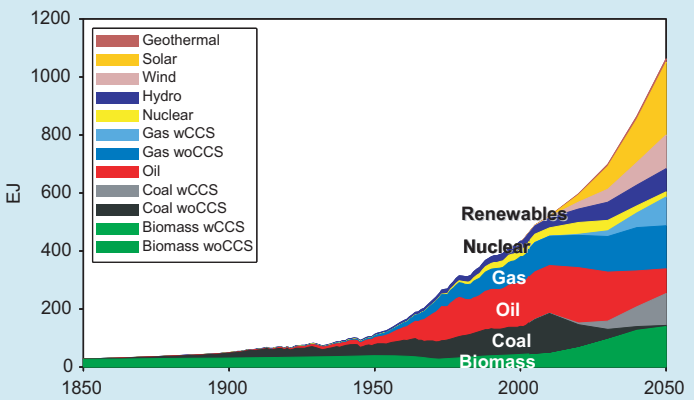

Figure TS-25 | Development of primary energy in the GEA-Supply pathway with a nuclear phase-out shortly after 2050. Source: Chapter 17 and the GEA online database.

The transportation sector configuration has profound implications for supply-side flexibility. In the case of rapid penetration of advanced transportation technologies (electricity or hydrogen), the GEA-Supply group of pathways was found to still be feasible if any one of BioCCS, carbon sink enhancement, nuclear energy, the full bioenergy supply, or large-scale renewable energy deployment are excluded as options in the future. In the case of restricted penetration of advanced transportation technologies, essentially the full set of supply-side options is needed to keep the GEA sustainability targets within reach (in GEA-Supply).

orientation of investments required. They would therefore require, at least in part, different policy packages and institutional arrangements for implementation.

The design and formulation of such policy packages needs to reflect the diversity and heterogeneity of national circumstances, the need to consider issues of sociopolitical feasibility and acceptability, and the need to adequately address implementation challenges, including institutional design.

This section describes the possible approaches, basic elements, and policy tools and instruments that may be utilized. Effective policy portfolios will require a combination of instruments, including regulatory and investment policies, as well as measures for strengthening capacity, stimulating innovation, and guiding behavior and lifestyle changes. Moreover, the energy goals cannot be pursued in isolation. Energy-focused policies must be coordinated and integrated with non-energy policies for socioeconomic development and environmental protection. These latter include, for example, policies that foster sustainable urban areas, preserve forested land and biodiversity, reduce poverty and inequality within and between countries, provide efficient and environmentally acceptable transportation, ensure vibrant rural areas, and improve human health.

The remainder of this section is organized as follows. Section TS-5.1 describes the main elements of, and areas for, policy intervention. We then consider two of the key challenges at the nexus of energy and development – those of universal access and of urbanization. Policies to address these challenges are discussed. Rapid improvement in energy efficiency, scaled up and accelerated development of renewables, and the modernization of fossil fuel systems (such as described in Section TS-3.3.2) form the key building blocks of all of the pathways meeting the sustainable goals. Policies to address these building blocks are discussed in Section TS-5.3. Section TS-5.4 examines the major areas of policy intervention – innovation, finance, and capacity building.

5.1 Framework for Policies and Policy Design[38]

If ***universal energy access*** is to be achieved by 2030, then energy policies must work in concert with economic development policies by harnessing the collective investment potential of markets, international organizations, central governments, regional governments, cooperatives, and local organizations. The global community must increase its support, including providing financial assistance for major clean-energy infrastructure, and leverage this where possible with private funds by creating a sound climate for sustainable energy-related investments. Bilateral cooperation and the role of Development Banks are key in supporting the necessary investments needed to achieve universal access.

Energy security can be enhanced by combined technically and strategically oriented policies, which various regions and countries will emphasize differently. The technical policies include steps that lead to timely energy network upgrades, greater interconnection and backup agreements between neighboring energy network operators, grid tariffs that induce short-term demand reductions in response to constrained market conditions, and long-term supply procurement strategies that foster local supplies and a diversity of external supplies. Strategically oriented policies would include international cooperation and agreements to reduce the risk of supply disruptions, such as coordination to protect international energy supply routes and to stockpile critical energy resources for release during acute market shortages.

Market power is a concern in much of the energy sector. Governments must recognize that policies to promote electricity competition must also prevent the short-term exercise of market power that results in unjustified excessive profits for some producers and speculators as well as price volatility for consumers. This will involve continued regulation and public involvement in energy system planning and long-term contracting to ensure operation of the system in a socially desirable manner.

The effective and transparent ***management of valuable resources*** is important in the energy sector. Oil and gas especially are valuable resource endowments that can provide great wealth if their exploitation is properly managed. Policies should maximize the collection of resource rents (via royalties, taxes, and, where applicable, national oil companies) for present and future generations, and should control the rate of exploitation to minimize inflationary harm to otherwise sustainable economic sectors. Depending on a country's current level of well-being, part of the resource rents should be streamed into sovereign wealth funds that are invested domestically to, among other goals, offset the negative impacts of resource exploitation at home, as well as abroad, in a balanced effort to maximize the benefits for future generations.

38 Section TS-5.1 is based on Chapter 22.

A multiplicity of policies is required to address the potential impacts of the energy system on ***human health and the environment***. A mix of regulations, information programs, and subsidies are needed, for example, to stimulate the rapid adoption of household energy-using devices that have virtually zero indoor emissions. Subsidies should be applied to equipment such as zero-emission stoves and efficient light bulbs to replace the indoor combustion of kerosene and other fuels for lighting and cooking.

Ambient air quality requires regulations on emissions from fuel combustion in buildings, industry, vehicles, power plants, and other sources. Some regulations may be highly prescriptive – specifying combustion technologies such as the use of catalytic converters, for instance, or restricting certain fuels – while others may focus on the absorptive capacity of a given air shed for a particular pollutant. The latter case could involve the establishment of air shed emission limits, perhaps using a cap-and-trade system. Similarly, regional air quality must be protected by technology and/or emissions regulations or by direct emissions pricing.

Extractive activities and the various uses of land and water – coal mines, oil and gas fields, hydropower dams, reservoirs, nuclear plants, storage sites for radioactive wastes and captured CO_2, wind farms, solar electricity farms – should all face a ***regulatory framework*** that assesses their benefits against a precautionary consideration of their impacts and risks, but that also ensures a streamlined regulatory process for more favorable projects.

Policies to foster ***energy from biomass*** should seek to minimize the trade-offs between biomass for food and biomass for fuel by encouraging the use of biomass residues and only the most sustainable and productive feedstocks and efficient conversion processes. Subsidies to corn-based ethanol could be replaced, for example, by emissions charges or by regulations requiring sustainability standards and minimum biofuel content in gasoline or diesel, motivating competitive markets to find the most efficient processes for producing biofuels. Many developing countries import all or most of their current liquid fuels at increasingly higher costs, and have, at the same time, large areas that are off-grid. One very successful example is that of *Jatropha* intercropped with food crops in an off-grid small town in Mali – which uses the jatropha oil to product electricity for a local grid.

GHG pricing policies will be key in shifting energy systems toward low-carbon emission technologies, fuels, and activities. While there is disagreement on which pricing method is best – carbon taxes or cap-and-trade – the two approaches can be designed so that their effects are quite similar. The price certainty of a carbon tax can be approximated with cap-and-trade by setting a price floor and a ceiling for permit prices. The revenues generated by a carbon tax can also be achieved by auctioning permits in cap-and-trade. Cap-and-trade will be difficult to apply at a global level, but the process could start with a subset of countries (as Europe and some countries and subregions of countries have done) and eventually link systems by various mechanisms. Or there could be parallel systems of cap-and-trade in some jurisdictions

with carbon taxes in others. In the final analysis, environmental sustainability will need to be achieved at the lowest cost, and in an equitable manner.

In addition to GHG emissions pricing, other policies will be needed to develop, and then support, ***new technologies*** through the various stages from laboratory research to prototype demonstrations to wide-scale commercialization. These include R&D support, subsidies for large-scale technology demonstrations, and, for emerging favorites, market sales requirements or guarantees. Such policies will apply to initiatives such as CCS, new nuclear power technologies, renewable energy innovations, highly efficient energy-using devices, energy storage devices, grid management systems, and zero-emission vehicles and other transportation technologies.

It is important to complement GHG pricing with a portfolio of other regulatory and market mechanisms. This is because different instruments are most effective in different sectors, geographic/cultural regions, and for different options. For example, owing to the magnitude and diversity of market barriers prevailing in the building sector, different regulatory and market-based instruments and their packages are needed and tailored to overcome the specific barriers.

As a new technological pathway, CCS requires additional targeted policies to clarify pore space, property rights, storage site risk assessment, short- and long-term liabilities at storage sites, and measurement and crediting protocols to ensure that such projects are valued as emission reductions in GHG regulatory frameworks. Some CCS demonstrations should target low-cost CO_2 sources (existing or new coal-chemicals or coal-fuels plants) and enhanced oil recovery for CO_2 storage.

In cities, regulatory policies such as land use zoning, building codes, development permitting, and local emission standards must drive the shift toward low- and near-zero emission buildings, in some cases in concert with low- and near-zero emission decentralized energy supply. In addition to buildings, new urban developments should be required – with greater stringency in industrial countries initially – to be low- or near-zero emission (of local air pollutants and GHG emissions) through the local supply of renewable energy sources, where feasible, and through the import of energy from near-zero emission external sources. These requirements, which in part apply to rural areas as well, should also be gradually phased in to the retrofit of existing buildings and the redevelopment of existing urban areas.

Policy integration is especially important for unlocking energy-saving potentials due to the many barriers as well as multiple benefits. Strategic alliances and strong coordination among various policy fields will be able to capture a much larger share of technological potential by improving the economics of efficiency investments through the addition of further benefits to the cost-efficiency considerations, such as security, employment, social welfare, regional development, reduced congestion, and so on.

5.2 Policies for Meeting Energy-development Challenges

The importance of energy for achieving development goals is outlined above. Two challenges are of particular importance –providing universal access to modern forms of energy, and addressing urbanization and the provision of urban energy services.

5.2.1 Energy Access[39]

Access to affordable modern energy carriers and cleaner cooking improves well-being and enables people to alleviate poverty and expand their local economies. Even among people who have physical access to electricity and modern fuels, a lack of affordability and unreliable supplies limit their ability to use these resources. In addition to access to modern forms of energy, there must be access to end-use devices that provide the desired energy services. Those who can afford the improved energy carriers may still not be able to afford the upfront costs of connections or the conversion technology or equipment that makes that energy useful.

The lack of access to modern forms of energy is due to a number of factors. They include low income levels, unequal income distribution, inequitable distribution of modern forms of energy, a lack of financial resources to build the necessary infrastructure, weak institutional and legal frameworks, and a lack of political commitment to scaling-up access. Public policies should develop the strategies, and create the conditions, to overcome the mentioned barriers.

While the scale of the challenge is tremendous, access to energy for all, electricity for all, and modern fuels or stoves for all by 2030 is achievable. This will require global investments of US$36–41 billion annually – a small fraction of the total energy infrastructural investments required by 2030. It is expected that as households with public-sector support gain access to modern energy and end-use devices and start earning incomes, the standard of living and ability to pay for the energy services utilized would successively expand.

Access to Electricity

Between 1990 and 2008 almost two billion people gained access to electricity, more than the corresponding population increase of 1.4 billion people over that period (see also Figure TS-26). By 2030, the 1.4 billion people currently without access to electricity, plus the projected population increase to 2030 of 1.5 billion people, need to be connected to meet the GEA goal on universal electricity access. To achieve this, a multitrack approach is needed, combining grid extension with microgrids and household systems.

39 Section TS-5.2.1 is based on Chapters 2, 17, 19, and 23.

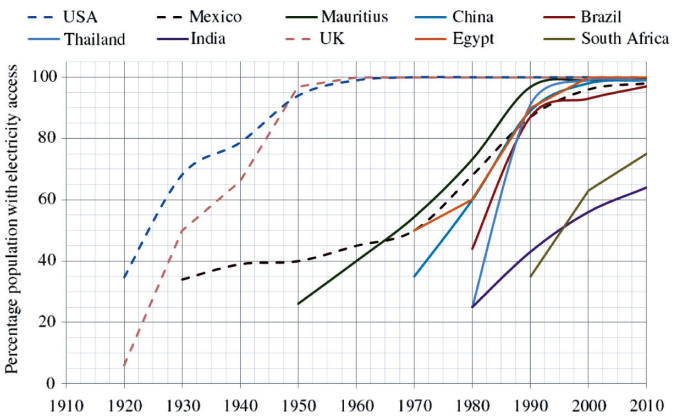

Figure TS-26 | Historical experience with household electrification in select countries. Source: Chapter 19.

Access to electricity can be arranged in several ways. In areas with high energy density, grid extension is currently the lowest cost per kWh delivered and also the preferred delivery form by most customers because of the capacity to deliver larger quantities of power for productive purposes. For many remote populations grid extension by 2030 will be highly unlikely and microgrids offer an alternative, based on local renewable energies or imported fossil fuels. An interesting approach to providing modern energy and development in remote villages is the multifunctional platform beginning to gain hold in West Africa (see Chapter 25). Household electrification is expanding rapidly in some countries, based on solar PVs that are financed by micro-credits and this has been done without increasing household expenses for energy (replacing candles and kerosene).

Experience shows that grid extension on commercial grounds is ineffective. Initial loads are small and provide insufficient income for the utilities. Privatizations of utilities have amplified this situation. The use of life-line rates or a free allocation of a small quantity of electricity per month per household has proven effective in starting a development process.

Grants should support equipment that uses energy more efficiently and more cleanly rather than subsidizing the energy used – except in the case of lifeline rates for the lowest-income customers, which can be achieved in part through cross-subsidies from other customers. Grants for high-voltage grid extensions and decentralized microgrids should involve competitive bidding to ensure the most cost-effective use of funds. Policies should support local participation in developing and managing energy systems, as this approach has been shown to have the best chance of providing a stable environment for new investment and reinvestment in increased energy access.

Cleaner cooking

About three billion people rely entirely, or to a large degree, on traditional biomass or coal for cooking and heating. This number has not changed appreciably over the last decades, particularly among households in rural areas. Indeed, more people rely on these fuels today than at any time in human history.

Access to cleaner cooking refers to liquid or gaseous fuels, especially biogas, LPG, ethanol, and others, or alternatively access to advanced biomass stoves with pollutants emissions similar to those of gas stoves. In many regions, current inefficient use of biomass fuels requires women and children to spend many hours per week collecting and carrying traditional biomass that is burnt in highly inefficient and polluting stoves. The resulting household air pollution leads to significant ill health (see Section TS-2.5).

Achieving universal access to modern energy is not likely to have negative implications for climate change. This is because transitioning to modern fuels (even in the case that these are fossil based) will displace large quantities of traditional biomass use. Current technologies that use traditional biomass are 4–5 times less efficient than cooking with modern fuels like LPG, and are associated with significant emissions of non-CO_2 Kyoto gases (e.g., CH_4, N_2O) and aerosols (e.g., black carbon, organic carbon) due to incomplete combustion.

Unlike the new biomass stoves, there is no feasible technology for burning coal cleanly at the household level. Attempts to provide 'clean coals' for household use attempted around the world over the last several decades had little success. Chimneys do not protect people sufficiently as they simply move the pollution from one place to another in the household environment. Country after country, therefore, has found that the only way to provide clean residential environments is to shift to other fuels. Only a few countries today, notably China, have significant household use of coal, which is a source of much ill-health, inefficient energy use, and high-climate impact per unit energy service delivered.

The observation that introducing cleaner cooking brings multiple benefits in terms of development (Section TS-2.2), situation of women, improved health from reduced exposure to household air pollution (Section TS-2.5), and reduced contributions to climate change (Section TS-2.4) should be very attractive for developing countries as well as for development cooperation organizations.

Policies for improving energy access in general

Providing universal and affordable access to electricity and cleaner cooking is possible if timely and adequate policies are put in place. Overall, and on the basis of successful experiences of increasing access to modern energy, no single approach can be recommended above others. What is clear, however, is that the current institutional arrangements and policies have met with mixed success, at best. Reforms are needed, on global and country levels, to strengthen the feasibility of energy projects for poor people, expand the range of players involved, open up the regulatory system, and allow for innovation.

Several examples demonstrate that the major features behind the success of programs include: political priority and government commitment; continued support and strengthening of programs through various administrations; effective mechanisms for targeting the available subsidies exclusively to poor families in need, thus ensuring highly efficient public expenditure; and integration of the energy-access program into governments' broader policies of social support for poverty alleviation.

Success depends on regional, national, and local circumstances. In some instances, a decentralized and participatory decision-making process and a holistic development approach is very important. This goes together with a strong community-mobilization process that focuses on organizational development, skills enhancement, capital formation, promotion of technology, environmental management, and empowerment of vulnerable communities.

Significant success has been achieved with small pilot projects to improve access in some rural areas and among poor communities in urban areas. But less thought has been focused on how to scale-up from these projects to market development and to meet the needs of the larger population.

A paradigm shift is needed in the approach to energy planning and policy implementation to facilitate access to modern forms of energy and cleaner cooking. Current supply-side approaches that simply take as their starting point the provision of electricity, petroleum, or gas, or of equipment of a particular type (solar technology, improved cookstoves, biogas, and other forms of bioenergy) are unable to reap the full potential of social and economic improvements that follow from improved energy access and cleaner cooking.

Several countries, including India, China, Argentina, Chile, Vietnam, Laos, and Brazil, have demonstrated that if effective political decisions are taken, the results are positive. This is not yet the situation in much of sub-Saharan Africa. Challenges and economic, sociocultural, and political barriers require more elaborate strategies and a higher global commitment to satisfy the GEA scenario objectives. Universal access in 20 years is not going to be available in Africa with micro actions and isolated measures unless they are integrated in long-term national programs with clear targets, dedicated and guaranteed funds, an adequate institutional framework, and robust strategies.

Policy recommendations in the form of general ideas or guidelines are provided below. Regional and national contexts should be considered in defining strategies, instruments, and measures.

- A better understanding and a clearer diagnosis of the structure and functioning of energy systems, along with the needs (energy services) to be supplied, are needed. These have often been absent in the discussion of proposals and the role of public policies. Good policies need good diagnoses. Support and funds for diagnosis and information should be part of the strategies.

- Subsidies are generally justified as a response to inequality and social expectations in energy provision. However, their net effect can be positive or negative depending on the intended goals of the subsidy, and the way a subsidy is implemented. An effective tariff and subsidy regime has to be transparent and minimize administrative costs to avoid gaming of the system and to maximize the benefits that accrue to the intended recipients. Subsidies to energy should be complemented with funds toward solving the first-cost capital financing problem, since upfront costs of equipment are, usually, the key barrier.

- Financing mechanisms are needed for every scale of energy intervention. Mobilizing affordable and genuine international, regional, national, and local funds is crucial.

- Energy-access policy is part of a wider development policy and should be aligned with other sector policies and objectives. If these policies are misaligned, they can reduce the effectiveness of any given policy. Policy misalignments can occur when different energy policies work at cross-purposes or when government priorities that could benefit from an effective energy policy are not aligned. In particular, there is a need to link rural and peri-urban energy supply more closely with rural development. This would shift the focus from minimal household supply to a more comprehensive approach to energy that includes productive activities and other welfare-enhancing uses of energy. Ideally, the linkages between energy and other policy priorities, such as health, education, and poverty alleviation, should be recognized explicitly and local solutions that address these needs should be encouraged and supported.

- Capacity development is needed, especially for the design and implementation of public policies oriented to poor people.

In the specific case of access to cleaner cooking, fuel subsidies alone will be neither sufficient nor cost-effective in terms of achieving ambitious energy-access objectives. Financial mechanisms, such as micro-credit, will need to complement subsidies to make critical end-use devices such as cleaner cookstoves affordable for poor people.

Leveraging funding and access to capital from public and private sources – for needed investments at the macro level and, at the micro level, for meeting costs for low-income households – is crucial in efforts to expand access to energy services for the poorest people. Figure TS-27 shows the estimated impacts of policy scenarios for cleaner cooking. It is only with the combined attention to fuel costs and equipment purchases that universal access is approached. Creative financing mechanisms and transparent cost and price structures will be critical to achieving the required scale-up and quick roll-out of solutions to improve access.

No single solution fits all in improving access to energy among rural and poor households. Programs need to be aware of local needs, resources, and existing institutional arrangements and capabilities. Diverse sources

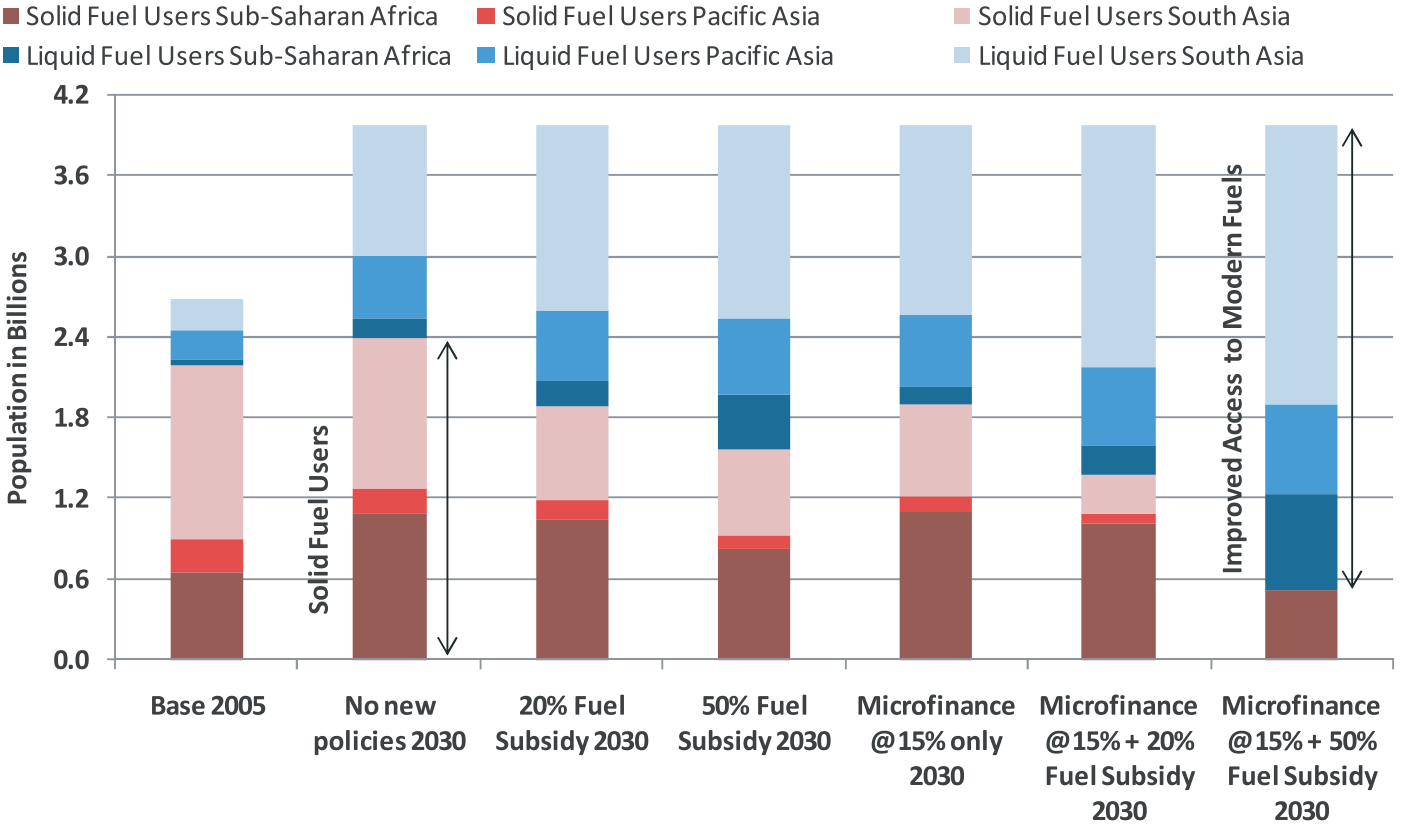

Figure TS-27 | Impact of alternative policy scenarios on access to cleaner cooking fuels in three developing regions. Subsidies are relative to consumer price levels and are additional to existing subsidies. Source: Chapter 17.

of energy supply (fossil and renewable), a wide portfolio of technologies, and a variety of institutional and innovative business models adapted to local circumstances are required to meet the challenge. An enabling environment shaped by sustained government commitment and enhanced capacity building at all levels is essential to ensure that access targets are met. Complementary development programs and enhancement of market infrastructure are needed to ensure sustained economic growth as well as steady employment and income generation for poor people to provide them with a means to pay for improved energy carriers.

As discussed in Chapter 12, establishing synthetic liquid transportation fuels in the market via gasification offers an innovative approach to expanding production of, and making more affordable access to, LPG, an inherent co-product of synthetic liquid transportation fuel manufacture. Such systems that co-produce electricity with CCS involving coal or the co-processing of coal and a modest amount of biomass (which could be deployed in this decade) would make available LPG with a significantly lower carbon footprint than LPG derived from petroleum sources, and with attractive system economics in a world with high oil prices.

Moreover, at GHG emissions prices that might be typical in the post-2030 period, small-scale systems making liquid transportation fuels from biomass with CCS would be able to provide substantial quantities of byproduct LPG for cooking at competitive costs in biomass-rich but regions lacking fossil fuels. Chapter 12 sketches out a plausible business model for making this domestically produced LPG affordable without subsidy, even for the very poorest households in such regions. Near-term actions to facilitate exploitation of this future opportunity include assessments of CO_2 storage capacity in such regions, building the human and physical infrastructure capacities needed to support these new industrial activities, establishing carbon trading systems that would facilitate realization of the attractive economics for these bioenergy with CCS systems, and testing alternative business models for providing the LPG to poor households without subsidy.

5.2.2 Urbanization[40]

Currently, about half the world population lives in urban areas, which also account for an overly large share of global economic output and energy use (an estimated 60–80% of the global total). Projections invariably suggest that almost all future population growth of some three billion people by 2050 would be absorbed by urban areas, which would also account for a majority of economic and energy demand growth. By 2050 the global urban population is expected to approach 6.4 billion people – about the size of the entire global population in 2005. In contrast, the global rural population would plateau around 2020 at 3.5 billion people and decline thereafter.

40 Section TS-5.2.2 is based on Chapter 18.

Most urban growth would continue to occur in small- to medium-size urban centers (between 100,000 and one million inhabitants) in the developing world, which poses serious policy challenges. In these smaller-scale cities, data and information to guide policy are largely absent, local resources to tackle development challenges are limited, and governance and institutional capacities are weak. Housing, infrastructure, energy and transport services, and a better urban environment (especially urban air quality) are the key sustainability challenges for urban poverty alleviation.

Several hundred million urban dwellers in low- and middle-income nations lack access to electricity and are unable to afford cleaner, safer fuels, such as gas or LPG. In addition to poverty and poor urban energy infrastructures, poor people face political or institutional obstacles to obtaining cleaner energy carriers.

Given capital constraints, daring new architectural and engineering designs of 'eco' or 'zero-carbon' cities can serve as inspirational goals and as field experiments, but they are unlikely to play any significant role in integrating some three billion additional urban dwellers by 2050 into the physical, economic, and social fabric of cities. (Building 'zero-carbon' cities for three billion new urban citizens along the Masdar model in Abu Dhabi would require some US$1000 trillion, or some 20 years of current world GDP.)

Cities in OECD countries generally have lower per capita final energy use than their respective national averages. Conversely, cities in developing and emerging economies generally have substantially higher per capita energy use than the national average, primarily due to substantially higher income levels than those in rural areas.

Urban systems are, however, by definition inherently open systems: they are characterized by vast imports of resources and commodities and by vast exports of goods and services to their respective hinterlands and the rest of the world. 'Embodied' energy (and GHG emissions) is, as a rule, several fold larger than the direct energy uses in urban settings, at least for the handful of megacities for which data are available.

The overall design of cities and their components affect the energy use to a large degree. For buildings, energy use for thermal purposes can cost-effectively be reduced by 90% or more, as compared with current standard practice (see Figure TS-15, Section TS-3.2.3). Not incentivizing the adoption of available building-efficiency technologies and practices will lock cities into a much higher energy-use level than necessary. Figure TS-16 illustrates this for energy use in buildings. Next to buildings, urban density, form, and usage mix are also important determinants of urban energy use and efficiency, especially in transportation (see Figure TS-13). Avoiding spatial lock-in into urban sprawl and ensuing automobile dependence should, therefore, be another important urban policy objective.

Significant potential co-benefits between urban energy and environmental policies do exist. However, they require more holistic policy approaches that integrate urban land use, transport, building, and energy policies with the more-traditional air pollution policy frameworks.

Urban energy and sustainability policies could focus on where local decision making and funding also provides the largest leverage effects:

- urban form and density (which are important macro-determinants of urban structures, activity patterns, and hence energy use, particularly for urban transport);
- the quality of the built environment (energy-efficient buildings in particular);
- urban transport policy (in particular the promotion of energy-efficient and 'eco-friendly' public transport and non-motorized mobility options); and
- improvements in urban energy systems through cogeneration or waste-heat recycling schemes, where feasible.

Illustrative model simulations for a 'synthetic' city suggest improvement potentials of at least a factor of two each by buildings that are more energy-efficient and by a more compact urban form (at least medium density and mixed-use layouts), with energy system optimization through distributed generation and resulting cogeneration of electricity, heat, and air conditioning adding another 10–15% improvement in urban energy use (see Figure TS-28).

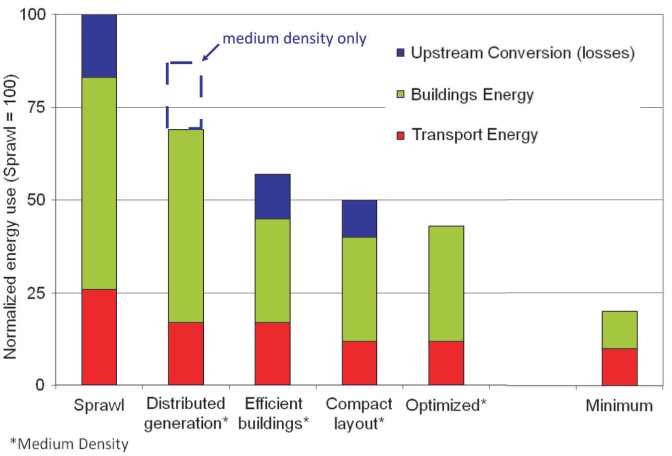

Figure TS-28 | Policy integration at the urban scale. Simulated energy use for an urban settlement of 20,000 inhabitants using the SimCity Model combining spatially explicit models of urban form, density, and energy infrastructures, with energy systems optimization. Individual policy options are first simulated individually and then combined in a total systems optimization. Baseline (index = 100) sprawl city corresponds to a secondary energy use of 144 GJ/capita; energy use is shown by major category: transport, buildings, and upstream energy conversion losses (which can be eliminated by local cogeneration of electricity and heat or by on-site energy systems). The potential for efficiency improvement of narrow energy sector-only policies (local renewables, cogeneration) at the urban scale is smaller than policies aiming at minimizing buildings energy use or at higher urban density and mixed uses, which minimize transport energy use. The largest improvement potentials can be realized by a combination of energy, building efficiency, and urban form and density policies. Source: Chapter 18.

There are important urban size and density thresholds that are useful guides for urban planning and policymaking. The literature review identified a robust density threshold of 50–150 inhabitants per gross hectare (5000–15,000 people per square kilometer) below which urban energy use, particularly for transport, increases substantially. Note that there is little empirical evidence to suggest substantial further energy efficiency gains at much higher densities. Energy-wise, there are pronounced diseconomies of scale of low urban densities (leading to lower efficiency and higher energy use), but no significant economy-of-scale effects beyond intermediary density levels.

5.3 Policies for Key Energy System Building Blocks

The GEA pathways describe the various combinations of transformations in energy systems required to meet the GEA's various goals and objectives simultaneously (see Section TS-4.) While they differ in terms of their relative proportions and the magnitudes of the various changes they involve, all of them include a dramatic increase in energy end-use efficiency, larger and more rapid deployment of renewables, decarbonization and modernization of fossil fuel systems, and the judicious use of nuclear energy. Policies to address the changes required in each of the building blocks are described below.

5.3.1 Energy Efficiency

Progress in accelerating the rate of energy efficiency improvement worldwide is critical to an energy system for sustainability. Quickly improving energy efficiency requires more focused and aggressive policies that: support rapid innovation; significantly tighten efficiency regulations in energy supply and demand; increase energy prices; create a culture of conservation among consumers and firms; change land use zoning to increase urban density; and integrate mixed land uses so that transportation needs decline and low-energy transportation modes flourish. In some cases, these policies will involve subsidies for new technologies, but these will not be effective unless they are combined with pricing of GHG emissions via taxes and/or cap-and-trade plus well-designed efficiency regulations.

Regulations, especially standards, are essential elements of energy policy portfolios of the transition. Building codes, appliance standards, fuel economy standards, and industrial energy management standards have proven to be very environmentally sound in improving efficiency and should be adopted globally. The combination of regulations, incentives (e.g., fiscal incentives), and measures to attract attention, (e.g., information, awareness, or public leadership programs) has the highest potential to increase energy efficiency. Policies encouraging the use of multi-generation and renewable energy in each end-use sector are important further components of energy policy portfolios.

The GEA analysis provides considerable evidence for the ability of such policy packages to deliver major change. However, the results from three decades of experience with energy efficiency policies in industrial countries also show other effects. For example, the adoption of energy efficiency devices has both a direct rebound effect (more-efficient fridges, with lower operating costs, encourage the adoption of larger fridges) and an indirect rebound effect (sometimes called a productivity rebound) that relates to the apparent causal link between energy efficiency breakthroughs and the development of new devices and new energy services (fridge efficiency improvements foster the development of new refrigeration devices, such as beer and wine coolers, water coolers, desk-top fridges and freezers, portable fridges, etc.). Evidence also shows that when estimating costs it is important to take into account all transaction costs and differences in technology risks and technology quality. Ideally, beyond transaction costs, all other indirect costs and benefits, including monetizable co-benefits, need to be integrated into cost-effectiveness assessments related to policy choices, as these can both be substantial and fundamentally alter final cost-effectiveness outcomes and thus instrument choices.

These cost factors and rebound effects mean that subsidies to encourage acquisition of energy-efficient devices are unlikely, on their own, to cause the dramatic energy efficiency gains called for in the GEA analysis. For these gains to be realized, a portfolio of stronger, carefully targeted policies is needed. Examples include: strong efficiency regulations that are updated regularly (say, every five years); incentives to reward manufacturers to push the technology design envelope toward advanced efficiency; increases in energy prices (because of direct or indirect emissions pricing); electricity tariffs that give high rewards to efficiency investments and behavior; land use planning and zoning that fosters efficient urban development and renewal; and public (and private) investments in efficient infrastructure such as mass transit, cycling paths, and CHP systems.

In the buildings sector, to be able to reduce final thermal energy use by over 40%, the goal in the GEA efficiency pathway, all jurisdictions need to introduce and strictly enforce building codes that mandate very low specific energy-use levels, equal or similar to passive-house levels. They also need to extend these requirements to renovations, and building retrofits will need to significantly accelerate the present rates. The remaining building energy needs can be met from locally generated renewable energy sources, where feasible, and economically and environmentally optimal – typically, low-density residential neighborhoods. Achieving the needed transformation in the buildings sector entails massive capacity-building efforts to retrain all the trades involved in the design and construction process, as well as the building owners, operators, and users.

Influencing energy use in the transport sector involves affecting transport needs, infrastructure, and modes, as well as vehicle energy efficiency.

Table TS-8 | Regulatory policies potential contribution to transport and GEA multiple goals.

GEA Overall Systemic Goals	Sustainable Transportation Systems Multiple Goals and Benefits	Aim: Establishing Clear Regulatory Framework								
		Vehicle Standards	Fuel Standards and Mandates	Reduce Travel Speed Limit in Urban Areas	Reduce Travel Speed/Volume of Freight Transport in Urban Areas	Reduce Speed of Airplanes	Reduce Speed of Commercial Maritime Transport	Improved Management Intelligent Transport System	Mandatory Vehicle Inspections	Traffic Safety Regulation
Economic Growth, Equity & Urbanization	Functionality, Efficiency									
	Accessibility									
	Affordability									
	Acceptability									
Health & Environmental Protection	Traffic Safety									
	Acces of less fit									
	Human Motion									
	Reduce Air Pollution									
	Reduce Noise									
	Reduce Congestion									
Climate	Reduce GHG									
Energy Security	Diversification Energy sources									
	Independence from Fossil fuels									

Legend: Role of Policies or potential contribution to attainement of goal according to literature

- uncertain
- complementary

Source: Chapter 9.

Policies for urbanization will have a large impact on transport needs, infrastructure, and the viability of different transport modes on the local scale. Both the decision to travel and the choice of how to travel affect fuel consumption. With a focus on urban transport, a transition to sustainable transport can follow the framework known as 'avoid–shift–improve'. This considers three major principles under which diverse policy instruments are grouped, with interventions assuming different emphasis in industrial and developing countries. They need to focus on improving technological options, not only with respect to climate mitigation, but also with respect to local environmental conditions and social concerns. The other two components – modal shift and avoiding travel – influence the level of activity and structural components that link transport to carbon emissions.

This approach to urban transport would include policies and measures for developing alternatives to car use, reducing the need for travel, improving existing infrastructure use, and setting a clear regulatory framework (alternative fuels and efficient vehicles). In addition, policies targeting freight and long-distance travel (shipping, trucks, rail, and air) are needed. To illustrate the complexity of transportation policy, Table TS-8 shows some regulatory options and their potential impact.

For energy efficiency in industry it is useful to separate what can be achieved when a new plant is being built and what can be done in existing industry. Most of the new industrial growth will occur in developing countries. Under the business-as-usual scenario, a mix of technologies would be installed with varying levels of specific energy use. In addition to regulations and economic incentives, regional centers for industrial energy efficiency could be set up that help disseminate information related to specific energy use and best-available technologies for different processes. There could also be web-based facilities established where any industry that is being proposed can compare its design energy performance with the best available benchmark technologies. An incentive scheme should provide

funding for energy performance analysis at the design stage. Governments could help provide financing of the incremental costs of energy-efficient technologies as low-interest loans through commercial banks.

In existing industries, realizing the potential for energy efficiency can be achieved through a combination of measures, including incentives for demand-side management. Regulatory commissions can provide regulations and standards for energy-using equipment and process improvements. Information gaps need to be reduced, especially the sharing and documentation of best practices. Capacity needs to be developed for systems assessment rather than individual components assessment.

In developing countries or jurisdictions with suppressed energy service levels, improved efficiency may lead to an increase in energy service levels rather than a decrease in energy demand. However, this should normally be the goal of efficiency policies in such jurisdictions. In industrial countries, such rebound effects need to be minimized through appropriate energy pricing and taxes that complement efficiency policies.

The transition into a very low energy future requires a shift in the focus of energy-sector investment from the supply-side to end-use capital stocks, as well as the cultivation of new innovative business models (such as performance contracting and ESCOs).

5.3.2 Renewable Energies

Increased use of renewable energy technologies can address a broad range of aims, including energy security, equity issues, and emission reductions, thereby linking beneficially with other policies related to poverty eradication, water provision, transport, agriculture, infrastructure development, industrial development, job creation, and development cooperation. For this to occur, policy measures must overcome the barriers within the current energy system that prevent wider uptake of renewables (see Table TS-9 for an overview). A key issue is how to accelerate the deployment of renewable energies so that their deep penetration into the energy system can be achieved quickly.

Given the enormous size and momentum of the existing global energy system, new technologies such as renewables face significant market barriers. To address these, policy measures should support a level playing field where renewables can compete fairly with other forms of energy; they should also support the development of renewables so that they can overcome additional hurdles to their deployment.

While competitive markets operate effectively for many goods and services, a number of failures need to be addressed in relation to energy. A central concern is the way that markets currently favor conventional forms of energy by not fully incorporating the externalities they are responsible for and by continuing to subsidize them – making it harder to incorporate new technologies, new entrants, and new services in the energy system. This both distorts the market and creates barriers for renewables.

Similarly, the potential benefits of renewables are also often not accounted for when evaluating the return on investment, such as increased energy security, access to energy, reduced economic impact volatility, climate change mitigation, and new manufacturing and employment opportunities. These issues are exacerbated by ongoing subsidies for fossil fuels that globally amount to hundreds of billions of US dollars per year, much more than the support renewables are receiving. It is through public policies that the values to society can be reflected in market conditions such that it will be advantageous for investors to seek out energy options that support and contribute to a sustainable future for all.

Using a portfolio of policies helps to increase successful innovation and commercialization, providing they complement each other. To expand renewable technologies, it is important to note that:

- market growth results from the use of combinations of policies;
- long-term, predictable policies are important;
- multi-level involvement and support from national to local players is important; and
- each policy mechanism evolves as experience of its use increases.

Policy approaches for renewable energy intend to address the innovation chain both technologically and socially, to pull technologies to the marketplace and commercialize them, and to improve the financial attractiveness and investment opportunities of renewables.

Of the market-pull policies, two are most common: a policy that sets a price to be paid for renewable energy and ensures connection to the grid and off-take (often known as a feed-in tariff or FIT), and a policy that sets an obligation to buy, but not necessarily an obligation on price (often known as a quota or obligation mechanism or a renewable portfolio standard). So far, FITs have been used for electricity only, although some countries, for example the United Kingdom, are now considering how to provide them for heat. Quotas have so far been used for electricity, heat, and transport. Biofuel quotas are now common globally.

A FIT that provides a strong, stable price for renewable electricity has proven successful in some countries for accelerating investment in renewables. Some jurisdictions prefer renewable portfolio standards that set a minimum, but growing, quota for renewable or low-emission electricity generation technologies. Although there is considerable debate between advocates of these two approaches, the detailed way in which they are implemented is the key to success. In addition, the GEA analysis for meeting climate stabilization goals shows that, currently, in industrial countries virtually no new investments in electricity generation should result in the new emission of GHGs. Unfortunately, such investments are still possible in countries with FITs, green certificate markets, or other renewable energy support schemes, and indeed this has been the case in most jurisdictions with such policies, although at a lower rate.

Table TS-9 | Summary of renewable energy policies.

Policy	Definition	End-use Sector		
		Electricity	Heat/ Cooling	Transport
Regulatory Policies				
Targets	A voluntary or mandated amount of renewable energy (RE), usually a percentage of total energy supply	X	X	X
Access-related Policies				
Net metering	Allows a two-way flow of electricity between generator and distribution company and also payment for the electricity supplied to the grid	X		
Priority access to network	Allows RE supplies unhindered access to network for remuneration	X	X	
Priority dispatch	Ensures RE is integrated into the energy system before supplies from other sources	X	X	
Quota-driven Policies				
Obligation, mandates, Renewable Portfolio Standards	Set a minimum percentage of energy to be provided by RE sources	X	X	X
Tendering/bidding	Public authorities organize tenders for a given quota of RE supplies and ensure payment	X		
Tradable certificates	A tool for trading and meeting RE obligations	X	X	
Price-driven Policies				
Feed-in tariff (FIT)	Guarantees RE supplies with priority access, dispatch, and a fixed price per unit payment (sometimes declining) delivered for a fixed number of years	X	X	X
Premium payment	Guarantees RE supplies an additional payment on top of their energy market price or end-use value	X	X	
Quality-driven Policies				
Green energy purchasing		X	X	
Green labeling	Usually government-sponsored labeling that guarantees that energy products meet certain criteria to facilitate voluntary green energy purchasing	X	X	X
Fiscal Policies				
Accelerated depreciation	Allows for reduction in tax burden	X	X	X
Investment grants, subsidies, and rebates	One-time direct payments usually from government but also from other actors, such as utilities	X	X	X
Renewable energy conversion payments	Direct payment by government per unit of energy extracted from RE sources	X	X	
Investment tax credit	Provides investor/owner with an annual tax credit related to investment amount	X	X	X
Other Public Policies				
Research and development	Funds for early innovation	X	X	X
Public procurement	Public entities preferentially purchasing RE or RE equipment	X	X	X
Information dissemination and capacity building	Communications campaigns, training, and certification	X	X	X

Source: Chapter 11

The obvious next step is to require that all new investments for electricity generation are in near-zero emissions technologies, and some jurisdictions have done this. Since 2006, for example, British Columbia in Canada has a 100% clean electricity standard for all new investments.

5.3.3 Modernized Fossil Fuels

Low-, zero-, or negative-emission fossil fuel use will require a transition to systems that co-utilize fossil fuels with renewable energy and with CCS. Co-processing of biomass with coal or natural gas for the co-production of power, fuels, and chemicals with CCS, is especially promising. New policies are needed that encourage environmentally acceptable deployment of such systems. Some of the following leading policies have already been enacted on an experimental basis, but these efforts would need to be intensified significantly over the next decades to realize a dramatic shift. Governments or regulators could, among others:

- implement GHG emissions pricing via carbon taxes and/or cap-and-trade systems;
- reduce all subsidies to fossil fuels without CCS. This includes fuel price subsidies that promote increased energy use; subsidies to

private vehicle use (e.g., untolled roads), and a host of subsidies to industrial, commercial, institutional, and other combustion uses of fossil fuels;

- provide demonstration and commercialization subsidies;
- offer to pay above-market rates for electricity, heat, or low-net GHG-emitting fuels provided via projects that co-process sustainable biomass and fossil fuel feedstocks in systems with CCS. This would be similar to the FIT for renewables;
- ban construction of new coal-fired electricity plants that lack CCS or are not CCS ready;
- require land use planning that facilitates socially and environmentally acceptable siting of underground carbon storage and CO_2 pipelines. There is also a need for land use planning to safeguard against potential impacts of carbon storage on other uses of the subterranean, such as geothermal energy, or at least consider a balance between the possible uses;
- legally clarify geological rights to underground pore spaces for CO_2 storage; and
- establish short- and long-term liabilities and risk management and monitoring responsibilities at CO_2 storage sites and on CO_2 pipeline right-of-ways.

5.3.4 Nuclear Energy

People's views on the value and risks of nuclear power differ greatly and are often polarized. Some people see nuclear power as a risky technology. These perceived threats from nuclear power include catastrophic accidents at nuclear plants (either through operational failures or terrorist attacks), the inability to safely transport and permanently store radioactive wastes, and the exploitation of civilian nuclear expertise for the proliferation of nuclear weapons.

Depending on the severity of these concerns about nuclear power, its regulatory burden (for design, permitting, operation, and decommissioning) can be such that nuclear power is a high-cost option for electricity generation. However, where public policy (local, national, international) is able to allay these concerns, then nuclear power can be a competitive energy option. However, everything hinges on risk preferences among the public and decision makers, particularly with respect to trading off the extreme event risks of nuclear power with the ongoing impacts and risks of its alternatives. The following policies therefore focus on how to ensure a safe use of nuclear power that is both real and perceived:

- At the international level, governments and the nuclear industry need to continue to improve their mechanisms for monitoring and controlling the use of nuclear power and the reprocessing of nuclear fuel to prevent acquisition of expertise and materials for nuclear weapons production.
- Governments need to collaborate in the establishment of permanent storage sites for radioactive materials.
- By facilitating collaborative investments, governments can help the nuclear industry settle on two or three dominant designs that have the best chance of achieving regulatory approval and thus reducing regulatory costs, which have been very high in jurisdictions like the United States.

5.4 Elements of Policy Packages

The preceding sections describe a variety of policy instruments, tools, and approaches for different objectives, whether energy access or decarbonization through the use of renewables. Across the various domains of intervention, there are some common requirements for transformative change. For example, whether in the context of CCS or renewable energy technologies, accelerating the process of research, development, demonstration, and deployment is a common requirement. Similarly, it is necessary to enhance and reorient investment. Capacity building is essential to ensure that countries, regions, and policymakers are able to design and implement policies. It is possible that fundamental rethinking of lifestyles and consumption patterns may be required for sustainability. This may require new knowledge (such as green accounting practices) as well as a range of tools to influence public thinking, opinion, and behavior.

5.4.1 Innovation[41]

Innovation and technological change are integral to the energy system transformations described in the GEA pathways. Energy technology innovations range from incremental improvements to radical breakthroughs and from technologies and infrastructure to social institutions and individual behaviors. The innovation process involves many stages – from research through incubation, demonstration, (niche) market creation, and ultimate widespread diffusion. Feedback between these stages influences progress and likely success, yet innovation outcomes are unavoidably uncertain. Innovations do not happen in isolation; inter-dependence and complexity are the rule under an increasingly globalized innovation system.

A first, even if incomplete, assessment of the entire global investments into energy technologies – both supply- and demand-side technologies – across different innovation stages suggests RD&D investments of some US$50 billion, market formation investments (which rely on directed public policy support) of some US$150 billion, and an estimated range

41 **Grubler, A. and K. Riahi, 2010:** Do governments have the right mix in their energy R&D portfolios? *Carbon Management*, **1**(1):79–87.

of US$1–5 trillion investments in mature energy supply and end-use technologies (technology diffusion) are required. Demand-side investments are of critical importance, particularly as the lifetimes of end-use technologies can often be considerably shorter than those on the supply side. Demand-side investments might thus play an important role in achieving pervasive and rapid improvements in the energy system.

Major developing economies have become significant players in global energy technology RD&D, with public- and private-sector investments approaching some US$20 billion – in other words, almost half of global innovation investments – and are significantly above OECD public-sector energy RD&D investments (US$13 billion).

Policies now need to move toward a more integrated approach, simultaneously stimulating the development and adoption of efficient and cleaner energy technologies and measures. R&D initiatives without simultaneous incentives for consumers to adopt the outcomes of innovation efforts risk not only being ineffective, but also precluding the market feedbacks and learning that are critical for continued improvements in technologies.

Few systematic data are available for private-sector innovation inputs (including investments). Although some of the data constraints reflect legitimate concerns to protect intellectual property, most do not. Standardized mechanisms to collect, compile, and make data on energy technology innovation publicly available are urgently needed. The benefits of coupling these information needs to public policy support have been clearly demonstrated.

The energy technology innovation system is founded on knowledge generation and flows. Increasingly these are global, but need to be adapted, modified, and applied to local conditions. Long-term, consistent, and credible institutions underpin investments in knowledge generation, particularly from the private sector. Yet consistency does not preclude learning. Knowledge institutions have to be responsive to experience and adaptive to changing conditions; see, for example the discussion on open and distributed innovation, university-industry linkages, and knowledge networks (in the North, the South, and North–South) discussed in Chapter 25.7. Although knowledge flows through international cooperation and experience, sharing at present cannot be analyzed in detail; the scale of the innovation challenge emphasizes their importance alongside efforts to develop capacity to absorb and adapt knowledge to local needs and conditions.

Clear, stable, and consistent expectations about the direction and shape of the innovation system are necessary for innovators to commit time, money, and effort with only the uncertain promise of distant returns. To date, policy support for the innovation system has been characterized by volatility, changes in emphasis, and a lack of clarity. An example is the development of solar thermal electric (STE) technology in the United States (see Figure TS-29). After successful development during one decade, sudden policy changes in 1992 terminated interest in STE in the country. Now US interest has revived, with some projects underway in California (although none completed yet) with all the knowledge and technology imported from Europe (Spain), as associated knowledge entirely depreciated in the United States after the 1992 sudden policy changes.

Policies have to support a wide range of technologies. However seductive they may seem, silver bullets do not exist without the benefit of hindsight. Innovation policies should use a portfolio approach under a risk hedging and 'insurance policy' decision-making paradigm. The portfolio approach is also emphasized in Chapter 25 as part of a capacity development approach, especially in developing countries. The whole energy system should be represented, not just particular groups or types of technology. The entire suite of innovation processes should be included, not just particular stages or individual mechanisms. Less capital-intensive, smaller-scale (that is, granular) technologies or projects are a lower drain on scarce resources, and failures have less-serious consequences.

Public technology policy should not be beholden to incumbent interests that favor support for particular technologies that either perpetuate the lock-in of currently dominant technologies or transfer all high innovation risks of novel concepts to the public sector.

Portfolios need to recognize that innovation is inherently risky. Failures vastly outnumber successes. Experimentation, often for prolonged periods (decades rather than years), is critical to generate the applied knowledge necessary to support the scaling-up of innovations into the mass market.

Public sector energy R&D as a function of total public sector financed R&D has declined since the early 1980s, with a small reversal in the trend over the last few years (see Figure TS-30). Spending on technology groups has been relatively constant over time. Nuclear energy has received the largest part of the funding.

Technology needs from the pathway analysis shows a very different picture (see Figure TS-31). Energy efficiency dominates this analysis which also shows a doubling or more for renewable energies, and a significant lower emphasis on nuclear energy. This historical energy R&D portfolio bias needs to be addressed urgently to stimulate the innovations needed for realization of the GEA transition pathways.

5.4.2 Finance[42]

Some of the policies for energy sustainability described above simply involve an improvement of existing policies, such as better management of the electricity sector or more responsible use of fossil fuel resource rents. But the dominant message of the GEA is that the global energy system must be rapidly modified and expanded to provide energy access to those who have none, and must quickly transform to an energy system more supportive of sustainable development. This transition will require considerable investments over the coming decades. Table TS-10 indicates the

42 Section TS-5.4.1 is based on Chapter 24.

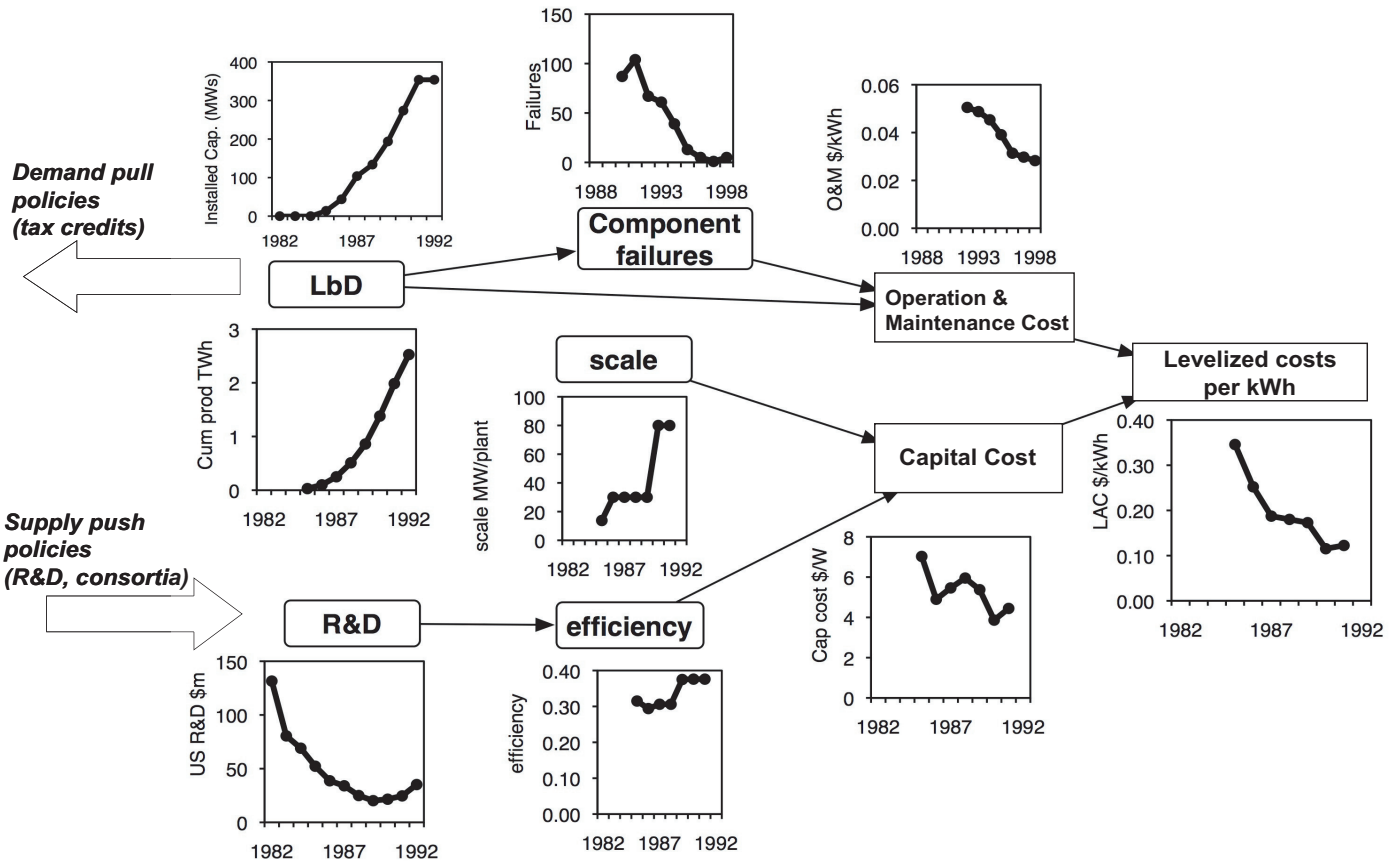

Figure TS-29 | History of the US solar thermal electricity program, 1982–1992. This shows a 'virtuous' technology development cycle as a result of well-coordinated policies. Demand pull policies enabled expanding market applications, which in turn enabled a scaling-up of the technology – reducing capital costs through economies of scale effects, learning by doing (LbD), and reductions in component failures (lowering operating costs). Supply push policies, such as R&D (even at declining budgets), led to technology improvements (efficiency) that further lowered capital costs. In the aggregate, levelized total costs per kWh declined by a factor of three over 10 years. This positive innovation development cycle came to an abrupt halt after 1992 with the sudden discontinuation of public policy support. Source: Chapter 24.

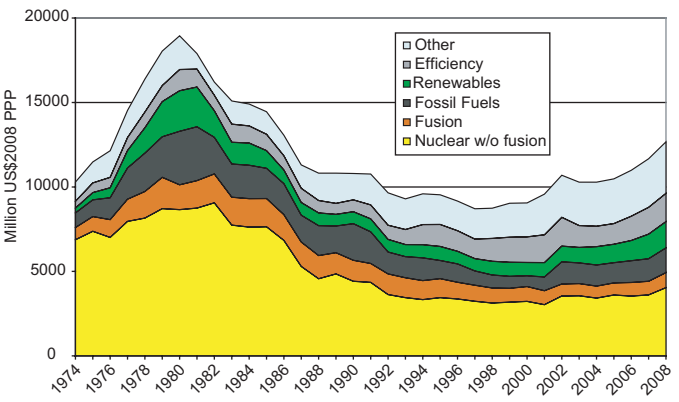

Figure TS-30 | Public sector energy RD&D in IEA Member countries by major technology group. Source: Chapter 24.[43]

necessary investments to achieve this, as estimated by the GEA, and links these to the types of policies needed. It also assesses these policies in terms of their necessity and their ability to complement or substitute for each other. Although considerable, these investment levels can be compared to estimates of global fossil fuel subsidy levels on the order of US$500 billion a year, of which an estimated US$100 billion goes to producers.

Table TS-10 compares the costs and policies for different technology options to those of promoting energy access. Different types of technologies and objectives will require different combinations of policy mechanisms to attract the necessary investments. Thus, Table TS-10 identifies 'essential' policy mechanisms that must be included for a specific option to achieve the rapid energy system transformation, 'desired' policy mechanisms that would help but are not a necessary condition, 'uncertain' policy mechanisms in which the outcome will depend on the policy emphasis and thus might favor or disfavor a specific option, and policies that are inadequate on their own but could 'complement' other essential policies.

The GEA findings indicate that global investments in combined energy efficiency and supplies have to increase to about US$1.7–2.2 trillion per

43 **IEA, 2009a:** *World Energy Outlook*. International Energy Agency, Organization for Economic Cooperation & Development, Paris.

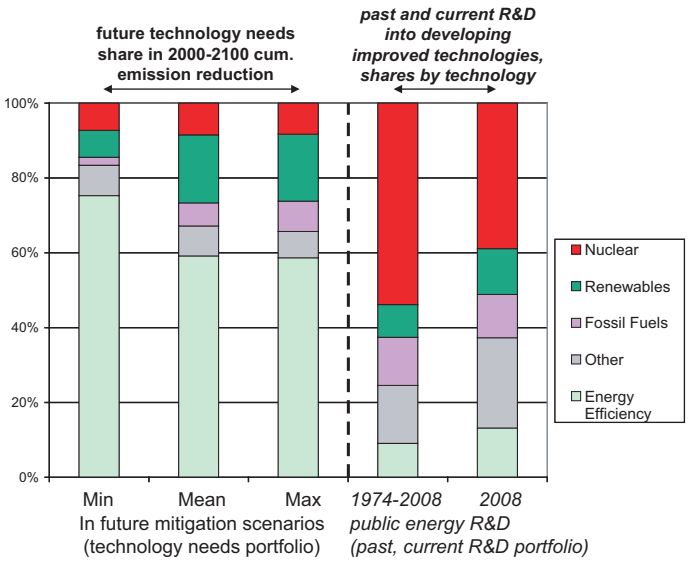

Figure TS-31 | Distribution of past (1974–2008) and current (2008) public sector energy technology R&D portfolios in member countries of the IEA (right) versus portfolios of future GHG mitigation needs (min/mean/max, left) derived from an extensive scenario uncertainty analysis. Source: Adapted from Grubler and Riahi, 2010, see Chapter 24.[44]

year compared with the present level of some US$1.3 trillion (2% of current world GDP). Given projected economic growth, this would be an approximately constant fraction of GDP in 2050.

For some objectives, such as energy access, future investment needs are comparatively modest. However, a variety of different policy mechanisms – including subsidies and regulation as well as capacity building programs – need to be in place. Regulations and standards are also essential for almost all other options listed in Table TS-10, while externality pricing might be necessary for capital-intensive technologies to achieve rapid deployment (such as a carbon tax to promote diffusion of renewables, CCS, or efficiency). Capital requirements for energy infrastructure are among the highest priorities of the options listed.

Increasing investments in the energy system as depicted by the GEA pathways requires the careful consideration of a wide portfolio of policies to create the necessary financial incentives and adequate institutions to promote and support them, and innovative financial instruments to facilitate them The portfolio needs to include regulations and technology standards in sectors with, for example, relatively low price elasticity in combination with externality pricing to avoid rebound effects, as well as targeted subsidies to promote specific 'no-regret' options while addressing affordability. In addition, focus needs to be given to capacity development to create an enabling technical, institutional, legal, and financial environment to complement traditional deployment policies (particularly in the developing world).

5.4.3 Capacity Development[45]

Wealthier countries need to improve mechanisms for supporting ***capacity development*** in developing countries, including financial support, technical training, and sharing of industry, trade, and institutional experiences. Any energy capacity strategy must, however, be tailored to the specific characteristics of a given country or region if it is to succeed in stimulating a rapid transition of the energy system to a more sustainable path. While this strategy must address basic needs for education and training, it must also be adapted to the local cultural norms and practices.

The transitions put forward in GEA require a transformation of energy systems that demand significant changes in the way energy is supplied and used today. These transitions are, by definition, long-term, socially embedded processes in the course of which capacities at the individual, organizational, and systems levels and the policies for capacity development themselves will inevitably change. From this perspective, capacity development can no longer be seen as a simple aggregation of individual skills and competences or the introduction of new 'technology'. Rather, it is a broad process of change in production and consumption patterns, knowledge, skills, organizational form, and – most important – established practices and norms of the players involved: in other words, a host of new and enhanced capacities. Energy transitions are thus innovative processes (Chapter 25.1).

The complexity, magnitude, and speed of the changes envisaged in these transitions will necessitate a major shift in the way that societies analyze and define the concept of 'capacities' and in the way in which they go about the important task of developing these capacities to meet the challenges of energy transitions. Different from some of the linear approaches to capacity development and to technology transfer and deployment used today, which often fail to appreciate the complexity of change processes, the concept of capacity development advanced by GEA is intimately linked to the energy transitions perspective based on multilayered processes of system change.

In these processes, special attention is paid to the informal institutions that arise out of historically shaped habits, practices, and vested interests of players in the system already in place and to the tendency for path dependence, where past choices constrain present options. They are given special attention because they constitute potential impediments to needed change. In the transitions perspective, both learning and unlearning such habits, practices, and norms in the course of change are important (Chapter 25.4).

Traditional habits, practices, and norms also shape the styles of communication in societies. Evidence shows that the more successful change processes take place in environments that tend to move away from top-down communication and consultation to more active and continuous

44 Section TS-5.4.2 is based on Chapter 6 and 17.

45 Section TS-5.4.3 is based on Chapter 25.

Table TS-10 | Energy investments needed between 2010 and 2050 to achieve GEA sustainability objectives and illustrative policy mechanisms for mobilizing financial resources.

Times	Investment (billions of US$/year)		Policy mechanisms			
		2010–2050	Regulation, standards	Externality pricing	Carefully designed subsidies	Capacity building
Efficiency	n.a.[a]	290–800[b]	*Essential* (elimination of less efficient technologies every few years)	*Essential* (cannot achieve dramatic efficiency gains without prices that reflect full costs)	*Complement* (ineffective without price regulation, multiple instruments possible)[c]	*Essential* (expertise needed for new technologies)
Nuclear	5–40[d]	15–210	*Essential* (waste disposal regulation and of fuel cycle, to prevent proliferation)	*Uncertain* (GHG pricing helps nuclear but prices reflecting nuclear risks would hurt)	*Uncertain* (has been important in the past, but with GHG pricing perhaps not needed)	*Desired* (need to correct the loss of expertise of recent decades)[e]
Renewables	190	260–1010	*Complement* (feed-in tariff and renewable portfolio standards can complement GHG pricing)	*Essential* (GHG pricing is key to rapid development of renewables)	*Complement* (tax credits for R&D or production can complement GHG pricing)	*Essential* (expertise needed for new technologies)
CCS	<1	0–64	*Essential* (CCS requirement for all new coal plants and phase-in with existing)	*Essential* (GHG pricing is essential, but even this is unlikely to suffice in near term)	*Complement* (would help with first plants while GHG price is still low)	*Desired* (expertise needed for new technologies)[e]
Infrastructure[f]	260	310–500	*Essential* (security regulation critical for some aspects of reliability)	*Uncertain* (neutral effect)	*Essential* (customers must pay for reliability levels they value)	*Essential* (expertise needed for new technologies)
Access to electricity and cleaner cooking[g]	n.a.	36–41	*Essential* (ensure standardization but must not hinder development)	*Uncertain* (could reduce access by increasing costs of fossil fuel products)	*Essential* (grants for grid, micro-financing for appliances, subsidies for clean cookstoves)	*Essential* (create enabling environment: technical, legal, institutional, financial)

[a] Global investments into efficiency improvements for the year 2010 are not available. Note, however, that the best-guess estimate from Chapter 24 for investments into energy components of demand-side devices is by comparison about US$300 billion per year. This includes, for example, investments into the engines in cars, boilers in building heating systems, and compressors, fans, and heating elements in large household appliances. Uncertainty range is between US$100 billion and US$700 billion annually for investments in components. Accounting for the full investment costs of end-use devices would increase demand-side investments by about an order of magnitude.

[b] Estimate includes efficiency investments at the margin only and is thus an underestimate compared with demand-side investments into energy components given for 2010 (see note a).

[c] Efficiency improvements typically require a basket of financing tools in addition to subsidies, including, for example, low- or no-interest loans or, in general, access to capital and financing, guarantee funds, third-party financing, pay-as-you-save schemes, or feebates, as well as information and educational instruments such as labeling, disclosure and certification mandates and programs, training and education, and information campaigns.

[d] Lower-bound estimate includes only traditional deployment investments in about 2 GW capacity additions in 2010. Upper-bound estimate includes, in addition, investments for plants under construction, fuel reprocessing, and estimated costs for capacity lifetime extensions.

[e] Note the large range of required investments for CCS and nuclear in 2010–2050. Depending on the social and political acceptability of these options, capacity building may become essential for achieving the high estimate of future investments.

[f] Overall electricity grid investments, including investments for operations and capacity reserves, back-up capacity, and power storage.

[g] Annual costs for almost universal access by 2030 (including electricity grid connections and fuel subsidies for cleaner cooking fuels).

dialogue practices. Capacity development has an important role to play in building mechanisms of support and capacities for interactive feedback, flexibility, and adaptive management and change. And because these traditional habits, practices, and norms are embedded in a broader social context, building capacities for dialogue at the local level is essential.

Market development and the role of feedback and flexibility at the local and project level are also essential in support of the diffusion of new energy technologies, but they are usually ignored in the design of capacity building initiatives. Also important is the need to build and strengthen capacities for local manufacture, repair, and distribution of new energy-related technologies, whether related to improved cookstoves, solar home systems or other forms of early energy-access initiatives, or to the introduction of more modern and decentralized forms of energy. Successful examples of energy technology development and diffusion also point to the need to develop and strengthen local research capacities, participating in collaborative R&D efforts and coordinating across sectors and disciplines.

Brazil's sustained research effort that led to its development of the biofuels industry and to multiple development goals ranging from energy-access improvements to lowering GHG emissions is a good example of this interaction and the success that it brings (see Chapter 25.6.1). Research and advisory services have also played an important role in the development of smallholder jatropha farms to produce oil for off-grid electricity production in Mali (Chapter 25.6.1). Other examples where bottom-up approaches have been critical to the successful introduction of new energy technologies include experiences in the introduction of small hydropower schemes in China and village power schemes in Bhutan (Chapter 25.6.2).

Because the need to transform energy systems applies to all economies – whether industrial, emerging, developing, or poorest – the new concept of capacity development for energy transitions in some of the examples just mentioned must also apply to all programs, whether they relate to small energy-access projects or major transitions and innovations across society and at the national level. The differences reside in the types of objectives and outcomes sought – ranging from countries where the main objective may be to attain the highest levels of cleaner, sustainable, and secure forms of energy to those where the goal is to provide access to cleaner and affordable modern forms of energy to the largest possible number of residents.

Making choices about transition pathways requires access to a wide range of knowledge and information as well as the capacities to use this knowledge in the policy process. Two new approaches have emerged recently from contemporary business practices that may have great relevance in future capacity development approaches. These have developed over the past several decades as production has become more knowledge-intensive, competition more globalized, and information technology more accessible to the population at large. These 'open innovation' and 'distributed innovation' systems require very different and complex approaches to capacity development, involving special skills for managing risks and for creating innovative partnerships that speed the development and diffusion of new energy technologies (Chapter 25.7).

Open innovation involves a network culture in which the world outside is used to generate knowledge inside, and knowledge flows in and out of the institution purposefully rather than at random. The main objective is to leverage existing knowledge rather than depend solely on intellectual property. Distributed innovation, in contrast, is more closely associated with the development of open source software such as Linux, but the innovation has spread and is being practiced in other fields, including the biosciences. In this case, existing practices are not just modified but disrupted. The innovation power comes from a collected set of individuals whose individual actions 'snap together' to create something new.

These approaches point to the importance of building very special capacities for networking and knowledge networks and for appreciating the increasing relevance of open and distributed systems. Brazil's systematic collaborative research since the early 1980s that led to the biofuels success and the Dutch use of 'transition platforms' to advance efforts toward a low-carbon economy, relying on bottom-up processes and open networks involving business, the non-governmental sector, and government, illustrate the applicability of this approach for industrial as well as developing countries (Chapter 25.8.3). In these and other examples, the lesson is that access to information and the capacity to use such inputs are critical in making choices for energy transitions – for individual players, the community, or a national government.

But these new and emerging forms of knowledge networking, coupled with new and innovative forms of finance and technology research collaboration and development, require new and enhanced capacities for effective participation at the international level that many countries, particularly developing ones, do not have, or are not well-developed today. The increasingly complex and fast-paced world of energy and climate change finance is a good example of an area where present capacities fall far short of the needs. The recent climate change negotiations alone have generated pledges of fast-start finance up to 2012 of some US$30 billion and promises to work collaboratively so that this funding can grow to some US$100 billion by 2020.

This is only a small part of the overall investment projections needed to meet the growth in energy demand – some US$1.7–2.2 trillion per year are needed up to 2050. The world of energy finance has always been a large and complex market. The difference today is that it is becoming even more complex, with new and innovative instruments of finance, including the carbon market, and with countries demanding more attention to the need to develop, introduce, and diffuse new technologies. Under these conditions, a multi-goal approach can both speed the diffusion of new energy technologies as well as stimulate the development and energy transition processes in developing countries.

6 Conclusions

The world is undergoing severe and rapid change involving significant challenges. Although this situation poses a threat, it also offers a unique opportunity – a window of time in which to create a new, more sustainable, more equitable world, provided that the challenges can be addressed promptly and adequately. Energy is a pivotal area for actions to help address the challenges.

The interrelated world brought about by growth and globalization has increased the linkages among the major challenges of the 21st century. We do not have the luxury of being able to rank them in order of priority. As they are closely linked and interdependent, the task of addressing them simultaneously is imperative.

Energy offers a useful entry point into many of the challenges because of its immediate and direct connections with major social, economic, security, and development goals of the day. Among many other challenges, energy systems are tightly linked to global economic activities,

to freshwater and land resources for energy generation and food production, to biodiversity and air quality through emissions of particulate matter and precursors of tropospheric ozone, and to climate change. Most of all, access to affordable and cleaner energy carriers is a fundamental prerequisite for development, which is why GEA places great emphasis on the need to integrate energy policy with social, economic, security, development, and environment policies.

The good news is that humanity has the resources, the ingenuity, and the technologies to create a better world. The bad news is that the lack of appropriate institutions, their interaction and integration, capacities, and governance structures makes the task difficult. Raising the level of political will to address some of these challenges could go a long way toward making significant progress in achieving multiple goals. This is a major task, however, given the tendency of current decision-making processes to aim for short-term, quick results. GEA endeavors to make a compelling case for the adoption of a new set of pathways – pathways that are essential, required urgently, and – most important – achievable.

GEA highlights essential technology-related requirements for radical energy transformation:

- significantly larger investment in energy efficiency improvements, especially end-use, across all sectors, with a focus on new investments as well as major retrofits;
- rapid escalation of investments in renewable energies: hydropower, wind, solar energy, modern bioenergy, and geothermal, as well as the smart and super grids that enable renewable energies to become the dominant sources of energy;
- reaching universal access to modern forms of energy and cleaner cooking through micro-financing and subsidies;
- use of fossil fuels and bioenergy at the same facilities for the efficient co-production of multiple energy carriers and chemicals;
- full-scale deployment of CCS; and
- on one extreme nuclear energy could make a significant contribution to the global electricity, but in the other, it could be phased out.

To meet humanity's need for energy services, comprehensive diffusion of advanced energy technologies and an increased contribution of energy efficiencies are required throughout the energy system – from energy collection and conversion to end-use. Rapid diffusion of renewable energies is the second, but equally most effective, option for reaching multiple objectives. Sustainable conversion to carriers such as electricity, hydrogen, and heat, along with smart transmission and distribution systems for the most important end-uses are crucial.

A major policy challenge is to resolve the current issue of split incentives, in the sense that those who would be paying for efficiency improvements and other energy investments are more oriented toward short-term rates of return than to the long-term profitability of the investments and, likewise, that they are rarely the beneficiaries of reduced energy bills and other public benefits.

GEA makes the case that energy system transformation is possible only if there is also an interactive and iterative transformation of the policy and regulatory landscape, thereby fostering a buildup of skills and institutions that encourage innovation to thrive, create conditions for business to invest, and generate new jobs and livelihood opportunities.

It is projected that, by mid-century, more than six billion people will live in urban environments. This underscores the importance for policymakers to consider the window of opportunity available in designing the urban landscape, specifically in terms of urban layout, transport structure, and individual buildings/structures and their energy use.

A major finding of GEA is that some energy options provide multiple benefits. This is particularly true of energy efficiency, renewables, and the co-production of synthetic transportation fuels, cooking fuels, and electricity with CCS, which offer advantages in terms of supporting all of the goals related to economic growth, jobs, energy security, local and regional environmental benefits, health, and climate change mitigation. All these advantages imply the creation of value. This value should be incorporated into the evaluation of these measures (and others) and in creating incentives for their use.

One implication of this is that nations and corporations can invest in efficiency and renewable energy for the reasons that are important to them, not just because of a global concern about, for example, climate change mitigation or energy security. But incentives for individual players to invest in options with large societal values must be strong and effective.

Finally, the GEA pathways describe the transformative changes needed to achieve development pathways toward a more sustainable future – a 'sustainable future' that simultaneously achieves normative goals related to the economic growth, energy security, health, and environmental impacts of energy conversion and use, including the mitigation of climate change.

In sum, GEA finds that attainment of a sustainable future for all is predicated on resolving energy challenges. This requires the creation of market conditions, via government interventions, that invite and stimulate investments in energy options that provide incentives for rapid investments in energy end-use and supply technologies and systems.

1.1 Introduction and Roadmap

Life is but a continuous process of energy conversion and transformation. The accomplishments of civilization have largely been achieved through the increasingly efficient and extensive harnessing of various forms of energy to extend human capabilities and ingenuity. Energy is similarly indispensable for continued human development and economic growth. Providing adequate, affordable energy is a necessary (even if by itself insufficient) prerequisite for eradicating poverty, improving human welfare, and raising living standards worldwide. Without economic growth, it will also be difficult to address social and environmental challenges, especially those associated with poverty. Without continued institutional, social, and technological innovation, it will be impossible to address planetary challenges such as climate change. Energy extraction, conversion, and use always generate undesirable by-products and emissions – at a minimum in the form of dissipated heat. Energy cannot be created or destroyed – it can only be converted from one form to another, along a one-way street from higher to lower grades (qualities) of energy. Although it is common to discuss energy "consumption," energy is actually transformed rather than consumed.

This Energy Primer[1] aims at a basic-level introduction to fundamental concepts and data that help to understand *energy systems* holistically and to provide a common conceptual and terminological framework before examining in greater detail the various aspects of energy systems from challenges and options to *integrated* solutions, as done in the different chapters of the Global Energy Assessment (GEA). Different chapters will quite naturally emphasize different aspects and components of the global energy system, but they all share this basic common understanding of the importance of *integrating* all aspects related to energy into a common systems framework. Given the focus on assessing *current* energy systems as well as possible transformation pathways into *future* energy systems throughout this publication, the Energy Primer also aims at providing historical context that helps to understand how current energy systems have emerged and what characteristic rates of change are in these large-scale systems.

After an introduction and roadmap to Chapter 1 (Section 1.1), Section 1.2 introduces the fundamental concepts and terms used to describe global energy systems (Section 1.2.1) and then proceeds with an overview of the fundamental driver: the demand for *energy services* (Section 1.2.2), which is key in this assessment. Section 1.2.3 then summarizes the major links between energy services and primary energy resources at the global level for the year 2005. The section also contains a summary of major energy units and scales (with technical details given in Appendix 1.A).

Section 1.3 then turns to a historical perspective on energy transitions, covering both energy end-use demand and services (Section 1.3.1), as well as energy supply (Section 1.3.2), and concludes with a brief introduction into the relationship between energy and economic growth (Section 1.3.3). A long historical perspective is important in understanding both the fundamental drivers of energy system transitions, as well as the constraints imposed by the typically slow rates of change in this large, capital-intensive system characterized by long-lived infrastructures (Grubler et al., 1999).

Section 1.4 then discusses the central aspect of energy efficiency, summarizing key concepts and measures of energy efficiency (Section 1.4.1), and estimates of global energy efficiencies based on the first (Section 1.4.2) and second law of thermodynamics (Section 1.4.3), as well as energy intensities (Section 1.4.4).

Section 1.5 provides a summary of key concepts (Section 1.5.1) and numbers of global *energy resources* that provide both key inputs and key limitations for energy systems. Fossil, fissile (Section 1.5.2), and renewable resources (Section 1.5.3) are covered comprehensively along with a basic introduction to energy densities, which are particularly critical for renewable energy (Section 1.5.4).

Section 1.6 provides a summary of major energy flows associated with production, use, and trade of energy (Section 1.6.2) and energy conversions (Section 1.6.3) that link energy resources to final energy demands. After an introduction and overview (Section 1.6.1), production, use, and trade of both direct (Section 1.6.2.1) and indirect "embodied" energy, (Section 1.6.2.2) are discussed, and all energy trade flows summarized in Section 1.6.2.3. The discussion of energy conversions is short, as it is dealt with in detail in the various chapters of this publication. After an introductory overview (Section 1.6.3.1), the electricity sector is briefly highlighted (Section 1.6.3.2).

Section 1.7 summarizes the main impacts of global energy systems on the environment in terms of emissions, including greenhouse gases (Section 1.7.2) and other pollutants where the energy sector plays an important role (Section 1.7.3). Emissions are central environmental externalities associated with all energy conversions.

Section 1.8 then complements the global synthesis of Chapter 1 by highlighting the vast heterogeneities in levels, patterns, and structure of energy use, by first introducing basic concepts and measures (Section 1.8.1), before addressing the heterogeneity across nations (Section 1.8.2), within nations (Section 1.8.3), as well as energy disparities (Section 1.8.4). This short section is of critical importance, especially in terms of a global assessment, as the inevitable top-down perspective involving Gigatonnes and Terawatts often glosses over differences in time, social strata, incomes, lifestyles, and human aspirations.

Section 1.9 provides a primer on basic economic concepts related to energy end-use and energy supply, using cooking in developing countries and electricity generation options as illustrative examples.

1 This text draws on, extends, and updates earlier publications by the authors including: Goldemberg et al., 1988; Nakicenovic et al., 1996b; 1998; Rogner and Popescu, 2000; Grubler, 2004; and WEA (World Energy Assessment), 2004.

Lastly, Section 1.10 leads into the full GEA, by providing an overview roadmap to the structure of GEA and its chapters.

Appendix 1.A returns to the rather technical, but nonetheless fundamental, aspect of units, scales, and energy accounting intricacies. This document uses uniformly the International System (SI) of (metric) units and has also adapted a uniform accounting standard for primary energy to achieve consistency and comparability across the different chapters. This is especially important in the energy field, that to date continues to use a plethora of vernacular units and accounting methods.

Appendix 1.B provides convenient summary tables of conversion and emission factors, and summarizes the various levels of regional aggregations used throughout GEA.

1.2 The Global Energy System

1.2.1 Description of the Global Energy System

The *energy system* comprises all components related to the production, conversion, and use of energy.

Key components of the energy system comprise: primary *energy resources* which are harnessed and converted to *energy carriers*[2] (such as electricity or fuels such as gasoline), which are used in end-use applications for the provision of *energy forms* (heat, kinetic energy, light, etc.) required to deliver final *energy services* (e.g., thermal comfort or mobility). The key mediator linking all energy conversion steps from energy services all the way back to primary resources are energy conversion *technologies*. Energy systems are often further differentiated into an *energy supply* and an *energy end-use* sector. The energy supply sector consists of a sequence of elaborate and complex processes for extracting energy resources, for converting these into more desirable and suitable forms of *secondary energy*, and for delivering energy to places where demand exists. The part of the energy supply sector dealing with primary energy is usually referred to as *"upstream"* activities (e.g., oil exploration and production), and those dealing with secondary energy as *"downstream"* activities (e.g., oil refining and gasoline transport and distribution). The energy end-use sector provides energy services such as motive power, cooking, illumination, comfortable indoor climate, refrigerated storage, and transportation, to name just a few examples. The purpose of the entire energy system is the fulfillment of demand for energy services in satisfying human needs.

Figure 1.1 illustrates schematically the architecture of the energy system as a series of linked stages connecting various energy conversion and transformation processes that ultimately result in the provision of goods and services. A number of examples are given for energy extraction, treatment, conversion, distribution, end-use (final energy), and energy services in the energy system. The technical means by which each stage is realized have evolved over time, providing a mosaic of past evolution and future options (Nakicenovic et al., 1996b).

Primary energy is the energy that is embodied in resources as they exist in nature: chemical energy embodied in fossil fuels (coal, oil, and natural gas) or biomass, the potential kinetic energy of water drawn from a reservoir, the electromagnetic energy of solar radiation, and the energy released in nuclear reactions. For the most part, primary energy is not used directly but is first converted and transformed into *secondary energy* such as electricity and fuels such as gasoline, jet fuel, or heating oil which serve as energy carriers for subsequent energy conversions or market transactions (Nakicenovic et al., 1996b).

Final energy ("delivered" energy) is the energy transported and distributed to the point of retail for delivery to final users (firms, individuals, or institutions). Examples include gasoline at the service station, electricity at the socket, or fuel wood in the barn. Final energy is generally exchanged in formal monetary market transactions, where also typically energy taxes are levied. An exception are so-called non-commercial fuels – i.e., fuels collected by energy end-users themselves such as fuel wood or animal wastes, which constitute important energy sources for the poor.

The next energy transformation is the conversion of final energy in end-use devices such as appliances, machines, and vehicles into *useful energy* such as the energy forms of kinetic energy or heat. Useful energy is measured[3] at the crankshaft of an automobile engine, by the mechanical energy delivered by an industrial electric motor, by the heat of a household radiator or an industrial boiler, or by the luminosity of a light bulb. The application of useful energy provides *energy services* such as a moving vehicle (mobility), a warm room (thermal comfort), process heat (for materials manufacturing), or light (illumination).

Energy services are the result of a combination of various technologies, infrastructures (capital), labor (know-how), materials, and energy forms and carriers. Clearly, all these input factors carry a price tag and, within each category, are in part substitutable for one another. From the consumer's perspective, the important issues are the quality and cost of energy services. It often matters little what the energy carrier or the "upstream" primary energy resource was that served as input. It is fair to say that most consumers are often unaware of the upstream activities of the energy system. The energy

2 In the literature (e.g. Rosen, 2010, Scott, 2007, Escher, 1983) also the term *energy currency* is used to highlight the fact that different energy carriers are to a degree interchangeable and can be converted to whatever form is most suitable for delivering a given energy service task. Like monetary currencies, energy currencies are also exchangeable (at both an economic and [conversion] efficiency price). In this assessment, the term energy carrier is used throughout. A concise compendium of energy-related concepts and terms is given in Cleveland and Morris, 2006.

3 Useful energy can be defined as the last measurable energy flow before the delivery of energy services.

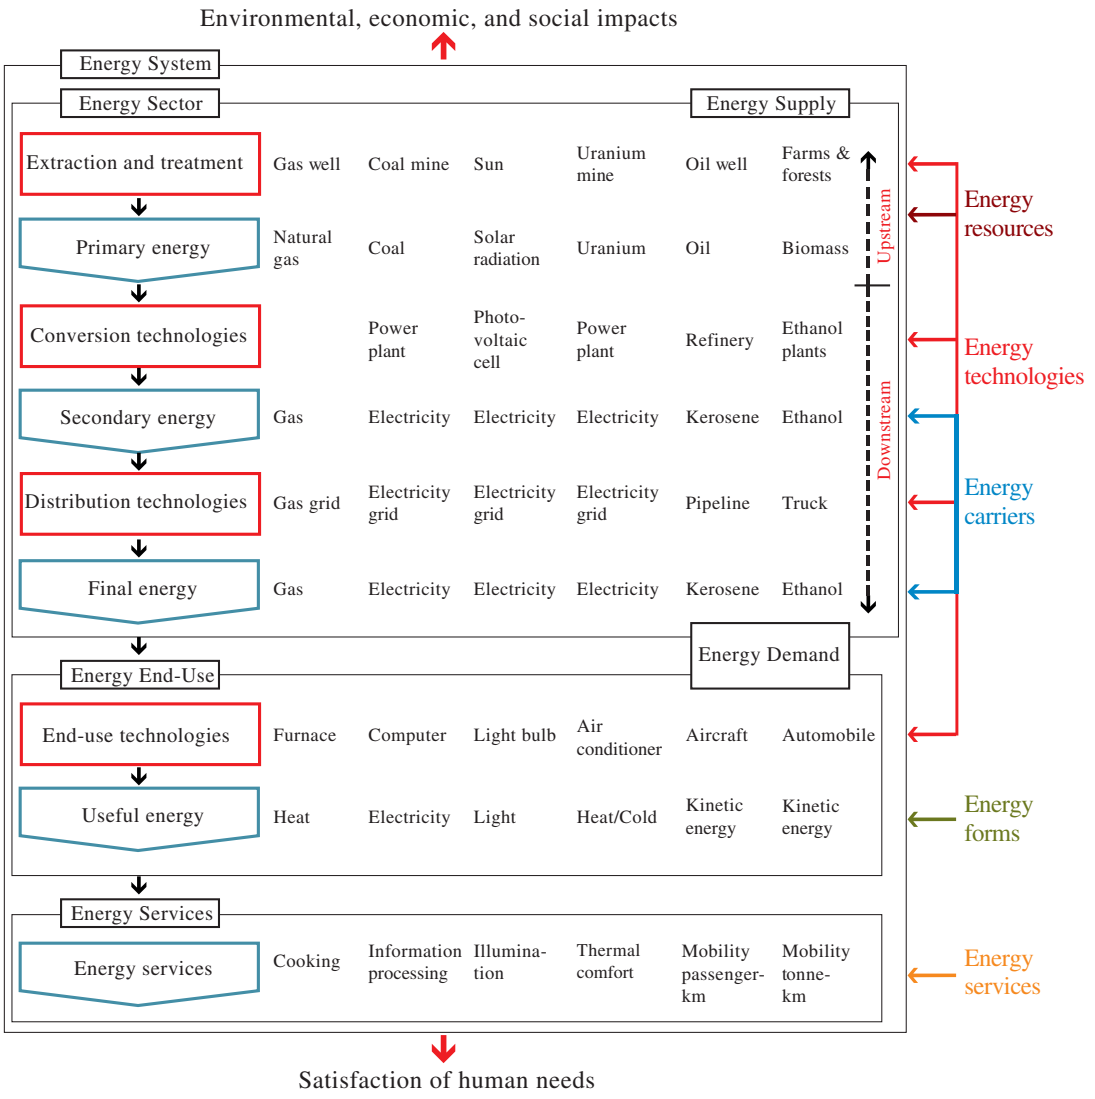

Figure 1.1 | The energy system: schematic diagram with some illustrative examples of the energy sector and energy end use and services. The energy sector includes energy extraction, treatment, conversion, and distribution of final energy. The list is not exhaustive and the links shown between stages are not "fixed"; for example, natural gas can also be used to generate electricity, and coal is not used exclusively for electricity generation. Source: adapted from Nakicenovic et al., 1996b.

system is *service driven* (i.e., from the bottom-up), whereas energy flows are driven by resource availability and conversion processes (i.e., from the top-down). Energy flows and driving forces interact intimately. Therefore, the energy sector should never be analyzed in isolation: it is not sufficient to consider only how energy is supplied; the analysis must also include how and for what purposes energy is used (Nakicenovic et al., 1996b).

Figure 1.2 illustrates schematically the major energy flows through the global energy system across the main stages of energy transformation, from primary energy to energy services, with typical examples. For an exposition of energy units see Box 1.1 below and Appendix 1.A.

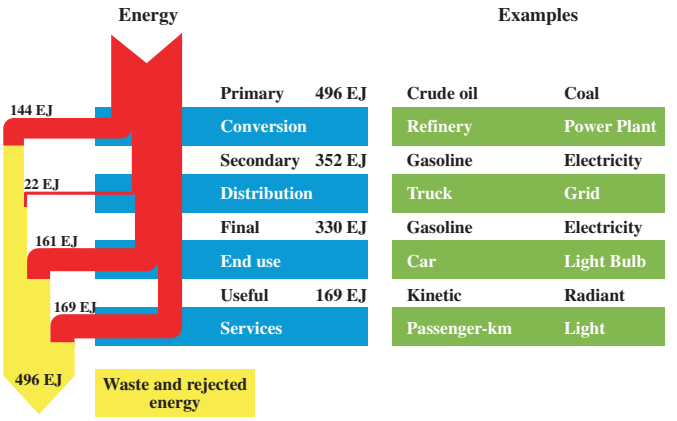

Figure 1.2 | Global energy flows of primary to useful energy, including conversion losses (waste and rejected energy), in EJ for 2005. Source: adapted from Nakicenovic et al., 1998, based on IEA, 2007a; 2007b; 2010.

Box 1.1 | Energy Units and Scales

Energy is defined as the capacity to do work and is measured in joules (J), where 1 joule is the work done when a force of 1 Newton (1 N=1 kg m/s^2) is applied over a distance of 1 meter. Power is the rate at which energy is transferred and is commonly measured in watts (W), where 1 watt is 1 joule/second. Newton, joule, and watt are defined as basic units in the International System of Units (SI).[4]

Figure 1.3 gives an overview of the most commonly used energy units and also indicates typical (rounded) conversion factors. Next to the SI units, other common energy units include kilowatt-hour (kWh), used to measure electricity and derived from the joule (1 kWh – 1000 Watt-hours – being equivalent to 3600 kilo-Watt-seconds, or 3.6 MJ). In many international energy statistics (e.g., by the IEA and OECD) tonnes of oil equivalent (1 *toe* equals 41.87 x 10^9 J) are used. Some national energy statistics (e.g., in China and India) report tonnes of coal equivalent (1 *tce* equals 29.31 x 10^9 J).

The energy content of combustible energy resources (fossil fuels, biomass) is expressed based on either the so-called higher (HHV) or lower heating value (LHV). For non-combustible energy resources (nuclear, hydropower, wind energy, etc.) different conventions exist to convert those into primary energy equivalents. (For a detailed discussion see Appendix 1.A). In this publication non-combustible energies are accounted for using the so-called substitution equivalent method, with 1 kWh of nuclear/renewable electricity equivalent to some 3 kWh of primary energy equivalent, based on the current global average conversion efficiency of 35%. Combustible energies are reported based on the LHV of fuels.

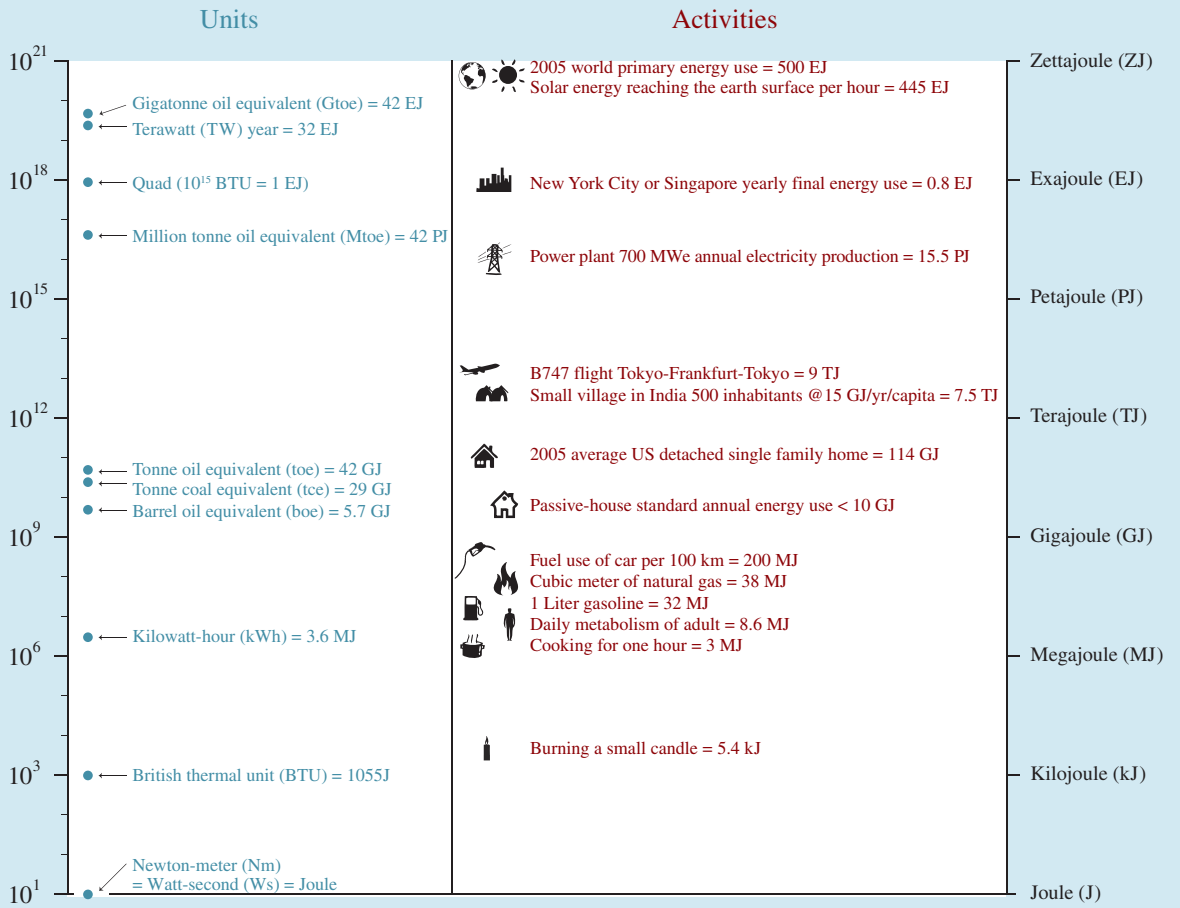

Figure 1.3 | Illustrative examples of energy units and scales used in the GEA.

4 International System of Units, *SI* from the French *le Système international d'unités*

1.2.2 Energy Services

Despite the centrality of energy services for the energy system, their measurement and statistical reporting is sparse. As the different types of energy services – from passenger and goods transport to illumination, to materials produced and recycled, to information communicated – are so diverse, activity levels are non-commensurable (i.e., cannot be expressed in common units). Hence energy service levels are often assessed via their required energy *inputs* (useful, final, or primary energy) rather than by their actual *outputs.* This can distort the picture quite substantially, as those energy services with the lowest conversion efficiency (and thus highest proportional energy inputs) are over-weighted in the energy accounts. Measuring services via inputs rather than outputs can also significantly mask the enormous efficiency gains which have historically characterized technological change in energy end-use applications (from candles to white diode lighting, or from horses to electric vehicles), and which generally go unnoticed in long-term estimates of economic productivity and welfare growth (see Nordhaus, 1998).

A notable global assessment of energy service provision is given by Cullen and Allwood (2010) and summarized in Table 1.1 below. The assessment used primary energy as a common energy metric, which is problematic for energy services due to the ambiguities of primary energy accounting conventions (see Appendix 1.A). Using primary energy inputs to characterize energy services also gives greater weight to lesser efficient energy service provision chains. A passenger-km traveled by car is accounted and weighted for by its much larger primary energy inputs (crude oil) compared to a passenger-km traveled by bicycle (food caloric intake). The multitude of energy services summarized here can be conveniently grouped into three broad categories and are assessed in separate chapters in this publication: Industry (Chapter 8), Transportation (Chapter 9), and Buildings (Chapter 10), which are the physical structures in which the remainder of energy services are provided.

It is useful to put these rather abstract engineering-type summary estimates of energy service levels into perspective – for example, on a per capita basis for a global population of 6.5 billion in 2005. These illustrative global average levels of energy service provision should not distract from the vast heterogeneity in levels of energy service provision between rich and poor, or between urban and rural populations (see Section 1.8 below).

Transport: The 46 trillion tonne-km and 32 trillion passenger-km translate into a daily average mobility of some 13 km/day/person, and transporting on average 1 tonne/day per capita over a distance of some 20 km.

Industry: The structural materials summarized in Table 1.1 translate in absolute terms into close to 2 billion tonnes (Gt) of cement, 1 Gt of crude steel, some 0.3 Gt of fertilizer, 0.1 Gt of non-ferrous metal ores processed, and over 50 million tonnes of plastics produced per year (UN, 2006a, 2006b). Estimates of the global total material flows reveal a staggering magnitude of the industrial metabolism (Krausmann et al., 2009). In terms of tonnage, humankind uses each year (values for 2005) some 12 Gt of fossil energy resources, some 6 Gt of industrial raw materials and metals (ores and minerals), 23 Gt of construction materials (sand, gravel, etc.), and an additional 19 Gt of biomass (food, energy, and materials), for a total material mobilization of approximately 60 Gt/year, or more than 9 tonnes/year per capita on average. The use of around 10 Gt of energy thus enables the "leverage" of the mining, processing, refinement, and use of an additional 50 Gt of materials.

Buildings: The size of the residential and commercial building stock worldwide (2005 data) whose internal climate needs to be maintained through heating and cooling energy services is estimated to be about 150 billion m^2 (including some 116 billion m^2 residential and 37 billion m^2 commercial floorspace, see Chapter 10) which corresponds to approximately 20 m^2 per person on average.

Table 1.1 | Estimated levels of energy services and corresponding shares in primary energy per service type for the year 2005.

Energy service	2005 levels	Units	As a percentage of pro-rated primary energy use (including upstream conversion losses)
Thermal comfort	30	10^{15} m^3K (degree-volume air)	19%
Sustenance (food)	28	10^{18} J (food)	18%
Structural materials	15	10^9 $MPa^{2/3}m^3$ (tensile strength × volume)	14%
Freight transport	46	10^{12} ton-km	14%
Passenger transport*	32	10^{12} passenger-km	14%
Hygiene	1.5 2.8	10^{12} m^3K (temperature degree-volume of hot water) 10^{18} Nm (work)	11%
Communication	280	10^{18} bytes	6%
Illumination	480	10^{18} lumen-seconds	4%

* The original passenger transport data have been corrected by adding non-reported categories provided in Chapter 9.

Source: adapted from Cullen and Allwood, 2010.

Useful energy as a common energy input denominator minimizes distortions among different energy service categories, as it most closely measures the actual energy service provided. Chapter 1 has, therefore, produced corresponding useful energy estimates based on the 2005 energy balances published by the International Energy Agency (IEA, 2007a and 2007b) using typical final-to-useful conversion efficiencies available in the literature (Eurostat, 1988; Rosen, 1992; Gilli et al., 1996; BMME, 1998; Rosen and Dincer, 2007). This method has some drawbacks, as the available energy balances are based on an economic sectoral perspective, which does not always perfectly correspond with

Table 1.2 | Energy service levels, world in 2005, as estimated by their corresponding useful and final energy inputs (in EJ, and as share of total; see also Footnote 5).

Energy service	Final energy [EJ]	*As percentage of total final energy* [%]	Useful energy [EJ]	*As percentage of total useful energy* [%]
Transport				
Road	66.9	*20.3*	13.7	*8.1*
Rail	2.3	*0.7*	1.1	*0.7*
Shipping	9.0	*2.7*	3.0	*1.8*
Pipelines	2.9	*0.9*	0.9	*0.5*
Air	10.3	*3.1*	3.0	*1.8*
Total transport	91.4	*27.7*	21.7	*12.9*
Industry				
Iron and steel	14.4	*4.4*	11.5	*6.8*
Non-ferrous metals	4.0	*1.2*	1.9	*1.1*
Non-metallic minerals	11.1	*3.4*	4.5	*2.7*
Other	58.7	*17.8*	44.3	*26.3*
Total industry	88.2	*26.8*	62.2	*36.9*
Other sectors				
Feedstocks	30.2	*9.2*	25.0	*14.8*
Agriculture, forestry, fishery	7.5	*2.3*	3.0	*1.8*

particular energy service types.[5] It needs to be emphasized that different forms of useful energy (such as thermal versus kinetic energy) are not interchangeable, even when they are expressed in a common energy unit and aggregated. Global totals for useful and final energy inputs per energy service category are summarized in Table 1.2 (see also Figure 1.5 below), with regional details given in Figure 1.6 below.

The largest category of energy service demands arise in **industry** (62 EJ of useful energy in 2005), with the dominant energy service application being (high-temperature) industrial process heat associated with the processing, manufacturing, and recycling of materials. *Feedstocks* refer to non-energy uses of energy, where energy carriers serve as a raw material (e.g., natural gas used for the manufacture of fertilizers), rather than as an input to energy conversion processes proper. Feedstocks are also associated with industrial activities (the chemical sector) and add another 25 EJ of useful energy to the 62 EJ of industrial energy service demands.

The residential and commercial sectors (some 57 EJ of useful energy in 2005) are dominated by the energy use associated with **buildings**, both in maintaining a comfortable indoor climate (heating and air conditioning), as well as various energy services performed *within* buildings such as cooking, hygiene (hot water), and the energy use of appliances used for entertainment (televisions) or communication (computers, telephones). Agriculture, forestry, and fisheries are comparatively minor in terms of useful energy (3 EJ) and are only summarily included in the "other sectors" category here.

Transport is comparatively the smallest energy service category when assessed in terms of useful energy, with an estimated level of 22 EJ (some 13% of total useful energy, but due to low conversion efficiencies, some 28% in total primary energy, see Table 1.1 above). Road transportation (cars, two- and three-wheelers, buses, and trucks) are the dominant technologies for providing mobility of people and goods. Due to the low final-to-useful conversion efficiency associated with internal combustion engines (some 20% only, with 80% lost as waste heat of engines and associated with friction losses of drive trains), road transport accounts for only 8% of useful energy but for approximately 20% of total final energy. This example once more highlights the value of an energy service perspective (Haas et al., 2008) on the energy system, by looking at service outputs rather than final or primary energy inputs that overemphasize the least efficient energy end-use applications. Nonetheless, it needs to be noted (see the discussion below) that transportation is one of the fastest growing energy demand categories. This adds further emphasis on efforts to improve transport energy efficiency, which has both technological (more efficient vehicles), as well as behavioral and lifestyle dimensions (changing mobility patterns, shifts between different transport modes – e.g., by using public transportation or bicycles instead of private motorized vehicles).

Global trends since 1971 for different energy service categories and in measuring final energy inputs are shown in Figure 1.4.

1.2.3 From Energy Services to Primary Energy

Figure 1.5 illustrates the interlinkages of global energy flows from useful energy up to the level of primary energy, and also shows major energy carriers and transformations. Different primary energies require different energy system structures to match the demand for type and quality of energy carriers and energy forms with available resources.

As a result, there is great variation in the degree and type of energy conversions among different fuels in the global energy system. At the one extreme, biomass is largely used in its originally harvested form and burned directly without intervening energy conversions. At the other extreme are nuclear, hydropower, and modern renewables that are not used in their original

5 For instance, transport energy use is reported by mode of transport (road, rail, sea, air) in the underlying IEA statistics, which does not allow differentiation between passenger and goods transport.

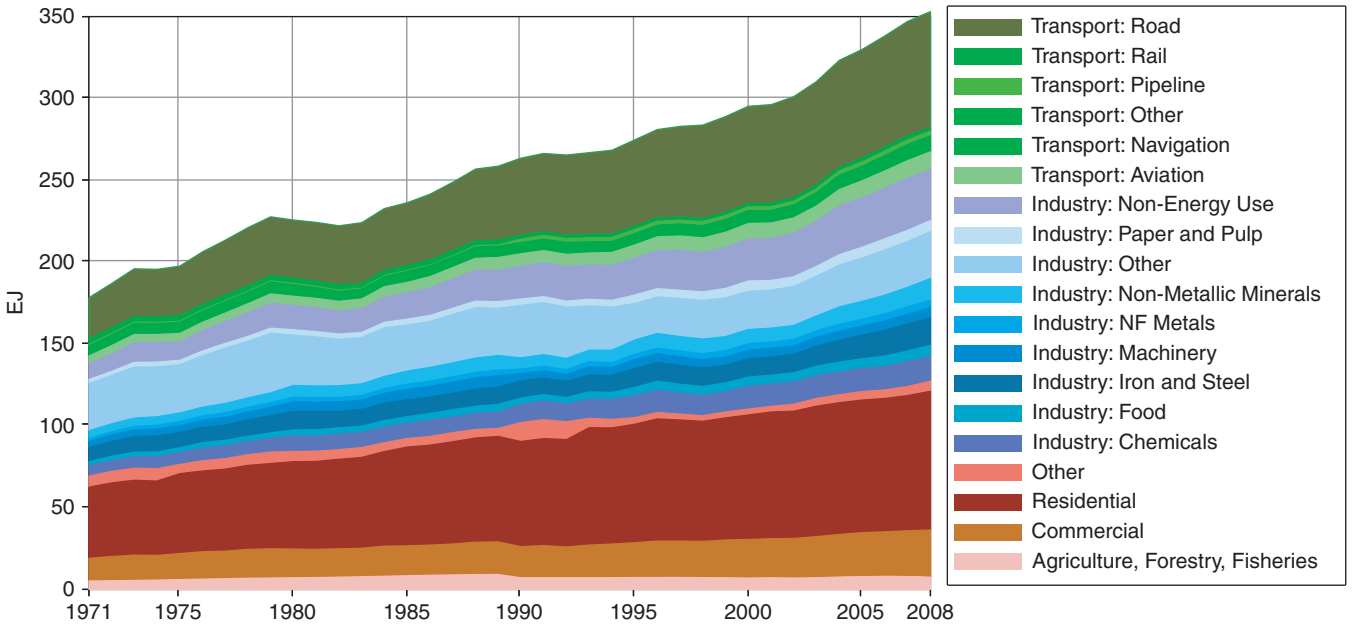

Figure 1.4 | Global final energy input into different energy services categories since 1971 (in EJ), by major energy service category. Source: adapted from IEA, 2010.

resource state but converted into electricity. Electricity is the energy carrier with the highest versatility of providing different energy forms required for various energy services (heat, light, mobility). Crude oil also needs to be converted (refined) to the liquid fuels required for energy end-uses (gasoline, diesel, kerosene, for cars, trucks, and aircraft), or for further secondary energy conversions (e.g., fuel oil-fired power plants generating electricity). Coal is a major input for electricity generation and for specific industrial uses (metallurgy) but is not often used in direct form outside these two applications (remaining uses for residential heating/cooking are declining rapidly due to air pollution concerns). Conversely, natural gas is a major energy carrier directly used as final energy and for end-uses, mainly due to its convenience (grid delivered, no combustion ashes to dispose of) and cleanliness. Natural gas is also increasingly being used in electricity generation, where the advent of highly efficient combined cycle power plants with flat economies of scale (i.e., costs per MW capacity are not significantly different across different plant sizes) allows fast construction of modular units. Due to the low emission characteristics of these highly efficient conversion processes, plants can also often be located in high demand density areas, thus opening up the possibility of using waste heat from electricity generation for industrial and residential customers, a scheme known as *cogeneration* or combined heat and power production (CHP).

From an energy systems perspective, the electricity sector assumes a special role (also the reason why it is discussed in greater depth in Section 1.6.3 on Energy Conversions below.) Electricity generation is the energy conversion process that can accommodate the greatest diversity of primary energy inputs. As shown in Figure 1.5, all primary energy carriers enter to different degrees into electricity generation, from biomass, to all fossils, nuclear, hydro, and new renewables. Electricity is also a very specific energy carrier: its absolute cleanliness at the point of end-use (not necessarily at the point of electricity generation, however) and its high energy quality translate into the greatest versatility and flexibility in delivering whatever type of energy form and energy service required. However, electricity cannot be stored easily, which means that generation needs to follow the inevitable intertemporal variations of electricity demand over the seasons, during the day, even during minute-intervals.[6]

Overall, there is great variation in energy systems structures across different regions as a result of differences in the degree of economic development, structure of energy demand, and resource availability, among others. These differences are summarized at the level of useful, final, and primary energy respectively for the 5 GEA regions and the world in Figure 1.6.

1.3 Historic Energy Transitions

1.3.1 Transitions in Energy End-Use (United Kingdom)

Levels and structure of energy services have changed dramatically since the onset of the Industrial Revolution, reflecting population and income growth and, above all, technological change. Due to the "granular" nature of energy services, the measurement intricacies discussed above, and the traditional focus of energy statistics on (primary) energy supply, it is not possible to describe long-term transition in energy services and

6 The variation in electricity demand over time is enshrined in the concept of *load curves* that describe the instantaneous use of electric power (in Watts or typically rather GW) over time (on a daily, weekly, or monthly basis). A cumulative load curve over all of the 8760 hours of a year, sorted by declining GW load, yields a *load duration curve* (or cumulative load curve) that helps to design a whole electricity system and to dimension different types of power plants used for *peak*, *intermediate*, and *base load* electricity generation.

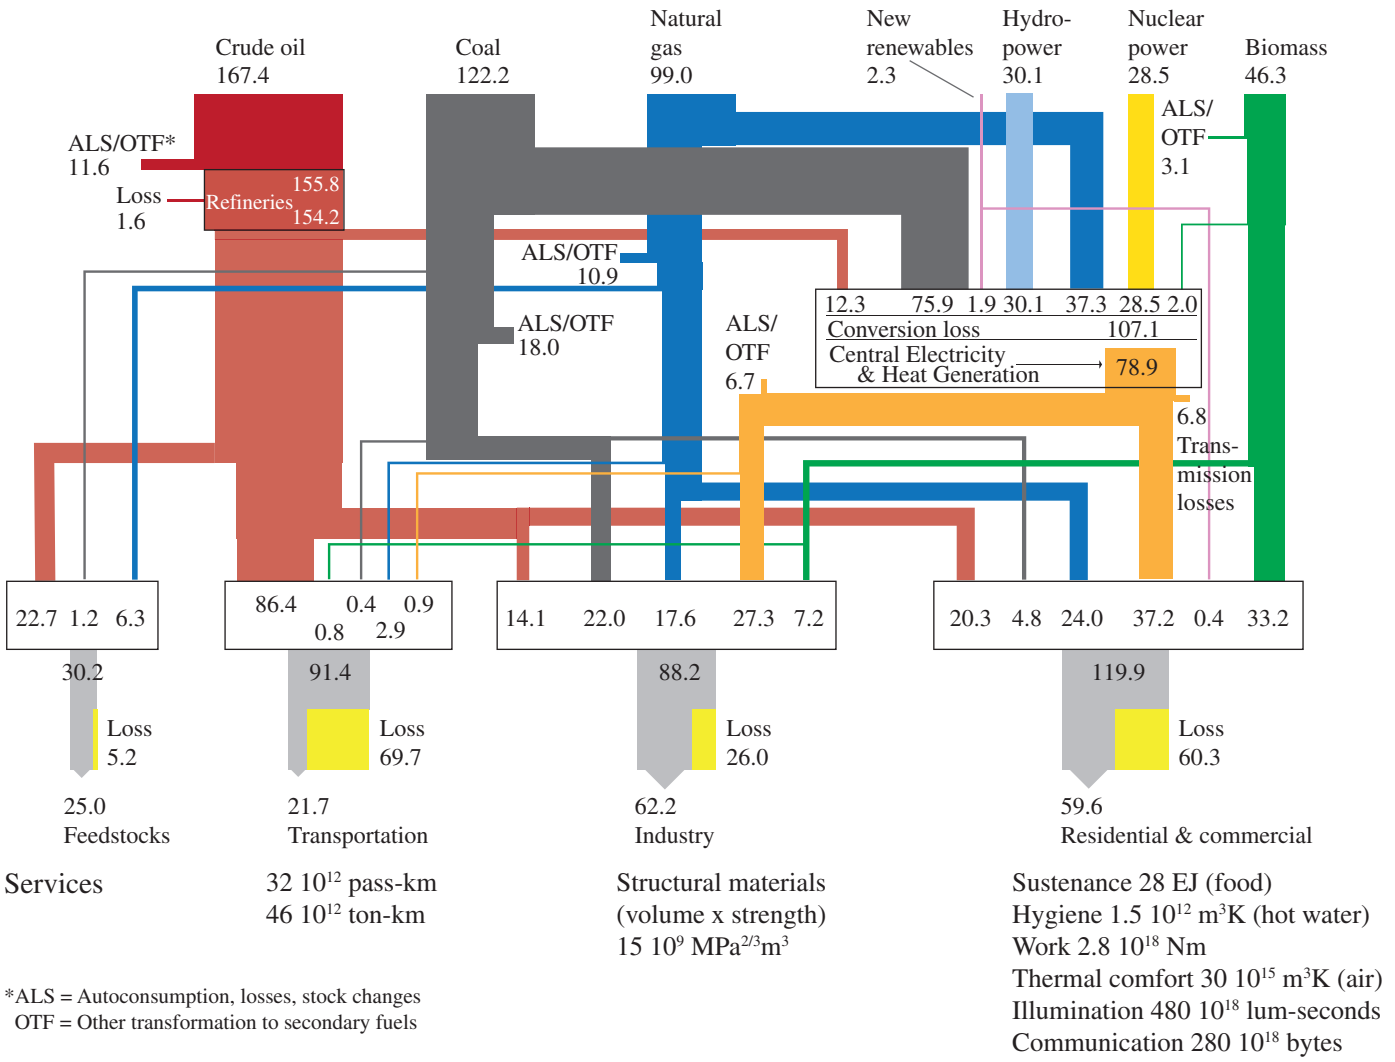

Figure 1.5 | Global energy flows (in EJ) from primary to useful energy by primary resource input, energy carriers (fuels) and end-use sector applications in 2005. Source: data from IEA, 2007a; b[7] (corrected for GEA primary energy accounting standard), and Cullen and Allwood, 2010.

7 Readers should note some small differences (1–5%) between the 2005 base year energy flows reported in Chapter 1 and the ones derived from Chapter's 17 scenario modeling and reported in the GEA Scenario Data Base. Whereas Chapter 1 is based exclusively on statistics as reported by the International Energy Agency (IEA), Chapter 17 and the GEA Scenario data base also include data revisions and draw at times different system boundaries for the accounting of energy flows, in line with standard energy modeling practices.

The largest global differences are for final energy (330 vs. 315 EJ in Chapters 1 and 17 respectively) related to: (a) new improved estimates of non-commercial energy use based on household surveys that have revised downwards the IEA statistics on residential, traditional biomass use; and (b) different accounting of energy use for pipeline transportation, and bunker fuels for international shipping which are accounted in Chapter 17 as energy-sector auto-consumption and at the international level only whereas in Chapter 1 they are accounted at the national and regional levels as final transport energy use. Differences in global primary energy are smaller (496 vs. 489 EJ between Chapters 1 and 17 respectively, for the same reasons as outlined above).

These small energy accounting differences are within the inevitable uncertainty range of international energy statistics (for a review see Appendix 1.A) and do not diminish the coherence of this Assessment.

energy end-use on the global scale. Long-term detailed national-level analyses are available for the United States (Ayres et al., 2003) and the United Kingdom (Fouquet, 2008), as well as (for shorter time horizons) in the form of useful energy balances for Brazil (BMME, 1998).

The long-term evolution and transitions in energy end-use and energy services is described below for the United Kingdom over a time period of 200 years. The United Kingdom is used as an illustrative example, not only due to the level of detail and time horizon of the original data available, but particularly because of its history of being the pioneer of the Industrial Revolution, which thus illustrates the interplay of industrialization, income growth, and technological change as drivers in energy end-use transitions.

Figure 1.7 illustrates the growth in energy service provision for the United Kingdom since 1800 by expressing the different energy services in terms of their required final energy inputs. Three main periods can be distinguished:

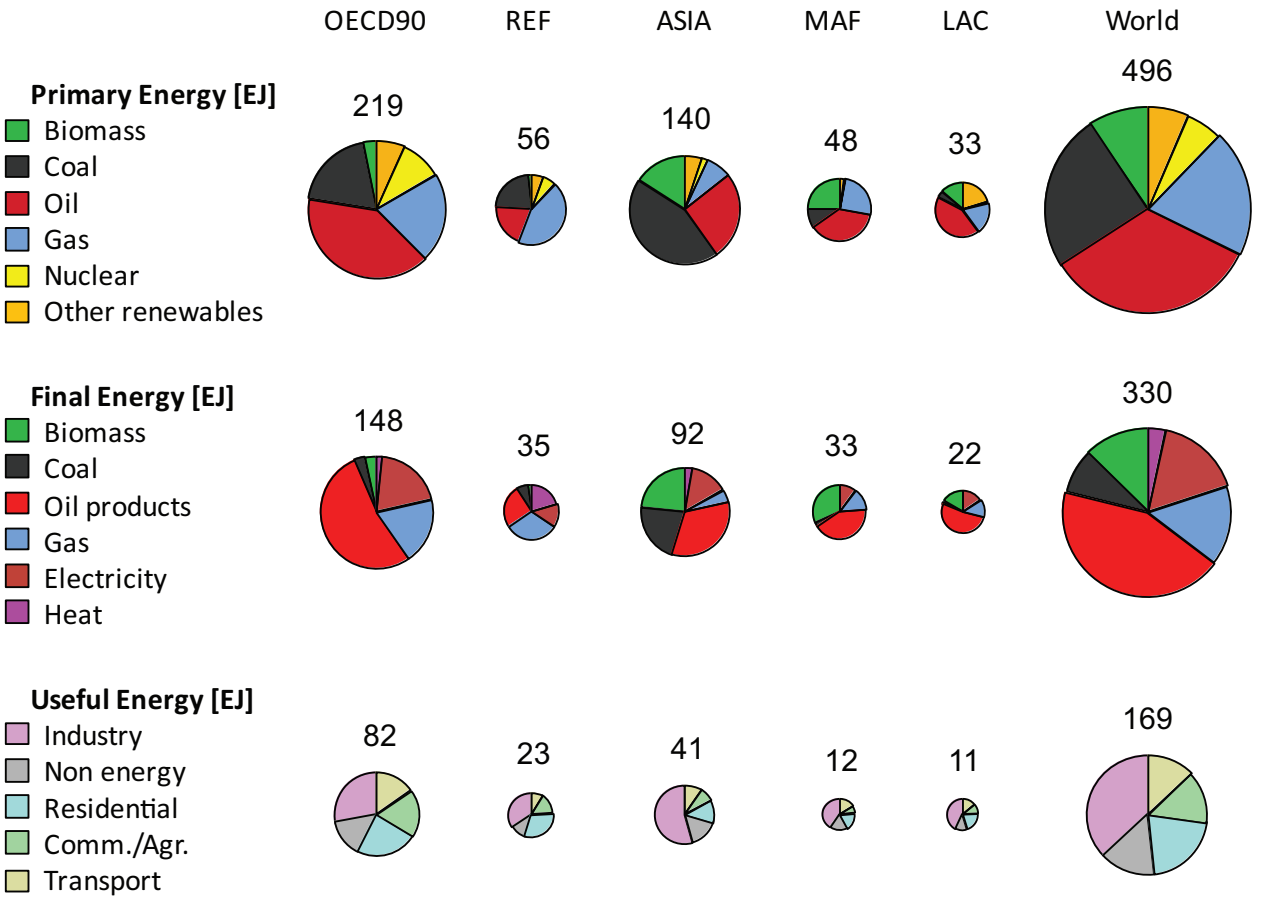

Figure 1.6 | World energy use: primary energy (by fuel), final energy (by energy carrier), and useful energy (by sector/type of energy service) for the world and five GEA regions for 2005 (in EJ). Source: based on IEA, 2007a and 2007b (corrected for GEA primary accounting standard, see also Footnote 5, above). For a definition of the GEA regions, see Appendix 1.B.

a regular expansion of energy services in the 19th century that characterized the emergence of the United Kingdom as a leading industrial power, in which growth is dominated by industrial energy service demands and to a lesser degree by rapidly rising transportation services enabled by the introduction of steam-powered railways;

a period of high volatility as a result of cataclysmic political and economic events (World War I, the Great Depression of 1929, and World War II) that particularly affected industrial production and related energy services; and

a further (more moderated) growth phase after 1950, again punctuated by periods of volatility, such as the energy crisis of the 1970s characterized by the gradual decline of industrial energy services, compensated by strong growth in passenger transportation resulting from the diffusion of petroleum-based collective, and individual transport technologies (buses, aircraft, and cars).

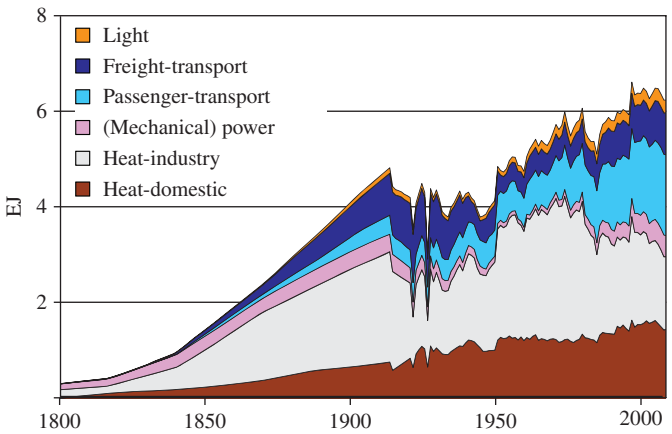

Figure 1.7 | Growth in energy service demand (measured by final energy inputs) United Kingdom since 1800, in EJ. Source: data from Fouquet, 2008. Updates after 2000 and data revisions courtesy of Roger Fouquet, Basque Centre for Climate Change, Bilbao, Spain.

At present, levels of energy services appear saturated at a level of above 6 GJ, or 100 GJ of final energy input equivalent per capita. Industry (with an ever declining share) accounts for about 30% of all energy services, residential applications (with a stable share) for another 30%, and transportation (with an ever growing share) for about 40% of total energy services.

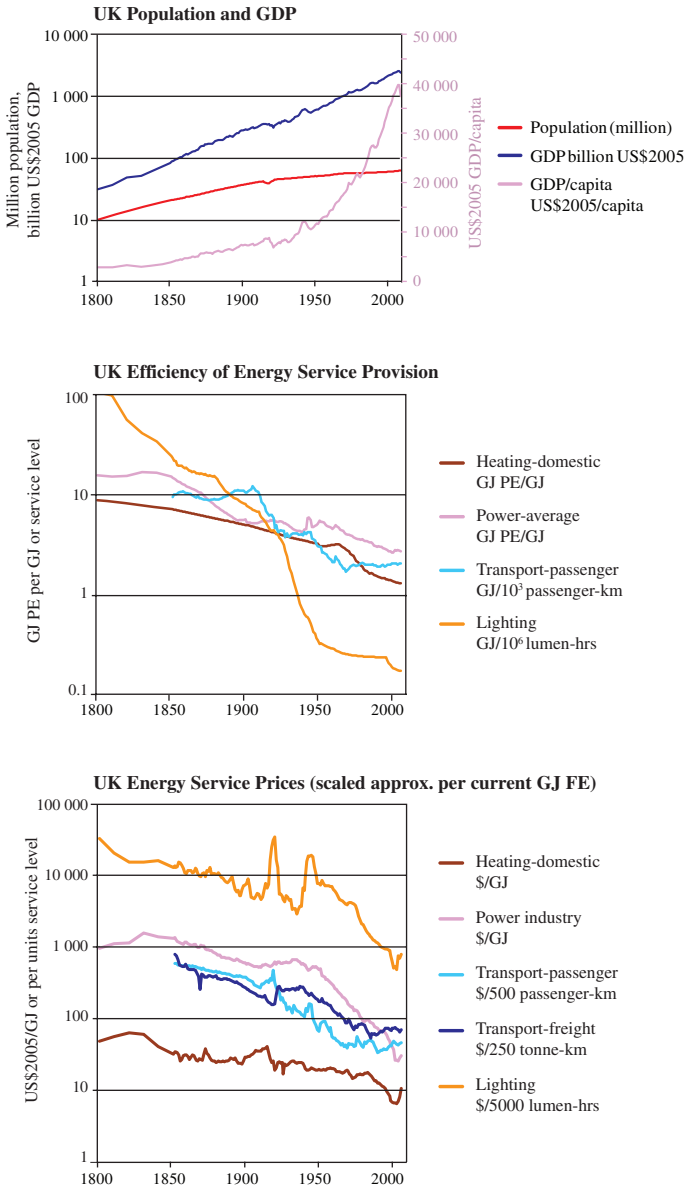

Figure 1.8 | Drivers of UK energy service demand growth: population, GDP and income per capita (panel 1); efficiency of energy service provision (per GJ service demand or service activity level – panel 2); and prices of energy services (per GJ service demand or activity level, activity level units have been normalized to approximately equal one GJ of current final energy use – panel 3). Source: data from Fouquet, 2008. Updates after 2000 and data revisions courtesy of Roger Fouquet, Basque Centre for Climate Change, Bilbao, Spain.

Figure 1.8 illustrates the evolution of the determinants of the growth in UK energy services and shows the mutually enhancing developments that led to the spectacular growth in energy services since 1800 (by a factor of 15 when measuring final energy inputs, and much more – perhaps as much as by a factor of 100 – when considering the significant improvements in the efficiency of energy service provision that have ranged between a factor of five for transportation, to up to a factor of 600 for lighting, see Fouquet, 2008). Population growth (from 10 million to 60 million people) and rising incomes (per capita Gross Domestic Product (GDP) has grown from some US$3000 at 2005 price levels and exchange rates in 1800, to close to US$40,000 at present) increase both the demand for energy services[8] and the purchasing power of the population to afford traditional, as well as novel energy services.

Improvements in the energy efficiency of service provision and other technological improvements in turn are key factors contributing to the significant lowering of energy service prices, which have declined by a factor of under 10 for heating to over 70 for lighting since 1800. In short, more consumers that became more affluent enjoy increasingly energy-efficient and cheaper energy services, which fuels growth in energy service demand (a positive feedback loop in the terminology of systems science). A narrow interpretation of this dynamic process of increasing returns to adoption (e.g., costs of technologies and energy services decline, the higher their market application) as a simple "take-back"[9] effect, represent a static "equilibrium" perspective of energy systems evolution. The history of technological revolutions in energy services and in energy supply suggests rather a "dis-equilibrium" interpretation of major energy transitions: the transformation is so far-reaching that the ultimate future state of the system could have never been reached by incremental improvements in efficiency and costs of existing technologies and energy services. *"Add as many mail-coaches as you please, you will never get a railroad by so doing"* (Joseph A. Schumpeter, 1935).

1.3.2 Transitions in Energy Supply Systems (Global)

The history of energy transitions is a story of development interlaced with periods of crisis and shortages. The Neolithic revolution brought the first transformational change. Hunters and gatherers settled and turned to agriculture. Their energy system relied on harnessing natural energy flows, animal work,

8 There are both direct as well as indirect effects on energy service demands. A larger population translates into more food to cook, more people needing housing, etc., and a corresponding growth in related energy services. Higher incomes from economic growth imply growth in energy service demand in industrial and commercial activities and related services. This growth in energy service demand is "indirect" in the sense that production-related energy services are embedded in the private consumption of goods and services by private households and public services (schools, hospitals, etc.). Lastly, higher incomes make traditionally expensive energy services (such as air transportation) affordable for larger segments of society, an effect amplified by decreasing prices for energy services resulting from energy efficiency and other technology improvements.

9 The "take-back" (or "rebound") effect describes a situation where an improvement in energy efficiency leads to lower energy costs and hence consumer savings, which are often spent on (energy-intensive) consumption activities. Part of the energy savings is thus "taken back" by changed consumer expenditures. For example, a new, more energy-efficient car, with lowered fuel costs, can lead to driving more, or alternatively to spending the saved fuel bill on additional recreational air travel. This effect was first postulated by William Stanley Jevons in 1865 (and hence is referred to also as "Jevons Paradox," see also Binswanger, 2001). Empirical studies suggest that in high-income countries the take-back effect can be anywhere between 0% and 40% (see the 2000 special issue of *Energy Policy* 28(6–7) and the review in Sorell et al., 2009). If absolute reductions of energy use are on the policy agenda, compensating for take-back effects leads to increases in energy prices via taxes. Studies in developing countries (Roy, 2000) – e.g., on compact fluorescent lighting – suggest that take-back effects can approach 100%. In this case, the effect of energy efficiency improvements are less in reductions of total energy use but rather in vastly increased human welfare.

and human physical labor to provide the required energy services in the form of heat, light, and work. Power densities and availability were constrained by site-specific factors, with mechanical energy sources initially limited to draft animals and later to water and windmills. The only form of energy conversion was from chemical energy to heat and light – through burning fuel wood, for example, or tallow candles (Nakicenovic et al., 1998). It is estimated that early agricultural societies were based on annual energy flows of about 10–20 GJ per capita, two-thirds in the form of food for domesticated animals and humans, and the other third in the form of fuel wood and charcoal for cooking, heating, and early industrial activities such as ore smelting (Smil, 2010). China already experienced acute wood and charcoal shortages in the north of the country by the 13th century. In Europe, and particularly in the UK, domestic fuel wood became increasingly scarce and expensive as forests were overexploited without sufficient replanting or other conservation measures (Ponting, 1992).[10]

The fuel crisis was eventually overcome through a radical technological end-use innovation: the steam engine powered by coal.[11] The steam cycle represented the first conversion of fossil energy sources into work; it allowed the provision of energy services to be site-independent, as coal could be transported and stored as needed; and it permitted power densities previously only possible in exceptional locations of abundant hydropower (Smil, 2006). Stationary steam engines were first introduced for lifting water from coal mines, thereby facilitating increased coal production by making deep-mined coal accessible. Later, they provided stationary power for what was to become an entirely new form of organizing production: the factory system. Mobile steam engines, on locomotives and steam ships, enabled the first transport revolution, as railway networks were extended to even the most remote locations and ships were converted from sail to steam. While the Industrial Revolution began in England, it spread[12] throughout Europe, the United States and the world. Characteristic primary energy use levels during the "steam age," (the mid-19th century in England), were about 100 GJ/year per capita (Nakicenovic et al., 1998). These levels exceed even the current average global energy use per capita. By the turn of the 20th century, coal had become the dominant source of energy, replacing traditional non-fossil energy sources, and supplied virtually all of the primary energy needs of industrialized countries.

Figure 1.9 shows the exponential growth of global energy use at a rate close to 2%/yr since the advent of the Industrial Revolution. Figure 1.10 is based on the same data and shows relative shares of different primary energy sources. Substitution of traditional energy sources by coal characterized the first phase of the energy revolution – the "steam revolution" – a transformation that lasted until the early 1920s when coal reached its maximal share of close to 50% of global primary energy.

The second "grand" energy transformation also lasted for about 70 years. Primary energy demand increased even more rapidly, reaching 5% or even 6% growth annually, from the late 1940s to the early 1970s. This development phase was characterized by increasing diversification of both energy end-use technologies and energy supply sources. Perhaps the most important innovations were the introduction of electricity as an energy carrier which could be easily converted to light, heat, or work at the point of end-use, and of the internal combustion engine, which revolutionized individual and collective mobility through the use of cars, buses, and aircraft (Nakicenovic et al., 1998). Like the transition triggered by the steam engine, this "diversification transformation" was led by technological innovations in energy end-use, such as the electric light bulb, the electric motor, the internal combustion engine, and aircraft, as well as computers and the Internet, which revolutionized information and communication technologies.

However, changes in energy supply have been equally far-reaching. In particular, oil emerged from its place as an expensive curiosity at the end of the 19th century to occupy the dominant global position, where it has remained for the past 60 years. The expansion of natural gas use and electrification are other examples of important changes in energy supply in the 20th century. The first electricity generation systems were based on the utilization of small-scale hydropower, followed by a rapid expansion of thermal power-generating capacity utilizing coal, oil, and more recently, natural gas. Commercial nuclear power stations were increasingly put into operation in the period from 1970 to 1990. Renewable sources other than hydropower have become more intensively explored for electricity generation since the mid-1970s, with most of the new capacity being added during the past decade.

Despite these fundamental changes in the energy system from supply to energy end-use, the dynamics of energy system transformations have slowed down noticeably since the mid-1970s. Figure 1.10 shows that after oil reached its peak market share of some 40% during the early 1970s, the 1990s and the first decade of the 21st century saw a stabilization of the historical decline in coal's market share, and a significant slowdown in the market growth for natural gas and nuclear. Since 2000, coal has even experienced a resurgence, mostly related to the massive expansion of coal-fired power generation in rapidly developing economies in Asia.

The shift from fuels such as coal with a high carbon content to energy carriers with a lower carbon content such as natural gas, as well as the introduction of near-zero carbon energy sources such as hydropower

10 See also Perlin (1989) on the role of wood in the development of civilization. In fact, the first coal uses in the UK date back to Roman times, and coal was already being used for some industrial applications (e.g., brewing beer) before the Industrial Revolution. The absence of new and efficient end-use technologies for coal use (the later steam engine) implied only very limited substitution possibilities of traditional biofuel uses by coal before the advent of the Industrial Revolution.

11 Note, however, that the fuel wood crises did not cause or induce the numerous technological innovations including the steam engine that led to the Industrial Revolution. These were not caused by price escalation associated with an early "fuel wood peak," but rather resulted from profound transformations in the social and organizational fabric and incentive structures for science and entrepreneurship (see Rosenberg and Birdzell, 1986).

12 Quantitative historical accounts for major industrial countries are given in Gales et al., 2007, Kander et al., 2008, and Warr et al., 2010.

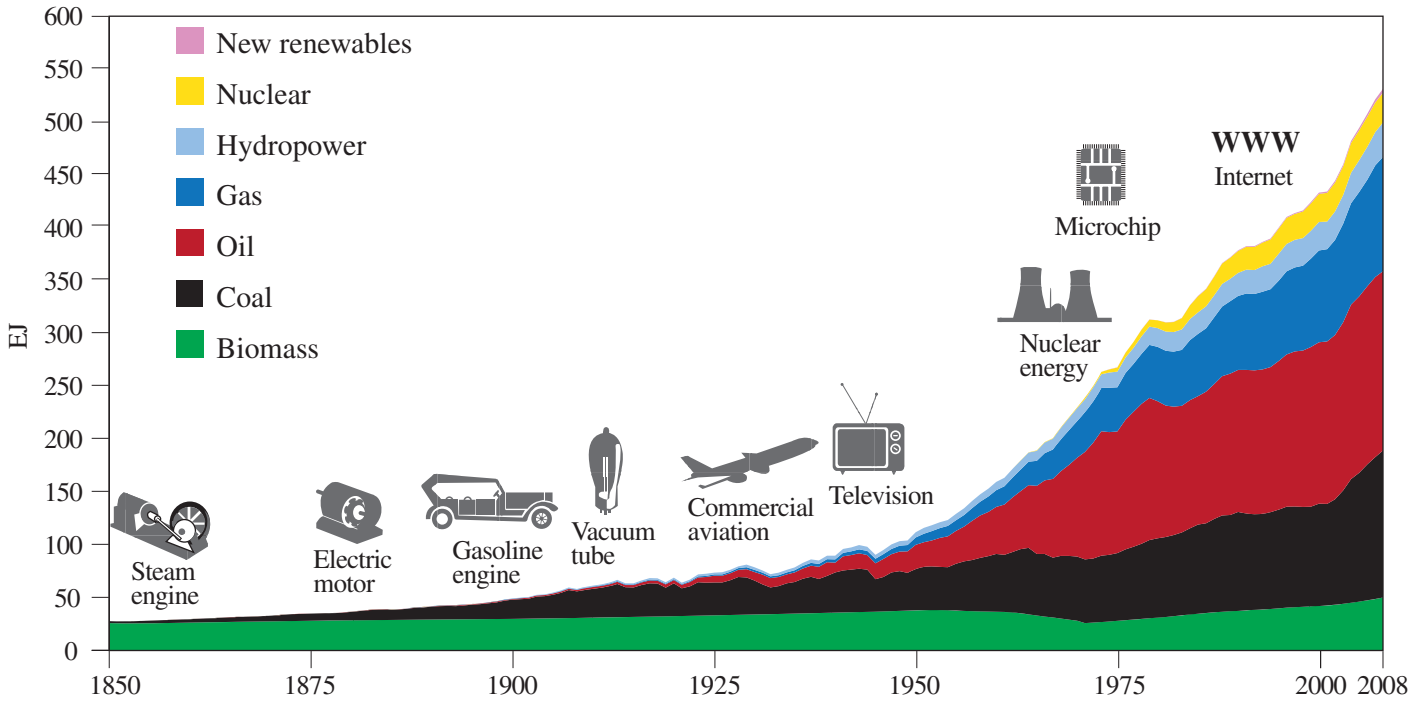

Figure 1.9 | History of world primary energy use, by Source (in EJ). Source: updated from Nakicenovic et al., 1998 and Grubler, 2008.

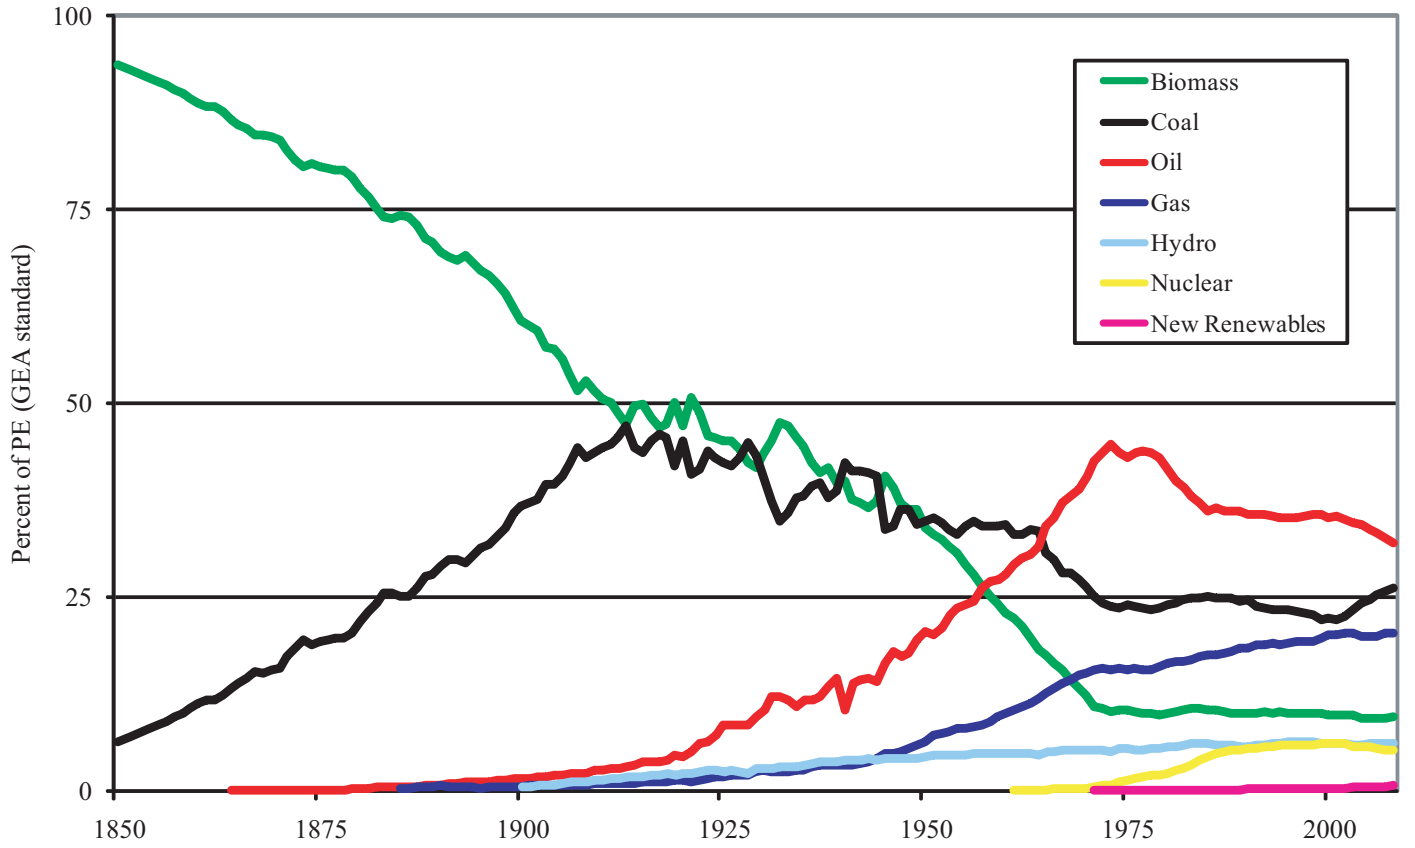

Figure 1.10 | Structural change in world primary energy (in percent). Source: updated from Nakicenovic et al., 1998 and Grubler, 2008.

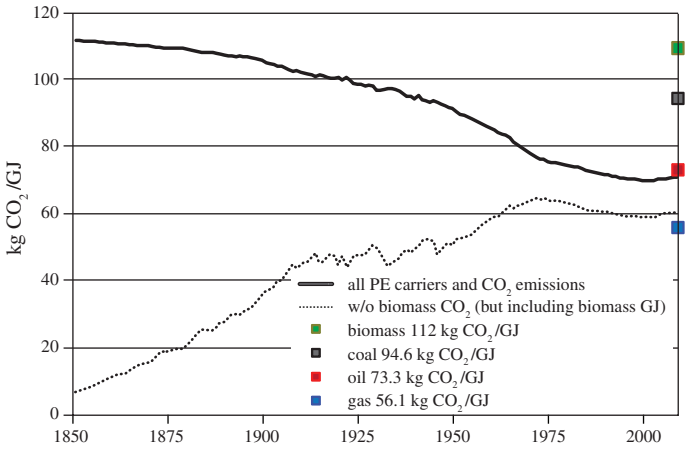

Figure 1.11 | Decarbonization of primary energy (PE) use worldwide since 1850 (kg of CO_2 emitted per GJ burned). Note: For comparison, the specific emission factors (OECD/IPCC default emission factors, LHV basis) for biomass (wood fuel), coal, crude oil, and natural gas are also shown (colored squares). See also discussion in text. Source: updated from Grubler and Nakicenovic, 1996.

and nuclear, has resulted in the *decarbonization* of energy systems (Grubler and Nakicenovic, 1996; Grubler, 2008). Decarbonization refers to the decrease in the specific emissions of carbon dioxide (CO_2) per unit of energy. Phrased slightly differently, it refers to the decrease in the carbon intensity of primary or any other energy form. Figure 1.11 illustrates the historical trend of global decarbonization since 1850 in terms of the average carbon emissions per unit of primary energy (considering all primary energy sources). The dashed line indicates the same trend but excluding biomass CO_2 emissions, assuming they have all been taken up by the biosphere under a sustainable harvesting regime (biomass regrowth absorbing the CO_2 released from biomass burning). Historically, emissions related to land-use changes (deforestation) have far exceeded[13] carbon releases from energy-related biomass burning, which suggests that in the past, biomass, like fossil fuels, has also contributed significantly to increases in atmospheric concentrations of CO_2.

The global rate of decarbonization has been on average about 0.3% annually, about six times too low to offset the increase in global energy use of some 2% annually. Again, the significant slowing of historical decarbonization trends since the energy crises of the 1970s is noteworthy, particularly due to rising carbon intensities in some developing regions (IEA, 2009), and in general due to the slowed dynamics of the global energy system discussed above.

Decarbonization can be expected to continue over the next several decades as natural gas and non-fossil energy sources increase their share of total primary energy use. Some future scenarios (for a review see Fisher et al., 2007) anticipate a reversal of decarbonization in the long term as more easily accessible sources of conventional oil and gas become exhausted and are replaced by more carbon-intensive alternatives. Others foresee continuing decarbonization because of further shifts to low-carbon energy sources, such as renewables and nuclear energy. Nonetheless, virtually all scenarios foresee some increases in the demand for energy services as the world continues to develop. Depending on the rate of energy efficiency improvement,[14] this mostly leads to higher primary energy requirements in the future. As long as decarbonization rates do not significantly accelerate, this means higher carbon emissions compared to historical experience.

1.3.3 Energy and Economic Growth

The relationship between economic growth and energy use is multifaceted and variable over time. The relationship is also two-directional: provision of adequate, high-quality energy services is a necessary (even if insufficient)[15] condition for economic growth. In turn, economic growth increases the demand for energy services and the corresponding upstream energy conversions and resource use.

Figure 1.12 summarizes the long-term history of economic and energy development for a few countries for which such long-term data (since 1800) are available. To separate the impacts of population growth, both economic output (GDP) and (primary)[16] energy use are expressed on a per capita basis. Thereby, the usual temporal dimension of historical comparisons is replaced by an economic development metric in which countries are compared at similar levels of per capita incomes (GDP).

13 Cumulative emissions of fossil fuels between 1800 and 2000 are estimated to have released some 290 GtC (gigatonnes of elemental carbon – to obtain CO_2 multiply by 44/12, yielding 1060 $GtCO_2$), compared to land-use-related (deforestation, but excluding energy-related biomass burning) emissions of some 155 GtC. Total cumulative energy-related biomass carbon emissions are estimated at 80 GtC from 1800 to 2000 (all data from Grubler, 2002). Houghton (1999) estimates a net biospheric carbon flux (deforestation plus biomass burning minus vegetation regrowth) over the same time period (net emissions) of 125 GtC, which suggests that only a maximum (attributing – quite unrealistically – all residual net biospheric uptake to fuel wood) of 30 GtC (155 GtC deforestation release minus 125 GtC net biospheric emissions), or a maximum of 38% (30/80) from energy-related biomass burning has been absorbed by the biosphere historically. In the past, biofuel combustion for energy can, therefore, hardly be classified as "carbon neutral." Evidently, in many countries (at least in Northern latitudes) forests and energy biomass are harvested currently under sustainable management practices that in many cases (avoiding soil carbon releases from changing vegetation cover) will qualify as "carbon neutral." The extent of current net carbon releases of energy-related biomass burning in developing countries remains unknown.

14 The growth in emissions can be conveniently decomposed by the following identity (where annual percentage growth rates are additive) covering their main determinants of emissions and their growth: population, income, energy efficiency, and carbon intensity: CO_2 = Population x GDP/capita x Energy/GDP x CO_2/Energy (proposed by Holdren and Ehrlich, 1971, and applied for CO_2 by Kaya, 1990). Due to spatial heterogeneity in trends and variable interdependence, caution is advised in interpreting component growth rates of this identity.

15 Human (education) and social (functioning institutions and markets) capital as well as technology (innovation) are recognized as important determinants of economic growth (see Barro, 1997).

16 The most direct link between energy and economic activity is revealed at the level of final energy use. However, historical data are mostly available for primary energy use. For the United Kingdom, both primary and final energy (see Figure 1.7 above) are shown.

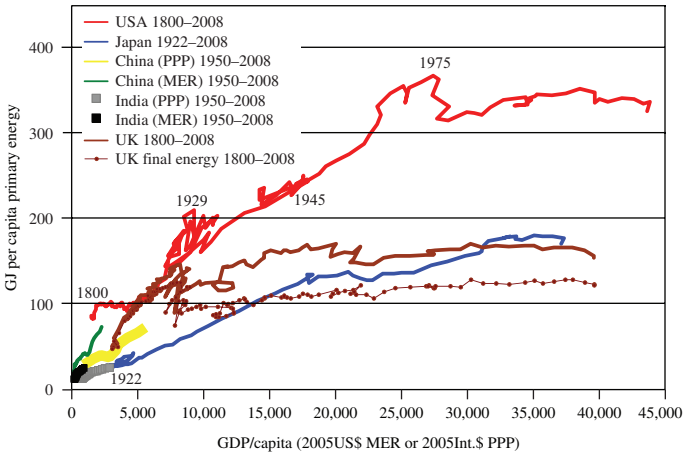

Figure 1.12 | Primary energy use (GJ) versus GDP (at market exchange rates (MER) in 2005US$) per capita. Source: USA, Japan: updated from Grubler, 1998, UK: Fouquet, 2008, India and China: IEA (2010) and World Bank (2010). Note: Data are for the United States (1800–2008), United Kingdom (primary and final energy, 1800–2008), Japan (1922–2008), China (1950–2008), and India (1950–2008). For China and India, also GDP at purchasing power parities (PPP, in 2005International$) are shown.

There are two ways of comparing GDP across different national economies depending on which exchange rate is used to convert a given national currency into a commensurable common currency (usually dollar denominated): at market exchange rates (MER) and in terms of purchasing power parities (PPP). The former are based on national accounts and official market (e.g., bank) exchange rates, while the latter are calculated based on relative prices for representative baskets of goods and services across countries denominated in an accounting currency of International$ (that equals the US$ in the United States). At present, differences between GDP rates denominated in MER and PPP exchange rates are comparatively minor among industrialized countries, and to simplify the exposition only MER-based GDP values are shown for the UK and Japan (MER and PPP GDPs are identical in the case of the US by definition). However, differences are significant in the case of developing economies (with PPP-based GDPs usually being larger than MER-based GDPs by a factor of two to three due to the much lower domestic price levels in developing countries –and hence the higher purchasing power of their population compared to industrialized ones), and, therefore, both GDP measures are shown in the case of China and India.

Three observations help to understand the relationship between economic and energy growth:
the importance of metrics;
the overall positive correlation, that is, however, variable over time; and
the distinctive differences in development paths among different countries and their economies.

First, both the starting points and the growth rates (the slopes of the trend lines shown in Figure 1.12) of economies are dependent on the economic metric chosen for comparing incomes across countries (MER or PPP). For instance, China's and India's GDP per capita in 1970 are estimated to have been approximately US$170 and US$250, respectively (in US$2005), based on MER, and $700 and $1000 (in International $2005), respectively, when based on PPP, which compares to the GDP of the US of approximately US$1000 (at US$2005 rates) of 200 years ago, and to that of Japan in 1885.[17]

Thus, developing countries are by no means in a better position for economic "take-off"; they are not comparatively "richer" today than today's industrialized countries were some 100 or even 200 years ago, albeit enjoying unique development opportunities due to new technologies and improved communication and trade flows (Grubler, 2004). This illustrates the time dimension of economic development that entails many decades. Developing countries are today at the beginning of a long uphill development path that will require many decades to unfold and is also likely to include setbacks, as evidenced by the historical record of the industrialized countries. However, overall levels of energy use can be expected to increase as incomes rise in developing countries.

The overall positive correlation between economic and energy growth remains one of the most important "stylized facts" of the energy development literature, even if the extent of this correlation and its patterns over time are highly variable. Although the pattern of energy use growth with economic development is pervasive, there is no unique and universal "law" that specifies an exact relationship between economic growth and energy use over time and across countries. The development trajectory of the US illustrates this point. Over much of the period from 1800 to 1975, per capita energy use in the US grew nearly linearly with rising per capita incomes, punctuated by two major discontinuities: the effects of the Great Depression after 1929, and the effects of World War II (recognizable by the backward-moving "snarls" in the temporal trajectory of both income and energy use per capita shown in Figure 1.12). However, since 1975, per capita energy use has remained remarkably flat despite continuing growth in per capita income, illustrating an increasing decoupling of the two variables as a lasting impact of the so-called "energy crisis" of the early 1970s, an experience shared by many highly industrialized countries. It is also important to recognize significant differences in timing. During the 100 years from 1900 to 2000, Japan witnessed per capita income growth similar to that experienced by the US over 200 years (Grubler, 2004). This illustrates yet another limitation of simple inferences: notwithstanding the overall evident coupling between economic and energy growth, the growth experiences of one country cannot necessarily be used to infer those of another country, neither in terms of speed of economic development, nor in terms of how much growth in energy use such development entails.

Lastly, there is a persistent difference between development trajectories spanning all of the extremes from "high energy intensity" (the US) at one end of the scale to "high energy efficiency" (Japan) at the other (see also the discussion on energy intensities in Section 1.4.4 below).

17 Based on MER. Using PPP, Japan's GDP per capita in 1885 is estimated to have been well above $4000 (in 2005International$).

The relationship between energy and economic growth thus depends on numerous and variable factors. It depends on initial conditions (e.g., as reflected in natural resource endowments and relative price structures) and the historical development paths followed that lead to different settlement patterns, different transport requirements, differences in the structure of the economy, and so on. This twin dependency on initial conditions and the development paths followed to explain differences among systems is referred to as "path dependency" (Arthur, 1989). Path dependency implies considerable inertia in changing development paths, even as conditions prevailing at specific periods in history change – a phenomenon referred to as "lock-in" (Arthur, 1994). Path dependency and lock-in in energy systems arise from differences in initial conditions (e.g., resource availability and other geographical, climatic, economic, social, and institutional factors) that in turn are perpetuated by differences in policy and tax structures, leading to differences in spatial structures, infrastructures, and consumption patterns. These in turn exert an influence on the levels and types of technologies used, both by consumers and within the energy sector, that are costly to change quickly owing to high sunk investment costs, hence the frequent reference to "technological lock-in" (Grubler, 2004).

The concepts of path dependency and technological lock-in help to explain the persistent differences in energy use patterns among countries and regions even at comparable levels of income, especially when there are no apparent signs of convergence. For instance, throughout the whole period of industrialization and at all levels of income, per capita energy use has been lower in Japan than in the US (Grubler, 2004). The critical question for emerging economies such as China and India is, therefore, what development path they will follow in their development and what policy leverages exist to avoid lock-in in energy- and resource-intensive development paths that ultimately will be unsustainable, which puts *energy efficiency* at the center of the relationship between the economic and energy systems.

1.4 Energy Efficiency and Intensity

1.4.1 Introduction

Energy is conserved in every conversion process or device. It can neither be created nor destroyed, but it can be converted from one form into another. This is the First Law of Thermodynamics. For example, energy in the form of electricity entering an electric motor results in the desired output – say, kinetic energy of the rotating shaft to do work – and in losses in the form of heat as the undesired by-product caused by electric resistance, magnetic losses, friction, and other imperfections of actual devices. The energy entering a process equals the energy exiting. Energy efficiency is defined as the ratio of the desired (usable) energy output to the energy input. In the electric motor example, this is the ratio of the shaft power to the energy input electricity. Or in the case of natural gas for home heating, energy efficiency is the ratio of heat energy supplied to the home to the calorific value of the natural gas entering the furnace. This definition of energy efficiency is sometimes called *first-law efficiency* (Nakicenovic et al., 1996b).

A more efficient provision of energy services not only reduces the amount of primary energy required but, in general, also reduces costs and adverse environmental impacts. Although efficiency is an important determinant of the performance of the energy system, it is not the only one. In the example of a home furnace, other considerations include investment, operating costs, lifetime, peak power, ease of installation and operation, and other technical and economic factors (Nakicenovic et al., 1996b). For entire energy systems, other considerations include regional resource endowments, conversion technologies, geography, information, time, prices, investment finance, age of infrastructure, and know-how.

As an example of energy chain efficiency, Figure 1.13 illustrates the energy flows in the supply chain for illumination services (lighting). In this example, electricity is generated from coal in a thermal power station and transmitted and distributed to the point of end-use, where it is converted to light radiation by means of an incandescent light bulb. Only about 1% of the primary energy is transformed to illumination services provided to the end-user. In absolute terms, the majority of losses occur at the thermal power plant. The conversion of chemically stored energy from the coal into high-quality electricity comes along with the production of a significant amount of low-grade heat as a by-product of the process. Idle losses[18] at the point of end-use reflect the amount of time when the light bulb is switched on with the illumination service not being needed at that moment – for example, when the user is temporarily not present in the room.

In this example, abundant opportunities for improving efficiency exist at every link in the energy chain. They include shifting to more efficient fuels (e.g., natural gas) and more efficient conversion, distribution, and end-use technologies (e.g., combined cycle electricity generation, fluorescent or LED lighting technologies), as well as behavioral change at the point of end-use (e.g., reducing idle times). Integration of energy systems is another approach to reduce losses and improve overall system efficiency. An example of such system integration is combined heat and power production, where low temperature residual heat from thermal power production is utilized for space heating, a technique which can raise overall first-law fuel efficiency up to 90% (Cames et al., 2006). At the point of end-use, idle losses can be reduced through changed user behavior and control technology such as building automation systems that adapt energy services to the actual needs of the user.

18 Similar concepts are captured by the term "load factor" referring to the capacity utilization of plant and equipment. In typical commuting situations in industrialized countries there are no more than 1.2 passengers per automobile, which is a lower load factor than for 2-wheelers (bicycles and scooters) in most cities of developing countries.

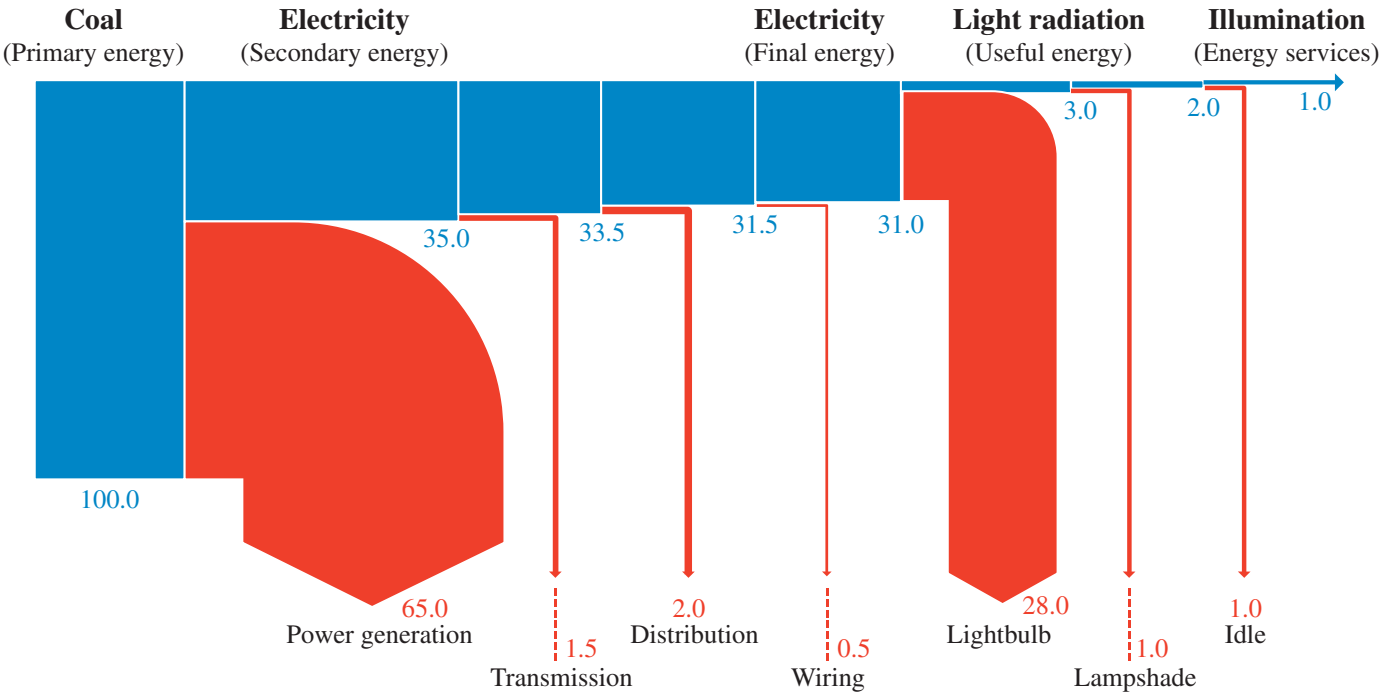

Figure 1.13 | Illustrative example of the compound First-Law efficiency of an entire energy chain to provide the energy service of illumination. Index: primary energy entering system = 100%.

1.4.2 First-Law Efficiencies

In 2005, the global efficiency of converting primary energy sources to final energy forms, including electricity, was about 67% (330 EJ over 496 EJ; see Figure 1.2 above). The efficiency of converting final energy forms into useful energy is lower, with an estimated global average of 51% (169 EJ over 330 EJ; see Figure 1.2). The resulting average global efficiency of converting primary energy to useful energy is then the product of the above two efficiencies, or 34%. In other words, about two-thirds of global primary energy use does not end up as useful energy input for providing energy services but is dissipated to the environment in the form of waste heat (or what is colloquially termed energy "losses"). The ultimate efficiency of the energy system in the provision of energy services cannot be determined by calculations based on the First Law of Thermodynamics but requires an extension of the discussion to the Second Law of Thermodynamics.

1.4.3 Second-Law Efficiencies and Exergy

How much energy is needed for a particular energy service? The answer to this question is not so straightforward. It depends on the type and quality of the desired energy service, the type of conversion technology, the fuel, including the way the fuel is supplied, and the surroundings, infrastructures, and organizations that provide the energy service. Initially, energy efficiency improvements can be achieved in many instances without elaborate analysis through common sense, good housekeeping, and leak-plugging practices. Obviously, energy service efficiencies improve as a result of sealing leaking window frames or the installation of a more efficient furnace. Or if the service is transportation, getting to and from work, for example, using a transit bus jointly with other commuters is more energy-efficient than taking individual automobiles. After the easiest improvements have been made, however, the analysis must go far beyond energy accounting.[19]

Here the concept that something may get lost or destroyed in every energy device or transformation process is useful. This "something" is called "availability," which is the capacity of energy to do work. Often the availability concept is called "exergy."[20]

The following example should help clarify the difference between energy and exergy. A well-insulated room contains a small container of kerosene surrounded by air. The kerosene is ignited and burns until the container is empty. The net result is a small temperature increase of the air in the room ("enriched" with the combustion products). Assuming no heat leaks from the room, the total quantity of energy in the room has not changed. What has changed, however, is the quality of energy. The initial fuel has a greater potential to perform useful tasks than the resulting

19 This section updates and expands on material that was first published in Nakicenovic et al. (1996b).

20 Exergy is defined as the maximum amount of energy that under given (ambient) thermodynamic conditions can be converted into any other form of energy; it is also known as "availability" or "work potential." Therefore, exergy defines the minimum theoretical amount of energy required to perform a given task. The ratio of theoretical minimum energy use for a particular task to the actual energy use for the same task is called exergy or *second-law efficiency* (based on the Second Law of Thermodynamics). See also Wall, 2006.

slightly warmer air mixture. For example, one could use the fuel to generate electricity or operate a motor vehicle. The scope of a slightly warmed room to perform any useful task other than space conditioning (and so provide thermal comfort) is very limited. In fact, the initial potential of the fuel or its exergy has been largely destroyed.[21] Although energy is conserved, exergy is destroyed in all real-life energy conversion processes. This is what the Second Law of Thermodynamics says.

Another, more technical, example should help clarify the difference between the first-law (energy) and second-law (exergy) efficiencies. Furnaces used to heat buildings are typically 70% to 80% efficient, with the latest best-performing condensing furnaces operating at efficiencies greater than 90%. This may suggest that minimal energy savings should be possible, considering the high first-law efficiencies of furnaces. Such a conclusion is incorrect. The quoted efficiency is based on the specific process being used to operate the furnace – combustion of fossil fuel to produce heat. Since the combustion temperatures in a furnace are significantly higher than those desired for the energy service of space heating, the service is not well matched to the source and the result is an inefficient application of the device and fuel. Rather than focusing on the efficiency of a given technique for the provision of the energy service of space heating, one needs to investigate the theoretical limits of the efficiency of supplying heat to a building based on the actual temperature regime between the desired room temperature, and the heat supplied by a technology. The ratio of theoretical minimum energy use for a particular task to the actual energy use for the same task is called exergy or *second-law efficiency.*

Consider the following case. To provide a temperature of 30°C to a building while the outdoor temperature is 4°C requires a theoretical minimum of one unit of energy input for every 12 units of heat energy delivered to the indoors. To provide 12 units of heat with an 80% efficient furnace, however, requires 12/0.8, or 15 units of heat. The corresponding second-law efficiency is the ratio of theoretical minimum to actual energy use – i.e., 1/15 or 7%.

The first-law efficiency of 80% gives a misleading impression that only modest improvements are possible. The second-law efficiency of 7% says that a 15-fold reduction in final heating energy is theoretically possible by changing technologies and practices.[22] In practice, theoretical maxima cannot be achieved. More realistic improvement potentials might be in the range of half of the theoretical limit. In addition, further improvements in the efficiency of supplying *services* are possible by task changes – for instance, in reducing the thermal heat losses of the building to be heated via better insulation of walls and windows.

What is the implication of the Second Law of Thermodynamics for energy efficiencies? First of all, it is not sufficient to account for energy-in versus energy-out ratios without due regard for the quality difference – i.e., the exergy destroyed in the process. Minimum exergy destruction means an optimal match between the energy service demanded and the energy source. Although a natural gas heating furnace may have a (First-Law) energy efficiency of close to 100%, the exergy destruction may be very high depending on the temperature difference between the desired room temperature and the temperature of the environment. The Second-Law efficiency, defined as exergy-out over exergy-in, in this natural gas home heating furnace example is some 7% – i.e., 93% of the original potential of doing useful work (exergy) of the natural gas entering the furnace is destroyed. Here we have a gross mismatch between the natural gas potential to do useful work, and the low temperature nature of the energy service space conditioning.

There are many examples for exergy analysis of individual conversion devices (e.g., losses around a thermal power plant) as well as larger energy systems (cities, countries, the entire globe). This literature is reviewed in detail in Nakicenovic (1996b). Estimates of global and regional primary-to-service exergy efficiencies vary typically from about 10 to as low as a few percent of the thermodynamically maximum feasible (see also Ayres, 1989, Gilli et al., 1996, and Nakicenovic et al., 1996a).

The theoretical potential for efficiency improvements is thus very large, and current energy systems are nowhere close to the maximum levels suggested by the Second Law of Thermodynamics. However, the full realization of this potential is impossible to achieve. First of all, friction, resistance, and similar losses can never be totally avoided. In addition, there are numerous barriers and inertias to be overcome, such as social behavior, vintage structures, financing of capital costs, lack of information and know-how, and insufficient policy incentives.

The principal advantage of second-law efficiency is that it relates actual efficiency to the theoretical (ideal) maximum. Although this theoretical maximum can never be reached, low exergy efficiencies identify those areas with the largest potentials for efficiency improvement. For fossil fuels, this implies the areas that also have the highest emission mitigation potentials. A second advantage of exergy efficiency is that the concept can be transferred to the assessment of energy service provision, which is not possible in first-law efficiency calculations. By comparing an actual configuration (a single driver in an inefficient car) with a theoretically ideal situation (a fuel-efficient car with five people in it), respective exergetic service efficiencies while maintaining the same type of energy service (i.e., not assuming commuting by bicycle) can be determined. This is important, especially as the available literature

21 Alternative example: In terms of energy, 1 kWh of electricity and the heat contained in 5 kg of 20°C (raised from 0°C) water are equal, i.e. 3.6 MJ. At ambient conditions, it is obvious that 1 kWh of electricity has a much larger potential to do work (e.g., to turn a shaft, provide light, or allow to run a computer) than the 5 kg of 20°C water that cannot perform any useful work.

22 For example, instead of combusting a fossil fuel, Goldemberg et al. (1988) give the example of a heat pump that extracts heat from a local environment (outdoor air, indoor exhaust air, ground water) and delivers it into the building. A heat pump operating on electricity can supply 12 units of heat for three to four units of electrical energy. The second-law efficiency then improves to 25–33% for this particular task – still considerably below the theoretical maximum efficiency. Not accounted for in this example, however, are the energy losses during electricity generation. Assuming a modern gas-fired combined cycle power plant with 50% efficiency, the overall efficiency gain is still higher by a factor of two compared to a gas furnace heating system.

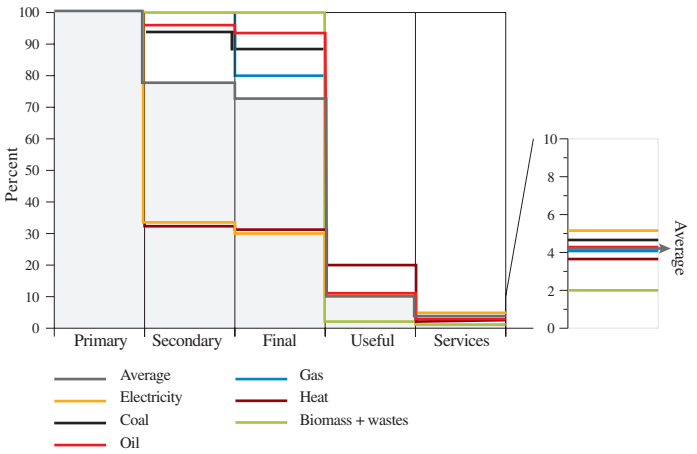

Figure 1.14 | Estimated exergy efficiencies (average for OECD countries) from primary exergy (= 100%) to useful exergy and to services by energy carrier (fuel). Source: adapted from Nakicenovic, 1993.

suggests that efficiencies in energy end-uses (in the conversion of final to useful energy and of useful energy to energy services) are particularly low (see Figure 1.14).

1.4.4 Energy Intensities

A related concept to that of energy efficiency is that of energy intensity. Instead of measuring input/output relations in energy terms, as is the case for energy efficiency, energy inputs are divided by a range of appropriate activity indicators that represent the energy service provided (such as tonnes of steel produced, vehicle-km driven, floorspace inhabited, monetary measures of output, number of employees, etc.) to yield energy intensity indicators. Such comparative benchmarking across countries, industries, or products, yields valuable insights into potentials for efficiency improvements related to various activities (comparing current intensities to best practice), and is applied widely in the corresponding energy efficiency improvement and greenhouse gas (GHG) mitigation literature (see Fisher et al., 2007; and the GEA end-use chapters 8, 9, and 10 in this publication). Extending this concept to entire energy systems and economies yields a widely used indicator of energy intensity, per unit of economic activity (GDP, which is the monetary quantification of all goods and services consumed in an economy in a given year subject to market transactions).[23] This parsimonious indicator is appealing because of its relative simplicity (usually a single number) and seeming ease of comparability across time and across different systems (global and/or national economies, regions, cities, etc.). However, its simplicity comes at a price. First, the indicator is affected by a number of important measurement and definitional issues (see the discussion below). Second, the underlying factors for explaining differences in absolute levels of energy intensities across economies and their evolution over time requires detailed, further in-depth analysis using a range of additional explanatory variables. They cannot be distilled from an aggregate indicator such as energy intensity of the national or global GDP.

The literature on energy intensities, their trends, and drivers is vast (for useful introductory texts see, e.g., Schipper and Myers, 1992; Nakicenovic et al., 1996b; Greening et al., 1997; Schäfer, 2005; Baksi and Green, 2007; Gales et al., 2007). Apart from definitional, accounting, and measurement conventions, differences in energy intensities have been explained by a set of interrelated variables including demographics (size, composition, and densities – e.g., urban versus rural population), economics (size and structure of economic activities/sectors – e.g., the relative importance of energy-intensive industries versus energy-extensive services in an economy; per capita income levels), technology and capital vintages (age and efficiency of the production processes, transport vehicles, housing stock, etc.), geography and climate, energy prices and taxes, lifestyles, and policies, just to name the major categories.

In terms of energy and economic accounting, energy intensities are affected by considerable variation depending on which particular accounting convention is used (and which is often not disclosed prominently in the reporting reference). For energy, the largest determining factors are whether primary or final energy is used in the calculations, and if non-commercial (traditional biomass or agricultural residues, which are of particular importance in developing countries) are included or not. Another important determinant is which accounting method is used for measuring primary energy (see Appendix 1.A). For GDP, the largest difference in energy intensity indicators is the conversion rate used for expressing a unit of national currency in terms of an internationally comparable currency unit based on either MER or PPP exchange rates (see the discussion in Section 1.3.3 above).

Figure 1.15 illustrates some of the differences in the evolution of historical primary energy intensity for four major economies in the world: China, India, Japan, and the United States. It shows a number of different ways of measuring energy intensity of GDP. The first example can be best illustrated for the US (where there is no difference between the MER and PPP GDP measure by definition).

The (thin red) curve shows the *commercial* energy intensity. Commercial energy intensities increase during the early phases of industrialization, as traditional and less efficient energy forms are replaced by commercial energy. When this process is completed, commercial energy intensity peaks and proceeds to decline. This phenomenon is sometimes called the "hill of energy intensity." Reddy and Goldemberg (1990) and many others have observed that the successive peaks in the procession of countries achieving this transition are ever lower, indicating a possible catch-up effect and promising further energy intensity reductions in

23 Like energy, GDP is a ***flow*** variable and, therefore, does not measure wealth or welfare (which are ***stock*** variables).

The measurement of GDP through market transactions (sales/purchases of goods and services) is at the same time a strength (measurability by statistical offices) and a weakness of the concept, as excluding non-market transactions (such as household and voluntary work that should increase GDP if valued monetarily) as well as environmental externalities (the negative impacts of pollution, congestion, etc. that would lower GDP).

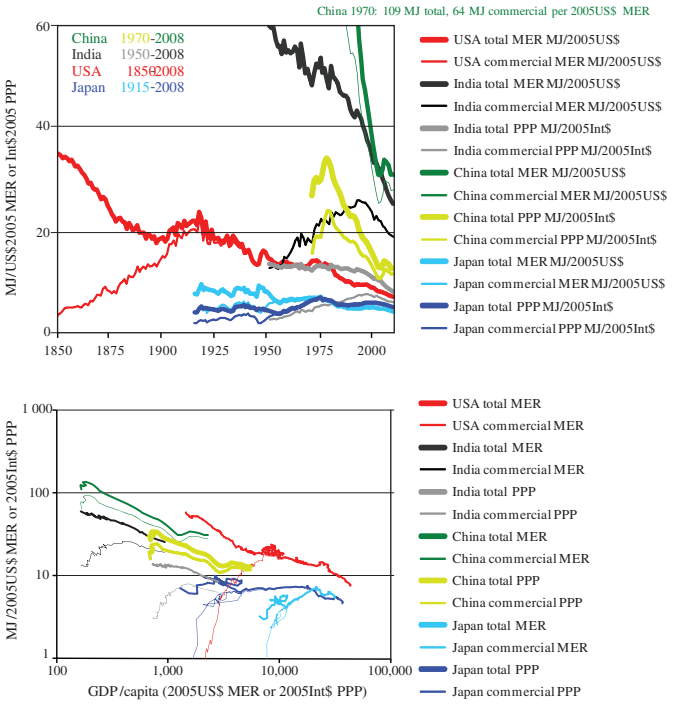

Figure 1.15 | Energy intensity improvements over time (top) and against per capita income (bottom) US (1800–2008), Japan (1885–2008), India (1950–2008), and China (1970–2008). Source: see Figure 1.12. Note: Energy intensities (in MJ per $) are always shown for total primary energy (bold lines) and commercial primary energy only (thin lines) and per unit of GDP expressed at market exchange rates (MER in 2005US$) and for China, India, and Japan also at purchasing power parities (PPP in 2005International$). For the United States, MER and PPP are identical.

developing countries that still have to reach the peak. In the US, for example, the peak of commercial energy intensity occurred during the 1910s and was higher than Japan's subsequent peak, which occurred in the 1970s (Nakicenovic et al., 1998). More important than this "hill" in commercial energy intensities is, however, a pervasive trend toward overall lower *total* energy (including also non-commercial energy) intensities over time and across all countries.

Figure 1.15 also shows energy intensities for China and India for two alternative measures of converting national GDP to an internationally comparable level: using MER or PPP exchange rates. In the cases of India and China, MER energy intensities are very high, resembling the energy intensities of the now industrialized countries more that 100 years ago (Nakicenovic et al., 1998). This gives the appearance of very low energy efficiency in producing a unit of economic output in China and India, and by implication in other emerging and developing countries. However, China and India's PPP-measured GDPs are much higher than official MER-based GDPs suggest (and resulting PPP-based energy intensities much lower) due to generally much lower prices in the two countries compared to industrialized countries. This translates into a more favorable PPP exchange rate of the local currency compared to MER (often by a factor of two to three). Consequently, with the same dollar amount, a consumer can purchase more goods and services in developing countries than in more industrialized countries. PPP-measured energy intensities are thus generally much lower for developing countries, indicating substantially higher energy efficiencies in these countries than would be calculated using MER.

The substantially lower energy intensity of GDP when expressed in terms of PPP rather than MER should be contrasted with the much lower energy intensity improvement *rates* in terms of PPP compared to energy intensities based on MER. The differences can indeed be substantial. In 2005 the energy intensity in China was about 33 MJ/US$2005 for MER, with an average historical reduction rate of 3.3%/year since 1971, compared with about 14 MJ per 2005International$ for PPP for the same year and an improvement rate of 1.9%/year. Since 1971, China's per capita GDP in terms of MER has grown by some 7%/year, whereas the estimated per capita GDP in PPP terms has grown by some 5%/year, compared to a growth rate of per capita primary energy use of some 3%/year (from 20 GJ in 1971 to 57 GJ in 2005 and 71 GJ in 2008). Therefore, caution is needed when interpreting the apparent rapid energy intensity improvements, measured by MER-based GDPs, which are reported for some countries. In theory, as countries develop and their domestic prices converge toward international levels, the difference between the two GDP measures largely disappears (see the case of Japan in Figure 1.15).[24]

Adding traditional (non-commercial) energy[25] to commercial energy reflects total primary energy requirements and yields a better and more powerful measure of overall energy intensity. Total energy intensities generally decline for all four countries in Figure 1.15. There are exceptions, including periods of increasing energy intensity that can last for a decade or two. This was the case for the US around 1900 and China during the early 1970s. Recently, energy intensities are (temporarily) increasing in the economies in transition, due to economic slowdown and depression (declining per capita GDP). In the long run, however, the development is toward lower energy intensities. Data for countries with long-term statistical records show improvements in total energy intensities by more than a factor of five since 1800, corresponding to an average decline of total energy intensities of about 1%/year (Gilli et al., 1990; Nakicenovic et al., 1998; Fouquet, 2008). Improvement rates can be much faster, as illustrated in the case of China discussed above (2–3%/year for PPP- and MER-based energy intensities, respectively. Energy intensities in India have improved by 0.8%/year (PPP-based) to 1.5%/year (MER-based) over the period from 1970 to 2005. The much higher improvement rates of China compared to India reflects both a

24 As by definition an International$ used for PPP accounting is equal to one US$, no distinction is made between PPP- and MER-based intensities in the case of the US in Figure 1.15.

25 Traditional biomass fuels are often collected by end-users themselves and thus not exchanged via formal market transactions. Their collection costs in terms of effort and time can be substantial but are not reflected in official GDP estimates.

less favorable (less energy-efficient) starting point as well as much faster GDP per capita growth in China than in India. Faster economic growth leads to a faster turnover of the capital stock of an economy, thus offering more opportunities to switch to more energy-efficient technologies. The reverse side also applies, as discussed above for the economies in transition (Eastern Europe and the former Soviet Union): with declining GDP, energy intensities deteriorate – i.e., increase rather than decline.

It is also useful to look at long-term energy intensity trends using a more appropriate "development" metric than a simple calendar year. Even if in many aspects not perfect, income per capita can serve as a useful proxy for the degree of economic development. From this perspective, the vast differences in energy intensities between industrialized and developing countries are *development gaps* rather than inefficiencies in developing economies. For similar levels of income, energy intensities of developing countries are generally in line with the levels that prevailed in industrialized countries about a century ago, when these had similar low income levels (see lower graph, Figure 1.15).

However, such a perspective also reveals more clearly distinctive differences in development patterns spanning all the extremes between "high intensity" (e.g., the US) and "high efficiency" (e.g., Japan). The United States has had at all times significantly higher energy intensities than other countries, reflecting its unique condition of originally prevailing resource abundance,[26] coupled with a vast territory, and a comparative labor shortage that led to early mechanization and the corresponding substitution of human and animal labor by mechanical energy powered by (cheap) fossil fuels (David and Wright, 1996). The concepts of path dependency and lock-in (introduced above) describe these differences in development patterns and trajectories. Current systems are deeply rooted in their past development history. Initial conditions and incentives in place (such as relative prices) structure development in a particular direction, which is perpetuated (path dependent), ultimately leading to lock-in – i.e., the resistance to change of existing systems (due to, e.g., settlement patterns, industrial structure, lifestyles). From this perspective, a rapid convergence of levels of energy intensity and efficiency across all countries would indeed be a formidable challenge, notwithstanding that all systems can improve their energy intensities toward an "endless" innovation "frontier" in energy efficiency.

Energy intensity improvements can continue for a long time to come. As discussed above, the theoretical potential for energy efficiency and intensity improvements is very large; current energy systems are nowhere close to the maximum levels suggested by the Second Law of Thermodynamics. Although the full realization of this potential is impossible, many estimates reflecting the potential of new technologies and opportunities for energy systems integration indicate that the improvement potential might be large indeed – an improvement by a factor of ten or more could be possible in the very long run (see Ayres, 1989; Gilli et al., 1990; Nakicenovic., 1993; 1998; Wall, 2006). Thus, reductions in energy intensity can be viewed as an endowment, much like other natural resources, that needs to be discovered and applied.

1.5 Energy Resources

1.5.1 Introduction

Energy *resources* – or rather *occurrences* – are the stocks (e.g., oil, coal, uranium) and flows (e.g., wind, sunshine, falling water) of energy offered by nature. Stocks, by definition, are exhaustible, and any resource consumption will reduce the size of the concerned stock. Flows, in turn, are indefinitely available as long as their utilization does not exceed the rate at which nature provides them. While the concept of stocks and flows is simple and thus intriguing, it quickly becomes complex and confusing once one is tasked with their quantification (the size of the "barrel") or recoverability ("the size and placement of the tap"). Crucial questions relate to the definition and characterization of, say, hydrocarbons in terms of chemical composition, concentration of geological occurrence, investment in exploration, or technology for extraction. Just by accounting for lowest concentration occurrences or lowest-density flow rates, stocks and flows assume enormous quantities. However, these have little relevance for an appreciation of which parts of the stocks and flows may be or become practically accessible for meeting societies' energy service needs. Private- and public-sector energy resource assessments, therefore, distinguish between *reserves* and *resources*, while occurrences are usually ignored for reasons of lack of technical producibility or economic attractiveness. Put differently, what is the benefit of knowing the size of the barrel when no suitable tap is available?[27]

Despite being used for decades, the terms energy *reserves* and *resources* are not universally defined and thus poorly understood. There are many methodological issues, and there is no consensus on how to compare reserves and resources across different categories fairly. A variety of terms are used to describe energy reserves and resources, and different authors and institutions have different meanings for the same terms depending on their different purpose.

The World Energy Council (WEC, 1998) defined resources as "the occurrences of material in recognizable form." For oil, it is essentially the amount of oil in the ground. Reserves represent a portion of resources and is the term used by the extraction industry. *Reserves* are the amount currently technologically and economically recoverable (WEC, 2007). *Resources* are detected quantities that cannot be profitably recovered with current technology but might be recoverable in the future, as well as those quantities that are geologically possible but yet to be found.

26 A similar case can be found in the development history of the former Soviet Union, whose long-term economic data are, however, too uncertain for cross-country comparisons of energy intensity.

27 This section updates and expands on material that was first published in Rogner et al. (2000).

Occurences include both reserves and resources as well as all additional quantities estimated to exist in the Earth's crust.

BP (2010a) notes that "proven reserves of oil are generally taken to be those quantities that geological and engineering information indicate with reasonable certainty, which can be recovered in the future from known reservoirs under existing economic and operating conditions." Other common terms include probable reserves, indicated reserves, and inferred reserves – that is, hydrocarbon occurrences that do not meet the criteria of proven reserves. Undiscovered resources are what remain and, by definition, one can only speculate on their existence. Ultimately recoverable resources are the sum of identified reserves and the possibly recoverable fraction of undiscovered resources, and generally include production to date.[28]

Then there is the difference between conventional and unconventional resources (e.g., oil shale, tar sands, coal-bed methane, methane clathrates (hydrates), uranium in black shale or dissolved in sea water). In essence, unconventional resources are occurrences in lower concentrations, different geological settings, or different chemical compositions than conventional resources. Again, unconventional resource categories lack a standard definition, which adds greatly to misunderstandings. As the name suggests, unconventional resources generally cannot be extracted with technology and processes used for conventional oil, gas, or uranium. They require different logistics and cost profiles and pose different environmental challenges. Their future accessibility is, therefore, a question of technological development – i.e., the rate at which unconventional resources can be converted into conventional reserves (notwithstanding demand and relative costs). In short, the boundary between conventional and unconventional resources is in permanent flux. Occurrences are in principle affected by the same dynamics, albeit over a much more speculative and long-term time scale. Technologies that may turn them into potential resources are currently not in sight, and resource classification systems, therefore, separate them from resources (often considering occurrences as speculative quantities that may not become technologically recoverable over the next 50 years).

In short, energy resources and their potential producibility cannot be characterized by a simple measure or single numbers. They comprise quantities along a continuum in at least three, interrelated, dimensions: geological knowledge, economics, and technology. McKelvey (1967) proposed a commonly used diagram with a matrix structure for the classification along two dimensions (Figure 1.16): decreasing geological certainty of occurrence and decreasing techno-economic recoverability (Nakicenovic et al., 1996b). The geological knowledge dimension is divided into identified and undiscovered resources. Identified resources are deposits that have known location, grade, quality, and quantity, or that can be estimated from geological evidence. Identified resources are further subdivided into demonstrated (measured plus indicated) and

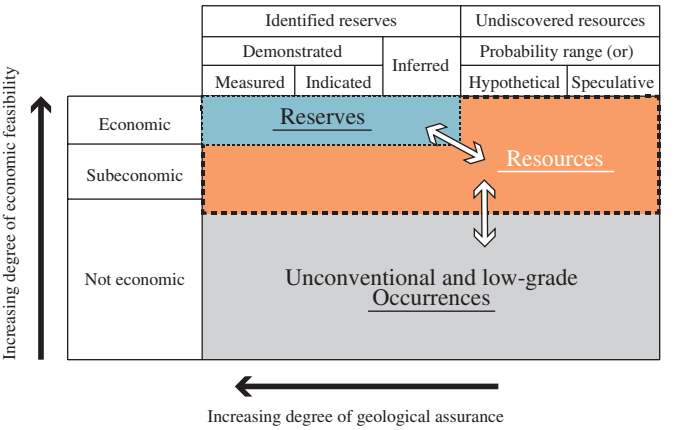

Figure 1.16 | Principles of resource classification, illustrating the definition of the three fundamental concepts: reserves, resources, and occurrences. Source: adapted from McKelvey, 1967.

inferred resources to reflect varying degrees of geological assurance. The techno-economic dimension accounts for the feasibility of technical recoverability and economic viability of bringing the resource to the market place. Reserves are identified resources that are economically recoverable at the time of assessment (see the BP definition above).

Undiscovered resources are quantities expected or postulated to exist under analogous geological conditions. Other occurrences are materials that are too low-grade, or for other reasons not considered technically or economically extractable. For the most part, unconventional resources are included in other occurrences.

Reserve and resource estimations, as well as their production costs, are subject to continuous revision for several reasons. Production inevitably depletes reserves and eventually exhausts deposits, while successful exploration and prospecting adds new reserves and resources. Price increases and production cost reductions expand reserves by moving resources into the reserve category and vice versa. Technology is the most important force in this process. Technological improvements are continuously pushing resources into the reserve category by advancing knowledge and lowering extraction costs. The outer boundary of resources and the interface to other occurrences is less clearly defined and often subject to a much wider margin of interpretation and judgment. Other occurrences are not considered to have economic potential at the time of classification. Yet over the very long term, technological progress may upgrade significant portions of occurrences to resources and later to reserves (Rogner et al., 2000).

In contrast, long-term supply, given sufficient demand, is a question of the replenishment of known reserves with new ones presently either unknown, not delineated, or from known deposits presently not producible or accessible for techno-economic reasons (Rogner, 1997; Rogner et al., 2000). Here the development and application of advanced exploration and production technologies are essential prerequisites for the

28 Physical and economic limitations of the *rates* of extraction do not enter the estimations of these stock variables.

Table 1.3 | Fossil and uranium reserves, resources and occurrences (in EJ).

	Historical production through 2005	Production 2005	Cumulative extraction GEA scenarios 2005–2100 [EJ]	Reserves	Resources	Additional Occurrences
	[EJ]	[EJ]		[EJ]	[EJ]	[EJ]
Conventional oil	6 069	147.9	6 600–10 000	4 900–7 610	4 170–6 150	
Unconventional oil	513	20.2	2–470	3 750–5 600	11 280–14 800	> 40 000
Conventional gas	3 087	89.8	7 900–11 900	5 000–7 100	7 200–8 900	
Unconventional gas	113	9.6	180–8 500	20 100–67 100	40 200–121 900	> 1 000 000
Coal	6 712	123.8	3 300–16 500	17 300–21 000	291 000–435 000	
Conventional uranium[b]	1 218	24.7	1 520–28 500	2 400	7 400	
Unconventional uranium[c]	n.a.	–			4 100	> 2 600 000

(a) The data reflect the ranges found in the literature; the distinction between reserves and resources is based on current (exploration and production) technology and market conditions. Resource data are not cumulative and do not include reserves.
(b) Reserves, resources, and occurrences of uranium are based on a once-through fuel cycle operation. Closed fuel cycles and breeding technology would increase the uranium reserve and resource dimensions 50–60 fold. Thorium-based fuel cycles would enlarge the fissile-resource base further.
(c) Unconvential uranium occurrences include uranium dissolved in seawater

Source: Chapter 7.

long-term resource availability. In essence, sufficient long-term supply is a function of investment in research and development (exploration and new production methods) and in extraction capacity, with demand prospects and competitive markets as the principal drivers.

For renewable energy sources, the concepts of reserves, resources, and occurrences need to be modified, as renewables represent (in principle) annual energy flows that, if harvested without disturbing nature's equilibria, are available sustainably and indefinitely. In this context, the total natural flows of solar, wind, hydro, geothermal energy, and grown biomass are referred to as *theoretical potentials* and are analogous to fossil occurrences. For resources, the concept of *technical potentials* is used as a proxy. The distinction between technical and theoretical potentials thus reflects the possible degree of use determined by thermodynamic, geographical, technological, or social limitations without consideration of economic feasibility.

Economic potentials then correspond to reserves – i.e., the portion of the technical potential that could be used cost-effectively with current technology and costs of production. Future innovation and technology change expand the techno-economic frontier further into the previously technical potential. For renewables, the technical and economic resource potentials are defined by the techno-economic performance characteristics, social acceptance, and environmental compatibility of the respective conversion technology – for instance, solar panels or wind converters. Like hydrocarbon reserves and resources, economic and technical renewable potentials are dynamically moving targets in response to market conditions, demand, availability of technology, and overall performance. Conversion technologies, however, are not considered in this discussion on resources. Consequently, no reserve equivalent (or economic potential) is given here for renewable resources. Rather, the deployment ranges resulting from the GEA pathways analyses (see Chapter 17) are compared with their annual flows.

1.5.2 Fossil and Fissile Resources

Occurrences of hydrocarbons and fissile materials in the earth's crust are plentiful – yet they are finite. The extent of the ultimately recoverable oil, natural gas, coal, or uranium has been subject to numerous reviews, and still there is a large range in the literature – a range that sustains continued debate and controversy. The large range is the result of varying boundaries of what is included in the analysis of a finite stock of an exhaustible resource – for example, conventional oil only, or conventional oil plus unconventional occurrences such as oil shale, tar sands, and extra heavy oils. Likewise, uranium resources are a function of the level of uranium ore concentrations in the source rocks considered technically and economically extractable over the long run.

Table 1.3 summarizes the global fossil and fissile reserves, resources, and occurrences identified in the GEA and contrasts these with the cumulative resource use (2005–2100) in the GEA pathways.

At the low end, cumulative global oil production in GEA pathways amounts to little more than total historical oil production up to 2005 – a sign of oil approaching peak production but also of a continued future for the oil industry. At the high end, future cumulative oil production is about 60% higher than past production without tapping unconventional oil in significant quantities.

1.5.3 Renewable Resources

Renewable energy resources represent the annual energy flows available through sustainable harvesting on an indefinite basis. While their annual flows far exceed global energy needs, the challenge lies in developing adequate technologies to manage the often low or varying

Table 1.4 | Renewable energy flows, potential, and utilization in EJ of energy inputs provided by nature.

	Primary Energy Equivalent in 2005	Utilization GEA pathways	Technical potential	Annual flows
	[EJ]	[EJ/yr]	[EJ/yr]	[EJ/yr]
Biomass, MSW, etc.	46	125–220	160–270	2200
Geothermal	1	1–22	810–1545	1500
Hydro	30	27–39	50–60	200
Solar	< 1	150–1500	62,000–280,000	3,900,000
Wind	1	41–715	1250–2250	110,000
Ocean	–	–	3240–10,500	1,000,000

Note: The data are energy-input data, not output. Considering technology-specific conversion factors greatly reduces the output potentials. For example, the technical potential of some 3000 EJ/yr of ocean energy in ocean thermal energy conversion (OTEC) would result in an electricity output of about 100 EJ/yr.

Source: Chapter 7 (see also Chapter 11 and IPCC, 2011 for a discussion of renewable resource inventories and their differences). Note: MSW = municipal (and other) solid wastes.

energy densities and supply intermittencies, and to convert them into usable fuels (see Section 1.5.4 below). Except for biomass, technologies harvesting renewable energy flows convert resource flows directly into electricity or heat. Their technical potentials are limited by factors such as geographical orientation, terrain, or proximity of water, while the economic potentials are a direct function of the performance characteristics of their conversion technologies within a specific local market setting.

Annual renewable energy flows are abundant and exceed even the highest future demand scenarios by orders of magnitude. The influx of solar radiation reaching the Earth's surface amounts to 3.9 million EJ/yr. Accounting for cloud coverage and empirical irradiance data, the local availability of solar energy reduces to 630,000 EJ. Deducting areas with harsh or unsuitable terrain leads to a technical potential ranging between 62,000 EJ/yr and 280,000 EJ/yr. By 2100 the GEA pathways, presented in Chapter 17, utilize up to 1500 EJ/yr of solar radiation (see Table 1.4). Note: The flows, potential, and utilization rates in Table 1.4 are given in terms of energy input – not as outputs (secondary energy or using any accounting scheme for equivalent primary energy – see Appendix 1.A). The production and utilization data, therefore, differ from the presentation in Chapter 17.

The energy carried by wind flows around the globe is estimated at about 110,000 EJ/yr,[29] of which some 1550 EJ/yr to 2250 EJ/yr are suitable for the generation of mechanical energy. The GEA pathways range of wind utilization varies between 41 EJ/yr and 715 EJ/yr. The energy in the water cycle amounts to more than 500,000 EJ/yr, of which 200 EJ/yr could theoretically be harnessed for hydroelectricity. The GEA pathways utilize between 27 EJ/yr and 39 EJ/yr compared to a technical potential estimated at 53 EJ/yr to 57 EJ/yr.

Net primary biomass production is approximately 2400 EJ/yr, which, after deducting the needs for food and feed, leaves in theory some 1330 EJ/yr for energy purposes. Accounting for constraints such as water availability, biodiversity, and other sustainability considerations, the technical bioenergy potential reduces to 160 EJ/yr to 270 EJ/yr, of which between 125 EJ/yr and 220 EJ/yr are utilized in the GEA pathways. The global geothermal energy stored in the Earth's crust up to a depth of 5000 meters is estimated at 140,000 EJ. The annual rate of heat flow to the Earth's surface is about 1500 EJ/yr, with an estimated potential rate of utilization of up to 1000 EJ/yr.

Oceans are the largest solar energy collectors on Earth, absorbing on average some 1 million EJ/yr. These gigantic annual energy flows are of theoretical value only, and the amounts that can be technically and economically utilized are significantly lower.

1.5.4 Energy Densities

The concept of energy density refers to the amount of energy generated or used per unit of land. The customary unit for energy densities is Watts per square meter (W/m^2), referring to a continuous (average) availability of the power of one Watt over a year. Typical energy densities for demand as well as supply are illustrated in Figure 1.17.

Energy demand and supply densities have co-evolved since the onset of the Industrial Revolution. In fact, one of the advantages of fossil fuels in the industrialization process has been their high energy density, which enables energy to be produced, transported, and stored with relative ease, even in locations with extremely high concentration of energy demand, such as industrial centers and rapidly growing urban areas. The mismatch between energy demand and supply densities is largest between urban energy use, which is highly concentrated, and renewable energies, which are characterized by vast, but highly diffuse energy flows.[30] The density of energy demand in urban areas is typically between 10 W/m^2 and 100

29 Wind, biomass, hydro, and ocean energy are all driven by the solar energy influx. Their numbers are, therefore, not additive to the solar numbers discussed above.

30 Exceptions are geothermal energy and urban (municipal) wastes, which are characterized by high energy density.

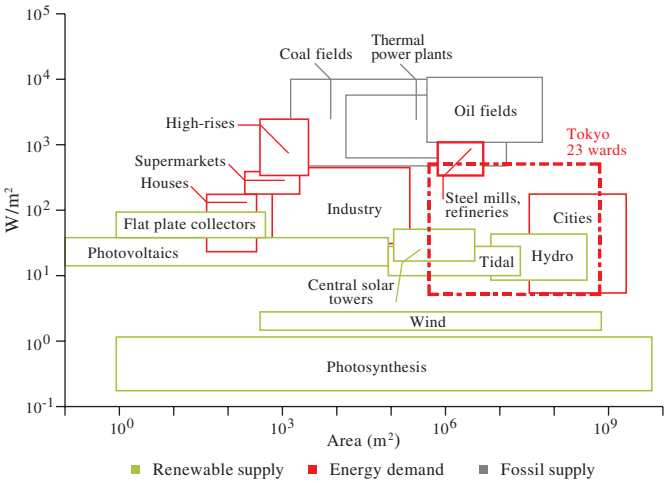

Figure 1.17 | Energy densities of fossil (grey) and renewable (green) energy supply and demand (red). Source: modified and adapted from Smil, 1991.

W/m² and can reach some 1000 W/m² in extreme locations, such as skyscraper complexes and high-density business districts (see Figure 1.17 for an illustration of Tokyo's 23 wards [districts]). Conversely, renewable energies have typical energy supply densities of a few W/m² under ideal conditions (assuming all land can be devoted to harnessing renewable energy flows). Under practical conditions (considering competing land-uses for agriculture and human settlements) renewable energies can yield typically between 0.1 W/m² and 0.5 W/m² (see Chapter 18). As a result, locally harvested renewable energies in densely populated areas such as cities can only provide a very small fraction (some one percent) of urban energy demand. Therefore, renewable energies also have to be harvested in locations where land and favorable renewable resource potentials are available, and need then to be transported over longer distances to urban centers with their high energy demand densities.

1.6 Production, Trade, and Conversions

1.6.1 Introduction

The energy system consists of an intricate web of energy conversion processes linking primary energy resources to the provision of energy services. A first overview of energy conversion, therefore, can be gained by looking at the associated energy flows (see Figure 1.5 above). Due to the associated conversion losses, the energy flows get larger the further upstream the energy system one moves, which is the reason why global primary energy flows (496 EJ) are about three times larger than useful energy flows (169 EJ).

As the geographical location of energy resources and "downstream" components of the energy system are distributed very unevenly, this section begins by describing major global primary energy flows from production, use, and trade of energy.

1.6.2 Production, Use, and Trade

The sheer size of global energy flows, that dwarf energy storage capacities, implies a fundamental energy market identity: production of energy flows needs to equal demand, and vice versa. As energy demand and production capacities are distributed unevenly geographically, this basic market identity translates into vast flows of *energy trade*. Energy is traded in three forms:

direct energy flows of primary energy (coal, crude oil, and natural gas) and secondary energy (primarily refined oil products); and

indirect (embodied) energy flows, in which energy is traded in the form of (energy-intensive) commodities (aluminum, steel, etc.) and products (fertilizer, steel rails, cars, etc.).

The following sections summarize the status of primary energy production, trade, and *use* (defined as "Total Primary Energy Supply" – or TPES – in energy balances) for fossil fuels, as they are the dominant form of current global energy trade flows.[31]

1.6.2.1 Direct Energy

Table 1.5 summarizes primary energy production, trade, and use for nine regions and the world in 2005. From the TPES of some 390 EJ of fossil fuels in 2005, some 230 EJ (or close to 60%) are represented by energy imports. The share of traded energy (direct primary and secondary energy trade) in TPES is markedly different for different fuels: it is lowest for coal (18%), followed by natural gas (30%), and reaches 80% for crude oil. Including trade in refined oil products (secondary energy), oil-related energy trade flows (172 EJ) actually exceed the global TPES of oil products (167 EJ). This apparent paradox results from the fact that large importers of crude oil have corresponding large refining capacities, becoming in turn large exporters of refined petroleum products. The international division of labor in energy means that a barrel of crude oil can be traded various times and in various forms across national boundaries (not to mention the multiple "virtual" trades of the same barrel on speculative and futures markets). A good (even if extreme) illustration is provided in the case of Singapore: total fossil fuel imports equal a staggering 880 GJ/capita, of which 210 GJ/capita are used as primary energy input to the Singapore economy (with 120 GJ/capita final energy use), 450 GJ/capita are re-exported as oil products, and an additional 220 GJ/capita exported as bunker fuels for international

31 Renewables are dominated by traditional biomass use that is harvested and used locally without international trade. Modern renewables such as hydropower, solar, or wind, or for that matter also nuclear power, enter the energy system as secondary energy carriers (predominantly electricity, with some direct heat), which are generally not traded internationally. International trade in biofuels remains comparatively modest at some 0.2 EJ in 2005. International trade in electricity is also small: slightly above 2 EJ in 2005.

Table 1.5 | World trade flows between regions (in EJ) for 2005.

Note: The five GEA regions have been expanded to nine to better represent international trade flows. These nine regions represent well the major international energy trade flows obtained from aggregating inter-country trade flows based on IEA statistics. Only for crude oil, the inter-regional trade flows cover only 70% of the true international trade in crude oil (the difference is intra-regional trade – e.g., within the EU27 countries, or within Latin America (LAC) countries.

Source: data from IEA, 2007a and 2007b.

shipping and aviation (Schulz, 2010). In addition, Singapore's energy trade is also characterized by vast energy flows embodied in exported products (petrochemicals) as well as in goods imported into this city state (see the discussion below).

The largest annual international trade flows (from aggregate country imports or exports) in 2005 were crude oil, with some 135 EJ, followed by oil products (40 EJ), natural gas (30 EJ), and coal (20 EJ).

In terms of regions, the largest[32] exporters for crude oil were the Middle East (MEA) region (some 50 EJ), the former Soviet Union (14 EJ), and Latin America and the Caribbean (LAC – 11 EJ), balanced from the oil import side with imports to Europe (27 EJ), the United States (24 EJ), and developing economies in Asia, excluding China, with 18 EJ. For gas trade, only exports from the former Soviet Union (10 EJ) and imports to Europe (13 EJ) are beyond the 10 EJ reporting threshold level adopted here. Inter-regional coal trade is comparatively small (with largest regional exports and imports of 8 EJ (Australia) and Europe (6 EJ), respectively).

Perhaps the least known aspect of international energy trade is the significant exports and imports of petroleum products. Europe, while a main crude oil importer (27 EJ), nonetheless exports 11 EJ of oil products, in order to import in turn a further 13 EJ of oil products. The trade in oil products to/from other regions is much smaller. The picture emerging from the international energy trade is thus less one of directed "source–sink" energy resource flows, but rather one of an increasingly complex "foodweb" in which energy is traded in primary and secondary forms across multiple boundaries.

1.6.2.2 Embodied Energy

The literature and statistical basis of embodied energy flows is thin, as existing studies almost invariably focus on embodied CO_2 emissions in international trade, without disclosing the underlying energy data. Notable exceptions are studies on embodied energy in the international trade of Brazil (Machado, 2000), China (Liu et al., 2010), and Singapore (Schulz, 2010). Current energy accounting and balances report direct energy flows, whereas *embodied energy* trade is quite under-researched and not reported systematically.

The only data source available for estimating embodied energy flows is the GTAP7 (Narayanan et al., 2008) database that contains data suitable for estimating the fossil fuel energy embodied in international trade flows by input-output analysis (Table 1.6). Important limitations and intricate methodological issues need to be considered when trying to estimate the energy embodied in internationally traded commodities

32 Flows below 10 EJ are not discussed separately. Details are given in Table 1.5. All data refer to the year 2005.

Table 1.6 | Trade in embodied energy between major regions (in EJ, only fossil primary energy) as derived from the GTAP7 Multi-Regional Input-Output Tables for 2005.

and products based on multi-regional input-output tables. The flows summarized in Table 1.6, therefore, need to be considered as order of magnitude estimates that await further analytical and empirical refinements. Nonetheless, even these "rough" data help to get a sense of proportion. GTAP estimates that (fossil) energy embodied in international trade amounts to some 100 EJ – i.e., some 20% of global primary energy use – compared to direct energy trade flows of some 190 EJ in 2005 when using the same regional aggregation[33] as reported in Table 1.6.

In other words, at least half of global primary energy use is traded among regions in either direct or indirect (embodied) form, which illustrates the multitude of interdependencies at play in the global energy system that go far beyond traditional concerns of oil import dependency. Assuming that the relative proportions of intra-regional to international trade flows hold for embodied energy flows in a similar way, as in the case of direct energy trade flows, then direct and embodied energy trade flows (of perhaps 400 EJ) approach the level of world primary energy use in the year 2005 (500 EJ). Evidently, these numbers must not be interpreted through the traditional lens of (additive) "net" energy trade flows. The nature of the international division of labor is precisely that a Joule of energy can be traded many times, hence the trade numbers discussed above include multiple double-counting. Consider two examples: Iran is a major oil producer and exporter but lacks sufficient domestic refining capacity. A barrel of oil exported to Singapore may be re-exported back to Iran in the form of gasoline, or it may be re-exported back in the form of plastic or chemical products. The same physical energy thus ends up being counted twice as an international energy trade flow. China is a major steel producer, Australia a major exporter of metallurgical coal (used in the steel industry), and Germany a major car manufacturer. In our example, coal is exported from Australia to China, where it serves to produce steel, and this steel is exported from China to Germany, where manufacturers use it to produce German cars for export to China. Direct energy trade (coal) becomes embodied energy trade (steel), which in turn becomes embodied energy trade again (cars), with a physical Joule energy counted three times as international energy trade. This example also illustrates the great difficulties in comprehensive accounting of energy (or GHG emission flows) through multiple exchanges and trade flows. Who ultimately "owns" the corresponding energy or GHG "footprint": the Australian coal producer, the Chinese steel manufacturer, the German car company, or the Chinese consumer (car buyer)?

1.6.2.3 Energy Trade Flows

Figure 1.18 summarizes all direct (primary and secondary) and indirect fossil fuel-related international trade flows in the form of a map to demonstrate the high degree of energy interdependence worldwide. The term interdependence suggests that the energy system is much more integrated than conventional wisdom or energy security concerns would suggest. Not only do many countries critically depend on oil exports from the Middle East, the Middle East also depends on numerous other countries for its supply of food, consumer products, and investment goods that all embody (part of) the region's previous energy exports.

1.6.3 Conversions

1.6.3.1 Introduction and Overview

One way of looking at energy conversion processes is to consider the associated energy conversion capacity, which is a proxy of the aggregated size of energy conversion technologies and hence an indicator of

33 The difference between the 190 EJ intra-regional trade (nine regions) and the 230 EJ reported as international energy trade reflects the energy trade between countries within a given region (e.g., between Germany and France in the EU region, or between Indonesia and Bangladesh in the Asia-sans-China region) which is not counted in the regional trade flows but included in the global total trade numbers (summed from national statistics).

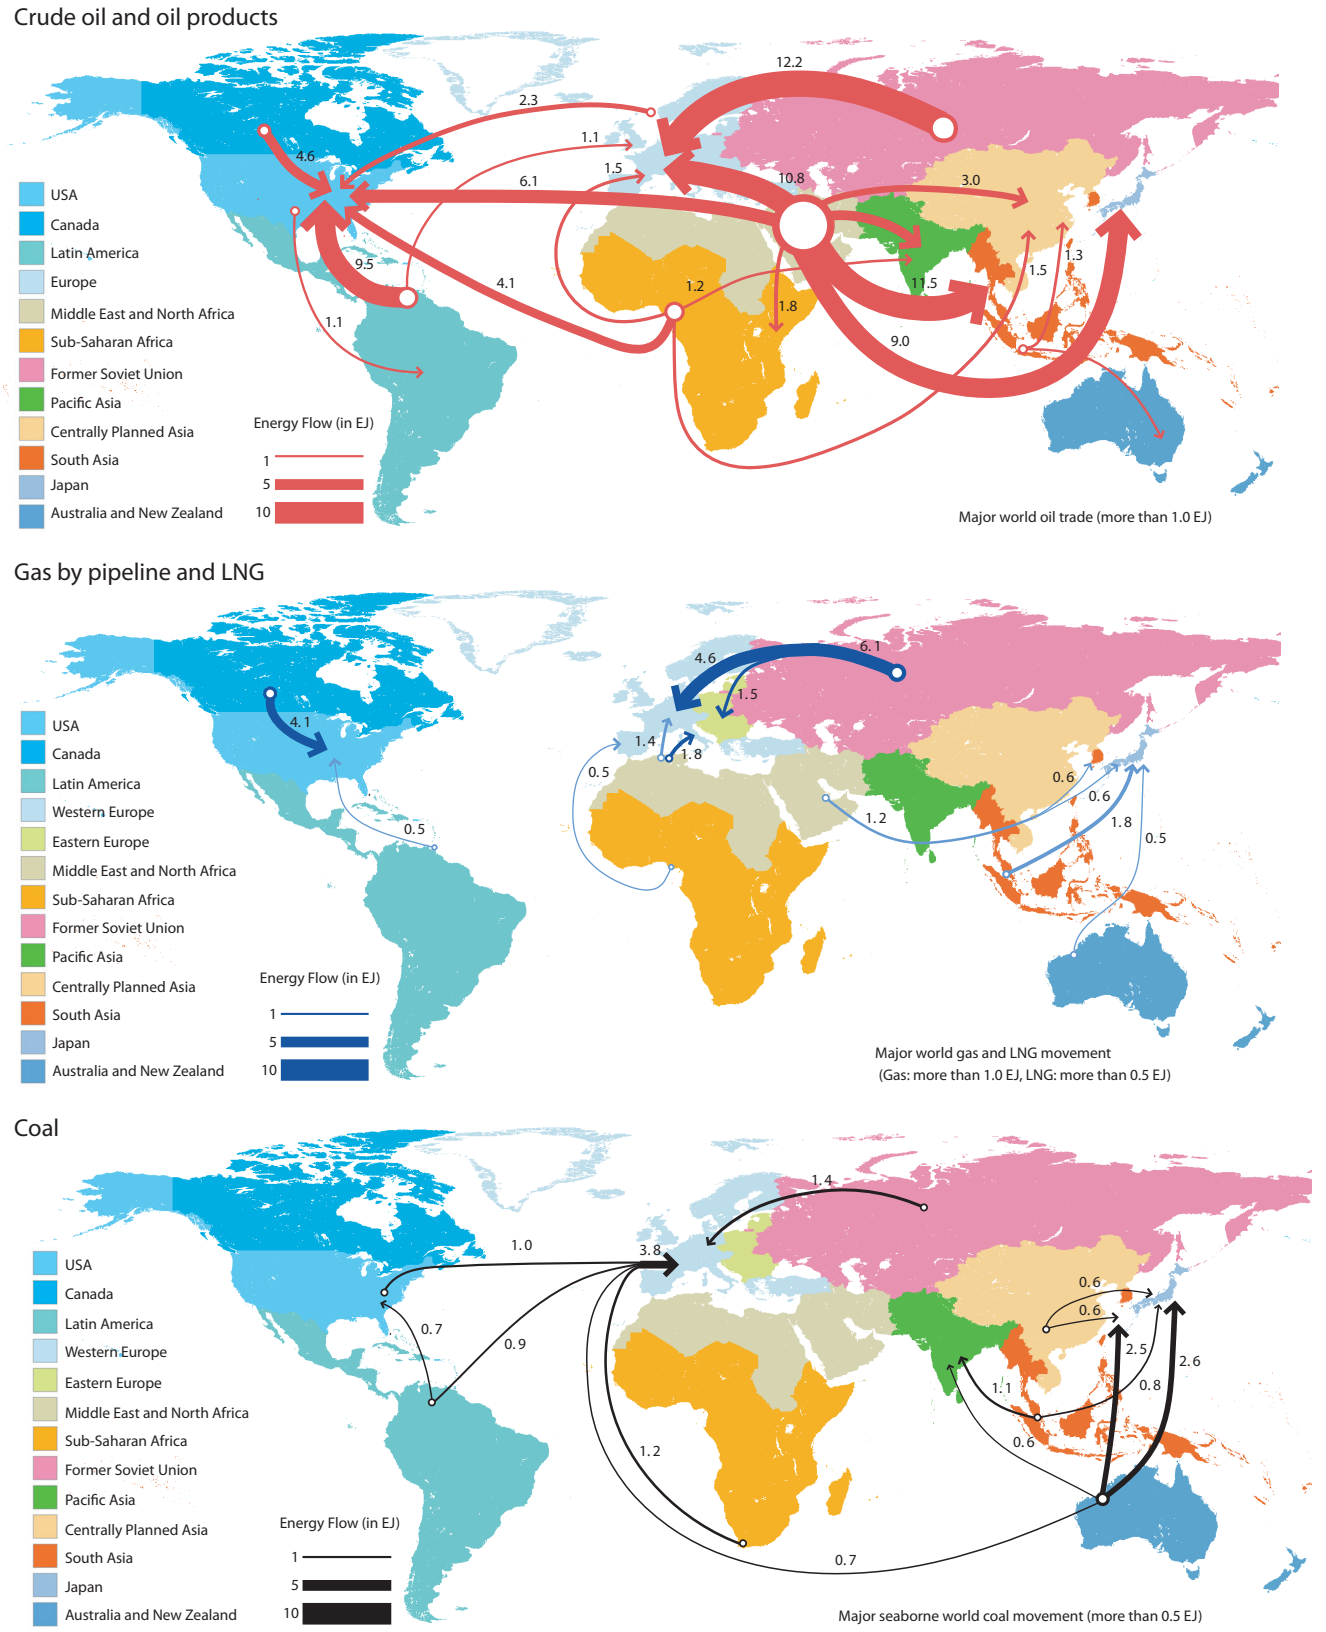

Figure 1.18a | World energy trade of fossil fuels: direct primary and secondary energy coal (black), oil and oil products (red) and gas (LNG light blue, pipeline gas: dark blue), in EJ. Source: Oil/gas energy trade for 2005 (BP, 2007), coal trade for 2008 (WCI, 2009).

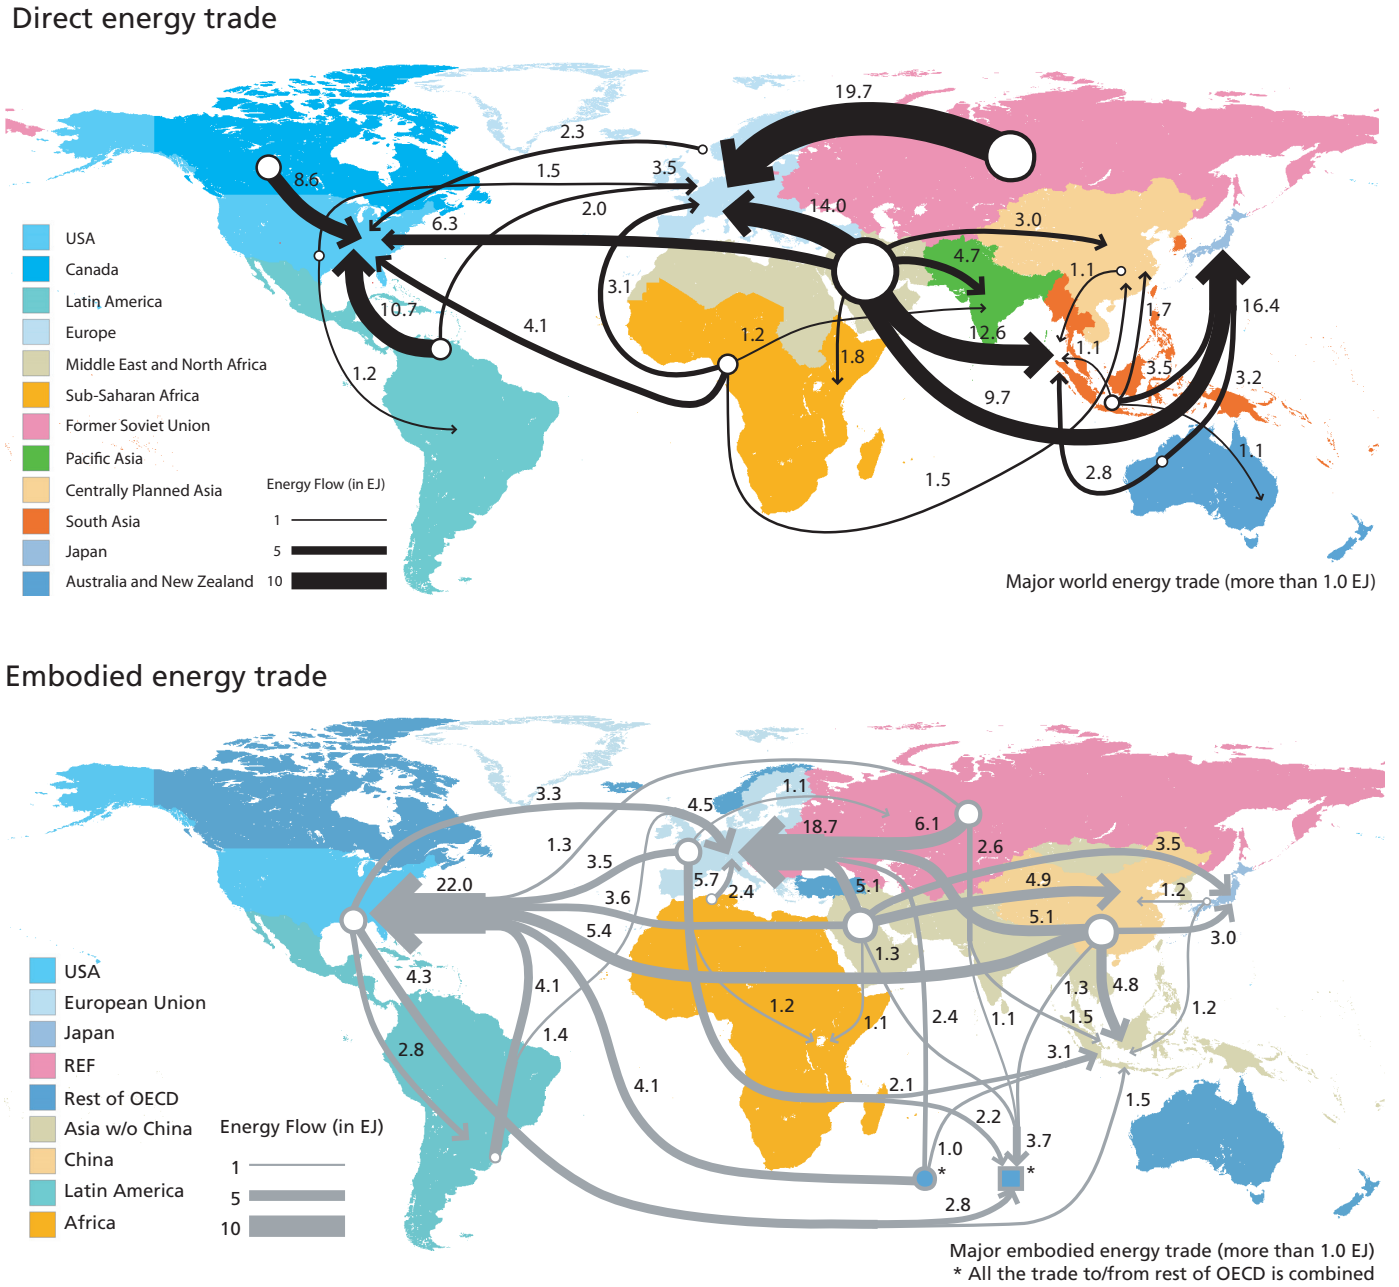

Figure 1.18b | World energy trade of total direct energy (black) as well as embodied energy in goods traded (grey), in EJ. Source: Embodied energy trade for 2004 (GTAP database, 2010), direct energy trade (BP, 2007; WCI, 2009).

the magnitude of technological change and capital replacement required for improving energy efficiency through the application of more efficient processes and technologies. Unlike the picture that emerges when looking at energy flows, the scale of energy conversion technologies portrays a different pattern in which energy end-use conversions dominate. Although global numbers are not available, this pattern of an increasing scale of energy conversion processes and devices revealed by the long-term history of the US energy system (Table 1.7) is quite characteristic of the global picture as well.

For instance, in 2000 the total installed capacity of all US energy conversion devices equaled a staggering 35 TW (that compares to a global energy flow of some 16 TW-yr).[34] Energy supply-related conversion processes account for some 5 TW, with 30 TW in energy end-use, most notably in the form of automobiles (25 TW). Assuming all cars ran on zero-emission hydrogen fuel cells, the installed capacity of the existing car fleet would be about ten times larger than that of all electricity-generating power plants and could easily substitute the traditional utility-dominated

34 In other words, if all US energy conversion devices operated 24 hours a day, 7 days a week, they would transform energy flows twice as large as the entire world energy use. The fact that US primary energy of 100 EJ is equal to 20% of global primary energy use illustrates the comparatively low aggregate capacity utilization of energy conversion devices, particularly in energy end use. (Transportation surveys suggest, for instance, that on average a car is used only one hour per day).

Table 1.7 | Installed capacity of energy conversion technologies (in GW) for the United States, 1850 to 2000.

GW (rounded)		1850	1900	1950	2000

centralized electricity-generation model by an entirely decentralized generation system, powered by cars during their ample idle times. Such drastic transformations in electricity generation have been proposed (e.g., Lovins et al., 1996), especially as a means of accommodating vastly increased contributions from intermittent renewables such as wind, solar thermal, or photovoltaic systems without the need for centralized energy storage. Even if currently futuristic, such daring visions of technology are a useful reminder that the analysis of energy systems needs to look beyond energy flows only and to always consider both major components of energy systems: energy supply *and* energy end-use.

1.6.3.2 Electricity Generation

Electricity is growing faster as a share of energy end-uses than other direct-combustion uses of fuels. Between 1971 and 2008, world electricity production almost quadrupled from 19 EJ to 73 EJ of secondary energy (see Figure 1.19 below) – an absolute increase of 54 EJ. Some 60% of this growth (32 EJ) was in countries outside the Organisation for Economic Co-operation and Development (OECD).

Figure 1.19 depicts the fuel share in global electricity production. About 68% of global electricity is generated from the combustion of fossil fuels, with coal accounting for more than 40% of total production. The share of oil in power production has decreased considerably from 23% to 6% since the first oil crisis in 1973. On the other hand, the share of natural gas has increased from 12% to 21%. Renewable energy sources contribute about 18%, with hydropower accounting for more than 85% of this. Following a rapid expansion in the 1970s and 1980s, nuclear electricity generation has seen little growth since.

Figure 1.19 also shows electricity production for the GEA regions for the base year 2005. Fuel mixes vary widely, primarily reflecting the

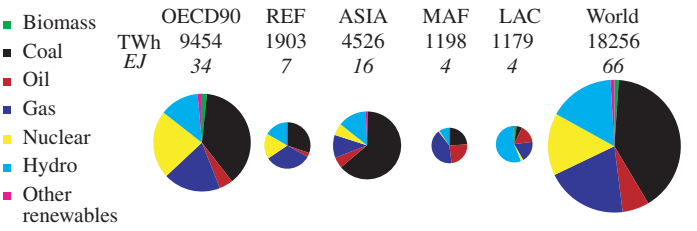

Figure 1.19 | Electricity output by generating source in 2005: World and five GEA Regions in TWh and EJ (in italics). Source: IEA, 2007a and 2007b. Note: Circle areas are proportional to electricity generated.

availability of local energy resources and to some extent also reflecting past technical and financial capacity to invest in advanced technologies such as nuclear. Coal for electricity generation is most prominent in Asia, accounting for almost 70% of production. OECD and Africa also have significant shares of coal-based power generation. Nuclear energy is primarily used in OECD countries as well as in Eastern Europe and the countries of the former Soviet Union. It makes only a minor contribution in developing countries, except China, which currently has the most nuclear power under construction in the world. Hydropower is unevenly used, providing 66% of electricity in Latin America and the Caribbean. Non-hydro renewable energy in electricity production is low in all regions. However, as a result of various policy support mechanisms in a rapidly increasing number of countries (see Chapter 11), about half of current investments in power generation are in renewable generation.

Figure 1.20 shows regional trends in electricity output: growth trends are across heterogeneous regions. Most additional electricity production since 1971 was actually in the OECD countries (+22 EJ), slightly larger than in the Asia region[35] (+20 EJ/yr). More recent growth trends, however, change this picture dramatically. Since 1990, growth in electricity generation has focused heavily on Asia (most notably in China, an additional 16 EJ of electricity generated), followed by the OECD

35 For the definition of GEA regions, see Appendix 1.B.

(+9 EJ) and all other developing countries combined (6 EJ). The REF region even experienced a slight drop in electricity output in the aftermath of its economic restructuring.

1.7 Environmental Impacts (Emissions)

1.7.1 Introduction

Energy extraction, conversion, and use are major contributors to GHG emissions and thus global warming. In addition, a host of energy-linked pollutant emissions, including suspended fine particles and precursors of acid deposition, contribute to local and regional air pollution and ecosystem degradation. Energy-related pollutants also result in adverse effects for human health. The largest single source of health impacts of energy is associated with indoor air pollution resulting from the use of traditional biomass in open fires or inefficient cooking stoves by poor people in developing countries. Its human health impacts are estimated to result in about 2 million premature deaths, or about 42 million person-years of life (DALYs[36]) lost per year, due to respiratory and other diseases, affecting particularly women and children, making access to culturally acceptable, clean, and efficient cooking fuels a priority policy concern.

Table 1.8 summarizes the major sources of global GHGs and selected[37] pollutant emissions. The main pollutants emitted in the combustion of fossil fuels are sulfur and nitrogen oxides, carbon monoxide, and black and organic carbon, including suspended particulate matter. In addition, fossil fuel combustion in the energy sector produces more CO_2 than any other human activity, and contributes to about 30% of global methane (CH_4) emissions. Altogether, the energy sector is thus the biggest source of anthropogenic GHG emissions that are changing the composition of the atmosphere.

1.7.2 CO_2 and other GHGs

CO_2 emissions from fossil energy use in 2005 are estimated at 7.2 Pg C or 26.4 Pg CO_2 (Boden et al., 2010). This represents 80% of all anthropogenic sources of CO_2 in that year, with the remainder associated with land-use changes (deforestation) (Houghton, 2008).

36 Thus, on average, each premature death is associated with close to 20 life-years lost. Estimates for the health impact of outdoor air pollution suggest close to 3 million pre-mature deaths/year and some 23 million DALYS. The health impacts of indoor and outdoor air pollution are not additive. See Chapters 4 and 17 for a more detailed discussion. Note: DALYS: "Disability-adjusted Life Years are units for measuring the global burden of disease and the effectiveness of health interventions and changes in living conditions. DALYs are calculated as the present value of future years of disability-free life that are lost as a result of premature death or disability occurring in a particular year. DALY is a summary measure of population health and includes two components, years of life lost due to premature mortality and years lost due to disability" (WHO, 2011).

37 Only emissions of pollutants where energy plays an important role are highlighted here. As such, Chapter 1 does not suggest that other pollutants and emissions sources are not important, but rather that their assessment is beyond the scope of this energy focused précis.

38 See www.iiasa.ac.at/web-apps/tnt/RcpDb.

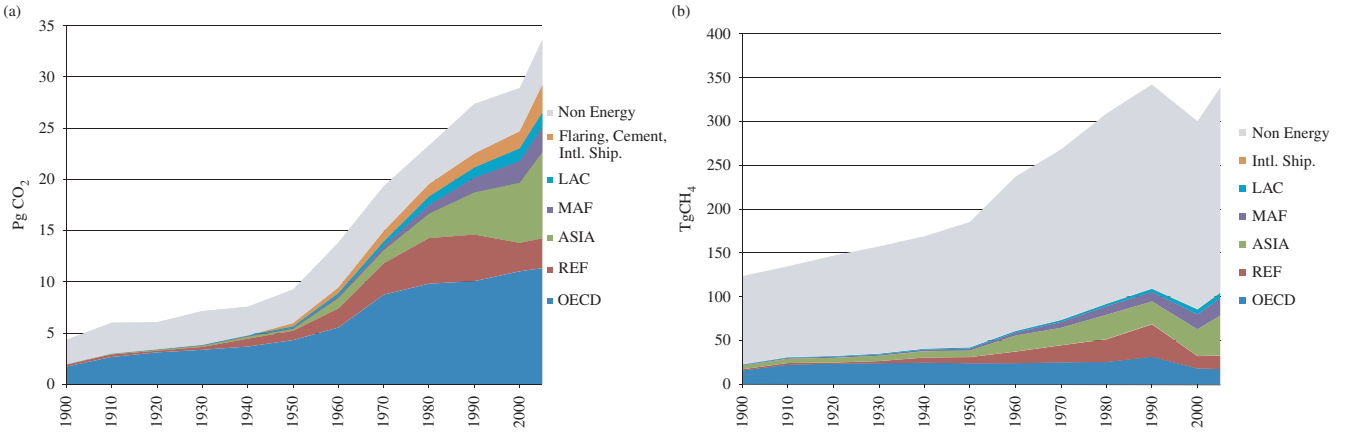

Figure 1.21 | Development of annual energy-related (a) CO_2 and (b) CH_4 emissions by region (compared to global non-energy sources) from 1900 to 2005 in Pg (Gt)(CO_2) and Tg (CH_4). Source: data from Boden et al., 2010; Houghton, 2008; IPCC-RCP database.[39]

Figure 1.21 shows the historical development of fossil energy CO_2 emissions by major world regions (compared to global non-energy-related sources of CO_2). Today's industrialized countries contribute most to the present global CO_2 emissions and have also emitted most of the historical emissions associated with the observed increase in atmospheric CO_2 concentrations. Although they are presently at lower absolute levels, emissions are growing more rapidly in developing countries. The largest source of energy-related carbon emissions are coal and oil (including oil products for feedstocks), with each about a 40% share, followed by natural gas, which represents about 20% of carbon emissions from the energy sector.

CH_4 is the second largest GHG contributing to anthropogenic global warming. Energy-related sources include coal production (where it is a major safety hazard), oil production (from associated natural gas), and natural gas production, transport, and distribution (leaks). Municipal solid waste, animal manure, rice cultivation, wastewater, and crop residue burning are the major non-energy-related sources of CH_4 emissions. While CH_4 emissions from energy accounted for only 30% of total CH_4 emissions in 2005, the relative share of the energy sector has been continuously increasing due to the rise of fossil fuel use throughout the 20th century (see Figure 1.21).

Other GHGs include nitrous oxide (N_2O), tetrafluoromethane (CF_4), sulfur hexafluoride (SF_6), and different types of ozone-depleting hydro-fluorocarbons (HFCs). These gases are predominantly emitted from non-energy sectors. N_2O is the largest contributor to global warming among these other GHGs (IPCC, 2001). Important sources of N_2O include agricultural soil, animal manure, sewage, industry, automobiles, and biomass burning, with energy contributing about 5% to total N_2O emissions. CF_4, SF_6, and HFCs are predominantly emitted by various industrial sources, with only minor contributions from the energy sector (and are, therefore, not reported separately here).

39 See www.iiasa.ac.at/web-apps/tnt/RcpDb.

1.7.3 Traditional Pollutants (SO_x, NO_x, Particulates, etc.)

Energy-related air pollution is responsible for a number of health effects including increased mortality and morbidity from cardio-respiratory diseases (Brunekreef and Holgate, 2002). Developing countries in particular face the greatest burden of impacts from air pollution, both outdoor and indoor. They tend to have high long-term levels of exposure from pollution sources such as forest fires, biomass burning, coal-fired power plants, vehicles, and industrial facilities, thus implying relatively high health impacts. In addition, indoor air pollution due to the lack of access to clean cooking fuels adds to exposure to air pollution, particularly in large parts of Asia and Africa. According to the *World Health Report 2002*, indoor air pollution is the second largest environmental contributor to ill health, behind unsafe water and sanitation (WHO, 2002).

Figure 1.22 shows the historical development of selected pollutant emissions by major world regions (compared to global non-energy-related sources). It builds upon the collaboration of major inventory experts (Lamarque et al., 2010; Smith et al., 2011).

Unfortunately for some important pollutants, such as lead or particulate matter, comparable global inventories with historical trends do not exist. Information for these pollutants is usually summarized at the regional, national, or city level only. Below, the trends for various pollutants are summarized, starting with those that are dominated by emissions from the energy sector.

Anthropogenic *sulfur emissions* have resulted in greatly increased sulfur deposition and atmospheric sulfate loadings and acidic deposition in and around most industrialized areas (Smith et al., 2011). High levels of ambient sulfur concentrations impact human health and cause corrosion. Sulfuric acid deposition can be detrimental to ecosystems, harming aquatic animals and plants, and is also damaging a wide range of terrestrial plant life. In addition, sulfur dioxide forms sulfate

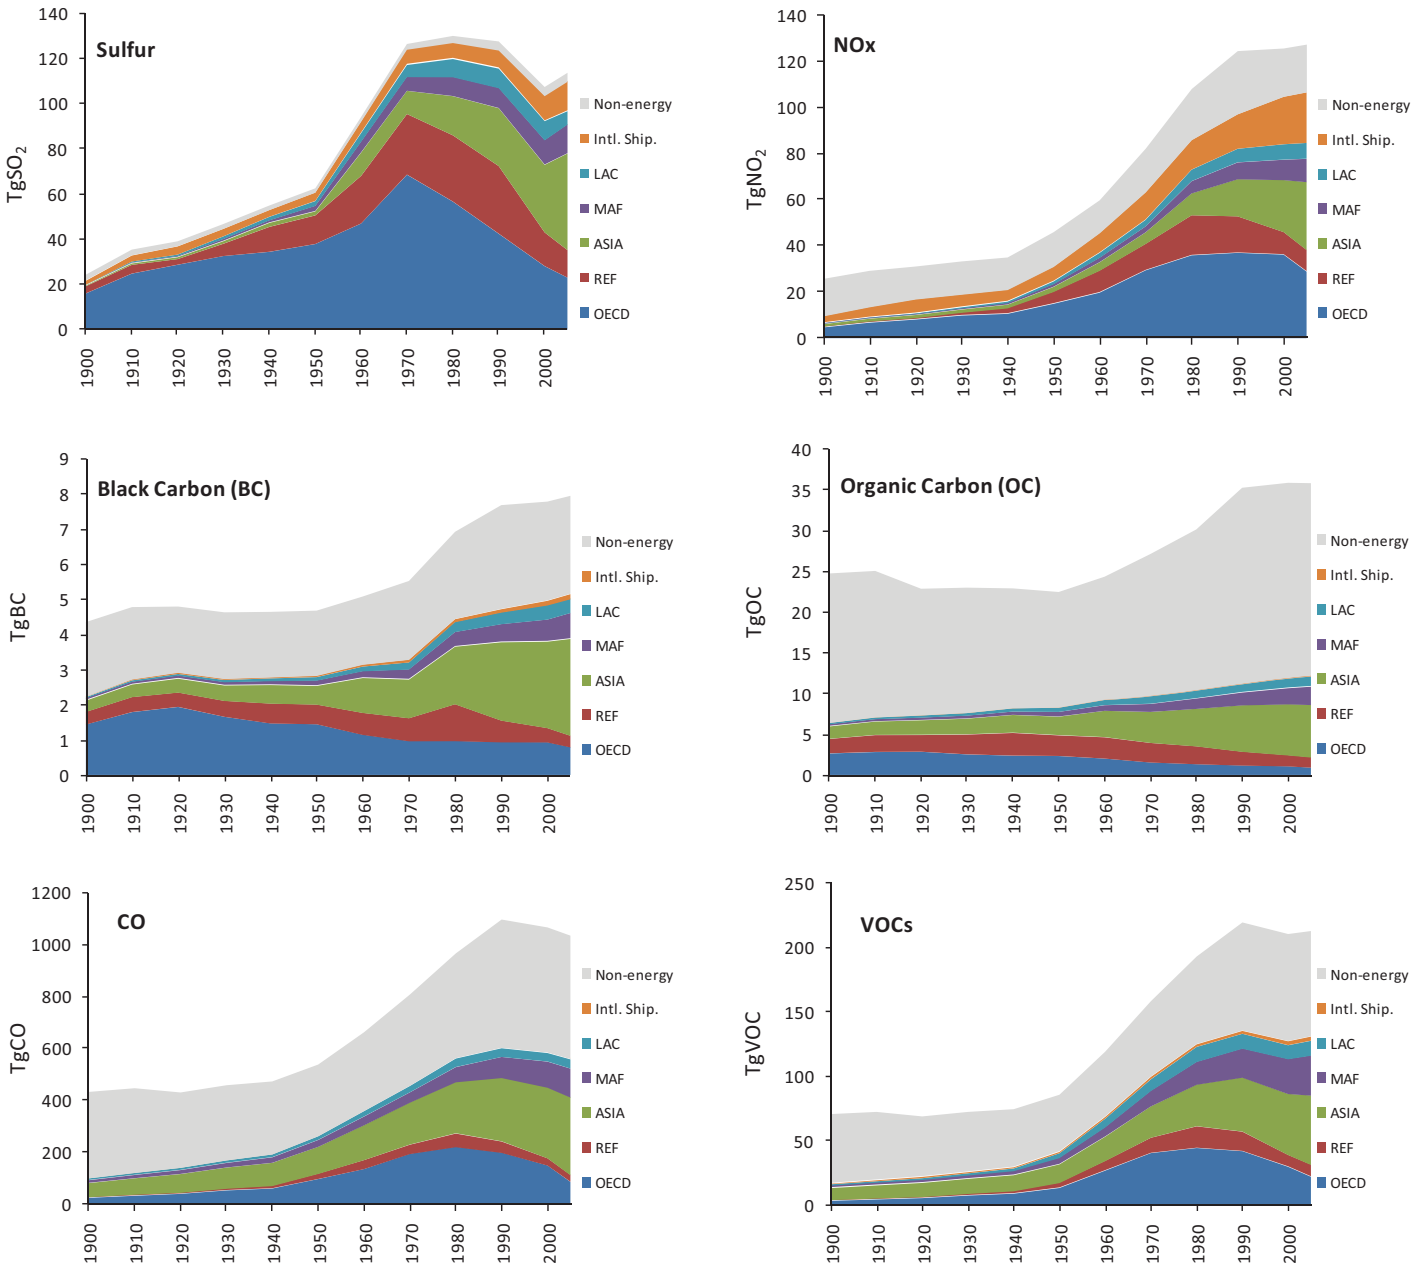

Figure 1.22 | Development of annual energy-related pollutant emissions in Tg: sulfur (SO_2), nitrogen oxides (NO_x), black carbon (BC), organic carbon (OC), carbon monoxide (CO), and volatile organic compounds (VOCs) by annual region (compared to global non-energy sources) from 1900 to 2005.

aerosols that have a significant effect on global and regional climates. The effect on global climate change of sulfate aerosols may be second only to that caused by CO_2, albeit in the opposite direction (Forster et al., 2007). Stratospheric sulfate aerosols back-scatter incoming solar radiation, producing (regional) cooling effects that mask the global warming signal from increased atmospheric concentration of GHGs. Sulfur is ubiquitous in the biosphere and often occurs in relatively high concentrations in fossil fuels, with coal and crude oil deposits commonly containing 1–2% sulfur by weight (and much higher in some deposits). The widespread combustion of fossil fuels from the energy sector has, therefore, greatly increased sulfur emissions into the atmosphere, with the anthropogenic component now substantially greater than natural emissions on a global basis (Smith et al., 2001; 2011). More than 90% of present sulfur emissions are released from the energy sector. Historically, global emissions peaked in the early 1970s due to the tightening of air pollution legislation particularly in industrialized countries and were decreasing until 2000. Sulfur emissions have resurged since (see Figure 1.22), with increased coal-related emissions in China, international shipping (using heavy fuel or "bunker" oil that has a particularly high sulfur content), and developing countries in general (Smith et al., 2011).

Emissions from nitrogen oxides (NO_x – predominantly nitrogen dioxide and nitric oxide) contribute to a wide variety of health and

environmental problems (respiratory diseases such as asthma, emphysema, and bronchitis; heart disease; damage to lung tissue; acid rain). NO_x is also a main component of ground-level ozone and smog and thus contributes to global warming. Similar to sulfur, NO_x emissions are dominated by the energy sector, which accounts for more than 80% of total anthropogenic NO_x emissions. Emissions from NO_x have continuously been increasing with the use of fossil fuels at the global level. Emissions trends differ significantly, however, at the regional level. While control measures in industrialized countries have resulted in improved air quality and decreasing NO_x emissions since the early 1980s, the rapid increase in NO_x emissions in Asia and from international shipping have more than compensated for improvements elsewhere, leading to an overall global increase in emissions (see Figure 1.22).

The incomplete combustion of carbon-containing fuels (fossil as well as biomass) causes emissions of *carbon monoxide* and other pollutants, including *particulate matter, black carbon,* and *organic carbon.*[40] In addition, black carbon strongly absorbs solar radiation and is contributing to climate warming (although its net aggregated effect is subject to uncertainty), and its deposition is a significant contributor to Arctic ice-melt. In 2005, combustion from the energy sector contributed about 75% of the total anthropogenic emissions of black carbon, with forest fires and savannah burning accounting for the remainder. Due to relatively higher emissions coefficients of organic carbon and carbon monoxide from vegetation fires, the contribution of the energy sector is between 35% and 50% and thus smaller than for black carbon (see Table 1.8 above). Historically, industrialized countries were once the primary source of emissions from incomplete combustion. However, emissions of black carbon and organic carbon in the industrialized world have been declining since the 1920s, as have those of carbon monoxide since the 1980s. Major drivers of this trend are improved technology and the introduction of air quality legislation. Today, the majority of energy-related emissions from incomplete combustion occur in developing countries (see Figure 1.22), resulting in significant health risks, particularly from household combustion of solid fuels (mostly biomass) that affect between half and three-quarters of the population in most poor countries, particularly in rural areas.

Volatile Organic Compounds (VOCs) are emitted by a variety of sources, including industrial processes (solvents), on-road vehicles, refineries, vegetation fires, and residential wood burning, as well as emanations from a wide array of household products. Total global anthropogenic VOC emissions are estimated at about 220 Tg in 2005, with the energy and industry sectors accounting for about 60% of the total. VOCs contribute to the formation of ground-level ozone and include a variety of chemicals, some of which have short- and long-term adverse health effects. As for other pollutants, the energy and industrial emissions have been increasing substantially, and in the recent decades the major sources of VOCs have moved from the industrialized world to developing countries, which contribute about 75% of present energy and industrial VOC emissions.

1.8 Heterogeneity in Energy Use

1.8.1 Introduction

In addition to the temporal variations in global energy use described in earlier sections, there is a huge degree of cross-sectional heterogeneity in energy use evident across the globe today. While aggregate energy statistics are insightful for describing the energy system globally, regionally, or nationally, they often mask the large disparities in energy use both across and within national and regional boundaries. Heterogeneities are evident both in the quantities of energy used and in the structure of use across different nations and sub-populations. These disparities stem, for the most part, from differences in incomes or levels of economic affluence, production and consumption activities, and lifestyles. Yet a small part of the variations might also be on account of differences in climatic conditions and thus energy service needs across regions (e.g., heating/cooling). Differences also exist in the types of energy carriers that are predominantly used and the levels of access to these across countries and populations.

1.8.2 Heterogeneity in Energy Use across Nations

Akin to the uneven development of economies around the world, energy use and service varies significantly across countries. In 2005, the total final energy use was about 330 EJ globally, with the average per capita final energy use about 50 GJ. However, this global average conceals enormous differences in final energy use per capita across nations. The starkest disparity in average national final energy use per capita can be found by comparing Qatar, the country with the highest average in 2005 (445 GJ/capita), with Eritrea, that with the lowest (<5 GJ/capita), a difference of a factor of about 94. The OECD countries, with less than a sixth of the world's population, account for over 45% of total final energy use (see Figure 1.23). Developing countries, with about four-fifths of the world's population, account for just under 40% of this total. OECD countries on average consume over 16 times as much energy per capita than developing countries in South Asia and Africa.

Differences in the amounts of final energy use per capita are mirrored in variations in the structure of energy use across nations and regions. In general, countries with higher levels of energy use per capita also use a larger proportion of their total final energy for transport uses. For instance, the OECD countries use over a third of their final energy for transport. In contrast, in Africa and Asia, over 40% of final energy is for residential and commercial uses. Finally, in addition to variations

40 Black carbon: pure carbon (soot) emitted ("black smoke") from the combustion of fossil fuels, biofuels and other biomass (vegetation burning). It absorbs sunlight and reradiates heat into the atmosphere, thus producing a climate warming effect. Organic carbon: carbon combined with oxygen/hydrogen atoms (organic radicals) mainly arising from the incomplete combustion ("brown" or "white smoke") of biomass. Organic carbon aerosols (fine particles suspended in the atmosphere) tend to back-scatter sunlight, producing a cooling effect on climate.

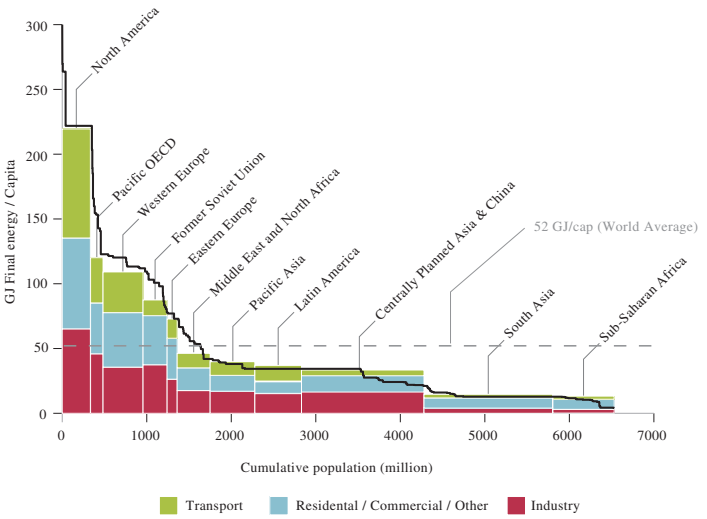

Figure 1.23 | World final energy (GJ) per capita versus cumulative population for 11 GEA regions sorted by declining per capita energy use (with final energy use disaggregated by sector and total, color bars); and total per capita final energy use for 137 countries in 2005 (black, solid line). Dashed horizontal line shows the average global final energy use per capita. Source: data from IEA, 2010.

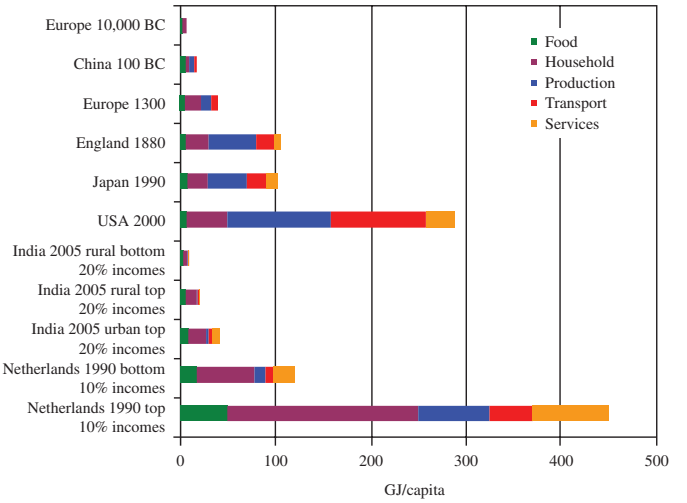

Figure 1.24 | Per capita primary energy use by service category over time and across different populations. Source: historical estimates: Smil, 1991; Japan, United States: IEA, 2010; India: Pachauri, 2007; Netherlands: Vringer and Block, 1995.

in the levels and purposes of energy use across nations, countries also exhibit very divergent patterns of energy use. Nearly a third of all final energy use in developing countries is unprocessed biomass, with this fraction being close to 90% for some least-developed countries. In addition, about 30% of the population in developing countries lack access to, and so do not use, any electricity. In developed OECD countries, however, almost all final energy use is in the form of electricity or oil/gas products. These differences in patterns have implications for the level of energy services across nations, as some carriers like traditional biomass used in traditional end-use devices have very low efficiencies, and are associated with high emissions, and social externalities.

1.8.3 Heterogeneity in Energy Use within Nations

Often the variance in energy use within nations can be of the same or greater order of magnitude as that across nations. In such instances, aggregate national indicators disguise intra-national disparities, sometimes grievously. Within nations, substantial differences in energy use exist across geographical regions, rural versus urban residents, and among other socio-economic and demographic sub-groups of the population. Spatial patterns of economic development and industrial activity are reflected in variations in quantities and structures of energy use between regions. In many developing countries, one can find evidence of a dual economy with substantial disparities in quantities and types of energy use between rural hinterlands, with poor infrastructure and formal development, and urban metropolitan areas that are the centers of industrial production and economic activity. Thus, for instance, as shown in Figure 1.24, the poorest 20% of the rural population in India have per capita energy use levels comparable to those estimated for the pre-agrarian European population some 10,000 years ago. Even the richest 20% of the rural population in India uses only about half as much energy per capita as the richest 20% of the urban population, with their energy use levels comparable to the estimates for China in 100 B.C. Some of this difference in the quantity of energy used can be explained by disparities in income levels across rural and urban regions. However, large disparities in the structure of energy use are also evident, both in terms of uses of energy and the types of energy used.

The starkest disparities in energy use within (and between) nations are those between rich and poor people. Thus, as Figure 1.24 illustrates, the richest decile of the Dutch population uses almost four times as much energy per capita as the poorest decile, which is about the same order of difference as between the richest and poorest urban Indian quintiles. The richest 20% of urban Indians use only a third as much of the energy used by the poorest 10% of the Dutch, albeit the richest 20% in India will include many examples of very wealthy individuals whose energy use vastly surpasses that of the average Dutch top 10% income class. As such, these illustrative numbers reflect the wide disparities in incomes and development levels across and within nations. The richest Dutch also use almost three times as much energy for food on average as their poorest compatriots. This, of course, does not imply that rich people eat three times as much as poor people in the Netherlands. However, the food habits and types of provisions consumed do differ. For instance, the rich Dutch eat more exotic fruits and vegetables (e.g., Kiwi fruit flown in from New Zealand) than the poor which explain their much larger food-related (embodied) energy use. The biggest differences in the structure of energy use between rich and poor people, both within and across nations, is the substantially larger share of energy used for transport and for the consumption of products and services. Poor people, by contrast, use the largest proportion of energy for basic necessities such as food and household fuels (cooking and hygiene). These differences illustrate the substantial variations in lifestyles and growing consumerism evident with rising incomes and retail market sophistication.

1.8.4 Disparities in Energy Use

While fairness and equity are normative, ethical concepts, several methodologies and metrics exist to measure dispersions and distributions which help to describe disparities in energy use. Lorenz curves and Gini indices or coefficients are widely used to measure inequalities in income and wealth. The Lorenz curve is a graphical representation of a cumulative distribution function, often with a ranked cumulative distribution of population on the x-axis versus a ranked distribution of cumulative value of a given variable such as income, wealth, or energy on the y-axis. A perfectly equal distribution is described by a straight line where y = x along the diagonal or along 45 degrees, where every given percentage of the population consumes or owns an equal percentage of the variable in question (e.g., energy, wealth, etc.). The greater the distance of the Lorenz curve from this diagonal, the greater the degree of inequality it represents. The Gini coefficient, also used as a measure of inequality, is mathematically represented as the ratio of the area between a Lorenz curve and the diagonal (or line of perfect equality) to the total area under the diagonal. The Gini coefficient can range from 0 to 1, with a value closer to 0 representing a more equal distribution. In addition to Lorenz curves and Gini coefficients, other measures of inequality commonly in use are ratios of percentiles, deciles, quintiles, or quartiles of the population.

Figure 1.25 illustrates inequality across nations by depicting the Lorenz curves for important energy and economic variables for the year 2000. The x-axis depicts the ranked cumulative distribution of population by nation, while the cumulative disposal of income (in PPP terms), final energy, and electricity are shown on the y-axis.

In terms of income and final energy use, the poorest 40% of the world's population only disposes of some 10% of global income and final energy use; the richest third disposes of two-thirds of global income and final energy. It is noteworthy that final energy use mirrors prevailing (vast) income inequalities closely. Energy and economic poverty and wealth thus go hand in hand. Access to electricity is even more inequitable. In 2005, some 23% of the world's population (1.4 billion people) had no access to electricity at all.

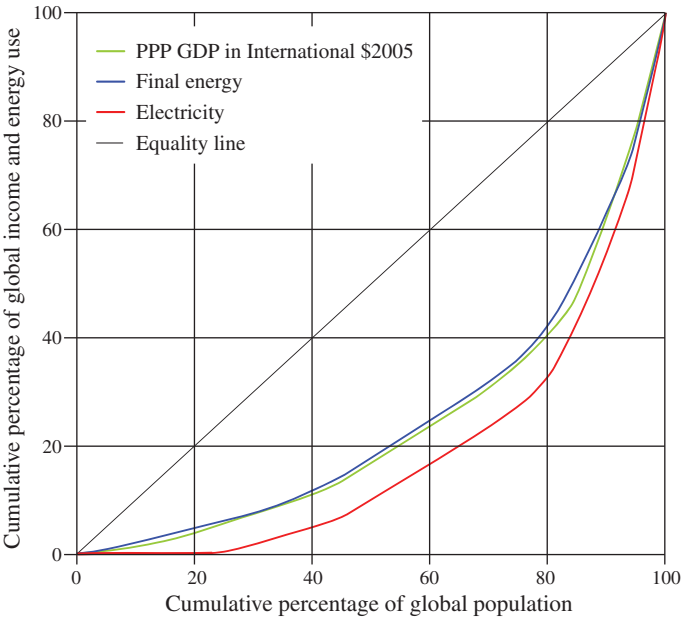

Figure 1.25 | Lorenz curves of energy inequality, measuring cumulative global population (in percent) disposing of corresponding fraction of cumulative income (in percent of PPP$ (green), final energy (blue), and electricity use (red) (in percent of Joules energy used) for the Year 2000. Source: IEA, 2010 and UNDP and WHO, 2009.

1.9 The Costs of Energy

1.9.1 Accounting Frameworks and Different Types of Costs

In one way or another, energy services carry a price tag. The price a consumer pays for a particular energy service based, for example, on electricity use is made up by a variety of components, the most important of which are generating costs, systems costs, rents, profits, taxes, subsidies, and externalities.

Generating costs are not only a key component determining the price of a service but also a central decision criterion for investment and operating decisions alike. Generating costs they consist of three major components: capital costs, fuel costs, and non-fuel operating and maintenance (O&M) costs. Capital costs are the costs associated with the construction/acquisition/purchase of a power plant, refinery, or home furnace. Fuel costs are the expenditures associated with the fuel supply for plant operation or service provision. O&M costs cover labor costs, insurance, consumables other than fuel, repairs, etc. More recently, capital costs also include decommissioning expenditures at the end of a plant's service life, while O&M costs may include waste disposal costs.

While fuel and O&M costs are largely incurred on a per-use basis, capital or investment costs occur upfront – for some technologies spread over several years of plant construction – before earning revenue or providing energy services for the investor. Capital costs must be recovered over the lifetime of the investment, reflecting the wear and tear of the plant (the investment) over its economic lifetime.

The levelized cost[41] of electricity (LCOE) is a widely used tool in policy analysis for comparing the generating costs of different technologies over their economic life. A critical parameter in the LCOE approach is the discount rate, which reflects the interest rate on capital (cost of capital or return) for an investor in the absence of specific market or technology risks. LCOE spreads the capital costs (including the finance costs) uniformly over the lifetime of an investment, accounts for the fuel and O&M costs, and calculates the specific costs per unit of energy delivered.[42]

41 For a review see Anderson, 2007. For a review quantitative cost estimates for electricity generation see Heptonstall, 2007 and NREL, 2010.

42 Note: LCOE assumes perfect knowledge about future fuel prices and interest rates several decades into the future. Scenarios of different price trajectories are commonly used to reflect uncertainty.

Table 1.9 | Total levelized costs of different electricity generation technologies (in percent using a 5% discount rate) and representative cost ranges in 2005US$/MWh as used in GEA. Note: These are direct energy (electricity generating) costs only, i.e. excluding externality costs; Data source: Chapters 12 and 17, and IPCC, 2011.

		Solar PV	Wind (onshore)	Nuclear[a]	Advanced coal	Adv. coal with CCS	Gas combined cycle
Capital	$/kWe	900–2800	900–1300	4000–6200	1100–1600	1700–2400	400–500
O&M	$/kWe	6–18	19–30	118–180	46–65	69–96	16–20
Fuel	$/GJ	0	0	0.7–0.9	1.3–2.8	1.3–2.8	2.6–6.5
Waste	$/MWh	0	0	1–2	0	6	0
Total generating costs	$/MWh	27–151	21–131	53–100	27–46	44–69	24–49

(a) Current (pre-2010) nuclear investment costs under construction in several developing countries range between 1800 and 2500 $/kWe.

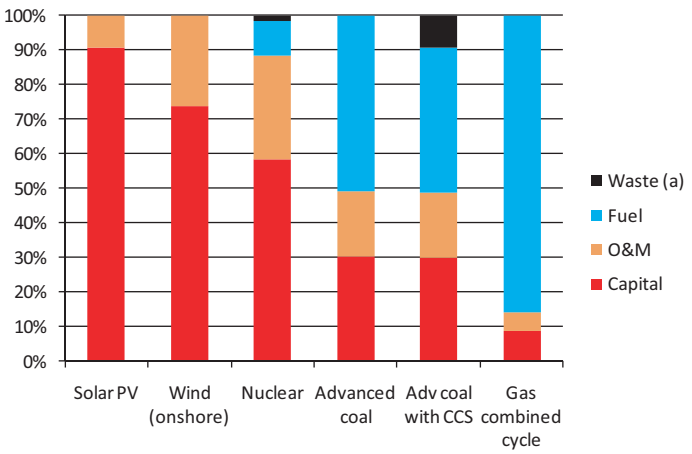

Figure 1.26 | Structure of total levelized costs of different electricity generation technologies (in percent using a 5% discount rate) and representative cost ranges for 2030 as used in the GEA pathways (cf. Chapter 17) for capital costs, operation and maintenance (O&M), fuel costs, as well as waste disposal costs for nuclear and advanced coal with carbon capture and sequestration (CCS). All values are given in 2005US$ and are shown in Table 1.9. Note: (a) Includes decommissioning costs for nuclear power and costs for transport and disposal of 90% of CO_2 emissions for advanced coal power plants with carbon capture and storage (CCS).

The relative structure of the various generating cost components varies significantly per unit of output for different generating options (see Figure 1.26 and Table 1.9, using a real annual discount rate of 5%), and the variation indicates the inherent risks associated with a particular option. For example, gas combined cycle technology (CCGT) has the lowest capital costs but the highest fuel costs of the options shown in Figure 1.26 and Table 1.9. Consequently, CCGT generating costs are almost all fuel costs. Any change in natural gas prices thus impacts its generating costs greatly. Conversely, nuclear power generation is dominated by high capital costs (>70%), with fuel cycle and O&M costs assuming approximately equal shares of the remaining costs.[43] The high share of capital costs exposes nuclear power projects to financial risks associated with rising interest rates and to cost escalation caused by delays in construction completion. Adding carbon capture and storage (CCS) can also increase costs substantially: typically adding some 50 $/MWh levelized costs to pulverized coal fired power plants (and 20–30 $/MWh for IGCC or natural gas electricity generation), see Chapter 12.

In addition to the generating costs, the price of electricity for consumers then includes transmission and distribution (T&D) costs and taxes or subsidies. Taxes and subsidies are policy instruments to influence consumer behavior. Taxes can be used to discourage politically undesirable behavior patterns, while subsidies provide incentives to adopt a more desirable investment or consumption pattern. Subsidized electricity or gasoline prices are also an instrument for extending access to energy services to low-income families, supporting small rural business developments, or connecting rural areas to markets.

Figure 1.27 compares gasoline prices with and without taxes for a variety of countries. While prices without taxes vary by a factor of two, this doubles to a factor of four when taxes are included. The taxes imposed by countries reflect national policy objectives, e.g. revenue needs, trade balances, etc., and not necessarily the countries' endowment with oil resources. For example, oil-exporting Norway features the second highest gasoline taxes in this comparison (equivalent to a carbon tax of US$576/tonne of CO_2), while oil-importing US has the second lowest gasoline taxation (equivalent to US$56/tonne of CO_2). Other oil-exporting countries such as Kuwait (not shown in Figure 1.27) even subsidize[44] domestic gasoline use.

43 Unlike natural gas or coal-fired generation, the fuel cost of nuclear power generation is not dominated by the resource (uranium) input price but by enrichment and fuel fabrication costs. Uranium accounts for approximately 25% of fuel costs only.

44 In the most general definition, an energy subsidy is represented by the difference between (low) local and prevailing (high) world market prices (without taxes). When the local gasoline price is below the marginal costs of producing and refining crude oil, this represents a direct financial transfer/subsidy from energy producers (usually nationalized industries – i.e., from the government) to energy consumers (households, taxi companies). Beyond that, any difference between local and world market prices is best conceptualized as opportunity costs associated with foregone potential export revenues, and also classified as energy subsidy. The marginal costs of producing a barrel of crude oil in many oil-exporting countries can be as low as US$5/bbl. The difference to a world market price of say US$100/bbl (in economic theory determined by the global marginal [i.e., highest] production costs plus profits) is referred to in economics as "scarcity rent," leading to vast financial transfers and wealth to energy producers, which may, however, not always have only beneficial effects (the so-called "resource curse," Humphreys et al., 2007).

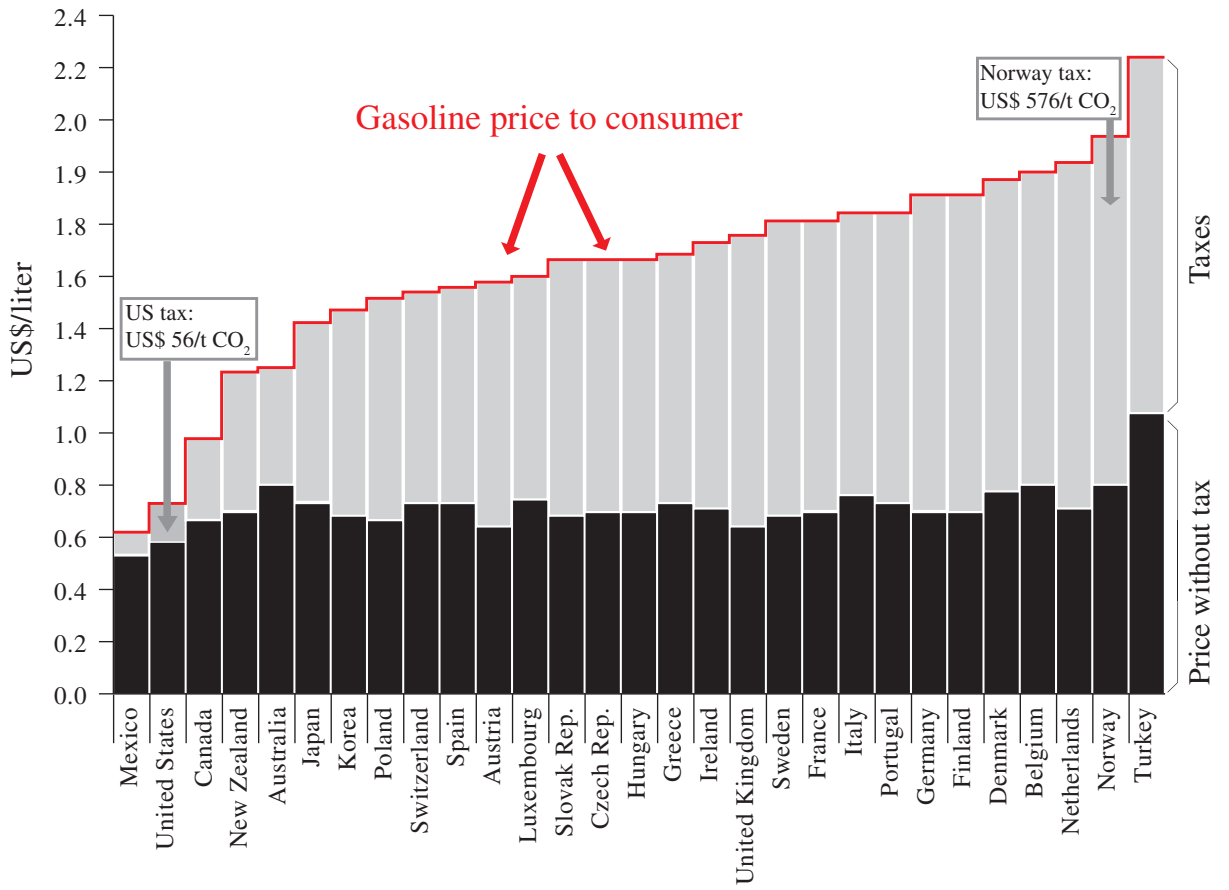

Figure 1.27 | Gasoline prices with and without taxes in US$/liter and implied price of carbon (US$/tCO$_2$) for 1st quarter of 2010. Source: data from IEA, 2011.

Finally there are cost elements caused by the conversion and use of energy and energy services which – although real – are not included in the price paid by the consumer but paid by society at large. Examples of such costs, called "externalities," are health and environmental damage costs resulting from air and water pollution from fossil fuel combustion or lower property values due to the proximity of a nuclear power plant or noise from wind converters. Ignoring externalities masks the true costs of energy and sends the wrong signal to the market place. Charges or taxes on carbon emissions or investment in carbon capture and storage (CCS) technology are ways to internalize externalities caused by GHG emissions. They also change the merit order of electricity generation favoring low-GHG emission technologies.

While investment decisions are guided by LCOE considerations, operating decisions and dispatch of an existing fleet of power stations are based on short-term marginal costs – in essence, fuel costs and possibly emission charges. Capital costs are no longer a decision criterion, as these are "sunk."

Figure 1.28 explains the inherent substitutability between capital and fuel costs using the example of providing heat for cooking. Higher-efficiency stoves are more capital-intensive but reduce fuel costs, which in a rural developing country context often mean time spent collecting wood for fuel. Shifting to more capital-intensive stoves (and higher-exergy fuels) reduces the time spent on fuel supply and at the same time improves indoor air quality through lower combustion-related emissions. The time released from gathering fuel is then available for more productive uses. This freed time, lower pollution exposure, and improved human health are important examples of positive externalities of moving to cleaner household fuels.

A transition to an improved cooking service can occur in one of two ways, as shown in Figure 1.28. A simple shift or substitution to higher-exergy energy carriers (e.g., from firewood to liquefied petroleum gas – LPG) will result in higher combustion efficiency, lower combustion-related emissions, lower time costs associated with fuel collection, but higher capital costs for stoves (and cash expenditure for commercial fuels). On the other hand, improvements in cooking services can also be achieved through the use of more

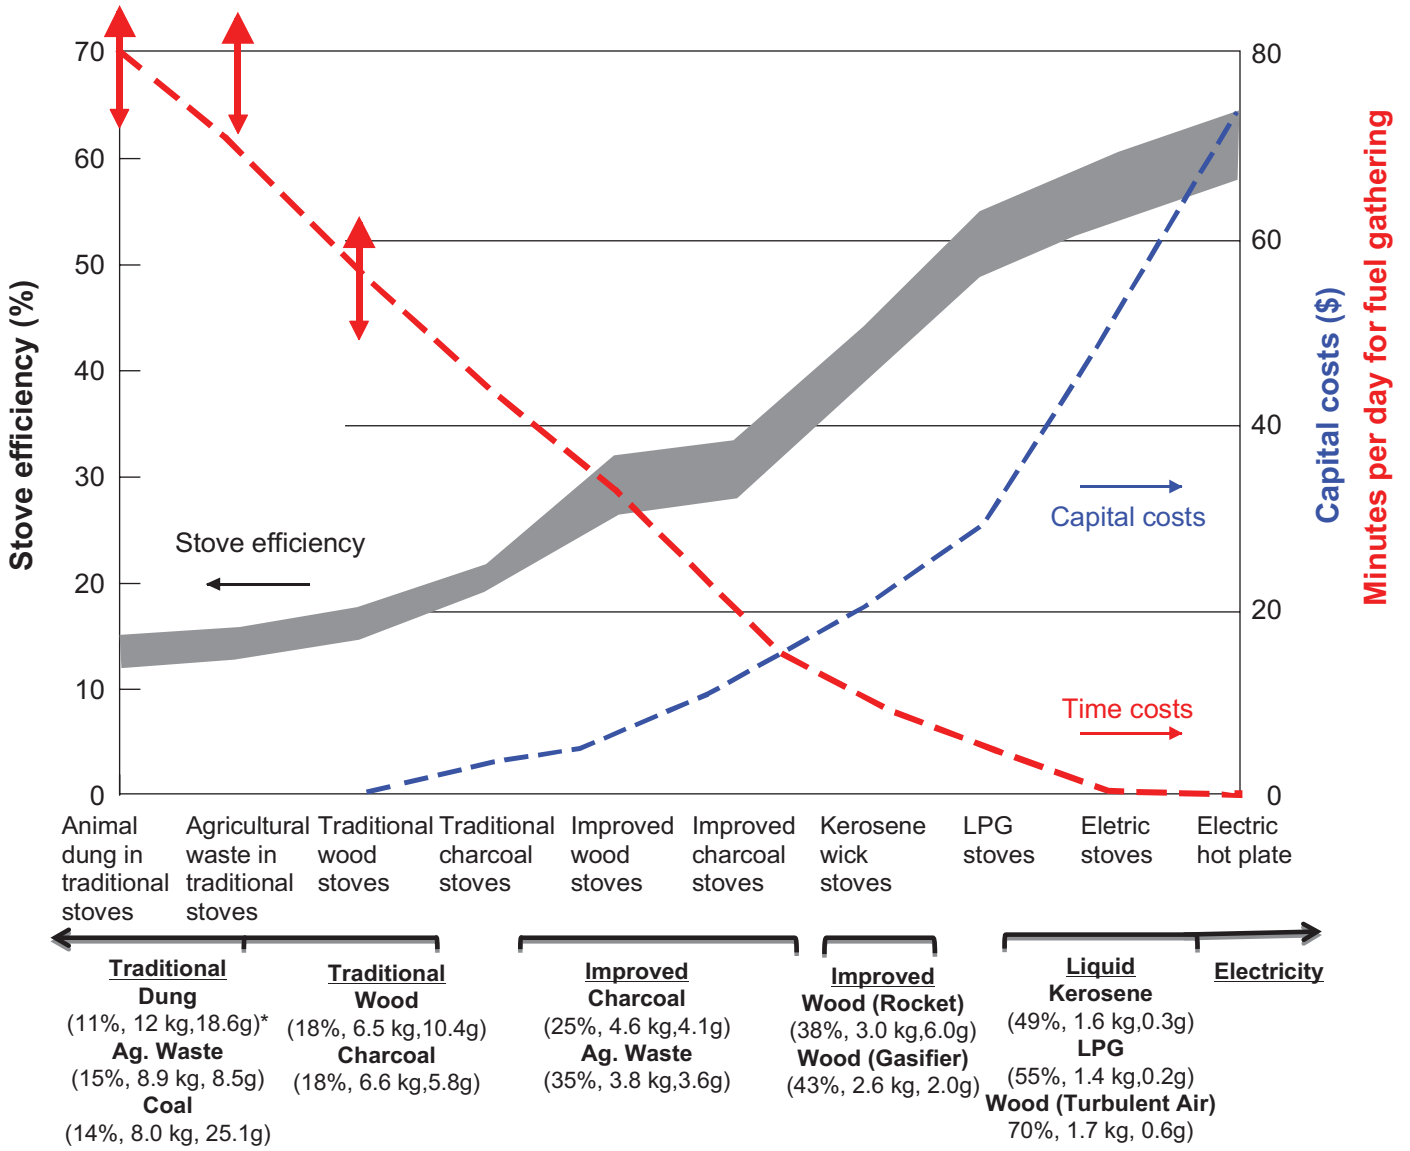

Figure 1.28 | Different costs of energy service provision. Example: cooking in developing countries. Notes: Red arrows show uncertainty ranges in time costs. GHG emissions are illustrative estimates and include all greenhouse gases and other emissions that affect radiative forcing. Emissions from fuel production and renewability of charcoal, wood, and agricultural residues are not included. Source: adapted from OTA, 1991 and Chapter 3.

capital-intensive improved technologies that continue to use traditional fuels (e.g., firewood and residues) but more efficiently (e.g., biogasifiers).

Further cost components related to Figure 1.28 are "inconvenience" or "opportunity" costs. Depending on the levelized costs of the heat for cooking, it might well be that using traditional fuel wood in an inefficient stove is the cheapest way to produce the required heat. However, factoring in alternative uses of the time spent for wood collection – for example, for other productive uses or just leisure activities – turns wood collection into an inconvenient task. A more efficient stove using commercial fuels reduces pollution and time spent gathering fuel wood, and hence reduces *inconvenience* costs. Likewise, the capital spent on a more efficient stove may not be available for other investments – say, a pump for irrigation – and thus represents an *opportunity* cost.

1.10 Roadmap to the Chapters of the GEA

Earlier transitions of the world's energy system, from biomass to coal, to oil, and now to a mix of coal, oil, and natural gas as the dominating energy carriers were all driven by convenience and cost reductions. Coming energy transitions will occur in a world that has changed through the "great acceleration" (Chapter 3) that started in the 1950s and is still ongoing. The next transitions will have to consider these changes that in

fact create demands on the performance of the coming energy systems in order for the world to develop in a sustainable manner.

The 25 chapters of the GEA are divided into four clusters.

Cluster I sets out to describe and assess the nature and magnitude of energy system changes required from a key set of conditions and concerns. Chapter 2 evaluates the role of energy in poverty alleviation and socio-economic growth and what will be required from the energy systems to make poverty a condition of the past, especially in terms of access to electricity and clean cooking fuels and practices. Chapter 3 reviews the environmental impacts of energy systems and what changes would be required, especially in terms of emissions reductions, to protect the environment as it is now known, including mitigating climate change. Chapter 4 addresses the health impacts of energy systems, especially indoor and outdoor air pollution, and health impacts of climate change. Chapter 5 analyzes energy security from several points of view, and Chapter 6 reviews the demands for energy services from a growing global population with increased standards of living, especially for the poorer parts of the world. Together, indicators defined and quantified for the purpose of the GEA in these five areas are used to define a "sustainable" state of the world from an energy systems perspective by 2050.

Cluster II reviews the resources and energy technologies available, or on the horizon, to address the energy sustainability challenges. Chapter 7 evaluates reserves and resources of fossil fuels, fissile material, and renewable energy flows. Chapters 8 through 10 deal with energy end-use in industry, transport, and buildings, respectively, and Chapters 11 through 16 review energy supply-side options, including renewable energy technologies, fossil fuel technologies, carbon capture and storage, nuclear energy, energy systems operation, and transitions to new energy systems.

Cluster III then explores how the elements of Cluster II can be combined into *systems* that address all the concerns identified in Cluster I, all at the same time. Chapter 17 presents this back-casting (normative scenario) analysis and identifies a number of conceivable energy systems that would meet the goals from Cluster I. Special attention is then given to urbanization (Chapter 18), energy access for development (Chapter 19), trade-offs in land and water use (Chapter 20) and life-styles (Chapter 21).

Cluster IV deals with policies and institutions to bring about the sustainable energy systems that were identified in Cluster III. Chapter 22 reviews the overall implementation situation, Chapter 23 the implementation of options for access to modern energy carriers and clean cooking fuels, Chapter 24 technology innovation systems, and Chapter 25 the capacity development required in terms of policies, institutions, and people that will be the agents of change to make the next energy transition toward sustainability happen.

Appendix 1.A Accounting for Energy

1.A.1 Introduction

The discussion of energy systems above described how primary energy occurs in different forms embodied in resources as they exist in nature, such as chemical energy embodied in fossils or biomass, the potential kinetic energy of water drawn from a reservoir, the electromagnetic energy of solar radiation, or the energy released in nuclear reactions. A logical question is, therefore, how to compare and assess the potential substitutability of these energy "apples and oranges." This is the objective of this more technical section.

The primary energy of fossil energy sources and biomass is defined in terms of the heating value (enthalpy[45]) of combustion. Together, combustibles account for about 90% of current primary energy in the world, corresponding to some 440 EJ in 2005. There are two different definitions of the heat of combustion, the *higher* (HHV) and *lower heating values* (LHV – see the discussion below), but otherwise the determination of apple-to-apple primary energy comparisons among combustible energy sources is relatively straightforward.

The situation is more complicated for non-combustible primary energy sources such as nuclear energy and renewables other than biomass. In these cases, primary energy is not used directly but is converted and transformed into *secondary energy* (energy carriers) such as electricity as in the case of modern wind or photovoltaic power plants. The measurable energy flow is the secondary energy, whereas the primary energy input needed to generate electricity needs to be estimated. In the two examples of wind and solar photovoltaics, primary energy estimates of the kinetic energy of wind and the electromagnetic energy of solar radiation are needed to determine primary energy equivalences to other energy sources. There are various conventions that specify the appropriate conversion from different renewable energy forms based on the generated electricity. For these conventions, the type of energy flow and its technological characteristics – such as the efficiency of the wind converters or photovoltaic cells – are needed. These various important accounting issues are dealt with below, starting with units and heating values.

1.A.2 Energy Units, Scale, and Heating Values (HHV/LHV)

Energy is defined as the capacity to do work and is measured in joules (J), where 1 joule is the work done when a force of 1 Newton (1 N=1 kg m/s^2) is applied over a distance of 1 meter. Power is the rate at which energy is transferred and is commonly measured in watts (W), where 1 watt is 1 joule/second. Newton, joule, and watt are defined as basic units in the International System of Units (SI).[46]

There is a wide variety of energy units which can be converted into each other. Figure 1.3 in Section 1.2.1 above, gives an overview of the most commonly used energy units and also indicates typical (rounded) conversion factors (see also Appendix 1.B). Typically, the choice of an energy unit depends on various factors such as the type of the energy carrier itself, the respective energy sector, as well as geographical and historical contexts. Next to the internationally standardized SI units, the most common energy unit used for electricity is the kilowatt-hour (kWh), which is derived from the joule (one kWh (1000 Watt-hours) being equivalent to 3600 kilo-Watt-seconds, or 3.6 MJ). In many international energy statistics (e.g., IEA and OECD) tonnes of oil equivalent (1 *toe* equals 41.87 x 10^9 J) is used as a core energy unit, but it is not included in the SI system. Certain energy subsectors often use units that apply best to their respective energy carrier. For example, the oil industry uses barrels of oil equivalent (1 *boe* equals 5.71 x 10^9 J or about 1/7 of a *toe*), the coal industry tonnes of coal equivalent (1 *tce* equals 29.31 x 10^9 J), whereas the gas industry uses cubic meters of gas at a normalized pressure (1 m^3 of methane equals 34 MJ – all numbers refer to LHV; see the discussion below). Some countries such as the US use the imperial system of units, which include British Thermal Units (1 BTU equals 1055 J) as a unit for energy, cubic feet (for natural gas, one ft^3 equals about 1000 BTU, or 1 MJ), and barrels as volumetric energy units (bbl is another name for *boe*).

The *calorific value* or *heating value* of a fuel expresses the heat obtained from combustion of one unit of the fuel. It is important to distinguish between the higher heating value (HHV or gross calorific value) and the lower heating value (LHV or net calorific value). Most combustible fuels consist of hydrocarbon compounds that are primarily mixtures of carbon and hydrogen. When the hydrogen combines with oxygen, it forms water in a gaseous state, which is typically carried away with the other products of combustion in the exhaust gases. Similarly, any moisture present in the fuel will typically also evaporate. When the exhaust gases cool, this water will condense into a liquid state and release heat, known as *latent* heat, which can be captured and utilized for low-temperature heating purposes.

The *HHV* of a fuel includes the latent heat recovered from condensing water vapor from combustion. Modern condensing natural gas or oil boilers can capture this latent heat.[47] The *LHV* excludes the latent heat of the water formed during combustion.

45 Enthalpy – from the Greek "to warm/heat" – is the product of the mass of a fuel times its specific enthalpy, which is defined as the sum of its internal energy (from combustion) plus pressure times volume. Heating values per unit mass of a fuel are, therefore, defined for standardized pressure/volume conditions.

46 International System of Units – ***SI*** from the French *le Système international d'unités.*

47 Commercial advertisements often inappropriately refer to furnaces as "more than 100% efficient," which is thermodynamically impossible. The seeming paradox simply results from comparing apples and oranges in the form of LHV fuel energy inputs but HHV combustion energy releases.

The differences between LHV and HHV are typically about 5–6% of the HHV for solid and liquid fuels, and about 10% for natural gas (IEA, 2005). Typically, the LHV is used in energy balances, since most current energy conversion devices are still not able to recover latent heat. The distinction between HHV and LHV becomes important when comparing international energy statistics and balances (usually based on LHV, as in IEA or UN statistics) with national ones that can sometimes be based on HHV (as in case of the US Energy Information Administration, EIA). Care is also required when applying fuel-specific emission factors – for example, for CO_2 – that are specified separately per HHV or LHV to the corresponding heating value of the fuel as defined in the underlying energy statistics but not always spelled out prominently. As a precautionary measure to avoid accounting errors, literature sources on emission factors and energy use numbers that do not specify their underlying heating value concept definition should be avoided. In this publication both definitions are used, but the LHV is the default, as in most international energy statistics (e.g., UN or IEA).

1.A.3 Accounting for Primary Energy

As discussed above, the determination of the primary energy equivalent of combustible fuels (all fossils as well as biomass) is straightforward (only a consistent HHV or LHV reporting format needs to be adopted). For non-combustible energies (modern renewables such as wind or solar photovoltaics, geothermal, hydropower, and nuclear), there are different conventions that specify the appropriate conversion factors to account for primary energy equivalents: the *substitution,* the *direct equivalent*, and the *physical energy content* method (which is a hybrid combination of the substitution and direct equivalent methods). The share of non-combustible energy sources in total primary energy supply will appear to be very different depending on the method used (Lightfoot, 2007; Macknick, 2009):

The (partial) *substitution* method estimates the primary energy from non-combustible sources as being equivalent to the LHV or HHV of combustible fuels that would have been required in conventional thermal power plants to substitute the generated electricity or some other secondary energy form. Basically, this means that some average or representative efficiency of thermal power plants is applied to calculate the equivalent primary energy from the generated electricity from nuclear and renewables outside biomass.[48] This method is used, for example, by BP (2010a) and WEC (1993) and as the default method in the GEA (see Annex-II Technical Guidelines) to maintain a consistent accounting framework across different energy options.[49] Throughout the GEA there is always a clear indication if another method is used. The difficulties with this method include choosing an appropriate thermal power generating efficiency factor and the fact that the method displays "hypothetical" transformation losses in energy balances which end up as reported primary energy use, but which do not have any physical basis.

The (direct) *equivalent* method counts one unit of secondary energy such as generated electricity from non-combustible sources as one unit of primary energy. This method is also often used in the literature – for example, by UN Statistics (2010) and in multiple IPCC reports that deal with long-term energy and emission scenarios (Watson et al., 1995; Nakicenovic and Swart, 2000; Morita et al., 2001; Fisher et al., 2007). The difficulties with this method are twofold: (i) an increase in the share of non-combustible energy sources results in the apparent efficiency improvement of the whole energy system because ever higher shares of primary energy have a definitional 100% "efficiency" of conversion into secondary forms, and (ii) actual conversion efficiencies even for these non-combustible sources of primary energy are substantially lower than 100% – for instance, the theoretical maximum efficiency (under optimal conditions) of converting wind kinetic energy into electricity is about 59%, but actual machines today achieve at best 47%.

The (physical) *energy content* method adopts a hybrid approach, using the direct equivalent approach for all energy sources other than those where primary energy is heat, such as nuclear, solar thermal, and geothermal energy sources. Thermal energy generated in a nuclear, geothermal, or solar power plant is considered primary energy equivalent. For example, in the case of nuclear energy, the heat released by fission is taken as primary energy, even though two-thirds are dissipated[50] to the environment through the turbine's condenser and the reactor cooling system and only one-third is actually delivered as electricity. This approach is identical to the case of fossil energy, for which the heat of combustion is taken as primary energy. In effect, the hybrid system leads to the following assumed primary energy accounting: (i) *substitution method* for heat from nuclear, geothermal, and solar thermal, and (ii) *direct equivalent method* for electricity from hydropower, wind, tide, wave, and solar photovoltaic energy. This hybrid method is used by the OECD, the International Energy Agency and Eurostat (IEA, 2005). The difficulty with this method is that it can result in confusion, as some energy forms such as hydropower are accounted for by the direct equivalent method, while for others such as nuclear conversion efficiencies are applied. Even though they both generate about the same electricity in the world, nuclear's primary energy equivalent is counted as three times larger than that of hydropower.[51]

48 Note, however, that different variants of the substitution method use somewhat different conversion factors. For example, BP applies 38% conversion efficiency to electricity generated from nuclear and hydro (BP, 2010), whereas the World Energy Council uses 38.6% for nuclear and non-combustible renewables.

49 In the GEA a uniform primary accounting equivalent of 35% conversion efficiency for electricity from non-combustible sources (equivalent to the global average of fossil-fuel power generation in 2005) and of 85% conversion efficiency for heat is applied.

50 In principle such waste heat could be "recycled" but would require a close co-location of nuclear power plants with main energy uses such as major cities, which raises issues of safety and public risk perception.

51 For example, in IEA/OECD (2005) the assumed conversion efficiency factor for hydropower, solar electricity, and wind is 100%, for nuclear power it is 33%, and for geothermal electricity it is 10%.

Table 1.A.1 | Comparison of global primary energy supply in 2005 using three different accounting methods for primary energy.

	GEA Substitution Method		Direct Equivalent Method		Physical Energy Content Method	
	EJ	%	EJ	%	EJ	%
Fossil fuels	389	78	389	85	389	81
Biomass	46	9	46	10	46	10
Nuclear	28	6	10	2	30	6
Hydro	30	6	11	2	11	2
Other Renewables	< 3	1	1	<1	3	1
Total	496	100	457	100	479	100

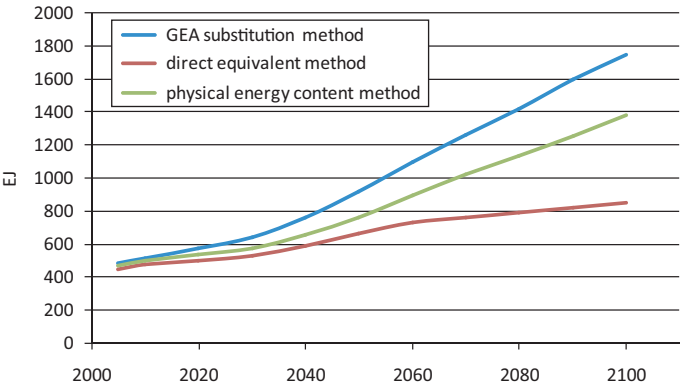

Figure 1.A.1. | Comparison of global total primary energy supply between 2005 and 2100 using three different primary energy accounting methods based on identical useful energy demands as quantified in the illustrative GEA-M set of pathways (see Chapter 17).

A detailed overview of differences in primary energy accounting from different energy statistics is described in Macknick (2009); see also Figure 1.A.2 below (the paper also contains a link to a data base where users can specify their own standardized accounting convention applied to the main international energy statistical data sources).

Table 1.A.1 compares the differences across the primary energy accounting methods for the world by energy source using the GEA primary substitution equivalent (see Technical Guidelines, Annex-II), the direct equivalent, and the physical energy content methods for the year 2005 based on IEA data (IEA, 2010). As is to be expected, the main differences in absolute terms across the methods are for nuclear, hydropower, and other renewables (except biomass). Great care is, therefore, advised when using and comparing reported primary energy across different statistical sources in general and in comparing the numbers reported in the GEA in particular.

1.A.4 Limitations of Primary Energy Accounting

The alternative primary energy accounting methods outlined above show significant differences in how non-combustible energy sources are presented in energy statistics. As the differences are significant for nuclear and renewables, the accounting method chosen has an impact on how the primary energy structure is interpreted. This in itself is an important limitation of the concept of primary energy. It is also a cause of considerable confusion in comparing different statistics, data sources, and analyses (and the ensuing emphasis on the importance of different energy options).

The differences of applying the three accounting methods to current energy use levels are relatively modest compared to those in scenarios of possible future major energy transformations where the structure of the global energy system changes significantly (see Chapter 17). The accounting gap between the different methods tends to become bigger over time as the share of combustible energy sources declines. The very concept of a statistically defined primary energy that has no real physical equivalence is thus becoming more limited as more radical future energy systems depart from current ones.

Figure 1.A.1 illustrates this growing divergence across the three primary energy accounting methods for an otherwise identical scenario in terms of final and useful energy demand (based on the intermediary GEA-M set of pathways; see Chapter 17). As the structure of the global energy system changes, different accounting methods differ by more than a factor of two in terms of implied primary energy growth. No such significant accounting ambiguities affect secondary and final energy, which are thus preferable descriptors for radical, transformative changes in energy systems.

1.A.5 Main Energy Statistics and Data Sources

Four institutions regularly publish globally comprehensive statistics on energy use: British Petroleum (BP), the US Energy Information Administration (EIA), the International Energy Agency (IEA), and the United Nations (UN). As Table 1.A.2 shows, these energy statistics differ in terms of energy coverage ranging from primary energy (PE), primary and secondary energy (EIA, IEA, UN), to primary, secondary, and final energy (IEA).

Data are mainly collected through questionnaires and exchanges between the organizations as well as with others, including but not limited to publications from the Statistical Office of the European Communities (Eurostat), the International Atomic Energy Agency (IAEA), the Organization of the Petroleum Exporting Countries (OPEC), the Organización Latinoamericana de Energía (OLADE), etc.

Statistics differ in the extent to which they include non-commercial energy (use of traditional biomass), which is fully covered in the IEA statistics (all sources) and partially in UN (mainly fuel wood), as well as modern renewables (outside hydropower), with only IEA and UN

Table 1.A.2 | Overview of the four major data sources for Global Energy Statistics.

	BP	EIA	IEA	UN
Primary energy	X	X	X	X
Secondary energy		X	X	X
Final energy			X	–[1]
New renewables[2]		X	X	X
Traditional biomass[3]			X	X
Electronic availability	Online free	Online free	Online subscription ($)	Offline tape order ($)

[1] Not reported directly by UN but can be calculated from full data base statistics.
[2] New renewable refers to solar, wind, modern bioenergy, and geothermal.
[3] Traditional biomass refers to fuel wood, dung, and agricultural residues.

providing (near) full coverage (with BP reporting selected modern renewables). Different reporting organizations also use different methods for expressing the primary energy equivalent of non-combustible energies (see Section 1.11.3 on Primary Energy Accounting above) and in their use of heating values (see the discussion above). LHV are used by the UN and IEA (and unless otherwise specified in this report). HHV are used in US EIA statistics (which therefore tend to report systematically higher energy use compared to other data sources), with BP using a hybrid approach which is closer to UN/IEA statistical values).

Both the UN and IEA provide comprehensive energy statistics on the production, trade, conversion, and use of primary and secondary, conventional and non-conventional, and new and renewable sources of energy covering the period from 1970 onwards (UN, 2010; IEA, 2010).[52] IEA's energy balances represent convenient aggregates of all energy flows in a common (non-SI) energy metric in tonnes of oil equivalent, summarized from IEA's energy statistics and for global and regional aggregates as well as for individual countries. The IEA statistics cover approximately 130 countries (of 192 UN Member countries), which represent about 98% of worldwide energy use (IPCC, 2006). BP statistics focus on commercial and conventional energy carriers and exclude fuels such as wood, peat, and animal waste and energy flows of other renewables such as wind, geothermal, and solar power generation[53] (BP, 2010a). Its statistics cover the period since 1965, are updated regularly,[54] and are available free of charge on the Internet. Cumulative installed renewable power capacity data are provided in BP's full workbook of historical statistical data from 1965–2009 (BP, 2010b). US EIA energy statistics, which are also freely available online, cover primary and secondary energy use by fuel category and per country since 1980, using the (non-SI) BTU as a common energy metric and based on HHV, which is different than other energy statistics.

As a result of differences in data collection sources, boundary conditions, methodologies, and heating values used in different statistics, global primary energy use numbers reported by these four organizations differ from 442 EJ (BP) to 487 EJ (EIA), or by some 10%, for the GEA base year 2005 and throughout their entire reporting horizon (see Figure 1.A.2). Adjusting[55] the different primary accounting conventions to the GEA standard and completing non-reported energies (non-commercial, traditional biomass using the IEA numbers) reduces this data uncertainty to a range from 495 EJ (IEA and BP) to 528 EJ (EIA[56]), or some 7%, with the UN statistics taking an intermediary position (506 EJ) for the GEA base year 2005 (see Figure 1.A.2). This assessment adopts a value of 495 EJ for the level of world primary energy use in the year 2005.

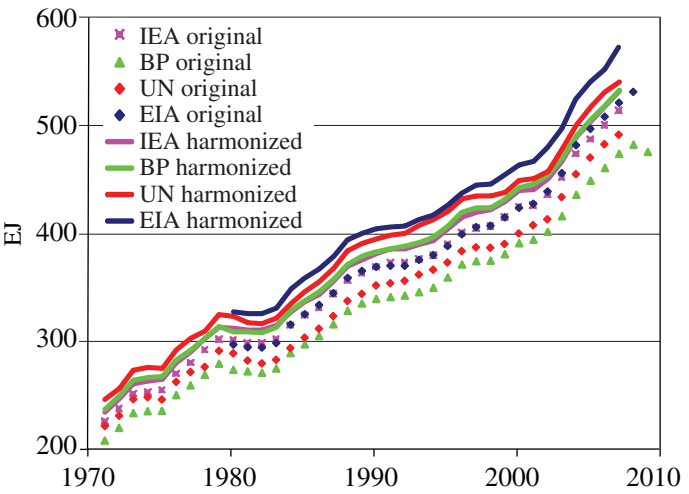

Figure 1.A.2. | World primary energy. Original data by four reporting agencies and harmonized primary energy equivalences. Source: data from Macknick, 2009.

52 Electronic data need to be purchased from the UN and processed with appropriate data base software tools as few aggregates are contained in the statistics. For instance final energy use is not reported directly by the UN, but can be calculated from a multitude of individual energy flows reported. The UN data portal allows free electronic access to statistics of individual energy flows as well as few aggregate energy indicators (primary energy use, electricity generation) from 1990 onwards. Full IEA energy balances, by energy flow, use, and sector since 1971 are available online to subscribers (including many universities) of the OECD iLibrary online publication and statistical query service: The statistics of the EIA and BP are available online free of charge but provide a somewhat more limited coverage as well as adopt differing accounting conventions to UN and IEA.

53 With exception of ethanol, only installed capacity data for geothermal, wind, and solar are reported by BP.

54 Updates are fastest among all energy statistics and available by September each year for the preceding year.

55 A software tool performing data comparison and adjustments to consistent and comparable accounting conventions for the 20 largest energy-using countries worldwide as well as the global total has been developed by Macknick (2009) and is available online: www.iiasa.ac.at/Research/TNT/WEB/Publications/Energy_Carbon_DataBase/.

56 Due to the use of HHV in the EIA statistics.

Regional acronyms	Regional definition
OECD90	UNFCC Annex I countries
REF	Eastern Europe and Former Soviet Union
ASIA	Asia excl. OECD90 countries
MAF	Middle East and Africa
LAC	Latin America and the Caribbean

OECD90 = OECD countries as of 1990 in Western Europe, North America, and Pacific Asia (and defined in UNFCCC as Annex-I countries)
REF = Countries undergoing economic reform, i.e. countries in Eastern Europe and the former Soviet Union
ASIA = non-Annex-I countries in Asia
MAF = Middle East and North, and Sub-Saharan Africa
LAC = Latin America and the Caribbean

For country listings and finer-resolution regional definitions see Annex-II.

Figure 1.B.1. | Definition of GEA regions, see also Annex-II Technical guidelines.

Executive Summary

There is often a two-way relationship between the lack of access to adequate and affordable energy services and poverty. The relationship is, in many respects, a vicious cycle in which people who lack access to cleaner and affordable energy are often trapped in a re-enforcing cycle of deprivation, lower incomes and the means to improve their living conditions while at the same time using significant amounts of their very limited income on expensive and unhealthy forms of energy that provide poor and/or unsafe services.

Access to cleaner and affordable energy options is essential for improving the livelihoods of the poor in developing countries. The link between energy and poverty is demonstrated by the fact that the poor in developing countries constitute the bulk of an estimated 2.7 billion people relying on traditional biomass for cooking and the overwhelming majority of the 1.4 billion without access to grid electricity. Most of the people still reliant on traditional biomass live in Africa and South Asia.

Limited access to modern and affordable energy services is an important contributor to the poverty levels in developing countries, particularly in sub-Saharan Africa and some parts of Asia. Access to modern forms of energy is essential to overcome poverty, promote economic growth and employment opportunities, support the provision of social services, and, in general, promote sustainable human development. It is also an essential input for achieving most Millennium Development Goals (MDGs) – a useful reference of progress against poverty by 2015 and a benchmark for possible progress much beyond that. Poverty alleviation and the achievement of the MDGs will not be possible as long as there are billions of people who do not have access to electricity and or to cleaner and better quality as well as adequate supplies of cooking fuels or with limited access to affordable and more efficient end-use energy devices such as improved cookstoves (those using traditional fuels but burning in a cleaner fashion), proper heating, more efficient lights, water pumps, low-cost agro-processing equipment as well as energy-efficient housing and transportation options.

The lack of modern and affordable forms of energy affects agricultural and economic productivity, time budgets, opportunities for income generation, and more generally the ability to improve living conditions. Low agricultural and economic productivity as well as diminished livelihood opportunities in turn result in malnourishment, low earnings, and no or little surplus cash. This contributes to the poor remaining poor, and consequently they cannot afford to pay for cleaner or improved forms of energy (often neither the fuels nor the equipment). In this sense the problem of poverty remains closely intertwined with a lack of cleaner and affordable energy services.

On the other hand, when the poor gain access to stable electricity supplies or cleaner fuels that can support job creation, trade, and value-adding activities within the family, they are able to accumulate the small levels of "surplus" or savings that facilitate access to education and health services, improved nutrition, or improved housing conditions that in turn enable them to gradually escape their poverty.

Cleaner affordable forms of energy and the energy services that they provide, reverses the aforementioned vicious cycle as they contribute to building a basis for supporting job creation, economic growth, agriculture, education, commerce, and health – the key areas that can contribute to overcoming poverty, as the following examples demonstrate:

- Energy plays a vital role in enhancing the food security of the poor through greater use of energy technologies for irrigation and water pumping. A number of these technologies not only ensure food supply throughout the year but also generate additional income for poor households, particularly in rural areas.

- Access to modern and affordable forms of energy is essential to creating employment, which can directly reduce poverty levels. Employment in formal and non-formal sector activities is positively correlated to increased access to cleaner energy options such as electricity, as is workers' productivity in value-adding processes.

- Increased access to modern forms of energy contribute to the transformation of agriculture-based economies – where significant animate energy is used – into industry-based economies, where modern forms of energy play a key role in the more-advanced value-added activities that characterize more industrialized economies.

- Improved low-cost cookstoves reduce the amount of fuel used, which translates into direct cash savings. They also reduce respiratory health problems associated with smoke emission from traditional biomass stoves and offer a better home and working environment. Other benefits include the alleviation of the burden placed on women and children in fuel collection, freeing up more time for women to engage in other activities, especially income-generating endeavors.

- Modern forms of energy play an important role in improving access to safe water and sanitation in developing countries.

- Modern health services (the facilities to provide them, and the professional and health sector workers who deliver them) are greatly enhanced by access to modern forms of energy and the services they provide, not only electricity for lighting, refrigeration and modern medical equipment but also heat-related services often linked to the availability of cleaner and affordable fuels for institutional uses.

- Access to modern forms of energy greatly improves the quality and availability of educational services and increases the likelihood that children will attend and complete schooling. Rural electrification helps retain good teachers in rural areas – a key lever for enhancing the quality of rural education.

- Gender parity and school enrollment of girls improve with greater access to cleaner and affordable energy options, especially in rural areas. Access to mechanical power for threshing and grinding grains help older girls stay in school by minimizing school absenteeism or desertion, while cleaner modern cooking systems reduce the time spent by girls on fuelwood collection for their families.

Universal access to electricity and modern as well as cleaner forms of energy for cooking provide a wide range of high-quality energy services even when the amount of energy used is modest. Given the important contribution of access to cleaner and affordable energy options to the improvement of livelihoods of poor people in developing countries, special attention should be paid to extending universal access to electricity and modern forms of energy for cooking in developing countries.

From a policy and public financing point of view, there is a need to alleviate the negative income effect of time use and family expenditure related to the use of traditional fuels and to overcome the barriers related to household energy. In developing countries, where poor people are highly dependent on traditional fuels that have incomplete combustion in inefficient devices, much greater emphasis must be given to increasing the availability and affordability of liquid and gaseous fuels and associated stove technologies. Special attention should also be paid to mechanical power solutions and labor-saving appliances that can provide homestead-based pumping, agro-processing, milling, and grinding, among other services. These are also critically important for gender and health reasons, as discussed later in this chapter.

The absence of mechanical options in many rural areas of the developing world, to provide access to mechanical power for water pumping, milling, or other household activities is also related to the absence of affordable and cleaner fuels or electricity to drive engines, mills, and pumps to supplement human labor (see Chapters 19, 23 and 25). The absence of mechanical power affects not only the poorest families, particularly girls and women, but often entire geographic areas due to the distances from electricity supply and cleaner fuel delivery systems.

Prioritizing access to electricity and energy-using technology for commercial/productive activities (as opposed to only low-load household activities) could increase employment opportunities that can contribute to income generation and the fight against poverty, especially for the working poor. Access to more efficient, cleaner and affordable energy options is an effective tool for combating extreme hunger by increasing food productivity and reducing post-harvest losses.

Low-cost energy-efficient transportation for both passengers and goods is crucial for economic development. This is particularly important for long-distance transit of passengers and goods. Rail transport is considered the least expensive energy-efficient land transport option for long-distance passenger travel and has been developed extensively in industrial countries in the form of surface and underground rail networks. For freight transportation, with the exception of India and China, many developing countries make limited use of lower-cost energy-efficient rail transport mainly due to its lack of sustained investment.

There are several health-related benefits associated with access to modern, cleaner and affordable energy options. Electricity in rural health centers, allows the provision of medical services at night, greater use of more advanced medical equipment, helps retain qualified staff in rural health centers among other benefits. In this regard, one of Global Energy Assessment (GEA)'s goals is achieving universal access to electricity and cleaner cooking by 2030. It should, however, be emphasized that access to electricity and cleaner cooking fuels constitute only a part of the desired policy objective of reducing poverty – they are a prerequisite, but electricity supply and cleaner cooking fuels, on their own, are not sufficient to move out of poverty.

Access to modern and affordable forms of energy can play an important role in improving access to safe water and sanitation in developing countries. Some of the energy solutions available are relatively affordable for the poor and do not require electricity or fossil fuels. Low-cost mechanical options can play an important role in ensuring access to safe water. For example, hand pumps and wind pumps are robust technologies that can dramatically expand access to safe water for domestic use as well as for irrigation and watering livestock.

The challenge of providing safe water and sanitation facilities is still immense particularly in sub-Saharan Africa where more than half the urban population lives in slums – a sizable part of the more than 825 million people living in urban dwellings without improved sources of drinking water and sanitation. Solar, wind, handpumps and biogas options can play an important role in enhanced access to safe water and sanitation in low-income peri-urban and urban of sub-Saharan Africa.

Prevailing energy systems in developing countries and associated economic and welfare policies need to be redesigned to ensure an emphatic pro-poor orientation that will move toward universal access to cleaner and affordable forms of energy in key economic sectors that the poor rely on such as health, water, education, agriculture and transport.

Access to electricity supply (both grid and non-grid) in many developing countries is almost an exclusive service enjoyed by the non-poor in urban areas. Even after two decades of energy sector reforms, initial indications from a wide range of developing countries indicate that few of the initiatives have resulted in significant improvement in the provision of electricity to the world's poor.

Experiences in developing countries point to an overarching conclusion: when power sector reforms were introduced with the sole intention of improving the performance of utilities, the expected and hoped-for social benefits did not necessarily follow. Where governments maintained a role as instigator or at least regulator of improved access to electricity by the poor, tariffs for poor households tended to decrease and levels and rates of electrification tended to increase.

In some cases, wide-scale deployment of renewable energy systems may provide the best options for providing access to cleaner and modern energy options while ensuring long-term sustainability. In the near term, however, cleaner fossil fuels such as liquefied petroleum gas (LPG) combined with more efficient and low-cost end-uses devices such as LPG cookstoves reduce a host of social, economic, and environmental barriers to overcoming poverty due to higher combustion efficiency.

The ongoing search for win-win solutions that are completely reliant on renewable energy must also put a time premium on overcoming social injustice and the conditions of inequality that entrench poverty and reproduce underdevelopment. From a policy point of view, it is unrealistic to support arguments for "near-term renewables only" options that delay the satisfaction of the basic needs of people who remain poor today and who constitute a negligible contributor to global historical and current carbon emissions. It is, therefore, important to retain cleaner fossil fuel options such as LPG combined with more efficient low-cost end-use devices in near-term priority action plans that would set the stage for eventually moving the poor to a fully sustainable path that they are able to rely more heavily on renewable energy.

2.1 Introduction

This chapter focuses on the situation of poor people – especially in developing countries – paying particular attention to their access to cleaner and affordable energy options. Poverty, as discussed in this chapter, includes concepts of both lack of access to income and inequality as well as limited access to services (such as access to cleaner energy options), opportunities and social exclusion, which are often intimately linked to inequality.

The chapter calls for setting of targets for bringing cleaner and affordable energy options to a wider proportion of the poor at affordable prices – plus the policy frameworks and the public and private investment needed to make this a reality.

The issue of access to cleaner and affordable energy options is emphasized here in line with the GEA goal of providing universal access to affordable electricity and affordable cleaner forms of energy for cooking by 2030. However, this 2030 goal requires substantial investments as well as a transition from the use of traditional solid fuels such as biomass and coal to cleaner energy carriers such as gas, electricity and liquid fuels. These investments and transition require sufficient time for low-income countries to establish the right institutions, regulation and policies that would enable mobilization and appropriate deployment of the required capital investments.

While the term "access" can simply refer to physical proximity to modern energy carriers such as electricity, natural gas, liquefied petroleum gas (LPG), biogas and ethanol, access also implies the availability of affordable improved and more efficient end-use energy devices such as improved cookstoves (those using traditional fuels but burning in a cleaner fashion), more efficient lights, water pumps, low-cost agro-processing equipment as well as energy-efficient housing and transportation options. In a much broader sense, access refers to the affordable and stable services of cleaner energy options that are delivered in a reliable fashion and ensure consistent quality (see also Chapter 19).

GEA considers universal energy access to refer to access to affordable modern energy carriers (e.g., electricity, natural gas, LPG, biogas, ethanol) including a wide array of efficient low-cost end-use options used by the poor in agro-processing, small-scale value addition processes, water pumping, housing and transportation as well as energy-efficient devices such as improved cookstoves and affordable, advanced stoves that use traditional fuels for cooking, by 2030.

This chapter focuses on developing countries for several reasons. The bulk of poor people in the world live in developing countries and require energy to support poverty alleviation, economic growth, social inclusion and development. The chapter focuses first on the concept of poverty: who are poor people and where they live.

It goes on to examine the historic worldwide relationship between access to energy services and development, arguing that developing countries also need to have access to improved energy services in order to overcome poverty, especially the most extreme forms faced by the lowest fifth of income earners around the world. The specific role of energy services – those provided by modern energy carriers such as electricity and fuels such as LPG, biogas and ethanol – is discussed in this chapter in relation to both household and productive energy applications. The essential role that energy plays in supporting job creation, economic growth, agriculture, transport, and commerce is reviewed, as these are key factors for overcoming poverty.

The importance of energy as an input to support the delivery of services such as education, health, and other social services is examined, followed by an analysis of the particular hardships faced by women in relation to traditional energy systems and their impacts on women's time use, literacy, and health. The importance of energy for the achievement of the Millennium Development Goals (MDGs) is also briefly illustrated by showing that energy is an essential input to each MDG. The local, regional, and global environmental impacts of energy use in developing countries are discussed, with an emphasis on the extremely small historical and current contribution made to global green house emissions by the poorest people in the world.

The chapter concludes that special emphasis must be given to extending universal access to electricity and modern forms of energy for cooking in developing countries and that the switch from traditional solid fuels to cleaner liquid fuels and combustion technologies constitute an essential step for overcoming poverty and supporting economic growth and sustainable human development. It is recommended that near-universal access is needed in developing countries due to the range of high-quality energy services that this carrier provides, even when it is available only in small amounts.

Specifically, with regard to electricity, this chapter argues that access to electricity as a carrier is only part of the desired policy objective of reducing poverty – it is a prerequisite, but electricity supply, in itself, is not sufficient for poor households to move out of poverty. The ultimate, well-being of people depends on the actual consumption of goods and services that electricity as a carrier can facilitate. Equally important is access to cleaner or modern forms of energy for cooking and fueling a wide array of energy efficient and low-cost end-use options and devices used by the poor in agro-processing, small scale value-addition processes, water pumping, housing and transportation.

Looking toward 2030, the need to focus on improving access to energy services in developing countries becomes even more crucial due to their higher population growth and their potential for higher economic growth rates, implying that the decisions taken regarding the nature of emerging energy systems in terms of energy sources, conversion technologies, and distribution and financing systems are important not only to developing countries but to the world as a whole throughout this century.

2.1.1 Poverty and Development

Economic growth is an essential prerequisite for overcoming poverty. No country has achieved sustained economic growth without improving access to cleaner and modern forms of energy and the services that they provide. It is also globally recognized – based on the experiences of most industrial countries – that policies to "share" the benefits of growth are needed to address inequality and combat poverty. Energy services to support economic growth and energy policies to combat inequality in human welfare are thus both critically important.

Using an absolute poverty line set at US_{2005}1.25 per day per capita (purchasing power parities (PPP)), the number of poor people worldwide fell from 1.8 billion in 1990 to 1.4 billion in 2005 (see Figure 2.1) in spite of population growth – a tremendous achievement based on the economic growth experienced worldwide during this period (UN, 2010a). According to the World Bank, the financial and food crises of recent years unfortunately pushed another 64 million people back into extreme poverty (World Bank, 2010a).

Table 2.1, provides a comparison of poverty trends in 1999, 2002 and 2005. It shows a substantial drop in poverty levels in East Asia and Pacific (particularly China) and highlights the continued high-levels of poverty in Sub-Saharan Africa and South Asia.

Using the multidimensional poverty index (MPI) recently developed jointly by Oxford University and United Nations Development Programme (UNDP), it is estimated that, worldwide, a larger proportion of humanity, about 1.75 billion, remains poor. The MPI is an advanced method of measuring poverty by determining the extent of deprivation among poor people across three key dimensions, namely: health, education and living standards. MPI also takes into account access to essential services such as electricity, water and sanitation in order to measure the magnitude of poverty (UNDP, 2010; Alkire et al., 2011).

Using the MPI methodology, available data (Figure 2.2) re-confirms the fact that the greatest concentrations of poor people live in the least developed countries of sub-Saharan Africa and South Asia.

Both income-defined and MPI poverty measurements leave out the fundamental issue of income distribution within countries. Today the World Bank, the United Nations system, and economists that work on poverty indicators at large argue that it is essential to look at not only the aspects of poverty expressed by income levels alone, but also at equity measures such as how the lowest 20% of the population (determined by income) fare in comparison to the top 20% in any given country. The more unequal the income distribution, the less likely it is that the poorest segment of the population will benefit from growth, although overall national statistics may show positive trends (UNDP, 2011).

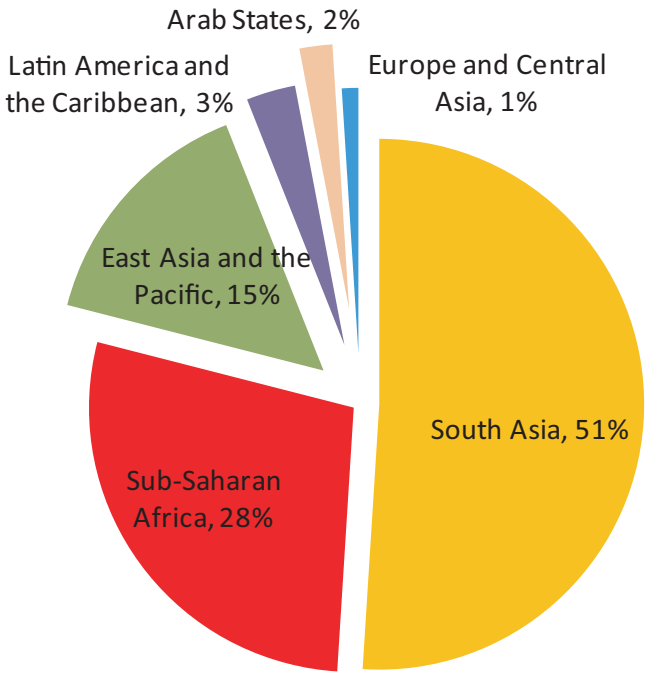

Figure 2.2 | Distribution of the poor (1.75 billion people) in developing countries (using multidimensional poverty measurement). Source: UNDP, 2010.

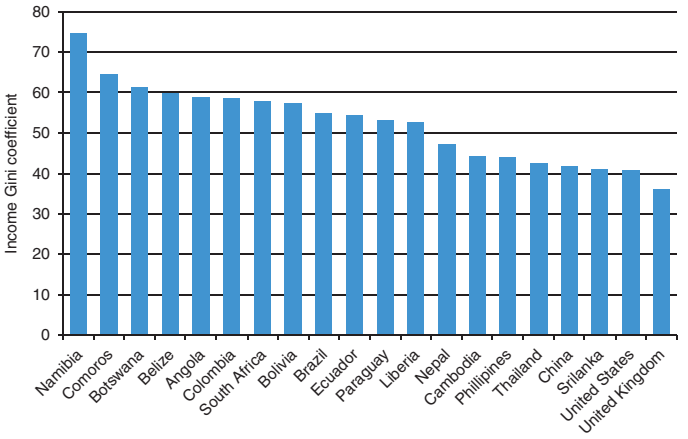

Figure 2.3 | Gini indices for selected developing countries (2000–2011*). Source: adapted from UNDP, 2010; 2011. *Data refer to the most recent year available during the period specified.

The Gini coefficient[1], which compares income levels among the richest and poorest segments of populations, is a useful indicator of inequality (see Figure 2.3). Comparing the lowest 20% of income earners to those who earn the most is also useful for understanding the role that inequality plays in defining country contexts. Inequality has been increasing alongside growth and economic development around the world triggering new development challenges – and therefore new energy challenges. Countries which have a higher coefficient, even in situations where energy access indicators show positive growth, the poorest segment of the population may not be benefiting from the growth. Currently, Latin America, the Caribbean region and Africa, are the most unequal regions in the world (Gasparin et al., 2009; Rosenthal, 2010; Gasparin and Lustig, 2011).

While many developing countries, particularly in Latin America, the Middle East, and Asia, have achieved significant growth and progress in development indicators over the last 20 years, progress has often not been evenly distributed across the population. As a result, inequality and increasingly unequal income distribution pushes more people into poverty thus creating new development as well as public financing and service delivery challenges for governments. Turkey, Gabon and South Africa, for instance, have made impressive advances in improving income per capita in the last decade, while levels of poverty and inequality have persisted (UNDP, 2010). As Andy Sumner notes in *Global Poverty and the New Bottom Billion*:

> The global poverty problem has changed because most of the world's poor no longer live in poor countries meaning low-income countries (LICs). In the past, poverty has been viewed as, predominantly, an LIC issue. Nowadays such simplistic assumptions/ classifications can be misleading because a number of the large countries that have graduated into the middle-income countries (MIC) category still have large number of poor people. In 1990, we estimate that 93 per cent of the world's poor people lived in LICs. In contrast, in 2007–8 we estimate that three-quarters of the world's approximately 1.3 billion poor people now live in MICs and only about a quarter of the world's poor – about 370 million people live in the remaining 39 low-income countries, which are largely in sub-Saharan Africa (Sumner, 2010).

The largest number of poor people who "moved" from poor countries to middle-income ones are found in India, Nigeria, and Pakistan (Sumner, 2011). The two-tiered concept is itself questionable as it divides the world into developing and developed countries, which is contradicted by the emergence of the BRICS group, the rapidly growing and industrializing countries of Brazil, Russia, India, China, and South Africa (Sumner, 2011). The recent creation of the G-20 group of countries with industrialized or industrializing economies includes the BRICS as well as Argentina, Indonesia, Mexico, South Korea and Turkey.

Yet these emerging economic powers continue to have millions of poor people, with conditions of wealth and poverty[2] often existing side by side – sometimes only neighborhoods away and sometimes defined by the rural-urban divide. Thus, in terms of poverty, development, and growth, the world is more heterogeneous now than it was in 1990. And looking forward to 2050, many emerging economic powers historically viewed as "developing" will take on new roles while entire segments of poor people remain a feature of their national makeup. This is evident in urban areas of emerging economies where high numbers of population live in deplorable dwellings, i.e., slums, without access to basic services thus constituting a major challenge to urban governance and design in developing countries (GNESD, 2008).

It should, however, be emphasized that the poor in emerging economic powers of Latin America and Asia have better prospects for moving out of the poverty largely due to the significant and abundant economic, institutional and skill resources that are available in these countries plus their growing clout in re-arranging international economic relationships to protect their national interests.

In contrast, the prospects for the poor in Sub-Saharan Africa are significantly less promising (see Table 2.1) because of the very limited economic, institutional and skill resources that sub-Saharan African countries have combined with modest and more importantly "diminishing" ability to influence global economic relationships that are disadvantageous to the sub-Saharan Africa region. As shown in Table 2.1,

1 Gini coefficient measures the extent to which the distribution of income, (at times it includes consumption expenditure) among people or households within an economy deviates from a perfectly equal distribution. The values vary between 0, which reflects complete equality and 1, indicating a complete inequality situation, where one individual has all the income or consumption, while all the others have none).

2 These countries poverty conditions are in terms of relative poverty: this refers to lack of the usual or socially acceptable level of resources or income as compared with others within a society or country. On the other hand absolute poverty refers to a common international poverty line of: population living on less than $1.25 at 2005 PPP.

well over half of sub-Saharan Africa's population is poor – higher than any other region of the world.

Virtually all future poverty scenarios show substantial reductions in poverty levels in the large emerging economic powers of Latin America and Asia with virtually the whole of sub-Saharan Africa and parts of South Asia continuing to be the epicenters of global poverty.

In conclusion, poverty includes concepts of low income and inequality as well as limited access to services (such as access to cleaner energy options), opportunities and social exclusion, which are often intimately linked to inequality.

2.2 Energy and Development

Access to modern forms of energy is an essential pre-requisite for overcoming poverty, promoting economic growth, expanding employment opportunities, supporting the provision of social services, and, in general, promoting human development. It is also an essential input for achieving most MDGs, which are a reference of progress against poverty by 2015 and a benchmark for possible progress beyond that date. As mentioned earlier, it is, however, important to underline that access to electricity and cleaner cooking constitutes only part of the desired policy objective of reducing poverty. They are a pre-requisite, but electricity supply and cleaner cooking fuels, on their own, are not sufficient for poor households to move out of poverty.

Table 2.2 illustrates how energy can contribute to the MDGs targets. It also shows clearly how the lack of access to energy can be a major constraint to achieving the MDGs (Modi et al., 2006; UN-Energy, 2005; UNDP, 2005, DFID, 2002). One of GEA's goals is the provision of universal access to affordable electricity and clean cooking by 2030 – a key target that would contribute to reducing poverty levels.

Human well-being, poverty reduction, social inclusion, and economic improvement cannot be advanced without access to electricity, fuels, mechanical power, and the range of services that they provide. Countries with the highest levels of poverty and underemployment tend to be those that also lack access to adequate levels of energy services and the modern conveniences that they provide. This is most pronounced in Africa and South Asia, where the number of people who depend on traditional biomass for heating and cooking and who lack access to electricity are the greatest. As shown in Figure 2.4, based on the Energy Development Index (EDI) developed by the International Energy Agency (IEA), all sub-Saharan African countries, with the exception of South Africa, feature in the bottom half of the EDI ranking.

The EDI was developed to track the progress in country's or region's transition to the use of modern energy and to better understand the role that energy plays in human development. It is computed by factoring in the UNDP's Human Development Index (HDI) and is composed of four indicators; per capita commercial energy use, per capita electricity consumption, share of modern fuels in total residential sector energy use and share of population with access to electricity (Bazilian et al., 2010; IEA, 2010a; Nussbaumer et al., 2011).

Abundant cheap and highly polluting energy supplies, while providing essential inputs for economic growth in the short term, result in unsustainable local, regional, and global environmental and health effects over the medium and long term, as seen throughout the industrial world and now increasingly in China and India (UNDP, 2011). From a sustainable human development perspective, therefore, the key challenge is how to make available modern and cleaner forms of energy that can support economic growth and human well-being, helping to reduce poverty while not establishing long-term structural and negative environmental consequences in energy systems that will eventually undermine development itself.

For industrial countries, this challenge largely results in a focus on cleaner energy systems, energy efficiency, and the drive to diversify the energy supply mix to include more renewable sources to address global climate change concerns and rising or unstable global oil prices. For the least developed countries, which have significantly less installed energy infrastructure and where in many cases the vast majority of the population does not have access to either modern and cleaner forms of energy or electricity, the key near-term question is how to promote the development of energy systems that can provide accessible and affordable services using new models of production, financing, and distribution as well as introducing technologies that can avoid the limits to growth that traditional energy systems will eventually run into.

Energy as a key input to development is undeniable, but significant debate exists about how to go forward, and the models must differ from those put in place by industrial countries that have proved to be unsustainable. To move forward, it is essential to understand the multiple linkages between access to energy services and social, economic, and human development. These linkages shape emerging energy markets, define and often limit poor peoples' options to escape the cycle of poverty, and will determine the opportunities and limitations to key issues of pertaining to sustainability of development. Putting peoples' needs at the center of the development model that defines the energy services required to overcome poverty is a key starting point.

Currently there are almost one and a half billion people worldwide who do not have access to electricity (IEA, 2010a; see also Chapter 19). Most of these people live in Africa and South Asia. An estimated 3 billion people primarily rely on solid fuels (coal and traditional biomass) of which 2.7 billion people cook and heat their homes with traditional fuels and low-efficiency stoves (UNDP and WHO, 2009; IEA, 2010a; see also Chapter 19). For many millions of people, especially women and school-aged children, the lack of mechanical power for pumping water and grinding food grains results in hours of manual labor carrying fuel and water and undertaking repetitive pounding and grinding activities that pumps and mills could do so much more efficiently.

Table 2.2 | Energy and the MDGs.

Goal and target	Some direct and indirect contributions of cleaner/affordable energy options
MDG 1. Extreme poverty and hunger: To halve, between 1990 and 2015, the proportion of the world's people whose income is less than one dollar per day. To halve, between 1990 and 2015, the proportion of people who suffer from hunger.	• Cleaner burning fuels and electricity can reduce the large share of household income spent on cooking, lighting and heat. The bulk of staple foods (95%) need cooking before they can be eaten and need water for cooking. • Post-harvest losses can be reduced through improved electric-powered preservation (for example, drying and smoking) and chilling/freezing. • Energy technologies such as wind pumps and treadle pumps can be used for irrigation in order to increase food production and improve nutrition. Access to affordable energy options from gaseous and liquid fuels and electricity can assist enterprise development. • Electrically driven machinery can increase productivity and provide opportunities for income generation. • Local energy supplies can often be provided by small-scale, locally owned businesses creating employment.
MDG 2. Universal primary education: To ensure that, by 2015, children everywhere will be able to complete a full course of primary schooling.	• Lighting at homes (e.g., through solar lanterns) allows children to study after school hours, with a significant impact on learning outcomes. • Lighting in schools can assist in retaining teachers, especially if their houses are electrified. • Availability of electricity can enable access to educational media and communications in schools and, at home, can facilitate distance learning. • Access to energy can provide opportunities for using specialized equipment for teaching. • Cleaner energy systems and efficient building design can reduce heating/cooling costs and thus school fees. • Energy can help create more child-friendly environments, thus improving attendance at school and reducing dropout rates.
MDG 3. Gender equality and women's empowerment: To ensure that girls and boys have equal access to primary and secondary education, preferably by 2005, and to all levels of education no later than 2015.	• Availability of cleaner energy options can free girls' and young women's time from survival activities (gathering firewood, fetching water, etc.). • Good-quality lighting can facilitate home study and organization of evening classes for girls and women who are often housebound due to traditional family responsibilities. • Affordable and reliable energy options can broaden the scope for women's enterprises, thereby fostering employment and income generation among women. • National decision-making by women representatives, especially on energy use at household level, can be beneficial, hence improving energy access among the poor.
MDG 4. Child mortality: To reduce by two-thirds, between 1990 and 2015, the death rate for children under the age of five.	• GEA estimates for 2005 put the burden of disease caused by household air pollution at about 2.2 million premature deaths annually, mostly affecting children and women (see Chapters 4 and 17). Gathering and preparing traditional fuels exposes young children to health risks and can reduce time spent on childcare. • Cleaner energy options facilitate the provision of nutritious cooked food and space heating, while boiled water contributes to better health. • Improved energy options can provide access to better medical facilities for pediatric care, including vaccine refrigeration and equipment sterilization. • Energy can be used to purify water or pump clean groundwater locally, which can reduce the burden of water-borne diseases.
MDG 5. Maternal health: To reduce by three-quarters, between 1990 and 2015, the rate of maternal mortality.	• Clean cooking fuels and equipment can reduce pregnant women's exposure to indoor air pollution and improve health. • Improved energy options can provide access to better medical facilities for maternal care, including laboratory services, medicine refrigeration, equipment sterilization, and operating theatres, as well as safer caesarean sections. • Improved energy options can also help retain qualified medical personnel in remote rural areas. • Cleaner energy options can reduce excessive workloads and heavy manual labor (carrying heavy loads of fuelwood and water), which could adversely affect a pregnant woman's general health and well-being.
MDG 6. HIV/AIDS, malaria, and other major diseases: By 2015, to have halted and begun to reverse the spread of HIV/AIDS, malaria, and other major diseases that afflict humanity.	• Electricity in health centers can help provide medical services at night, retain qualified staff, and allow the use of more advanced medical equipment (e.g., sterilization). • Energy for refrigeration can facilitate vaccination and medicine storage for the prevention and treatment of diseases and infections. • Energy is needed to develop, manufacture, and distribute drugs, medicines, and vaccinations. • Electricity can enable access to health education media through information and communications technologies.
MDG 7. Environmental sustainability: To stop the unsustainable exploitation of natural resources. To halve, between 1990 and 2015, the proportion of people who are unable to reach or afford safe drinking water and sanitation.	• Increased agricultural productivity can be facilitated by the greater use of electric-powered machinery and irrigation, which in turn reduces the need to expand the amount of land under cultivation. • Increased renewable energy technology use can contribute greatly to alleviation of deforestation and reduction of green house emissions that lead to climate change. • Cleaner burning fuels can reduce greenhouse gas emissions, which contribute to climate change conversion technologies. • Simple cleaner energy solutions such as low-cost sterilization of drinking water can save many lives.
MDG 8. Global partnership for development	• Global and subregional partnerships are valuable for ensuring cross-border trade and exchange of skills in cleaner energy options as well as joint lower-cost development of transmission interconnections.

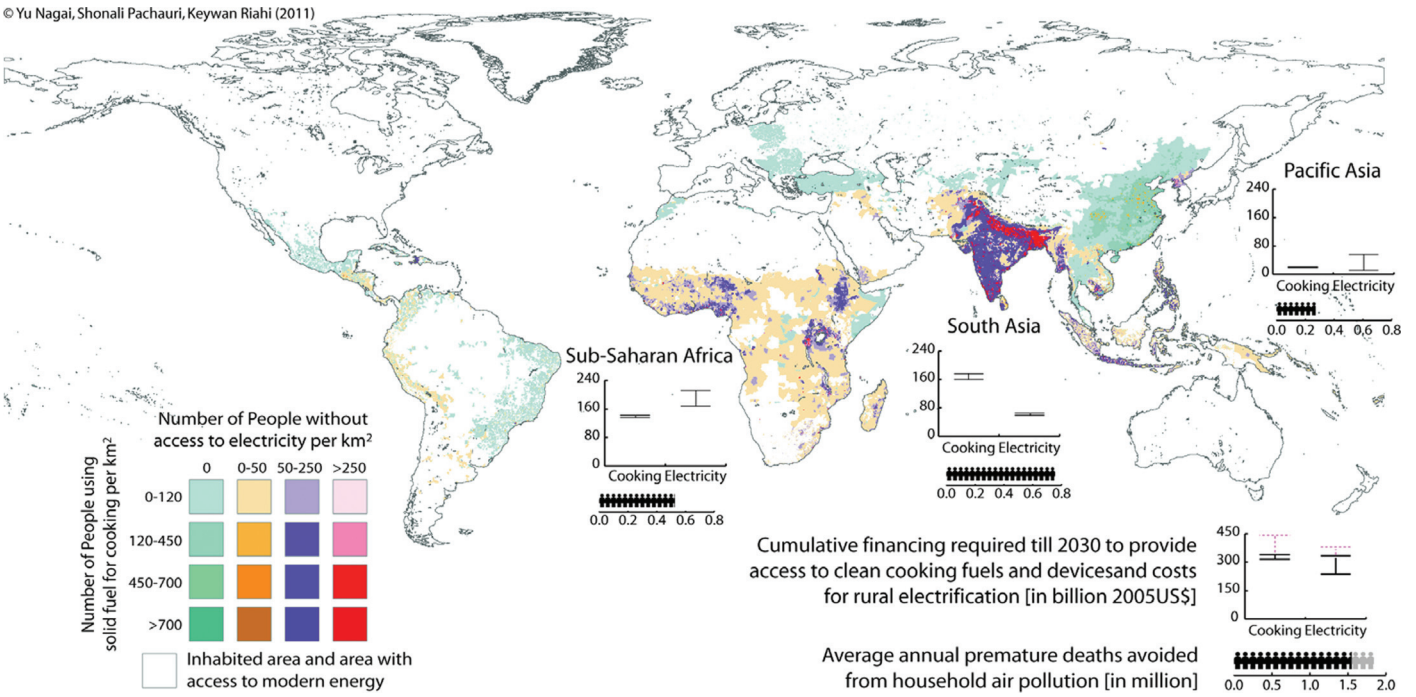

Figure 2.5 | Proportion of population without access to electricity and using solid fuels. Source: Compiled by IIASA using data from UNDP and WHO, 2009.

Figure 2.5 shows the proportion of people without electricity and using solid fuels for cooking. The figure indicates that, among developing countries, sub-Saharan Africa has the highest proportion of its population having a combination of low access to electricity and reliance on solid fuels (see also Table 2.4 and Table 2.6) while the absolute largest number of the people with limited access live in Asia. According to projections by IEA (2010a), the population without electricity will continue to rise in sub-Saharan Africa, unlike in other parts of the developing world, which still have pockets of underserved populations but which are projected to significantly increase access to electricity (e.g., Latin America and North Africa).

As shown in Table 2.3, within countries, there is a significant disparity in terms of access to electricity between rural and urban populations (IEA, 2010a).

As shown in Table 2.4, in many developing countries, especially those in sub-Saharan Africa and some parts of Asia, low electrification rates are compounded by very low levels of electricity consumption implying very limited use of this important and flexible energy service.

As mentioned earlier, while there are different approaches to defining poverty, there is a positive worldwide correlation between energy services and GDP per capita (approximately average personal income) as well as in relation to human development. As shown in Figure 2.6, there is a correlation between the level of well-being (shown by the HDI) and access to modern forms of energy (indicated by per capita electricity consumption). As the electricity consumption per capita increases, the HDI indicator increases, while an increase in income and electricity access has a direct relationship in the increase of electricity consumption per capita.

India	381	23
Other developing countries in Asia	328	59
Latin America	27	4
Total	**1209**	**206**

Source: IEA, 2010a.

As mentioned earlier, provision of and access to modern, cleaner and affordable energy options *per se* does not, in itself, alleviate poverty. However, there is growing consensus that enhancing access to modern, cleaner and affordable energy options can play a key contributing role to reducing poverty, especially for the poorest people (the lowest fifth in a population) and the poorest countries. Figure 2.7 illustrates the link between high poverty levels and low access to electricity. Energy services therefore, are a means to facilitate development given that energy is an essential input for productive, household and social sectors.

It is, however, important to note that at higher levels of incomes, this correlation begins to break down at a national level – an important indicator of wasteful energy use which highlights the importance of energy efficiency in richer industrialized nations.

Table 2.4 | Snapshot of electricity access and consumption in developing countries, 2008.

Country	Population with electricity access (%)	Electricity consumption per person (kWh)

Source: IEA, 2009; 2011; World Bank, 2011a.

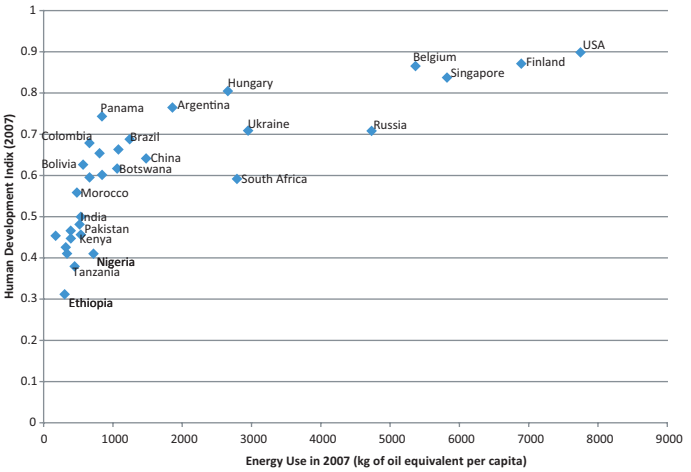

Figure 2.6 | Correlation between HDI and electricity consumption per capita. Source: adapted from UNDP, 2009; World Bank, 2007.

The correlation between access to cleaner energy and poverty reduction is corroborated by a number of recent World Bank studies. For example, according to a study by Barnes et al. (2010), increased access to cleaner and affordable energy options contributes to monetary gains among the poor and leads to better quality of life, such as an improved diet and amount of food intake, the ability to afford better health and education facilities, etc.

There tends to be a two-way causal relationship between poverty and the lack of access to adequate and affordable energy forms. The relationship can be characterized as a vicious cycle because poor people who lack access to cleaner and affordable energy are often trapped in a repeating cycle of deprivation, limited incomes and the means to improve their living conditions while at the same time using significant amounts of their very scarce income on expensive and unhealthy forms of energy that provide poor or unsafe services such as dry cell batteries, rudimentary and inefficient kerosene lamps, charcoal and candles.

The lack of modern and affordable forms of energy affects agricultural and economic productivity, time budgets, opportunities for income generation, and more generally the ability to improve living conditions. Low agricultural and economic productivity as well as diminished livelihood opportunities in turn result in malnourishment, low earnings, and no or little surplus cash. This contributes to the poor remaining poor, and consequently they cannot afford to pay for cleaner or improved forms of energy (often neither the fuels nor the equipment). In this sense the problem of poverty remains closely intertwined with a lack of cleaner and affordable energy services.

On the other hand, when the poor gain access to stable electricity supplies or cleaner fuels that can support job creation, trade, and value-adding activities within the family, they are able to accumulate the small levels of "surplus" or savings that facilitate access to education and health services, improved nutrition, or improved housing conditions that in turn enable them to gradually escape their poverty (UNDP, 2006).

A number of developing countries have set targets for enhancing access to electricity, cleaner fuels, improved stoves, and mechanical power

(see Table 2.5). In overall terms, however, the total number of developing countries with such targets is relatively small.

As shown in Figure 2.8, nearly all 140 countries assessed in a UNDP-WHO study have some data on electricity access/supply, but none had data on mechanical power.

Table 2.5 | Developing countries with access targets for modern energy availability.

Energy Source/ Application	Number of Developing Countries with Target	Number of Sub-Saharan African Countries with Target
Electricity	68	35
Modern fuels	17	13
Improved cookstoves	11	7
Mechanical Power	5	5

Source: adapted from UNDP and WHO, 2009.

2.3 Household Energy

For the poorest people in the world, especially those who live in the poorest countries, the most inelastic segment of demand for energy is that for cooking and heating to ensure basic survival. This "household

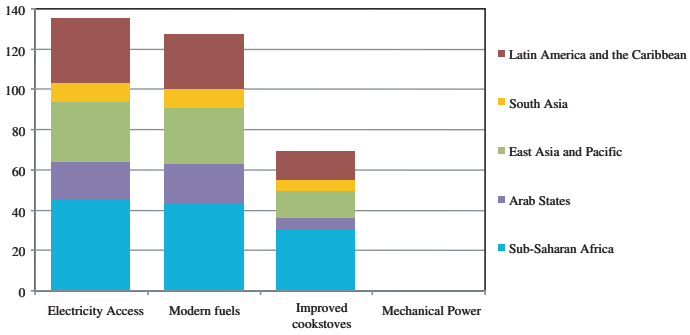

Figure 2.8 | Number of countries with data on energy sources and applications. Source: adapted from UNDP and WHO, 2009.

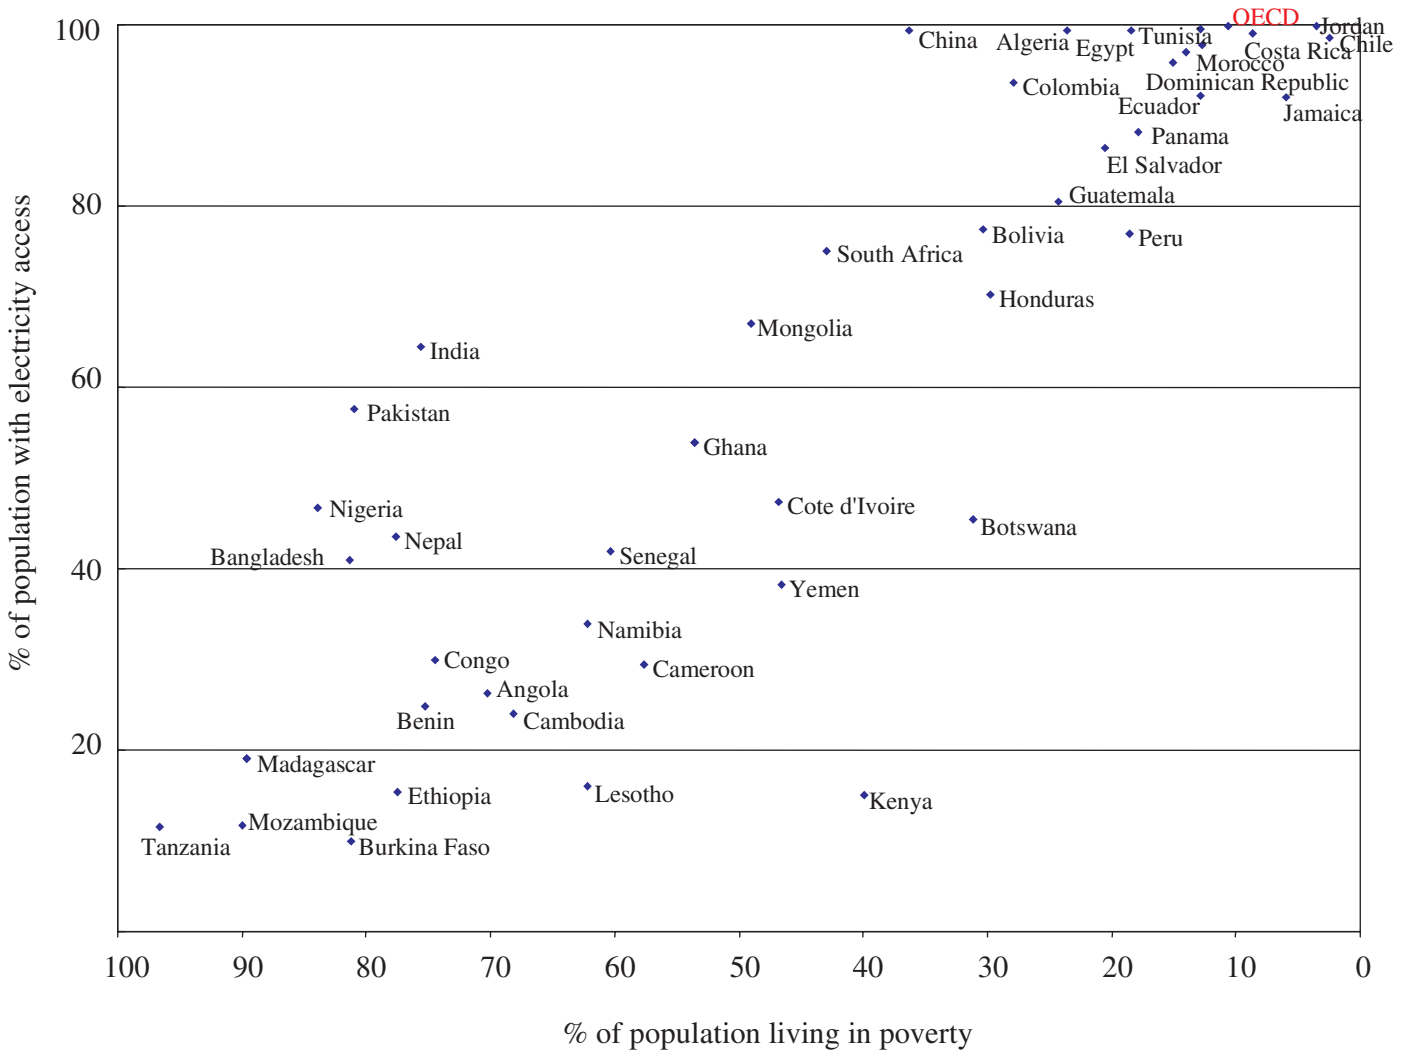

Figure 2.7 | Access to electricity versus poverty levels. Source: adapted from World Bank, 2011a; IEA, 2008.

energy" is often poorly understood by development planners at large, and within the energy sector it is often not considered in policies that historically have been focused on electricity supply rather than other household fuels. Even poor families do not have a choice of whether to use heat to cook their food because 95% of all basic staples must be converted to food through heat for cooking (ESMAP, 2004).

All families worldwide, rich or poor, depend on heat to cook their food, boil water, and, where the climate requires it, provide space heating. While traditional fuels such as wood, agricultural residues, or dung can be gathered locally, considerable time is spent collecting them (ESMAP, undated) (see Figure 2.19). As traditional fuels become scarcer due to overharvesting, agricultural decline, or increased competition among growing populations, more and more unpaid time is dedicated to fuel collection, leaving less time for income-earning activities.

In many poor countries, biomass, mainly for cooking, accounts for over 90% of household energy use. According to IEA (2010a) estimates, about 2.7 billion people rely on traditional biomass, such as fuelwood, charcoal, agricultural waste, and animal dung, to meet their energy needs for cooking. A significant proportion of these people are the majority of the poor, who live on less than $US_{2005}$$2 a day (PPP).

As shown in the Table 2.6, sub-Saharan Africa and parts of Asia currently rely heavily on traditional biomass (IEA, 2010a). In all subregions of the developing world, people in rural areas account for the highest proportion of the population relying on traditional biomass, a key indication that rural areas in most developing countries have limited access to cleaner energy options, especially for cooking.

According to available data, if access to cleaner cooking fuels remains constrained, a large proportion of the population in sub-Saharan Africa and parts of South Asia will continue relying on traditional biomass for cooking for the next couple of decades. And as shown in Figure 2.9, in sub-Saharan Africa the number of people relying on traditional biomass for cooking is projected to increase at a much steeper pace than in other regions over the next two decades (Brew-Hammond, 2007) if current trends continue.

Unlike other regions and developing countries where traditional biomass energy use is expected to stagnate or decline, Africa's traditional biomass use is likely to increase sharply by 2030 unless there is a significant increase in access to cleaner and affordable energy carriers for cooking (IEA, 2006a). In the meantime, there is evidence that in areas where local prices of energy carriers have increased because of recent high international energy prices, the shift to cleaner and more efficient energy options for cooking has actually slowed and even reversed (IEA, 2006a; UNDP, 2007a; World Bank, 2010a).

Enhancing the poor's access to modern and cleaner forms of household energy is important due to its potential for increasing income levels for

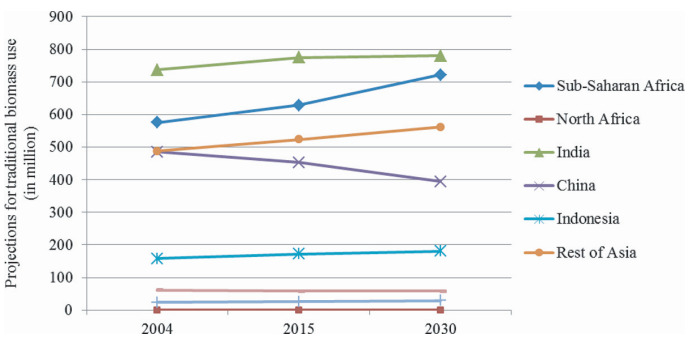

Figure 2.9 | Projections for traditional biomass use in developing regions (million people). Source: based on IEA, 2006a.

Table 2.6 | Rural and urban populations relying on traditional biomass as principal household energy option, by region and selected country.

Subregion	Total number of people relying on traditional biomass (million)			Proportions of population relying on biomass within subregion (%)		Population relying on biomass as share of subregion's population (%)
	Rural	Urban	Total	Rural	Urban	
Africa	481	176	657	73.2	26.8	67
Sub-Saharan Africa	477	176	653	73.1	26.9	80

this group. Just as important, however, is the need to reduce the poor's expenditure on energy services. As shown in Table 2.7, the poor spend a higher share of their income on energy than the non-poor, which underscores the need to ensure affordable energy options for people with lower incomes.

Traditional fuels are typically used in low-efficiency stove technology – for the poorest people, nothing more than stones or very basic stoves. Relatively poor-quality heat is derived from the use of traditional fuels. This is not the nature of the fuels themselves but a byproduct of stove technology.

Global analysis conducted by World Health Organization (WHO) evaluated different intervention scenarios if the number of people cooking with solid fuels were halved by providing them with access to LPG by 2015. The analysis, conducted in 11 WHO subregions, showed a payback of US_{2005}91 billion a year on an investment of US_{2005}13 billion a year (See Table 2.8).

In poor countries, due to scarcity, rural people are unable to collect all the fuels they need (UNDP, 2005; UN-Energy, 2005). Increasingly, traditional fuels including wood, charcoal, and other biomass are bought in commercial markets. The share of poor families' incomes spent on fuels is a significant portion of their total expenditures and can sometimes overtake other essential items such as schooling and health costs when local fuel prices rise (Modi et al., 2006; UNDP, 2005). This is also true for the urban poor, who rely on traditional fuels for cooking and heating and who must buy such fuels.

It is essential to put to rest two myths regarding the use of traditional fuels. The first myth is that all traditional fuels are free or available at no monetary cost (even those that are harvested locally for family consumption are not free as they involve a high opportunity cost based on the time spent on their collection). The second is that traditional fuels are mainly used in households in rural areas in terms of absolute numbers of consumers. In sub-Saharan Africa, much of the rural deforestation and overharvesting of fuelwood can, in part, be traced to trees cut down for feedstock for the charcoal industry. This is not to supply rural consumers with energy but to provide a steady supply of cheap fuels for cooking and household energy use for urban dwellers, as indicated by the thriving charcoal markets throughout the African continent (AFREPREN/FWD, 2006a).

Table 2.8 | Remarkable returns from investing in household energy. Benefits of household energy and health interventions (US_{2005} million), by type of benefit, 2005.

	If 50% of the population cooking with solid fuels in 2005 switch to cooking with liquefied petroleum gas by 2015	If 50% of the population cooking with solid fuels in 2005 switch to cooking with modern forms of biofuels by 2015	If 50% of the population cooking with solid fuels in 2005 switch to cooking on an improved stove by 2015
Health care savings	384	384	65
Time savings due to childhood and adult illness prevented: school attendance days gained for children and productivity gains for children and adults	1460	1460	510
Time savings due to less time spent on fuel collection and cooking: productivity gains	43,980	43,980	88,100
Value of deaths averted among children and adults	38,730	38,730	13,560
Environmental benefits	6070	5610	2320
Total benefits	**90,624**	**90,164**	**104,555**

Note: Costs and benefits of different intervention scenarios were estimated using 2005 as the base year and a 10-year time horizon, taking into account demographic changes over this period. The analysis was conducted for 11 WHO subregions to reflect variations in (i) the availability, use and cost of different fuels and stoves; (ii) disease prevalence; (iii) health care seeking as well as quality and cost of health care; (iv) the amount of time spent on fuel collection and cooking; (v) the value of productive time based on Gross National Income per capita; and (vi) variations in environmental and climatic conditions. A 3% discount rate was applied to all costs and benefits.

A reduction in energy expenditure or time spent collecting fuel can liberate much-needed financial resources for other important expenses, such as increasing the quantity and quality of food or investing in new income-generating activities or expanding existing income-generating activities – thereby enhancing income as well as creating employment. For example, by switching from traditional to improved cookstoves, the poor can significantly reduce their expenditure on fuel and also save time spent in fuel collection (Galitsky et al., 2006). Improved charcoal cookstoves modelled on the Kenya Ceramic Jiko (KCJ) can cut charcoal consumption by up to half. The money thereby saved can be reinvested in more or better-quality food, partially contributing to minimizing extreme hunger, or in an income-generating activity. The KCJ reduces emissions and particulate matter, the latter of which contributes to acute respiratory infection among women and infants under the age of five. The relevance of the KCJ experience in Kenya is demonstrated by its introduction into Burkina Faso, Ethiopia, Ghana, Malawi, Mali, Rwanda, Senegal, Sudan, Tanzania, and Uganda, to mention just a few countries. Other successful improved biomass cookstoves as well as ethanol cookstoves are also being disseminated in Asia and Latin America.

Liquid and gaseous fuels can provide better cooking and heating options due to the combustion efficiency and quality of heat they provide. Unfortunately, fuels such as kerosene and LPG are often not available in local markets, especially in rural areas. In addition, due to their higher costs, they cannot compete with traditional biomass-based fuels. Poor people also face challenges associated with the upfront cost of stoves. For example, families who would be able to afford the recurring fuel costs of LPG versus charcoal may not be able to afford the requisite LPG stove, thereby eliminating the possibility of switching fuels (Quansah et al., 2003).

In most developing countries, there has been a significant increase in the use of LPG over the past decade (Karekezi et al., 2008b), but this has occurred among people with higher disposable incomes except in countries where active interventions to reach the poor are in place. In Senegal, for example, about 90% of Dakar's inhabitants rely on LPG for cooking (ANSD, 2006; Schlag and Zuzarte, 2008; Fall et al., 2008). To reach the poor, a number of LPG distributors have promoted smaller LPG cylinders, thus lowering upfront costs. India and Brazil have registered impressive progress in promoting LPG use through the use of subsidies to promote market wide changes in consumption patterns (Shankar, 2007; Coelho, 2009). However, world oil prices are highly variable, and in a time of increasing resource scarcity, a significant price increase is likely to erode some of the gains made in LPG use among the poor.

Socioeconomic determinants can be expected to have a significant influence on fuel or other intervention choices (such as improved stoves or improved household ventilation). Household fuel demands have been shown to account for more than half of the total energy demand in most countries with per capita incomes under US_{2005}1000 (PPP), while accounting for less than 2% in industrial countries (UNDP, 2007b). While it is known that households switch to cleaner, more-efficient energy systems for their domestic energy needs as per capita incomes increase (i.e., they move up the "energy ladder"), these changes have largely been due to increases in affordability, demand for greater convenience, and energy efficiency (IEA, 2010a). Figure 2.10 is a partial depiction of a typical "energy ladder" with regard to some of the fuels associated with cooking.

From a policy and public financing point of view, there is a need to alleviate the negative income effect of time use and family expenditure related to the use of traditional fuels and to overcome the barriers

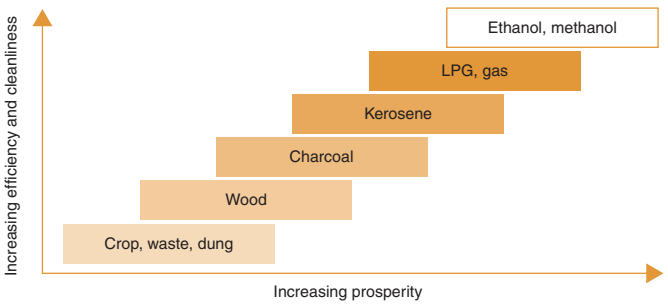

Figure 2.10 | Typical "energy ladder" for cooking fuels[3]. Source: UNDP, 2007b.

related to household energy. In developing countries, where poor people are highly dependent on traditional fuels that are poorly combusted in inefficient devices, much greater emphasis must be given to increasing the availability and affordability of liquid and gaseous fuels and associated stove technologies. Special attention should also be paid to mechanical power solutions and labor-saving appliances that can provide homestead-based pumping, agro-processing, milling, and grinding, among other services. These are also critically important for gender and health reasons, as discussed later in this chapter.

The absence of mechanical options in many rural areas of the developing world, to provide access to mechanical power for water pumping, milling, or other household activities is also related to the absence of affordable and cleaner fuels or electricity to drive engines, mills, and pumps to supplement human labor (see Chapters 19, 23, and 25). The absence of mechanical power affects not only the poorest families, particularly girls and women, but often entire geographic areas due to the distances from electricity supply and cleaner fuel delivery systems (UN Energy, 2005; UNDP, 2005). Overcoming the mechanical power deficit that affects the household energy balance is also related to the appliances (pumps, mills, and engines) that convert energy carriers into the service of mechanical power. In this sense, it has many similarities with the cooking and heating challenges in the household energy mix.

2.4 Energy and Production

Virtually all value-adding activities, both paid and unpaid, require energy as an input in the production process (Modi et al., 2006; UN-Energy, 2005). In its simplest form it can be human or animal energy transporting goods, doing manual work, or providing manual power through simple machines such as mills. As greater degrees of technology are applied in the production process, different forms of energy are used. This could be heat energy in manufacturing processes requiring ovens or kilns and therefore fuels, in which case the quality of the heat, access, and affordability of the fuels and efficiency of the ovens used all affect the final product (from bread to bricks). Other productive processes require motors, machines, or other tools that often use liquid fuels (such as petrol for motors) or electricity (for sewing machines, welders, etc.) to power them. Table 2.9 illustrates various mechanical power technologies and applications that could help minimize the amount of human energy spent on different productive activities.

In addition to production activities in which energy and machines are applied to raw materials and other inputs to produce final products, service industries also require energy as inputs. This includes telephones, computers, other information technology, or air conditioners, specialized equipment, or security systems – all of which consume electricity.

In short, from the simplest manufacturing industries to the most complex technology-intensive ones, energy – whether electricity or fuels – is an essential input. It therefore would seem obvious that there is a link between energy and the development objectives of achieving full and productive employment and decent work for all. Yet while many countries have active programs to promote employment through workers' training or other skills-building activities, sources of energy for machines or financing schemes to get access to the energy-using equipment itself is often not part of the job creation agenda.

Many working conditions, especially for the poorest people, are hazardous or life-threatening. In countries where a work-related injury can greatly reduce the economic conditions of entire families due their vulnerability to a range of factors beyond their control (food and fuel price rises, access to affordable housing, increases in education or health service fees), access to decent work is a key determinant of the ability of people, communities, and entire countries to overcome conditions of poverty. Cleaner energy options can enhance working conditions and open opportunities to generate livelihoods, increase the number of jobs, and provide decent work for entire populations are directly related to access to energy services for value-adding processes, whether this be in manufacturing, the services sector, government, or social services (Modi et al., 2006; UN-Energy, 2005).

Employment in formal and non-formal sector activities is positively correlated to access to cleaner energy options such as electricity, as is workers' productivity in value-adding processes. In addition, increased access to cleaner energy contributes to the transformation of economies from being agriculture-based – where significant animate energy is consumed – to industry-based, where cleaner energy plays a key role in the production of commodities. Figure 2.11 illustrates that economies with relatively high cleaner energy use (due to high access levels) have lower contributions of agriculture to the GDP implying that reliance on agriculture is inversely proportional to cleaner energy use as more non-agricultural industries are established contributing to economic development. Conversely, economies with very low cleaner energy use show relatively high levels of contribution of agriculture to GDP, as their industrial sector is not developed, in part, due to an inadequate supply of cleaner energy options (Modi et al., 2006; UN-Energy, 2005; UNDP, 2005).

3 Electricity represents the highest rung on the 'energy ladder' and produces different energy services than fuels.

Table 2.9 | Mechanical power technologies and applications.

Activity	Service	Traditional technology	Mechanical power alternative
Water supply	Drinking	Container (bucket) for lifting/carrying water	Diesel pump Treadle pump Rope pump Ram pump Persian wheel Hand pump River turbine Wind pump
	Irrigation		
	Livestock watering		
Agriculture	Tillage/plowing	Animal-drawn tiller/hand hoe	Power tiller/ two-wheel tractor
	Harvesting	Scythe Animal-drawn mower Manual practices	Harvester
	Seeding	Hand planting	Bed planter Row planter Seed drill
Agro-processing	Milling/Pressing	Hand ground/Flail	Powered mill Oil expellers
	Cutting/Shredding	Knife	Sawmills Powered shredder
	Winnowing/Decorticating	Winnowing basket	Powered shaker Grinder
	Spinning	Manual spin	Powered spinner
	Drying	Handheld fan Sun drying	Powered fan Solar dryer

Source: adapted from Bates et al., 2009.

In the countries with the least access to electricity countrywide, or in specific geographic areas within national borders that have limited electricity access or an unreliable supply, limits to productive employment and income generation are also likely to be present. The cost, reliability, and ease of access to energy services are also factors in creating conditions for jobs creation, production, and decent work.

For example, lack of reliable electricity supply in sub-Saharan Africa has significant impacts on job security, especially among casual laborers in industry. On annual basis, cumulative time of electrical supply interruptions is equivalent to about three months of production time lost (IEA, 2010a), a significant duration that implies little or no production, thereby risking loss of jobs. In addition, it is estimated that businesses

lose production worth 6.1% of their turnover due to electrical outages (IEA, 2010a). Table 2.10 summarizes the reliability of electricity supply in sub-Saharan Africa and developing countries in general.

At the macroeconomic level, lack of a reliable supply of electricity is estimated to have a significant impact on economic growth and productivity. Figure 2.12 shows the proportion of GDP lost to unreliable electricity supply in some countries in sub-Saharan Africa.

Table 2.10 | Summary of electricity supply reliability in sub-Saharan Africa and developing countries.

Indicator	Sub-Saharan Africa	Developing Countries
Cumulative electrical interruptions (days/year)	90.9	28.7
Lost Production (% of turnover)	6.1	4.4
Firms owning/sharing generators (% of total)	47.5	31.8
Number of days for new electrical connection	79.9	27.5

Access to modern and affordable forms of energy options is essential for creating employment, thereby contributing to a reduction in poverty levels. According to a survey of a rural Indian village by Hiremath and

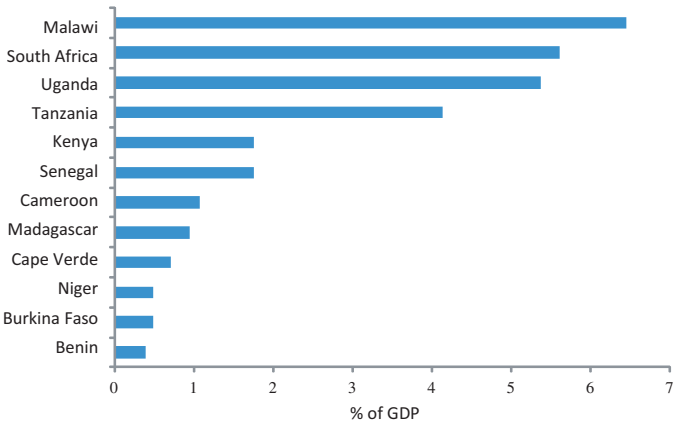

Figure 2.12 | Proportion of GDP lost due to unreliable power supply in 2007. Source: Vivien and Briceno-Garmendia, 2010.

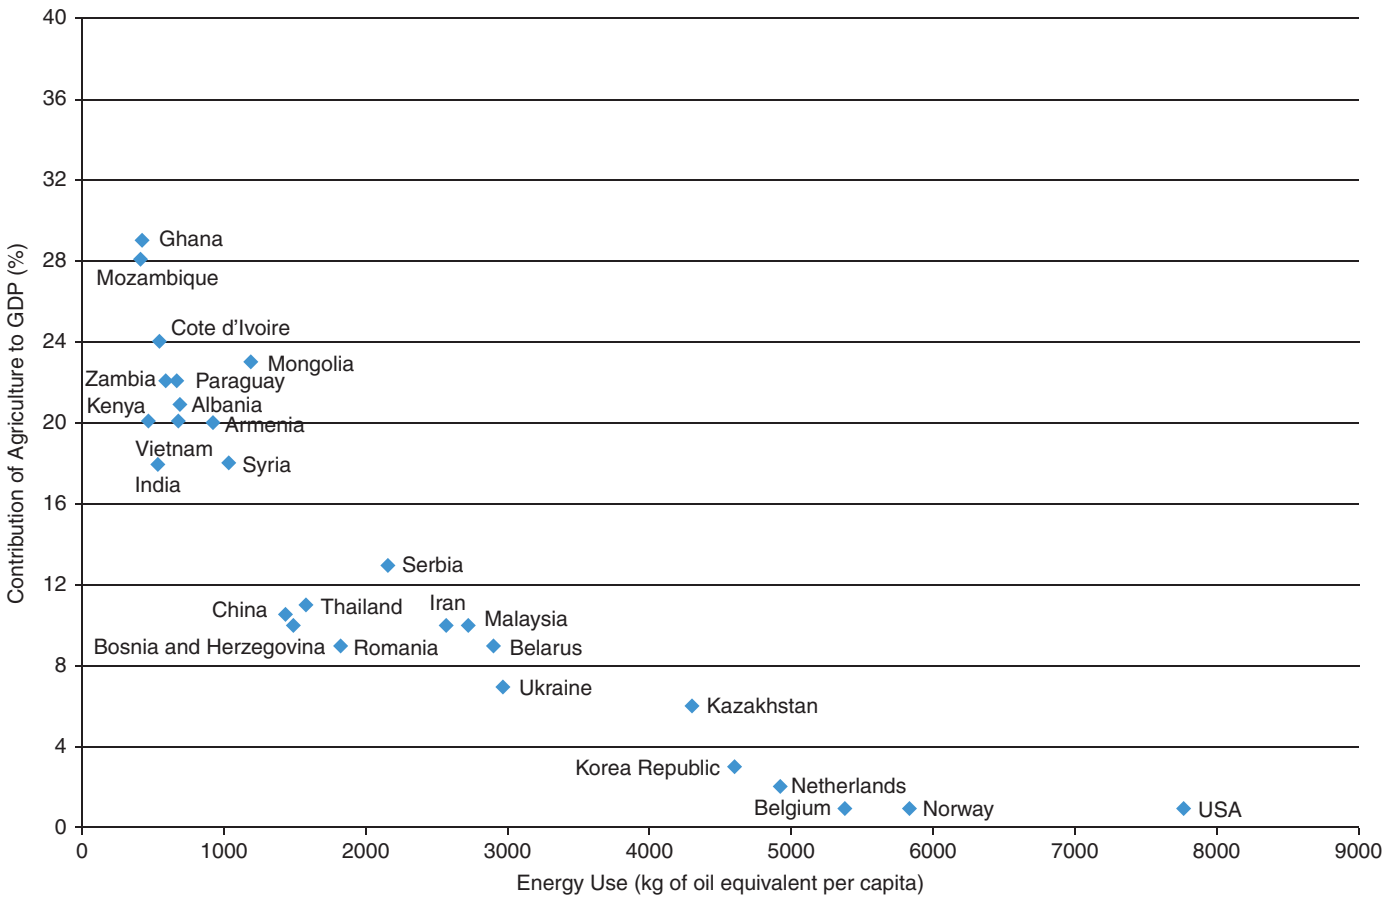

Figure 2.11 | Correlation between cleaner and modern forms of energy use and contribution of agriculture to GDP, 2007. Source: adapted from World Bank, 2011a.

Misra (2009), modern forms of bioenergy systems can create opportunities for 25–45 jobs in one village alone. The jobs would arise from developing forests for feedstock, preparing wood feedstock, collecting cattle dung or leaves, operating and maintaining biogas/gasifier systems, etc., as well as the operation, repair, and maintenance of associated equipment such as generators, pumps, flour mills, diesel engines, and domestic appliances.

World Bank studies in Asia have attempted to quantify the benefits of rural electrification. For example, a survey in Bangladesh revealed that rural electrification could lead to an increase of income in the range of 9–30% (Khandker et al., 2009). The value of benefits of rural electrification accrued by households in the Philippines is shown in Table 2.11 (World Bank, 2008b), which are substantial in comparison to Philippine's per capita GDP of US$146 in 2009.

Thus although the presence of electricity or fuels does not, on its own, guarantee full employment or enough value-adding jobs to ensure decent work and poverty elimination, access to electricity and fuels for formal and informal sector work expands the range of employment options in both urban and rural areas, with the most dramatic effects being seen in the countryside. This is not because of the electricity or the fuel itself but because of the expansion in the range of services for manufacturing, communication, mechanical power, and illumination that they provide.

Prioritizing access to electricity and energy-using technology for commercial activities (as opposed to only low-load household activities) could increase employment opportunities that can contribute to income generation and the fight against poverty, especially for the working poor.

2.5 Energy and Agriculture

Most of the caloric intake of the poorest people worldwide comes from basic grains such as rice, corn, millets, and wheat. In all cases not only do basic grains need to be cooked to be consumed, which requires heat energy, but their very production, harvest, and processing require energy inputs for cultivation, irrigation, transport, and, for some foodstuffs, preservation.

By facilitating irrigation, cleaner and affordable energy options can help ensure food security among the poor in spite of increasingly frequent drought conditions in many countries. As shown in Table 2.12, irrigation is still an embryonic practice in sub-Saharan African countries but it is widely practiced in Asia (FAO, 2011). Most of the Asian countries represented in Table 2.12 source more than half of their grain production from irrigated land. In comparison, in most of sub-Saharan African countries, grain production from irrigated land accounts for around 20% or less (FAO, 2011).

Energy can play a vital role in enhancing food security among the poor through technologies that can be used for irrigation and water pumping. Energy for mechanical power (water pumping or distribution) can come from grid-connected electricity, local motors using fuels, or renewable-energy-derived water-lifting devices.

Some irrigation and water pumping technologies have significant potential for not only ensuring food supply throughout the year but also generating additional income for households (Karekezi et al., 2005). Table 2.13 provides estimates of the initial investment required to buy and install various irrigation or water pumping technologies. However, where farmers are supplied with excessively subsidized or extremely low-cost electricity there are possibilities of misusing it, for example by use

Table 2.11 | Quantifying electrification benefits for typical households in rural Philippines.

Benefits	Value of benefits (US$/month)	Beneficiary
Less expensive and expanded use of lighting	36.6	Household
Less expensive and expanded use of radio and television	19.6	Household
Improved returns on education and wage income	37.1	Wage earner
Time savings for household chores	24.5	Household
Improved productivity of existing home business	34.0	Business
Productivity of new home business	75.0	Business

Table 2.13 | Initial investment and specific cost of irrigation water, various technologies.

Component	Treadle pumps[4]	Hydrams (hydraulic ram pumps)	Wind pump	Diesel pump
Cost + installation (US$)	171	295	2981	2,000
Lifetime (years)	6	40	20	10
Rate of discharge (m^3/hour)	4.3	4.5	7.5	10.0
Specific cost of water (US$/$m^3$/year)	0.03	0.05	0.29	0.18

Note: The costs in the table assume that the requisite renewable energy resources are available at the site where the pump is located and also that the water source is within a reasonable distance for the pump to operate at its optimum.

Source: Karekezi et al., 2005; Karekezi et al., 2008a.

of inefficient pumps, which leads to increased electricity consumption as well as wasteful use of water which can lower water table levels.

As Table 2.13 indicates, not all technologies may be affordable to poor households due to high upfront cost. However, the treadle pump appears to have the least upfront cost and is likely to be the most attractive option for the poor. This technology – widely used in Asia and parts of sub-Saharan Africa – is reportedly very effective in enhancing food production.

Many sub-Saharan African farmers are still irrigating very small plots of land using bucket-lifting technologies, which are slow, cumbersome, and labor-intensive, especially for women. Small-scale irrigation is usually developed privately by farmers in response to family and local market requirements, often with limited government interventions.

Small-scale irrigation using treadle pumps is one of the success stories in many countries in Africa at a time when large-scale water developments have failed to meet expectations. Case studies from Kenya, Niger, Zambia, and Zimbabwe show that by using animate energy-driven treadle pumps instead of bucket irrigation, farmers can increase irrigated land, reduce work time, improve crop quality, grow new crops, and increase the number of cropping cycles (AFREPREN/FWD, 2006b). Treadle pumps make it easier for farmers, especially women, to retrieve water for their fields or vegetable gardens, and they are cheap and easy to handle. Treadle pump technology has enabled poor rural farmers, especially women, to increase their incomes by selling surplus produce in the local market.

In some cases, cropping intensity has been extended to three crops per year. In Zimbabwe, treadle pumps are mostly used for irrigation of small vegetable gardens. And because these pumps usually reach water only within five meters, they do not deplete valuable groundwater resources. It is noted that the local water table would drop only if a large number of farmers were operating in the same area.

4 A treadle pump is a human-muscle powered irrigation device.

In Kenya, treadle pumps were introduced in 1991 and have generated a wide range of benefits for users, manufacturers, promoters, and retailers. The low-income owners in Kenya purchase them mainly through their savings as well as from the sale of crops and livestock and use of retirement benefits. While men own 84% of the treadle pumps, women manage nearly three-quarters of them, which are mainly used for irrigating crops and to some extent for supplying water for household use and animals (Karekezi et al., 2005).

According to available data, the areas under irrigation increased among users by 700% from an average of 0.03–0.24 ha in 1999 to 0.59 ha in 2004 (Karekezi et al., 2005). For farmers not involved in irrigation previously, the number of crop cycles increased from 1.2 to an average of 2.3. One advantage associated with an increased number of crop cycles is the timing of cropping, in order to harvest when the crop fetches higher prices from the market.

If pumps are produced locally, they can also create jobs and income – the pumps cost less than US_{2005}200 and can be built with ordinary workshop equipment (AFREPREN/FWD, 2006b). Some 186,804 pumps are reported to have been sold across West, East, and Southern Africa since 1991 (Kickstart, 2011).

Wind pumping technologies can supply water for irrigation as well as for household use and livestock (Harries, 2002). The wind speeds in most regions (even in sub-Saharan Africa, which is located in a generally low wind-speed zone that straddles the equator) are sufficient for windpumps. In sub-Saharan Africa, South Africa and Namibia possess large numbers of wind pumps. An estimated 400,000 wind pumps are in operation in South Africa (Karekezi et al., 2009) and are believed to have played a major role in the past in supporting irrigated agriculture and transforming South Africa into a food-surplus country.

Another key area in which better energy options can help combat hunger is post-harvest losses. These are related to inadequate facilities for food harvest, storage, and transport; a lack of conversion technologies to preserve or otherwise extend the life of food products; and the lack of protection from pests, disease, and other threats to the quality and quantity to harvested food products.

FAO estimates that post harvest losses among food grains in developing countries account for 15–50 % (FAO, 2009). However, more alarming are the post-harvest losses of fruits and vegetables (such as tomatoes, bananas, and citrus fruit) as well as of sweet potatoes and plantains, which can be as high as 50% (Farm Radio International, 2006a). It is also estimated that between 20% and 50% of the fish caught in Africa are lost after capture (Farm Radio International 2006b).

The impact of high post-harvest losses on the poor is twofold: first, it implies that less nutritious food is available, which exposes the poor to undernourishment. Second, post-harvest losses equate lost potential income. This means that the poor end up with less income from the sale of food crops. In addition, lower income erodes any potential cushioning

Table 2.14 | Various options for low-cost options for minimizing post-harvest losses and the requisite energy inputs.

Fruit/vegetable	Post-harvest transformation	Type of energy inputs required
Most fruits & vegetables	Dried fruits and vegetables	Solar thermal using solar drier
African locust bean	Traditional mustard	Heat for cooking
Peanuts	Peanut butter	Heat for cooking and animate energy for grinding
Tomato	Tomato paste	Heat for cooking
Most fruits	Jams and sauces	Heat for cooking and sterilizing storage containers

Source: adapted from Farm Radio International, 2008.

against food price hikes as well as reduces poor people's ability to afford better-quality food.

Several modern, cleaner and affordable forms of energy options could reduce post-harvest losses of fruits and vegetables. One important technology directly linked to energy services is transportation, especially on-time transportation to get harvested foods to markets and processing centers. In rural areas with difficult terrain, the use of motorized transportation can be a significant challenge. Alternative and low-cost options for such areas include animate energy and the use of mechanical ropeways[5]. In parts of Nepal, ropeways have dramatically reduced transportation of farm produce from 3–4 hours to a mere five minutes (Bates et al., 2009).

Processing options involve transforming fruits and vegetables into other forms of foodstuff with longer life spans (see Table 2.14). Energy for cooking and drying (solar drying) is an important input for transforming fruits and vegetables into longer-lasting food products that can go on the shelf or to market, thereby extending consumers' access and increasing the income of small scale poor rural farmers. However, it is noteworthy that for more-sophisticated industrial-level food processing, during which food is transformed into high-value products such as canned food, a significant amount of modern forms of energy are required, such as electricity and steam. Due to the limited access to modern forms of energy in rural areas, where most food is grown, most advanced food processing plants in developing countries are located in urban areas, in some cases far away from where the crops are grown, thereby denying rural areas of employment opportunities.

Industrial-scale agricultural production, while in some cases providing less local employment, has also contributed to increasing overall food production. In the case of basic grains, the globalization of markets for rice, soya, wheat, maize, and other staples implies that the benefits of energy inputs in one country can benefit consumers in other countries due to global trading systems. Without exception, these systems have relied on energy inputs for fertilizer production, irrigation, harvesting, and the transport of their products.

Energy technologies required to increase food production and reduce post-harvest losses, can be produced locally, are relatively affordable, and in many cases may not require electricity to operate. For example, pico and micro hydro for shaft power can be used to process agricultural produce and increase its value for a prolonged period, thereby improving food security. Low-cost efficient hand tools and animal-drawn implements can increase the agricultural productivity of rural areas in the developing world.

In conclusion, access to more efficient, cleaner and affordable energy options is an effective tool for combating extreme hunger by increasing food productivity and reducing post-harvest losses.

2.6 Energy and Transport

Mobility is an essential requirement that ensures the delivery of goods and services. For the poor, it is an essential factor in providing options for employment, production, and livelihoods. The more limited the transport options, often due to lack of access to energy, the more limited the livelihood options.

In recent years, the high cost of motorized transport due to rising oil prices is a major challenge, especially for the poor in developing countries who need to transport to take their agricultural produce to the market and to take up employment.

In rural areas, poor road conditions and networks limit the availability of motorized transport. Consequently, in some rural areas of sub-Saharan Africa, Asia, and Latin America, people walk 10 kilometers a day one way to attend to their chores (e.g., fuelwood or water collection, farm work) as well as attend school or visit health facilities (See Chapter 9).

In urban areas, the high cost of public transport has a negative impact on the poor. Table 2.15 shows the proportion of income spent by the poor on motorized transport in selected cities.

In poorer parts of the developing world, particularly sub-Saharan Africa and some parts of Asia, the urban poor cannot afford motorized transport and largely rely on walking. The relatively high cost of motorized transport for the urban poor is partially linked to the limited attention

Table 2.15 | Proportion of urban poor's income spent on motorized transport in four cities.

City	Share of income spent on motorized transport (%)
Colombo	21
Mumbai	15
Manila	14
São Paulo	8

Source: Chapter 9; Gomide, 2008; Kumarage, 2007; Baker et al., 2005.

5 A ropeway is a form of lifting device used to transport light goods across rivers or ravines.

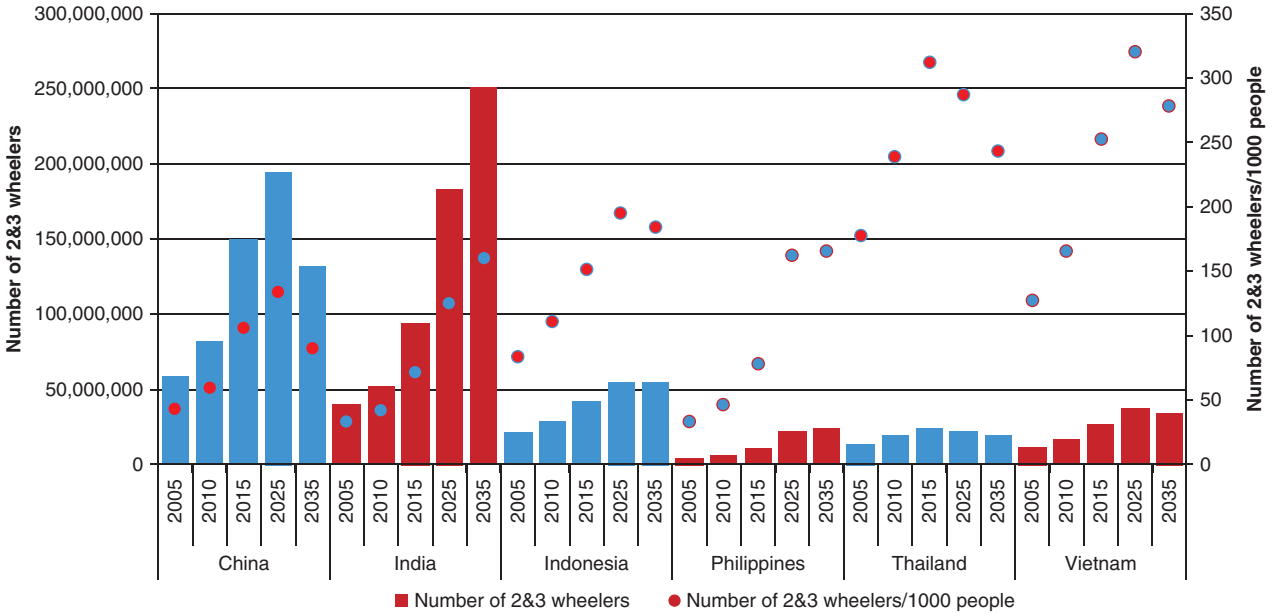

Figure 2.13 | Population of 2 and 3-wheelers in selected Asian countries[6]. Source: CAI-Asia, 2011.

being paid to the development of energy-efficient non-motorized transport options and of low-cost efficient mass transit systems in cities of developing countries. Most road network systems and infrastructure in these cities appear to favor the convenience of private motorized transport, although most people use either non-motorized transport or motorized public transport.

In the cities, the increased demand for low-cost motorized transport, especially for short trips, has led to a sharp increase of two- and three-wheelers in developing countries, especially in Asia (see Figure 2.13). In Asia more than two-thirds of the total vehicle population consists of two- and three-wheelers in many countries (Hook and Nadal, 2011).

The relatively high uptake of two- and three-wheelers in developing countries is mainly linked to their low upfront cost compared with cars. In certain parts of the developing world, however, such as in sub-Saharan Africa, two- and three-wheelers have received a mixed reception. Among the poor in both urban and rural areas these vehicles are perceived as a lucrative source of employment as well as an affordable and convenient form of motorized transport. But in urban areas of sub-Saharan Africa, the high rates of fatal accidents linked to undisciplined driving and absence of dedicated lanes has discouraged use of 2 and 3-wheelers in many sub-Saharan African countries.

Low-cost energy-efficient transportation for both passengers and goods is crucial for economic development. This is particularly important for long-distance transit of passengers and goods. Rail transport is considered the least expensive energy-efficient land transport option for long-distance passenger travel and has been developed extensively in industrial countries in the form of surface and underground rail networks. For freight transportation, with the exception of India and China, many developing countries make limited use of lower-cost energy-efficient rail transport mainly due to its lack of sustained investment.

2.7 Energy and Education

While basic educational services and basic literacy can be achieved without the use of cleaner energy inputs, access to energy services can improve the quality and availability of educational services and increase the likelihood that children will attend and complete school (IEA, 2010a; UNDP, 2005; UN-Energy, 2005).

Global education goals place emphasis on the primary education due to its long-lasting impact on literacy and social inclusion. According to recent estimates of the World Bank (2010a), about 50 developing countries have already achieved the goal of universal primary education. Although seven others are likely to attain the goal by 2015, nearly 40 developing countries, mostly in sub-Saharan Africa, are very unlikely to achieve universal primary education by 2015 (World Bank, 2010a). This is clearly indicated in Figure 2.14. Sub-Saharan Africa has the highest proportion of countries seriously off track in making progress toward universal primary education.

Modern, cleaner and affordable energy options can help create a more child-friendly environment that encourages school attendance and reduces the significant dropout rates experienced in many low-income countries (Mapako, 2010; UNEP, undated). For example, cleaner and affordable energy can enhance access to clean water, sanitation,

6 In Asian cities 2 and 3-wheelers account for 50–90% of total vehicle fleet.

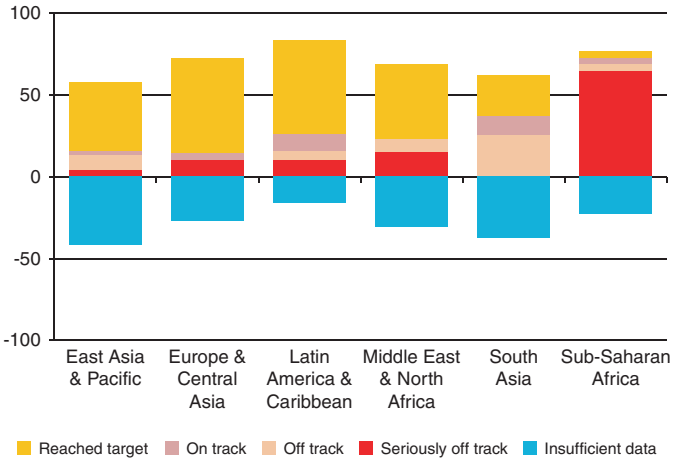

Figure 2.14 | Status of progress (%) on achieving universal primary education. Source: World Bank, 2010a.

lighting, space heating/cooling, and energy for cooking lunch (and other meals in the case of boarding schools).

There is growing evidence of the positive impact of rural electrification (particularly grid extension to rural schools) on the retention of the math and science teachers who are much sought after in rural areas. When the general quality of life increases due to the rural electrification, teachers are willing to relocate to rural schools thus mitigating the problem of shortage of teachers in rural areas (AllAfrica, 2004; Cabraal et al., 2005; World Bank, 2008a; Harsdorff and Peters, 2010).

Electricity can facilitate access to educational media and communications in schools and in homes. It can increase use of distance-learning modules. Access to electricity provides the opportunity to use more sophisticated equipment for teaching (such as overhead projectors, computers, printers, photocopiers, and science equipment), which allows wider access to more-specialized teaching materials and courses (Mapako, 2010).

In addition, cleaner energy systems and efficiently designed buildings reduce heating/cooling costs and thus school fees thus increasing the poor's access to education. As discussed in more detail in Chapter 6, education is the key for higher world economic growth. Education is a long-term investment associated with near-term costs, but in the long-term it is arguably one of the best investments societies can make for their future.

One of the indicators for monitoring progress in universal primary education is the proportion of pupils who start grade one and reach the last grade of primary school. Often children, especially girls, face family pressure to contribute to household energy supplies through the collection of wood and other fuels and of water for home heating and cooking purposes. Access to cleaner fuels, efficient stoves, and alternative fuelwood management practices can reduce fuel collection times significantly, which can translate into increased time for education of rural children.

Table 2.16 | Impact of rural electrification on children's study time in Bhutan (number of children).

Electrification status	Study hours of children in the evenings			Total (children)
	< 1 hour	1–2 hours	>2 hours	
Electrified	67	23	21	111
Non-electrified	71	32	7	110
Total (children)	138	55	28	221

Source: Bhandari, 2006.

When families make the hard decision as to which children to keep home from school to help with such activities as fuel and water fetching and basic cooking and cleaning, preference is often given to boys' education over that for girls, whose traditional roles mean these tasks fall disproportionately on them and they are withdrawn from school before completing the full primary cycle (UNDP, 2004). (See also Section 2.10 on Energy and Women.)

When girls who do go to school help their mothers in the kitchen, they lose valuable study time (Mapako, 2010). In addition, inhalation of kitchen smoke exposes them to illnesses associated with the respiratory system, which can lead to significant school absenteeism from poor health. Cleaner energy options, especially in rural areas, can free up time for girls to study and improve their academic performance.

For both boys and girls, modern energy options can provide quality lighting for comfortable night-time studying (Mapako, 2010). A study in Bhutan found that with modern forms of energy options such as electricity, children can study much later in the evening (see Table 2.16). In addition, good lighting reduces risks to children's eyesight (WHO, 2011a). In many rural areas of the developing world, energy for transportation is also essential if children are to reach schools that are beyond walking distance.

One of the suitable ways to enhance access to cleaner and affordable energy in schools and other institutions of learning is to piggy-back on existing school-related programs. For example, the World Food Programme has introduced "school feeding" initiatives in many developing countries. These focus on poverty-stricken areas as a means of encouraging primary school attendance through the incentive of onsite meals, thus combating malnutrition among the poor (WFP, 2010). Use of improved biomass stoves in the school feeding initiatives reduces cost as well as provides live demonstrations of improved cookstoves and encourages local people to adopt cleaner and more-efficient stoves.

To sum up, access to cleaner and affordable energy options can contribute to achieving universal primary education as well as enhance the quality of education (Meisen and Akin, 2008; Mapako, 2010; Harsdorff and Peters, 2010):

- Providing improved cookstoves that reduce the cost of school feeding programs, which is instrumental in maintaining high attendance levels in rural primary schools;

- Helping to create a more child-friendly environment (access to clean water, sanitation, lighting, and space heating or cooling), thus improving attendance at school and reducing dropout rates;
- Introducing cleaner energy systems and efficient building design that reduce heating/cooling costs and thus school fees which, in turn, expands the poor's access to education;
- Retaining qualified teachers in rural areas by providing electricity for their residences;
- Providing the opportunity to use advanced teaching aids and equipment (overhead projector, computer, and science equipment);
- Enabling access to educational media and communication in schools and at home, hence increasing education opportunities and allow distance learning;
- Allowing children to study after school hours, which can have a significant impact on learning outcomes; and
- Saving girls' time doing household chores, thereby giving them time to study at home and also attend school.

2.8 Energy and Health

Modern health services, the facilities to provide them, and the professional and health sector workers who deliver them require access to energy options in the form of electricity and cleaner and affordable fuels for both institutional and household use. Detailed energy-related health issues are covered in greater depth in Chapter 4.

Public expenditures on health care provision in developing countries have typically been low. When public-sector spending on health services increases, urban and peri-urban areas are often been given priority, leaving the rural poor with inadequate health care options that are distant and of poor quality as well as often unaffordable. Access to health care services varies based not only on the rural-urban divide but also on the income bracket of the people and families in question.

From a human development point of view, the most grievous negative health effects are loss of life, especially among the youngest and most vulnerable, as well as shortened life spans due to poor overall living conditions. Global efforts have prioritized reducing infant mortality in recent years. While deaths of children below the age of five dropped in developing countries by more than 25% between 1990 and 2008, the absolute number of children dying before age five increased (UN, 2010a; World Bank 2010a). Sub-Saharan Africa appears to have made the least progress in terms of reducing child mortality (see Figure 2.15) with one child in seven there dying before the age of five (World Bank, 2010a).

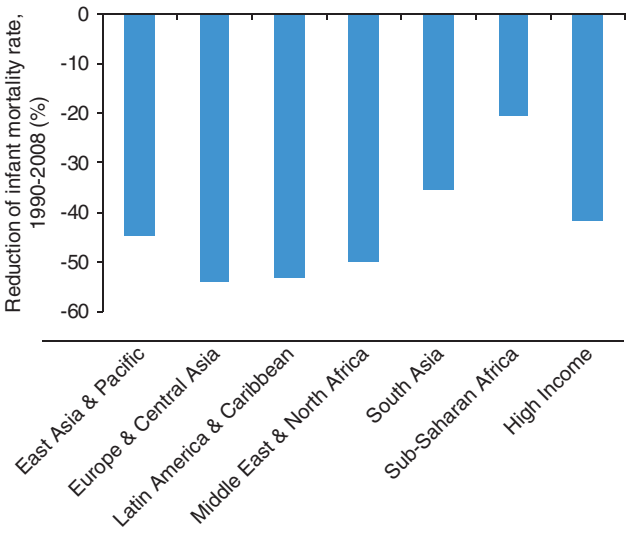

Figure 2.15 | Reduction of infant mortality rate. Source: World Bank, 2010a.

The leading causes of under-five child mortality worldwide (after neonatal causes) are diarrhea and pneumonia (14% each), both of which can be directly linked to inadequate access to cleaner and affordable energy options (UN 2010a).

In the case of waterborne diseases such as diarrhea that has a particularly detrimental impact on children's health, the contributing factors that are energy-related include lack of pumping systems from clean water sources, lack of energy or fuels to boil water, and lack of industrial processes for water treatment and purification.

Pneumonia cases among children under the age of five from poor households are mainly linked to household air pollution due to reliance on traditional biomass for cooking (WHO, 2006). The inefficient burning of solid fuels in an open fire or traditional stove indoors creates a dangerous cocktail of hundreds of pollutants, primarily carbon monoxide and small particles, but also nitrogen oxides, benzene, butadiene, formaldehyde, polyaromatic hydrocarbons, and many other health-damaging chemicals. Day in and day out, for hours at a time, women and small children breathe in amounts of smoke equivalent to consuming two packs of cigarettes per day. Where coal is used, additional contaminants such as sulfur, arsenic, and fluorine may also be present in the air – see Chapter 4 for a more detailed assessment of the health impacts of using solid fuels.

As shown in Figure 2.16, the prevalence of tuberculosis is highest in developing countries that predominantly use traditional biomass energy for cooking. As noted earlier, modern, cleaner and affordable energy options for cooking can play a significant role in reducing acute respiratory infections such as tuberculosis by improving the kitchen environment where women and infants spend a significant amount of time (WHO, 2006; see also Chapter 4). Examples of energy options

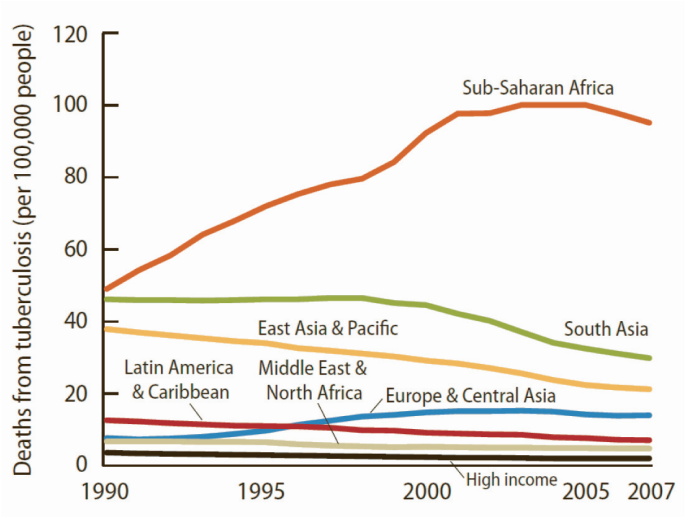

Figure 2.16 | Tuberculosis prevalence by region. Source: WHO, 2011b.

that could replace the traditional biomass energy for cooking include improved fuelwood and charcoal cookstoves, kerosene, LPG, ethanol, and biogas.

The quality of the medical care available in health care institutions can be determined by access to energy services. Examples include electricity for illumination and communication, to power diagnostic machines and provide refrigeration for medicines, fuels for hot water and sterilization processes to maintain sanitary conditions, and fuels to provide space heating or cooking.

One of the critical moments in a person's life for access to health care facilities is during pregnancy and birth. Every year, hundreds of thousands of women die from complications related to pregnancy or childbirth, most of which are preventable. About 99 percent of these deaths occur in developing countries. Indeed, childbirth and complications during childbirth are still the leading cause of death among women aged 20 to 45 in developing countries (UNFPA, 2005). In some areas, one in every seven pregnant women dies in childbirth (WHO, 2008).

Access to health care in the first trimester of pregnancy and having doctors attend births is directly correlated with improved maternal health and reduced infant mortality (UNFPA, 2009). In rural areas of sub-Sahara Africa, women often deliver without skilled care. About a third of maternal deaths are due to hemorrhage that could be stopped by skilled medical personnel.

Many complications associated with pregnancy can be detected and rectified early with the use of advanced technologies such as ultrasound equipment, which needs a reliable source of electrical power. The absence of electricity in rural areas denies rural women such essential health services. Thus both directly (through support the provision of health services) and indirectly (by removing barriers to attracting medical personnel), access to electricity in rural areas can contribute to averting needless maternal deaths.

In some sub-Saharan African countries, life expectancy has actually reverted to below 1970 levels over the last two decades. Largely due to deaths from Human Immunodeficiency Virus /Acquired Immune Deficiency Syndrome (HIV/AIDS), this is the case in the Democratic Republic of Congo, Lesotho, South Africa, Swaziland, Zambia, and Zimbabwe (UNDP, 2010). The HIV pandemic appears to be disproportionately affecting women, tragically highlighted by the phenomenon of AIDS orphans being raised by grandmothers – a common occurrence in many parts of sub-Saharan Africa (UN, 2011a). Although the global spread of HIV has finally begun to slow worldwide, combating this global pandemic requires energy services in a variety of applications. For example, safe disposal of used hypodermic syringes by incineration prevents re-use and the potential further spread of HIV/AIDS.

Education, prevention, condom use, and reproductive health services for women and men are key ingredients to combating new AIDS infections. These require communication campaigns, distribution routes for condoms, and health workers to reach at-risk populations, all of which benefit from energy services in terms of transportation and communication. When HIV infections occur, quality of life and longevity are directly related to access to medical services, anti-retroviral drugs, and overall health maintenance, including good nutrition. Clean energy options for the poor can contribute to improving access to health services and ensure better nutrition.

The challenging nexus of energy, poverty, and health can also be found in industrial countries. The symptoms of energy problems of the poor in richer industrialized economies include high levels of debt to the energy utilities, disconnections from supply because of debt, cold homes in winter, and an increase of cold-related ill health and death. During hot weather periods, energy is needed to power fans and home conditioning. Inadequate access can lead to increased ill health and death of elderly people. The 2003 heat wave in Western Europe led to 35,000 deaths (Bhattacharya, 2003).

A concerted international effort to meet the globally agreed development goals related to human health is starting to make inroads, but more resources need to be allocated to cleaner low-cost energy options for powering for pro-poor health services.

To sum up, there are several health-related benefits associated with access to modern, cleaner and affordable energy options. Electricity in health centers allows the provision of medical services at night, greater use of more advanced medical equipment as well as helps retain qualified staff in rural health centers. Energy for refrigeration can facilitate vaccination and medicine storage for the prevention and treatment of diseases and infections. Energy is needed to generate and maintain basic sanitary conditions to support health services. Finally, energy is needed to develop, manufacture, and distribute drugs, medicines, and vaccinations as well as to provide access to health education media through information and communications technologies.

2.9 Energy and Water

Sanitation and access to improved water in developing nations are key environmental concerns of the poor. Recent estimates indicate that about 1.2 billion people lack access to safe water (IAEA, 2007; UN Women, 2011) and about 2.6 billion people lack access to toilets, latrines, and other forms of improved sanitation in developing countries (UN, 2011). Progress has been slowest in South Asia and sub-Saharan Africa. To halve the proportion of people without basic sanitation by 2015, more than 1.3 billion people would have to gain access to an improved facility (World Bank, 2010a).

On the positive side, rapid progress is being made in improving access to safe water, especially in East Asia, where access to drinking water increased by 30% between 1990 and 2008 (UN, 2010a) to reach 89% of the population. Access to safe water in Latin America in 2008 reached 93%, while for developing countries as a whole the figure was 84% (UN, 2010a). These encouraging indicators of progress are marred by the appalling situation in sub-Saharan Africa where only 48% of rural households have access to piped clean water (World Bank, 2011a).

The higher safe water access that characterize richer developing countries hide a continuing rural-urban divide. Figure 2.17 compares access to improved water supply in rural and urban areas in selected developing countries. In most developing countries, a much larger proportion of the urban population enjoys access to improved sources of water (which includes household piped water connection, public standpipe, borehole, protected well or spring, and rainwater collection).

Inadequate supplies of safe water and poor sanitation, particularly in rural areas accounts for nearly 80% of all illnesses in developing countries (BPN, 2010). In addition, patients with waterborne ailments account for half of the people in hospital beds (TWP, 2010; BPN, 2010). Some of these ailments include cholera, typhus, and dysentery, which account for an annual death toll of 1.6 million deaths (SODIS, 2010b).

Access to water is key to not only improved health but also to increased agricultural output through irrigation

Lack of sanitation facilities in many developing countries contributes to a loss of a sense of dignity, especially among the poor. Inadequate access to sanitation has a disproportionate large impact on women and girls, especially during menstruation. Lack of adequate sanitation in schools in many developing countries has been reported as a key contributor to absenteeism and even school dropouts among one in ten girls at the puberty stage (IMW, 2008; WaterAid, 2009).

Access to modern and affordable forms of energy can play a vital role in improving access to safe water and sanitation in developing countries. Some of the energy solutions available are very low-cost and do not require electricity or fossil fuels. For example, solar water disinfection (SODIS) only requires a clear glass or plastic polyethylene terephthalate bottle, which is filled with water and placed on the roof in the sun for at least six hours to eliminate most disease-causing pathogens (Wegelin and Sommer, 1997; EAWAG/SANDEC, 2002; Foran, 2007; SODIS, 2010a).

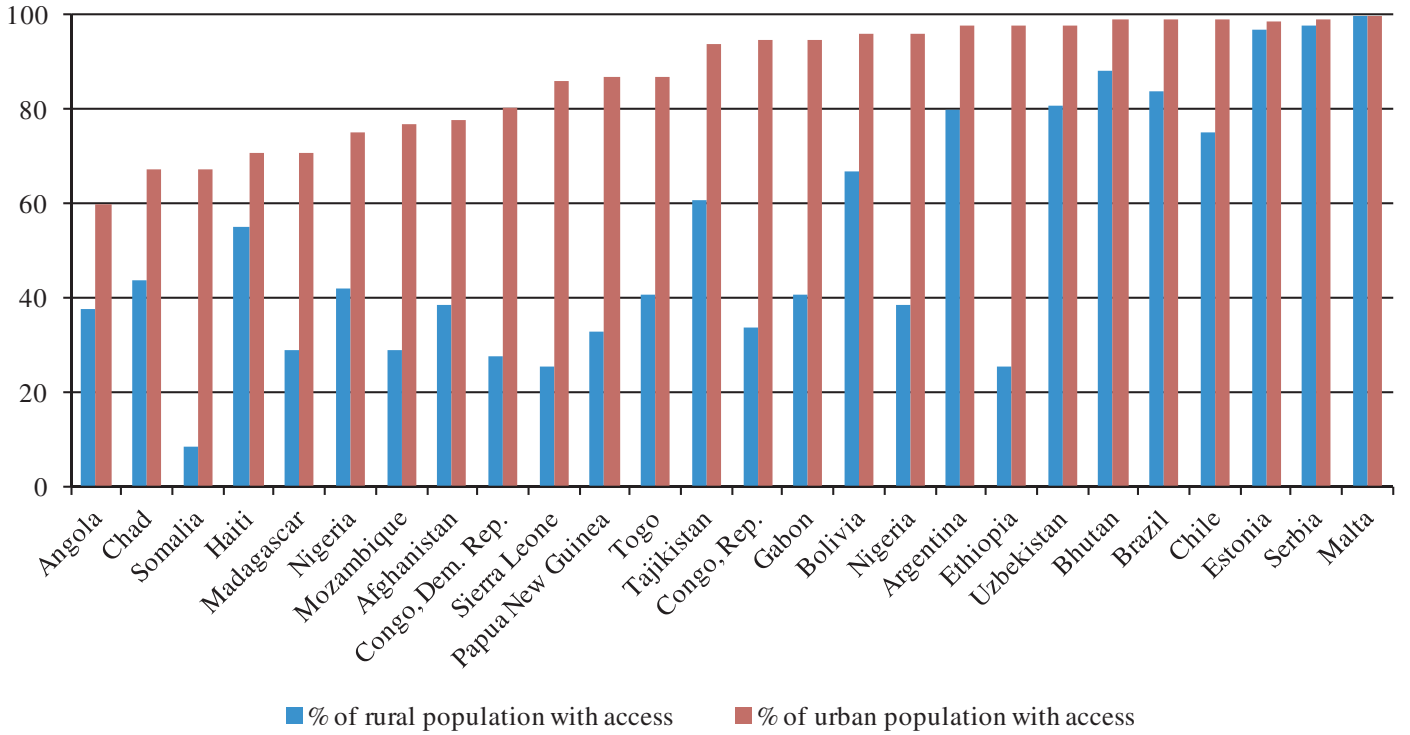

Figure 2.17 | Access to improved sources of water (%), selected developing countries, 2008. Source: adapted from World Bank, 2011a.

Table 2.17 | Scientific results of solar water disinfection technology.

Bacteria	Disease caused by bacteria	Reduction with SODIS method (6h, 40°C)
Escherichia coli	Indicator for water quality & enteritis	99.999%
Vibrio cholera	Cholera	99.999%
Salmonella species	Typhus	99.999%
Shigella flexneri	Dysentery	99.999%
Campylobacter jejuni	Dysentery	99.999%
Yersinia enterocolitica	Diarrhea	99.999%
Virus	**Disease caused by virus**	**Reduction with SODIS method (6h, 40°C)**
Rotavirus	Diarrhea, dysentery	90%
Polio virus	Polio	99.99%
Hepatitis virus	Hepatitis	Reports from users
Parasites	**Disease caused by parasite**	**Reduction with SODIS method (6h, 40°C)**
Giardia species	Giardiasis	Cysts rendered inactive
Cryptosporidium species	Cryptosporidiasis	Cysts rendered inactive after >10h exposure
Amoeba species	Amibiasis	Not rendered inactive Water temperature must be above 50 °C for at least 1h to render inactive

Notes: 1) The SODIS method needs relatively clear water. The source of the water (well, surface water) does not matter. 2) Relative levels of pathogens used in tests.

Source: SODIS, 2009.

As shown in table 2.17, through heat and ultraviolet radiation from the sun, SODIS can reduce diarrhea-related cases in developing countries by nearly 40% (Wegelin and Sommer, 1997; EAWAG/SANDEC, 2002; Foran, 2007; Heaselgrave et al., 2006; SODIS, 2010a).

Low-cost mechanical options can play an important role in ensuring access to safe water. For example, hand pumps and wind pumps are robust technologies that can dramatically expand access to safe water for domestic use as well as for irrigation and watering livestock. Hand-pumps and wind-pumps are well suited for rural areas as they are robust and their maintenance is relatively simple. The ease-of-maintenance of hand-pumps has been demonstrated in Uttar Pradesh, India, where women have successfully repaired hand pumps, thereby ensuring a continuous flow of clean water (WaterAid, 2009).

There are other cleaner energy options but somewhat higher-cost cleaner energy options that can address problems of sanitation and at the same time provide energy. For example, a biogas digester linked to a toilet can be an effective means of treating sewage (Karekezi and Ranja, 1997), while the methane gas produced can be used for heating applications such as cooking or running a genset[7] to produce electricity. This technology is widely used in Asian countries, especially in Bangladesh, Bhutan, China, India, Laos, Nepal, and Sri Lanka (SNV 2007).

Biogas technology can also be used to improve sanitary conditions in large institutions such as schools, hospitals, and prisons. In Africa, prisons in Rwanda and Kenya have used large-scale biogas plants resolve long-standing sanitation challenges (Ashden Awards for Sustainable Energy, 2005). The gas is used for cooking, thereby reducing woodfuel consumption by half. Similar applications, but at a smaller scale, have been reported in other African and Asian countries, where biogas technology has been adopted in schools and mainly used for cooking (Huba and Paul, 2007; AFREPREN/FWD, 2010).

The challenge of providing safe water and sanitation facilities is still immense particularly in sub-Saharan Africa where more than half the urban population lives in slums; a sizable part of the more than 825 million people living in urban dwellings without improved sources of drinking water and sanitation (World Bank, 2010a). Solar, wind, handpumps and biogas options can play an important role in enhanced access to safe water and sanitation in low-income peri-urban and urban of sub-Saharan Africa.

2.10 Energy and Women

Promoting gender equality and empowering women is an agreed national and global priority and is reflected in major global conferences and intergovernmental agreements on the need to enhance the status of women, including in economic and political life (CEDAW, 2011). In 1979, the UN General Assembly adopted the Convention on the Elimination of All Forms of Discrimination against Women to protect fundamental human rights and equality for women around the world (CEDAW, 2011).

Global studies indicate that a higher percentage of women than men live in poverty (UNECA, 2010). Gender-related studies of the poor in sub-Saharan Africa, parts of South Asia, and Latin America and the Caribbean demonstrate that poverty affects women and men differently, with women often experiencing the most severe levels of deprivation, in part, demonstrated by inadequate access to cleaner energy options (Karekezi et al., 2002).

Gender equality and empowering women are also important issues because they foster progress toward other development outcomes, such as reducing poverty, hunger, and disease and improving access to education and maternal health. Educational opportunities for girls have expanded since 1990. Enrollment patterns in upper-middle-income countries now resemble those in high-income countries, and those in lower-middle-income countries are nearing equity. However, gender gaps remain large in low-income countries, especially at the primary and secondary levels in sub-Saharan Africa (World Bank, 2010a).

Girls in poor households and rural areas are least likely to be enrolled in school. Cultural attitudes and practices also pose formidable obstacles

7 A "genset" is also known as an "engine-generator," which is a machine used to generate electricity.

to gender parity. Currently, 64 developing countries have achieved gender parity in primary schools and 21 others are on track to achieving the target. However, about 29 countries (more than two-thirds of them in sub-Saharan Africa) are seriously off track and unlikely to achieve parity by 2015 if current trends prevail (World Bank, 2010a).

Wider access to cleaner and affordable energy options can improve gender parity and school enrollment of girls. For example, access to cleaner energy options (electricity for lighting in schools and cleaner cooking fuels at home such as LPG) can extend studying hours for girls by reducing the time they spent collecting fuel. Access to pumped water can reduce the time that girls spend carrying water for household use.

Ensuring girls in developing countries are educated is important for their future life as mothers. Global evidence has shown that better-educated women will chose to have fewer children and have more access to family planning methods, while illiterate women overall are the least well able to gain access to health services and medical care at large (UNFPA, 2008; SIL International, 2011). The cycle of exclusion from education and literacy arising from preoccupation with household chores of collecting fuel, water, cooking, cleaning and looking after younger children can lead to early onset of reproduction and a higher risk for maternal health caused by frequent multiple pregnancies. According to Population Action International (2001), teenage mothers face twice the risk of dying from childbirth as women in their twenties. In addition, their children are more vulnerable to health risks.

Although most rural households use biomass, women in poor households will spend more time searching for firewood than those in households with higher incomes (Energia, 2008). In areas where there is decreased vegetation cover, women and children are required to walk longer distances to collect firewood (Ekouevi, 2001; Kammen et al., 2001; Ward, 2002; ESMAP, 2003; BIC, 2009). As shown in Figure 2.18, in Africa this can take up to four hours a day (Njenga, 2001; WHO, 2006) – and these distances increase as wood from stressed ecosystems.

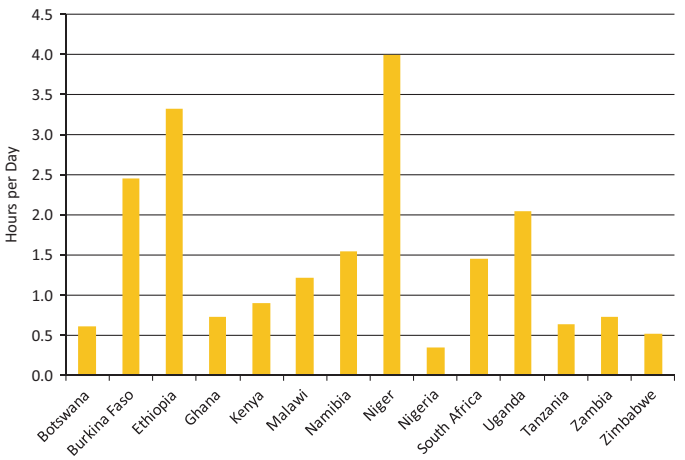

Figure 2.18 | Time ticking away: daily hours that women spend collecting fuel in different African geographical settings, by country, 1990–2003. Source: WHO, 2006.

The energy that women and girls expend fetching water, carrying fuel, and preparing food has received virtually no treatment in traditional energy sector policies because, as it is not traded, it has no "price" as determined by the market and therefore is considered "free." The time people spend carrying water that is not transported by pumping systems or fuels that have been harvested or bought locally, or pounding and grinding maize, wheat, rice, sorghum, or other basic staples, has an opportunity cost. It is time that could otherwise be spent on more economically productive or socially beneficial activities such as paid agricultural work, commercial activities, pursuit of education, or physical rest to preserve the health of women, especially the poorest women.

Access to mechanical power for threshing and grinding grains can help older girls stay in school by minimizing school absenteeism and drop-out rates among girls. It is difficult to change cultural practices where food preparation is assumed to be the responsibility of women and girls. With mechanical power, however, food preparation can be made easier and faster, which liberates valuable time for girls to study and attend school.

Lack of close proximity to safe water places a huge burden on women and girls in many developing countries. For example, on average, women travel 6 kilometers daily in search of water (IAEA, 2007; BPN, 2010). In rural areas, the distances walked by women can be as high as 16 kilometers; during drought, the distance could be at least twice as long (IMW, 2008).

The long distances travelled carrying a load of approximately 20kg pose serious long-term health risks for women, including spine and pelvic deformities that can create complications during childbirth (WaterAid, 2009). In addition, these distances imply that a significant amount of time is spent obtaining this precious commodity, especially in rural areas. According to WaterAid (2009), in rural Africa, about 26% of women's time is spent fetching water. In rural Ghana, a study by Costa et al. (2009) revealed that women spend far more time than men fetching water (see Figure 2.19).

As noted earlier, fuelwood is not always collected. Often it is a commercial commodity bought and sold through markets like any other fuel. This is especially the case in urban areas, where cleaner liquid fuels are either unavailable or unaffordable for poor families. Here, too, women must spend time on the purchase and transport of traditional fuels for household use. And this too has an opportunity cost for women.

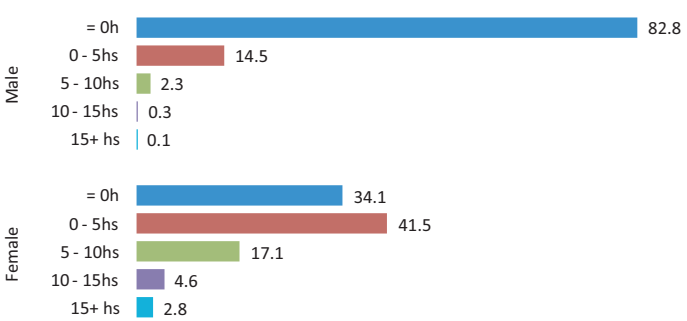

Figure 2.19 | Comparison of time spent by men and women fetching water in rural Ghana (hours/week). Source: Costa et al., 2009.

While improved biomass energy technologies such as cookstoves have several benefits for poor women, a more pronounced switch to cleaner fuels and more efficient cooking devices can lead to increased economic, health, and environmental benefits. As shown in Table 2.18, for example, in India, using a typical LPG stove for cooking can reduce cooking time by slightly over 1 hour compared with a conventional woodstove (Kanagawa and Nakata, 2005). Similar benefits can also be accrued from use of ethanol stoves.

The use of improved cookstoves can result in savings in the amount of fuel used, which translates into direct cash savings. They can also reduce respiratory health problems associated with smoke emission from biomass stoves and offer a better home and working environment for rural housewives and cooks/operators in institutions.

The production and dissemination of improved biomass energy technologies and associated sustainable fuel supply initiatives provide employment opportunities for a significant proportion of the population, particularly women. In Senegal, for example, the sustainable forestry subsector earns the country about US_{2004}12.5 million a year, with women in control of one-third of this revenue stream (World Bank, 2010a).

The development linkages between women and energy are not limited to cooking fuels and water collection challenges, although policy and analysis in development debates often stops there. Women are disproportionately affected by the lack of cleaner and affordable energy options for maintaining households and enterprises that can be a source of income (Energia, 2008). This is particularly perverse given that the best means to combat absolute poverty is through the stimulation and increase in women's income – either through productive activities or targeted state transfers aimed at women. Women have a relatively higher propensity to reinvest in family welfare expenditures such as food, education, and health, especially for their dependent children.

Women are key users of energy for productive activities, and as is the case for productive employment for men, access to labor-saving energy-using technologies allows the amount of time spent on non-paid work to be reduced in favor of time spent on paid work, which greatly improves the overall welfare of women, their families, and especially their children. The limited access to cleaner energy and labor-saving technological options therefore has a double negative effect on women: first through limiting the opportunities to generate income and second through the forgone benefits that the additional income could bring to poor families when spent by women on inputs and services that benefit the family.

Table 2.18 | Comparison of cooking times (in hours) of woodstove and LPG in India.

	Time spent on cooking-related activities		
	Fuel collection[a]	Food preparation and cooking	Total time
Woodstove	0.67	2.73	3.4
Gas Stove	-	2.30	2.30
Time saved by gas stoves	0.67	0.43	1.10

[a] The time spent taking gas cylinders for refilling is negligible when spread over the time the newly refilled gas cylinder is used.

Source: adapted from Kanagawa and Nakata, 2005.

Affordable and reliable energy options can broaden the scope of women's enterprises. In West Africa, for example, mechanical power to grind grains and other agricultural products through a fee-for-service model not only was able to meet household grain consumption processing needs but also freed up women's time for other household and agricultural activities (Morris and Kirubi, 2009). In addition, the volumes of milled grain produced surpluses that could be marketed, thereby supplementing limited family cash income that was used to support children's schooling.

The upfront cost of cleaner and affordable energy options is in most cases beyond the reach of the rural poor. This affects women who are the major collectors, managers, and users of traditional energy sources for household activities (BIC, 2009). In developing countries, since many women lack the money to pay for energy services, small-scale food production and processing – a large component of which is often dominated by women – largely relies on human and animal energy (Clancy, 2004) – further discussion on this issue is found in Chapter 20.

An important approach for enhancing access to cleaner and affordable energy for women is to develop programs specifically aimed at financing the upfront costs of energy using equipment for household use as well as targeting income-generating activities that involve a high number of women or women's groups. A number of financing institutions in developing countries have emerged focusing solely on financing women. In Bangladesh, for example, the Grameen Bank has a credit program in which 98% of its borrowers are women (Giridharas and Bradsher, 2006). These funds could be used to mechanize farming and the water supply, hence reducing the burden on women, as well as improving lighting and cooking energy technologies at the household level.

Since in many areas women are the primary users of energy, especially for cooking, it makes sense for them to be involved in designing and implementing policies and projects to meet their own energy needs. Globally, as more women obtain positions of political leadership, it is anticipated that the increased political representation by women will have significant policy implications. For example, it is expected that women politicians are more likely to push for increased access to cleaner and affordable energy options that would benefit women and cleaner cooking fuels such as LPG, ethanol stoves, and improved biomass stoves. Other modern energy options that benefit women are summarized in Table 2.19.

To sum up, access to cleaner and affordable energy options can play an important role in gender equality and women empowerment:

- Available energy services can free girls' and young women's time from household activities (gathering firewood, fetching water, cooking inefficiently, crop processing by hand, manual farming work). This

Table 2.19 | Summary of some energy options favoring women.

Energy Option	Benefits for women
Electricity	Radio, TV, and telecommunications can improve access to the outside world and provide useful information for women.
	Street lighting improves safety for women, especially in slum areas, and enables them to trade after dark.
	In urban areas, electricity helps women to cope with modern lifestyles.
	Availability of electricity enables women to operate specialized enterprises such as hair dressing.
Mechanical power	Women can irrigate crops and water livestock, thereby enhancing food security and nutrition.
	Mechanized tillage and weeding can contribute to higher crop yields.
	Briquette presses can help women obtain cleaner and sustainable biomass fuel supplies.
	Oil presses can help women earn more from agriculture by selling a higher-value product.

Sources: adapted from Bates et al., 2009; UNDP, 2007a.

time can be productively used to generate more income or acquire education.

- Cleaner cooking fuels and equipment can reduce exposure to indoor air pollution and improve health.
- Street lighting can improve women's safety.
- Modern, cleaner and affordable energy options can broaden the scope for women's enterprises, thereby fostering employment and income generation among women.
- Representation of women at the national level can influence energy policies and investments to ensure wider access to cleaner and affordable energy options that benefit women.
- Specific policy initiatives that prioritize "women's" or household energy needs, especially for fuels and mechanical power, can provide a balance to the focus on rural electrification, bringing about a host of family welfare benefits.

2.11 Energy and Environment

This section briefly discusses energy and environmental sustainability in the context of development, while the broader issue is covered in depth in Chapters 3, 4, and 20.

Many of the world's poor depend on forests for their livelihoods as well as to meet their energy needs for cooking. In sub-Saharan Africa about 80% of the population relies on biomass (IEA, 2010a). Although the major cause of deforestation comes from land use change, excessive harvesting of biomass fuel, especially from forests, also contributes to this deforestation. The loss of forests threatens the livelihoods of the poor, destroys habitats that harbor biodiversity, and eliminates important carbon sinks that offset global warming. Since 1990, forest losses have been substantial (more than 1.4 million square kilometers), especially in Latin America and the Caribbean, East Asia and the Pacific, and sub-Saharan Africa (World Bank, 2010a). Some of this deforestation is due to excessive harvesting of biomass fuel.

As mentioned earlier, much of the rural deforestation and overharvesting of fuelwood experienced in sub-Saharan Africa, can, in part, be traced to trees cut down for feedstock for the charcoal industry. This is not to supply rural consumers with energy but to provide a steady supply of cheap fuels for cooking and household energy use for urban dwellers, as indicated by the thriving charcoal markets throughout the African continent (AFREPREN/FWD, 2006a). Important options for addressing the charcoal and deforestation challenge include dissemination of proven improved cookstoves such as the charcoal-burning KCJ that can cut charcoal consumption by half and switching to LPG.

As shown in the Figure 2.20, biomass – mainly traditional biomass biofuels – accounts for about 44% of the world's final renewable energy use. The bulk of this supply is from developing countries.

Poor households using open fires and traditional biomass stoves for cooking, tend to be highly inefficient due to incomplete combustion of the biomass. Consequently, methane, a more potent greenhouse gas than carbon dioxide (CO_2), is released. The use of traditional and unsustainable biomass cooking energy fuels has significantly higher greenhouse gas (GHG) emissions compared to fuels such as LPG and biogas (see Chapter 19). Use of cleaner cooking fuels and technologies can reduce the GHGs of developing countries.

Although developing countries emit fewer emissions on a per capita basis, in gross terms and, if one ignores, historical emissions or per capita emissions, some emerging industrializing countries account for a significant share of current global GHGs emissions comparable to those of industrialized countries. For example, China's CO_2 emissions in 2008 exceeded those of the entire European continent and compare with those of the United States, Canada, and Mexico combined (see

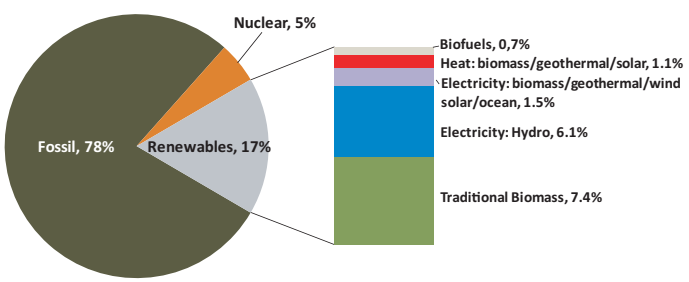

Figure 2.20 | Renewable share of final energy use in 2009 (528 EJ). Source: fossil and nuclear fuel use: IEA 2011b; renewables: Chapter 11.

Chapter 3). However, the picture changes dramatically if historical and per capita emissions are included. Wealthy western countries of Europe and North America account for a dominant share of historical emissions and are by far the highest emitters of GHGs on a per capita basis.

It can therefore be argued that the poor in developing countries should not be restricted when the current high GHGs emissions levels are still largely a result historical and of high per capita emissions of industrialized countries of North America and Europe.

On a per capita basis, poor people and poor countries in the world generate fewer GHGs than either the people who are well-off in poor countries or the inhabitants of industrialized countries. The poor contributions to global greenhouse gas emissions is negligible. For example, Africa has very low levels of access to GHGs-intensive energy options and, as a result, the continent generates only 3% of the global aggregate GHG emissions (UNIDO, 2009; IEA, 2010b). But lifting the poor out of poverty through improving access to jobs, social services, and improved living conditions requires greater energy inputs, as has been argued throughout this chapter, which would inevitably result in increasing emissions further from the developing countries. Replacement of traditional biomass (with incomplete combustion) with LPG could lead to lower overall GHG emissions especially when particulate matter is accounted for.

In some cases, wide-scale deployment of renewable energy systems may provide the best options for providing access to cleaner and modern energy options while reducing GHGs emissions. In the near term, however, cleaner fossil fuels such as LPG combined with more efficient and low-cost end-uses devices such as LPG cookstoves reduce a host of social, economic, and environmental barriers to overcoming poverty due to higher combustion efficiency.

The ongoing search for win-win solutions in low-income areas of poor developing countries that are completely reliant on renewable energy must also put a time premium on overcoming social injustice and the conditions of inequality that entrench poverty and reproduce underdevelopment. As mentioned earlier, from a policy point of view, it is unrealistic to support arguments for "near-term renewables only" options that delay the satisfaction of the basic needs of people who remain poor today and who constitute a negligible contributor to global historical and current carbon emissions. It is, therefore, important to retain cleaner fossil fuel options such as LPG combined with more efficient low-cost end-use devices in near-term priority action plans that would set the stage for eventually moving the poor to a fully sustainable path that relies more heavily on renewable energy.

There is, however, a growing interest on the part of energy decision makers in developing countries in examining efficient, environmentally sound, climate-friendly energy options that also deliver substantial development benefits and reduce the climate risk profile of their energy industries. Studies indicate that many of these options (such as demand-side management, renewable energy use and efficient energy end-user devices such as tube lights, compact fluorescent lamps, biomass cogeneration, ethanol, etc.) are not as capital-intensive as conventional centralized energy options (DuPont, 2009).

2.12 Conclusions and the Way Forward

The intrinsic link and positive relationship between energy and overcoming poverty – whether income-defined poverty or poverty linked to inequality in income distribution within countries – is very strong in developing countries. It is clearly demonstrated by the fact that poor people constitute the bulk of the estimated 3 billion people primarily relying on solid fuels (coal and traditional biomass) of which 2.7 billion people cook and heat their homes with traditional fuels and low-efficiency stoves (UNDP and WHO, 2009; IEA, 2010a; see also Chapter 19) and almost one and a half a billion without access to electricity (IEA, 2010a; see also Chapter 19).

Access to electricity supply (both grid and non-grid) in many developing countries is almost an exclusive service enjoyed by the non-poor in urban areas. Even after two decades of energy sector reforms, initial indications from a wide range of developing countries indicate that few of the initiatives have resulted in significant improvement in the provision of electricity to the world's poor (GNESD, 2010; Karekezi and Sihag, 2004; IMF, 2008). Access to modern and cleaner forms of energy improves the livelihoods[8] of the poor in developing countries. As discussed in earlier sections, increased access to cleaner energy in rural areas opens up these regions to greater economic productivity.

In most cases, market-led reforms were primarily designed to improve the financial health of electricity companies and were introduced into countries where a large sector of the potential "market" consisted of very poor people not served by national grids or who resided in geographic areas with low levels of energy use. Expanding access to electricity to the poor meant attempting to service low-income consumers whose incomes may well be highly unstable and who often live in isolated areas that are difficult to access or in urban areas that are characterized by high degrees of informality. To provide electricity services, the "reformed" companies had to cover operating and investment costs (required by market-oriented reforms) while providing expensive transmission lines and connections as well as maintenance, billing, and collection services in a market where return on investment was far from assured. In the majority of the countries, these contradictory demands proved to be irreconcilable. It is therefore not surprising that newly privatized or reformed electricity companies tended to "cherry pick" the most lucrative markets (i.e., non-poor urban areas), raised their tariffs, and virtually ignored widening of their networks to poorer consumers.

8 Livelihood refers to "means of support, subsistence or securing the necessities of life." Livelihoods can be improved through increased agricultural production, better social welfare – including increased income among other factors.

Thus, experiences in developing countries point to an overarching conclusion: when power sector reforms were introduced with the sole intention of improving the performance of utilities, the expected and hoped-for social benefits did not necessarily follow. Where governments maintained a role as instigator or at least regulator of improved access to electricity by the poor, tariffs for poor households tended to decrease and levels and rates of electrification tended to increase.

The excessive reliance on private sector-driven approaches that have proven detrimental to widening access to electricity in many parts of the developing world, especially sub-Saharan Africa and some parts of Asia, are also becoming prevalent in efforts to disseminate improved cookstoves and scale up the use of renewables in developing countries. There is heavy emphasis on bottom-of-the-pyramid profit-driven approaches with limited attention being paid to the important role of public interventions that have the resources and long-term horizon to engineer the scale-up required to reach millions of the unelectrified homes in the developing world that currently rely on inefficient and traditional biomass-based cookstoves to meet their cooking and heating needs. A more balanced approach is needed that judiciously combines large-scale and long-term public initiatives with innovative pilot private sector based programs that rely on the bottom-of-the-pyramid profit-driven small and medium scale enterprises.

In order to ensure that modern, cleaner and affordable forms of energy are accessed by poor people, the right choice of energy supply has to be made. For example, large-scale renewable energy technologies have lower running costs, hence might be, in the long-term, the most attractive options. In addition, some fossil fuels such as LPG can also be attractive due to their cleaner combustion and higher efficiency characteristics.

Based on political and policy considerations, there is need to minimize any delays to the satisfying the basic need of the poor. Therefore, appropriate solutions to overcoming social injustice and the conditions of inequality that entrench poverty and reproduce underdevelopment must be achieved within the shortest possible time. It is for this reason that GEA shares a goal with the UN proposed targets of achieving universal access to electricity and cleaner cooking fuels by 2030 (UN, 2010b). Current estimates indicate that achieving the aforementioned goal will require significant investment (see Chapter 17) and political commitment (see Chapters 19 and 23). In addition, the relationship between poverty and energy requires a better understanding of the demand profile of this segment of the energy market and the recognition that poor people are energy users. This is demonstrated by the fact that, for example, at current electrification rates it is estimated that about 15% of the world population will not have access to electricity in 2030 (IEA, 2010a). As shown in Table 2.20, most of these people will be in sub-Saharan Africa and some parts of Asia. However, it is noted that the IEA baseline contrasts with GEA pathways of achieving universal access by 2030.

In order for national leaders in developing countries to deliver the much-needed political commitment required to address the access question, approaches to dealing with the issue need to be "homegrown." The rationale for this approach is that policymakers in developing countries have successfully used a similar quantified campaign strategy with the MDGs to accelerate the pursuit of globally agreed social indicators fundamental to overcoming underdevelopment and poverty. The community of nations should adopt global goals for minimum levels of energy services, especially universal access to electricity and cleaner cooking fuels, to address poverty and support sustainable human development.

It is worth pointing out that while promoting access to electricity is generally given more attention due to the services it typically provides, such as communications, lighting, refrigeration, and motor power, equally important is the role that nonelectric forms of energy, in particular fuels and mechanical power, play in both the household and the social sectors. This second set of energy issues has been given much less attention in energy sector planning, especially in developing countries. In order to ensure that modern, cleaner and affordable forms of energy are accessed by poor people, the right choice of energy supply has to be made. For example, large-scale renewable energy technologies have lower running costs, hence might be, in the long-term, the most attractive options. More challenging still is that while power sector reform has received much attention in developing countries, energy policies addressed at fuel switching and improving heating and cooking systems, especially in rural areas, have received very little policy attention in energy sector reform. Electricity is not synonymous with energy, a concept which is much broader. Some fossil fuels such as LPG can

Table 2.20 | Current and projected electrification levels in developing countries.

Region/Country	2009		2030	
	Unelectrified population (million)	Proportion of all unelectrified (%)	Unelectrified population (million)	Proportion of all unelectrified (%)
Latin America	31	2.2	10	0.8
Sub-Saharan Africa	585	40.7	652	53.8
North Africa	2	0.1	2	0.2
South & East Asia	812	56.5	549	45.3
China	8	0.6	0	0
Total	1438	100.0	1213	100.0

Source: adapted from IEA, 2010a; 2010c.

also be attractive due to their cleaner combustion and higher efficiency characteristics and therefore it is crucially important that all fuel options are given consideration when designing energy sector strategies. Finally many of the energy issues treated here fall outside the energy sector per se and are intimately linked with service and supply decisions taken in other sectors and policy frameworks including those in education, health, agriculture, water, housing etc.

As this chapter indicates, for the poorest segments of the population and especially for poor women and their children, the role of cleaner energy carriers for cooking, household use and homestead-based productive activities are disproportionately more important in reducing the day-to-day barriers to education, health, and family food security. Access to modern and cleaner forms of energy contribute to a general improvement in social welfare – including increased income – due to improved health, sanitation, education, etc. For example, in Bangladesh, an impact assessment of its rural electrification revealed that 63% of electrified households surveyed reported an increase of income as a direct result of electrification (Berthaud et al., 2004). In Lao PDR rural electrification using solar systems has demonstrated the viability of decentralized renewable energy systems in enhancing rural livelihoods through increased income, improved healthcare and access to information (Theuambounmy, 2007).

In short, to ensure the poor's access to cleaner and affordable energy options, energy policy must see the poor as a consuming market that, when better served, will generate income and opportunities for value-adding activities that can have benefits at the family, community and sector wide levels. However, the excessive reliance on private sector-driven approaches that have proven detrimental to widening access to electricity in many parts of the developing world, especially sub-Saharan Africa and some parts of Asia, should not become the only route to expand poor's access to cleaner energy options. The almost exclusive recourse to private sector-driven approaches to disseminate improved cookstoves and scale up the use of renewables in developing countries is of some concern. There is heavy emphasis on bottom-of-the-pyramid profit-driven approaches with limited attention being paid to the important role of public interventions that have the resources and long-term horizon to engineer the scale-up required to reach millions of the unelectrified homes in the developing world that currently rely on inefficient and traditional biomass-based cookstoves to meet their cooking and heating needs. A more balanced approach is needed that judiciously combine large-scale and long-term public initiatives with innovative pilot private sector based programs that rely on the bottom-of-the-pyramid profit-driven small and medium scale enterprises.

Prevailing energy systems in developing countries need transformational change in order to have a pro-poor orientation as well as to ensure universal access to modern forms of energy and energy services in key economic sectors providing livelihoods to poor people. In addition, universal access serves both to advance education and all other concerns, and to avoid the detrimental effects of dependence on traditional fuels in terms of women's time, health effects, pollution, global warming etc. Chapters 17, 19, and 23 discuss how universal access, especially of electricity and cleaner cooking fuels, could be achieved. All GEA pathways lead to universal access to electricity and cleaner cooking fuels by 2030.

Executive Summary

Modern energy systems have been central to the development of human societies. They have perhaps been the single most important determinant of growth of our industrial societies and our modern economy. Unfortunately, they have also been a key driver of many of the negative environmental trends observed in the world today. For example, current energy systems are the predominant source of carbon dioxide (CO_2) emissions, accounting for 84% of total global CO_2 emissions and 64% of global greenhouse gas (GHG) emissions related to human activities. Past trends suggest that this percentage is likely to increase in the future if our energy needs continue to be met by fossil fuels.

The impact of GHG emissions on climate is arguably the most significant environmental impact associated with our energy systems, as the effects of such emissions are felt globally. However, these effects will not necessarily be equitable. Due to the realities of global and national economics, the areas that may suffer the greatest impacts from climate change may be those that have to date contributed the least in terms of GHG emissions. Our fossil fuel-based energy systems also emit substantial quantities of other atmospheric pollutants, for example sulphur dioxide (SO_2), nitrogen oxides (NO_x), primary particulate matter (PM), and non-methane volatile organic compounds (NMVOCs), which degrade air quality and cause damage to health and ecosystems through processes such as acidification, eutrophication, and the formation of ground-level ozone (O_3) and secondary PM. Biomass-based energy systems can also have substantial impacts on land and water resources.

Nevertheless, climate change and the reduction of CO_2 emissions are issues that need to be addressed immediately if we are to prevent irreversible environmental change on a planetary scale. This requires an international effort to develop alternative pathways that will enable our global energy systems to keep us within safe limits of environmental change whilst still providing the energy required for our human development. There has been much discussion of what such 'safe limits' might be for climate change, with scientists urging for constraining the temperature increase to 2°C, or even 1.5°C. The Global Energy Assessment (GEA) scenarios have been developed with a view towards achieving the former target by stabilizing concentrations of GHGs to less than 450 parts per million (ppm) CO_2 (equivalent). This target is considered to provide a reasonable chance of avoiding average global mean surface temperature (GMT) increases of above 2°C. However, it is important to realize that even if these alternative pathways are achieved in the future, there is still a significant risk of substantial environmental change, since it is not certain how the climate will respond to changes in GHG emissions. It is also important to note that although the focus of the GEA scenarios is on long-lived GHGs, short-lived climate forcers are always emitted along with CO_2 from combustion sources in energy systems, and have both warming (e.g., black carbon (BC)) as well as cooling properties (e.g., sulphur, particulate organic carbon (OC)). Therefore, energy policies that seek to mitigate climate change should also consider these other radiative forcers. Doing so could have co-benefits, since many of these short-lived climate forcers are air pollutants, impacting human health as well as the environment. Ideally, mitigation policy would target emission reductions that improve the situation for both climate and air quality, though such efforts may well be confounded by gaps in our scientific knowledge and by socioeconomic conditions and political priorities that vary by global region.

In view of such considerations, this chapter discusses the role of our energy systems in relation both to climate change and air quality. The latter is achieved by assessing current knowledge about air pollutants whose major sources are energy-related activities. The scale of the stresses placed on ecosystems from climate change and air quality vary by global region. This is in part due to the fact that regions are situated at different points along the energy-transition pathway, with transitional progress determining both their energy mix and associated emissions. For example, biomass energy may release carbon monoxide (CO), NMVOCs, and primary PM including BC and OC, but the net CO_2 emissions are typically small. Hence, economic regions that tend to rely on these more traditional types of energy (e.g., many African countries) will tend to contribute less to climate change and may suffer from more localized effects of poor indoor and outdoor air quality. In contrast, rapidly industrializing countries, such as those in Asia, rely heavily on fossil fuels (in particular coal), which leads to emissions of SO_2, NO_x, PM, and CO_2. As a result, such economies will be contributing to climate change as well as suffering the effects of eutrophication, acidification, elevated concentration of fine PM and ground-level O_3. Finally, those economies that have industrialized and are now putting efforts into

renewable energy (including some economies in Europe) are seeing improvements in air quality, but still have a long way to go to achieve the reductions in CO_2 emissions that would be needed to achieve the 2°C limit to global warming.

Of course, changes in atmospheric composition are not the only way in which energy systems are causing environmental degradation. Energy systems, especially those reliant on biomass and hydropower, are also having substantial impacts on land and water resources. The potential threat posed by the trend towards increased biomass energy, in particular through the displacement of food crops and the added pressure this places on already scarce water resources, also needs to be considered when identifying future pathways to sustainable energy.

Finally, it is not enough to try to identify sustainability criteria that focus only on particular and individual environmental threats caused by energy systems. Rather, it is necessary to develop indicators that treat all threats in a holistic manner, recognizing the connections that exist between sources, processes, and impacts that result in environmental degradation. Only by understanding such connections will it be possible to identify pathways of change that will truly lead us towards energy systems that are able to meet demand while keeping within the safe limits of change of the Earth's biophysical processes. As such, an important conclusion of Chapter 3 is that a move towards redefining global sustainability criteria for energy following the 'planetary boundaries' approach may be advisable. Such a move could provide the holistic framework necessary to ensure that our global energy systems develop to achieve sustainability on a planetary scale.

3.1 Introduction

Growing evidence indicates that humanity has entered a global phase of development, in which anthropogenic pressures on Earth-system processes are at risk of reaching the limits of hardwired biophysical processes on a planetary scale (Crutzen, 2002; Steffen et al., 2007). The human pressures on the climate system, the oceans, the stratosphere, and the biosphere have now reached a point where the prospect of large-scale deleterious impacts on human development cannot be excluded (Lenton et al., 2008; Schaeffer et al., 2008; Gordon et al., 2008).

The Earth may be entering a new geological era, the Anthropocene, in which humanity constitutes the main driver of planetary change (Steffen et al., 2007; Zalasiewicz et al., 2010). This change may be threatening the environmental stability of the current geological era, the Holocene. The perception of these risks has been amplified by newly acquired knowledge that Earth systems may cross 'tipping points,' resulting in nonlinear, abrupt, and potentially irreversible change, such as the destabilization of the Greenland ice sheet or the tropical rainforest systems (Schellnhuber, 2009).

Energy systems play a critical role in determining our ability to achieve global sustainability in the short- and long-term, as they depend on natural resources and are among the most significant drivers of environmental impacts on the Earth's physical and living systems (Steffen et al., 2007). Easy access to energy was a prerequisite for the rapid improvements in human welfare and the rapid growth of the world's population, which began at the start of the industrial revolution. Empirical evidence shows that in the mid-1950s, humanity embarked on a 'great acceleration' (Steffen et al., 2007), characterized by an exponential exploitation of natural resources and ecosystems (Figure 3.1) and closely associated with a similar exponential growth in global population, economic growth, and energy use (see Chapter 1).

Increased energy use is also accompanied by heavy environmental costs. The true magnitude of these costs is only now being fully realized. Perhaps the most threatening of these environmental impacts is the marked increases in atmospheric concentrations of trace gases, in particular CO_2 (Keeling and Whorf, 2005), which have occurred in parallel with this rapid human development (Steffen et al., 2007). Observations of increases in global surface temperature (GMT) (IPCC, 2007) provide evidence that these increases in GHGs are causing climate change and that, when data are compared from the same source regions, this change has been rising as quickly in the past decade as in the previous two decades, and has been steadily increasing over the last century (Figure 3.2).

Other impacts associated with energy systems, historically viewed as acting at the local or regional level, are now also threatening at the global level. Increases in energy use per capita and exponentially increasing populations have led to an agglomeration of local impacts, which pose global threats (e.g., deforestation from the harvesting of wood fuel and limited availability of fresh water due to water extraction and pollution). Additionally, environmental impacts resulting from extreme events such as nuclear accidents and oil spills can also have global implications, both in terms of environmental consequences and in terms of changes in public perception of 'safe' energy that would make up our future energy systems.

This chapter addresses the environmental impacts of energy systems, focusing on those that place pressure on the atmosphere, the terrestrial biosphere and the hydrosphere while health related impacts are discussed in Chapter 4. The chapter considers how these impacts, in particular those associated with atmospheric emissions related to energy systems, vary across the globe in Europe, the Americas, Africa, Asia and polar regions. The chapter then considers all these impacts in relation to current environmental sustainability criteria used in energy systems, giving thought to how these criteria could be modified to capture the full range of environmental impacts. Such a holistic approach is appropriate for efforts that seek to ensure planetary-scale sustainability.

3.2 The Atmosphere and Energy Systems

Energy-related activities are responsible for a major share of anthropogenic emissions of GHGs, other radiative forcing substances, and air pollutants into the atmosphere. For example, energy-related GHG emissions, mainly from fossil fuel combustion for heat supply, electricity generation, and transport, account for approximately 64% of total emissions, including carbon dioxide (CO_2), methane (CH_4) and some traces of nitrous oxide (N_2O) (IPCC, 2007a). These atmospheric pollutants are primarily associated with impacts caused either by their radiative forcing (RF) properties leading to climate change, by their deposition to sensitive ecosystems causing damage through processes such as acidification and eutrophication, or by high PM concentrations leading to health impacts. In some cases, the atmospheric pollutants may have a role in all these types of impacts. For example, ground-level ozone (O_3), which is a secondary pollutant formed from a series of chemical reactions involving nitrogen oxides, (NO_x), volatile organic compounds (VOC) and carbon monoxide (CO), may cause direct damage to human health, and vegetation and is a powerful GHG.

First, we begin by describing the most important energy-related atmospheric pollutants, their major emission sources, and how emissions have varied over recent decades (see Section 3.2.1). Emission trends are derived from the Emissions Database for Global Atmospheric Research (EDGAR) which provides data on global annual emissions for 1990, 1995, and 2000 for direct GHG, precursor gases, and acidifying gases (van Aardenne et al., 2001; Olivier et al., 2005).[1] We then describe how these emissions lead to impacts on climate, both in the long-term and short-term (Section 3.2.2) and on air quality leading to impacts on terrestrial and aquatic ecosystems resulting from acidic deposition and eutrophication

1 The GEA scenarios are based on more recent emission inventories from the Reference Concentration Pathways developed for the IPCC Fifth Assessment Report, to be published in 2013 and 2014. See www.iiasa.ac.at/web-apps/tnt/RcpDb/.

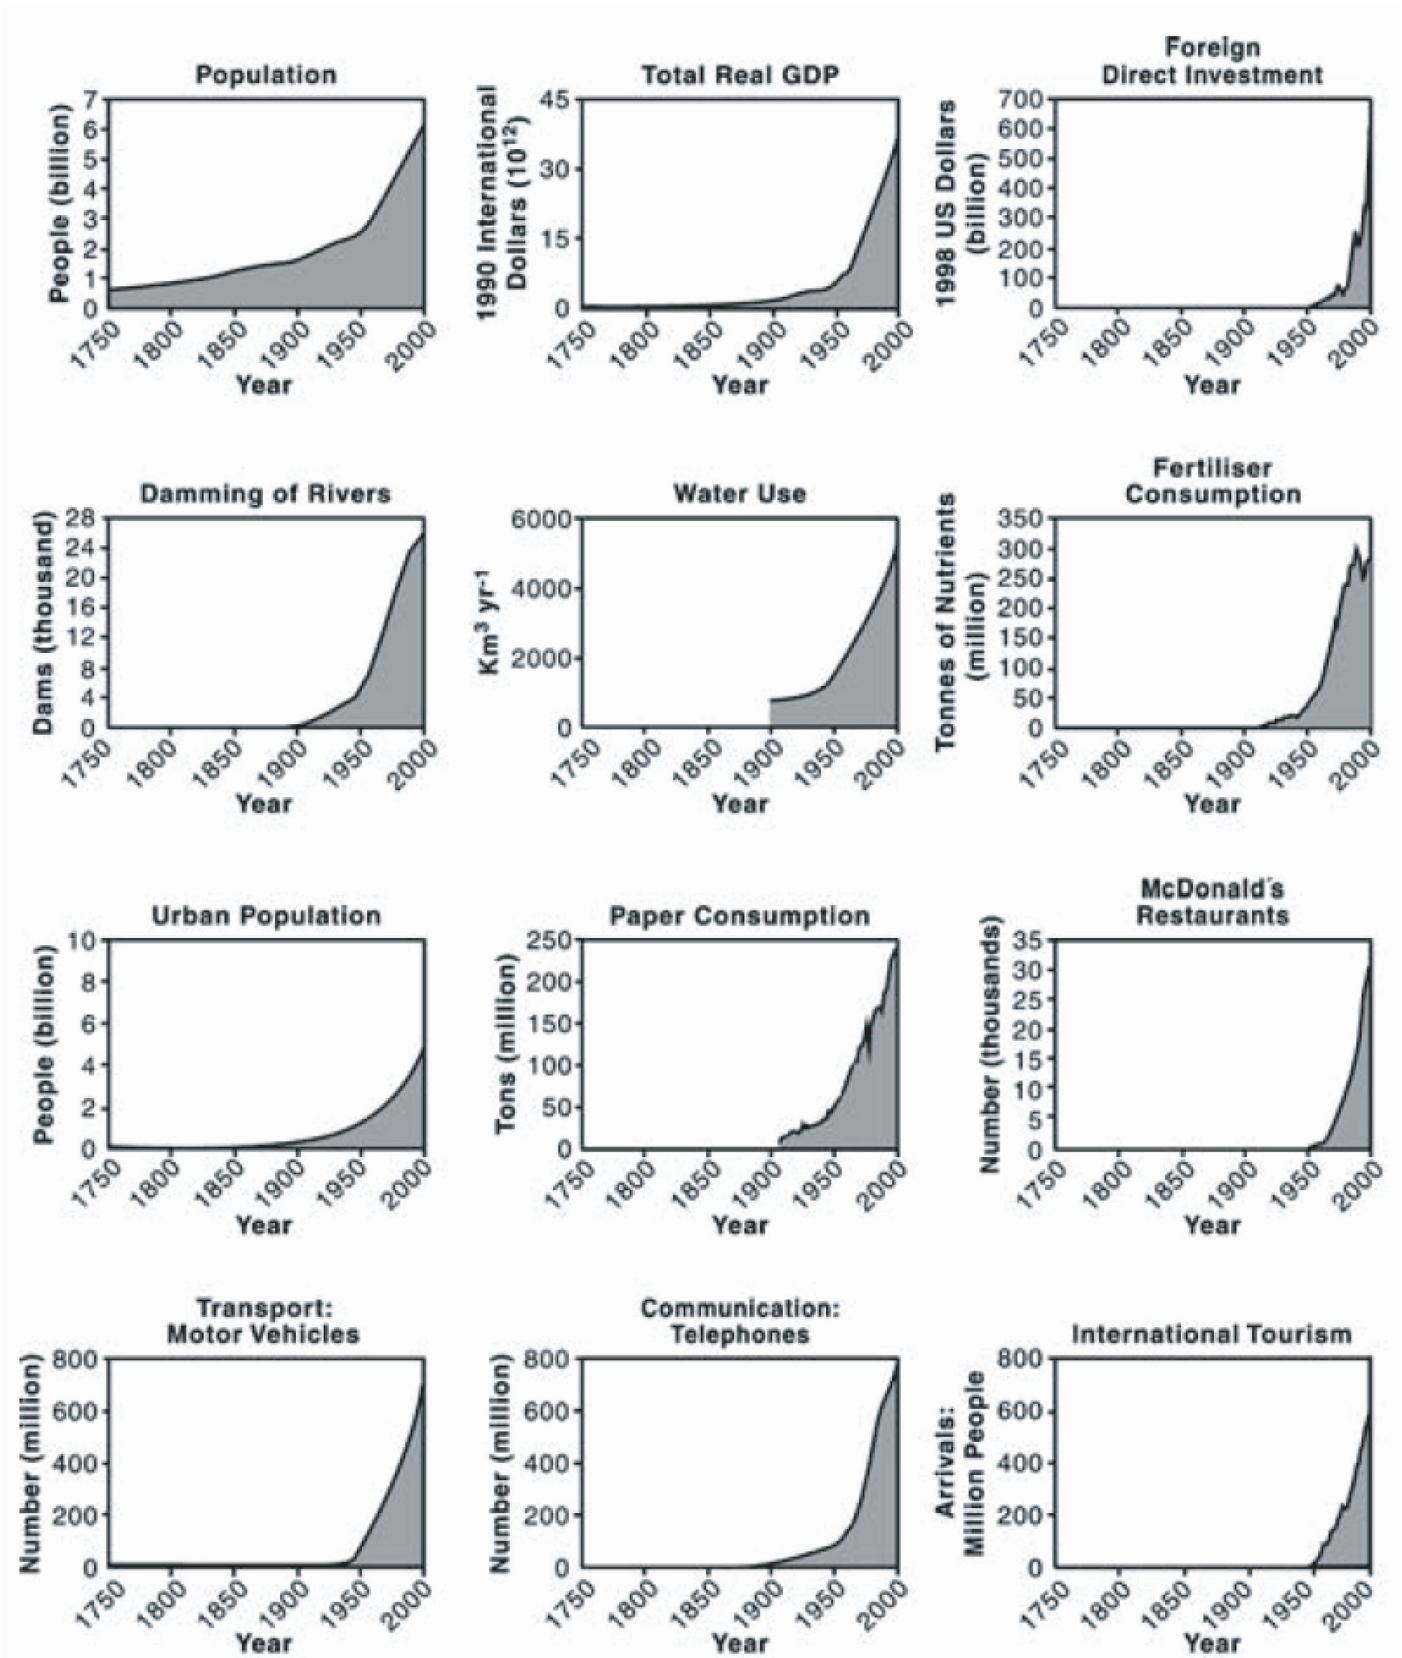

Figure 3.1 | Observed global trends of key environmental processes providing the evidence of the 'great acceleration' in human enterprise in the mid-1950s. Source: Steffen et al., 2007.

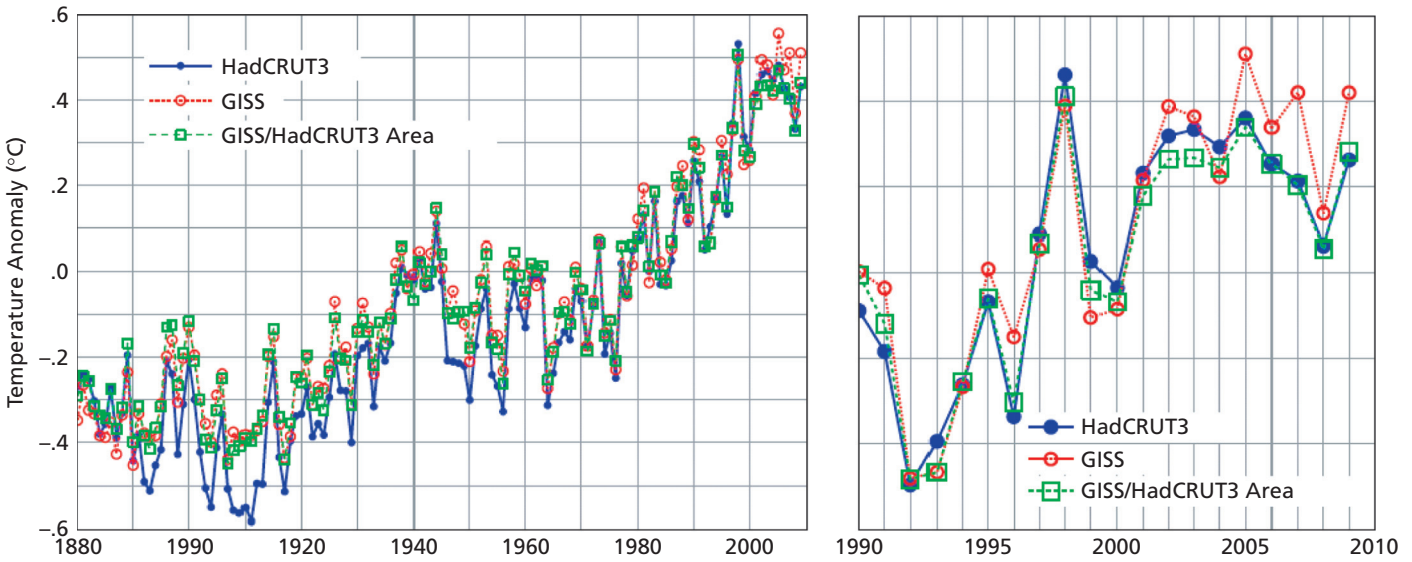

Figure 3.2 | Global surface temperature anomalies (°C) relative to 1961–1990 base period for three cases: HadCRUT, GISS, and GISS anomalies limited to the HadCRUT area. Source: Hansen et al., 2010.

(e.g., overfertilization with nitrogen), and through damage to ecosystems resulting from ground-level O_3 (Section 3.2.3); the health impacts from PM are discussed in Chapter 4. The regional variation in emission sources, climate change, and air quality impacts are discussed in Section 3.2.4.

3.2.1 Major Energy-related Sources of Atmospheric Pollution

3.2.1.1 Carbon Dioxide (CO_2)

Carbon dioxide released from anthropogenic sources has been identified as the key contributor to observed climate change (IPCC, 2007a). These sources include fossil fuel combustion, cement production, and emission flux from land-use changes. The largest sources of CO_2 emissions globally are related to energy, mainly from the combustion of fossil fuels such as coal, oil, and gas in power plants, vehicles, industrial facilities, and residential homes. In 2005, these energy-related activities accounted for 84% of total global anthropogenic CO_2 emissions (IEA, 2009).

Carbon dioxide emissions have increased continuously during the last century. The EDGAR database shows that global CO_2 emissions increased by 16% from 1990 to 2000 (Olivier et al., 2005), and a more recent analysis showed that global CO_2 emissions from fossil fuel combustion in 2008 have increased by 41% since 1990 (Le Quere et al., 2009). Although emissions increased in both developed and developing countries, the scale of the increase has varied between different global regions. For example, emissions of CO_2 in the United States increased by 16%, from 18.7 gigatonnes (Gt) of CO_2 in 1990 to 21.3 $GtCO_2$ in 2008 (US EPA, 2010a), while Chinese emissions increased by approximately 160%, from 9.2 $GtCO_2$ in 1990 to 23.8 $GtCO_2$ in 2007. However, when CO_2 emissions are expressed per capita, a different picture emerges. In 2007, the United States was the biggest per capita emitter at 18.7 tonnes, compared to China, which emitted only 4.6 tonnes per capita (IEA, 2009).

3.2.1.2 Methane (CH_4)

Methane is a potent GHG with a global warming potential (GWP) 25 times greater than that of CO_2 over a 100-year time horizon (IPCC 2007a). Importantly, CH_4 has an atmospheric lifetime of just over 10 years, which is fundamentally different from CO_2 and N_2O. Decreases in CH_4 emissions will therefore lead to a relatively rapid reduction in atmospheric concentrations of this GHG. Given the high RF of this pollutant, decreasing CH_4 emissions may be an attractive mitigation option.

Although CH_4 is relatively unreactive compared with other VOCs, it has a highly significant role in determining background O_3 concentrations on large geographic scales. Thus, higher emissions of CH_4 lead to elevated ground-level O_3 concentrations. The anthropogenic sources of CH_4 include rice agriculture, livestock, landfill, biomass burning, and fossil fuel combustion. Natural CH_4 is emitted from sources such as wetlands, oceans, forests, wildfires, termites, and geological sources. Total global pre-industrial emissions of CH_4 were dominated by natural sources (approximately 90%), with anthropogenic sources accounting for the rest (IPCC, 2007a). In contrast, anthropogenic emissions dominate present-day CH_4 budgets, accounting for more than 60% of the total global budget. Estimates of the share of anthropogenic CH_4 emissions due to fossil fuel extraction and combustion range from 20–30% (IPCC, 2007a).

3.2.1.3 Suphfur Dioxide (SO_2)

Sulphur dioxide and its atmospheric products (e.g., sulphate aerosols, sulphuric acid) cause a number of environmental problems. They can

act as atmospheric radiative forcers (with implications for climate change), as air pollutants causing acidic deposition and acidification of terrestrial and aquatic ecosystems, and as air pollutants adding to the atmospheric PM load (with impacts on human health). These pollutants also act at a range of spatial levels, from local to global, depending on atmospheric circulation patterns. Sulphur dioxide is emitted into the atmosphere from both anthropogenic sources (e.g., fossil fuel combustion, industrial process) and natural sources (e.g., volcanic eruptions). It is estimated that anthropogenic sources account for more than 70% of SO_2 global emissions, 85% of which are from fossil fuel combustion (Olivier et al., 2005). The largest anthropogenic sources of SO_2 emissions are related to fossil fuel combustion at power plants and other industrial facilities. Smaller anthropogenic sources of SO_2 emissions include industrial processes such as extracting metal from ore, and the burning of high sulphur-containing fuels by locomotives, large ships, and non-road equipment.

The EDGAR database shows that global anthropogenic SO_2 emissions in 2000 were 150 megatonnes (Mt) of SO_2, coming mainly from power generation (54 $MtSO_2$, 35.6% of total), industrial fossil fuel combustion (24 $MtSO_2$, 16.2%), nonferrous metals melting (21 $MtSO_2$, 14.2%), other fossil fuel (10 $MtSO_2$, 6.8%), residential fossil fuel (8 $MtSO_2$, 5.4%), and international shipping (7 $MtSO_2$, 4.8%), according to Olivier et al. (2005).

Global SO_2 emissions have risen dramatically over the last century, approximately in parallel with increased fossil fuel use. Emission sources have changed considerably with time, both geographically and by sector. For example, emissions in most industrialized countries have fallen over the past two decades, due to the implementation of sulphur controls and a shift to lower sulphur fuels (Smith et al., 2011). Emissions in the United States have decreased from a high of 28 $MtSO_2$ in 1970 to 10 $MtSO_2$ in 2008 (US EPA, 2009). European anthropogenic SO_2 emissions have also decreased over the last two decades, from 55 $MtSO_2$ in 1980 to 15 $MtSO_2$ in 2004 (Vestreng et al., 2007). Conversely, anthropogenic SO_2 emissions in China are of increasing concern; they contributed about one quarter of the global total and more than 90% of East Asian emissions during the 1990s. A recent study showed that from 2000 to 2006, total SO_2 emissions in China increased by 53%, from 21.7 $MtSO_2$ to 33.2 $MtSO_2$, at an annual growth rate of 7.3% (Lu et al., 2010).

3.2.1.4 Nitrogen Oxides (NO_x)

Nitrogen oxides ($NO_x = NO + NO_2$) play a key role in tropospheric chemistry. Nitrogen oxides can either be deposited directly to ecosystems through dry deposition or through wet deposition, caused when nitrates (NO_3^-) form in cloud and rain. Both processes can cause eutrophication of ecosystems. Nitrogen oxides also play a role in the production of O_3 in the troposphere, where the abundance of O_3 is controlled by atmospheric concentrations of NO_x and VOCs. Nitrogen oxides can also contribute to fine particle pollution through the formation of nitrate aerosols. Nitrogen oxides are therefore linked to climate change (through contributions to RF atmospheric aerosols and tropospheric O_3 formation), to eutrophication (through wet and dry deposition), and ecosystem damage (again though tropospheric O_3 formation). Nitrogen oxides have also been linked to impacts on human health, as they can cause adverse effects on the respiratory system. They can also directly impact vegetation.

Like SO_2 emissions, global NO_x emissions have risen dramatically during the past century. It is estimated that global anthropogenic NO_x emissions increased five-fold between 1890 and 1990, from 6.9 MtN to 35.5 MtN (van Aardenne et al., 2001). After 1990, NO_x emissions from some industrialized regions began to decrease, mainly due to regulations in the transportation sector. Emissions in the United States decreased from 23 $MtNO_2$ in 1990 to 14.8 $MtNO_2$ in 2008, due to reductions in emissions from vehicles and power plants (US EPA, 2009). In Europe, road transport has been the dominant source of NOx emissions, accounting for 40% of the total emissions in 2005 (Vestreng et al., 2009). As a result of the combined control measures, the total NO_x emissions in Europe decreased by 32% between 1990 and 2005 (Vestreng et al., 2009). Nitrogen oxide emissions in China have continuously increased over the past two decades; the growth rate itself accelerated during this period. It is estimated that NOx emissions in China were 10.9 $MtNO_2$ in 1995 and 18.6 $MtNO_2$ in 2004, increasing by 70% during the period, at a 6.1% annual average growth rate (Zhang et al., 2007). More recent data estimates that nearly 21 $MtNO_2$ of NO_x have been emitted in China, compared to a value of 36.7 $MtNO_2$ of NO_x for the whole of Asia (Zhang et al., 2009).

3.2.1.5 Carbon Monoxide (CO)

Carbon monoxide is a significant air pollutant, capable of damaging human health as well as being an O_3 precursor. Carbon monoxide is emitted whenever fossil fuels and vegetation are incompletely combusted, whether in residential stoves, industrial boilers, vehicles, or through biomass burning. According to the EDGAR global inventory, in 2000 about 50% of CO emissions came from open biomass burning, 23% from biofuel combustion, and 22% from fossil fuel combustion, with the rest coming from industrial processes and waste treatment (Olivier et al., 2005).

Since the 1960s, great strides have been taken to reduce CO levels in the United States and Europe. However, in the developing world, few regulatory steps have been implemented. Emissions in the United States decreased from 185 MtCO in 1970 to 70 MtCO in 2008 (US EPA, 2009), while emissions in Asia increased from 207 MtCO in 1980 to 340 MtCO in 2003 (Ohara et al., 2007). A recent inventory study found that global CO emissions decreased by only 2–3% globally between 1988 and 1997, as increases in eastern Asia of 51% caused by rapid economic development were offset by declines in Europe and North America (Duncan et al., 2007). The largest decline, in Eastern Europe (45%), was largely caused by the economic contraction of the former Soviet Union (FSU). There were smaller declines in Western Europe (32%) and North America (17%), caused primarily by increasing levels of emissions control on vehicles (Duncan et al., 2007).

3.2.1.6 Non-methane Volatile Organic Compounds (NMVOCs)

Non-methane volatile organic compounds include a variety of chemicals that play an important role in atmospheric chemistry through tropospheric O_3 formation. There are many sources of NMVOCs in the atmosphere, including natural or 'biogenic' sources, such as trees and vegetation. Anthropogenic sources of NMVOCs include combustion of fossil and biofuels; biomass burning; the production, processing, and storage of liquid fuels; solvent use; and many other industrial processes. According to the EDGAR global inventory for 2000, about 42% of NMVOC emissions came from the combustion and processing of fossil fuels, 26% from open biomass burning, 16% from biofuel combustion, and 14% from solvent use and other industrial processes. Sectoral distribution might vary strongly between regions (e.g., Klimont et al., 2002; Wei Wei et al., 2008). Geographically, about 33% of the emissions came from Asia, 20% from Europe, 17% from Africa, 15% from Latin America, and 13% from North America (Olivier et al., 2005).

Global anthropogenic NMVOC emissions have risen dramatically during the past century. It is estimated that emissions increased from 24.8 MtNMVOC to 181 MtNMVOC between 1890 and 1990 (van Aardenne et al., 2001). After 1990, NMVOC emissions from some industrialized regions began to decrease. Emissions in the United States have decreased from 21.8 MtNMVOC in 1990 to 14.4 MtNMVOC in 2008 (US EPA, 2009), mainly due to emissions control on vehicles, as well as improved technologies related to solvent use. Meanwhile, emissions in Asia have increased from 21.9 MtNMVOC in 1980 to 45.5 MtNMVOC in 2003 (Ohara et al., 2007). As for NO_x, more recent estimates of 54 MtNMVOC for the whole of Asia for 2006 are provided by Zhang et al. (2009).

3.2.1.7 Black Carbon (BC) and Organic Carbon (OC)

Recent work has suggested that climate forcing by carbonaceous aerosols is probably a significant component of anthropogenic forcing. Forcing by BC from fossil fuel combustion ranges from about +0.1 to +0.3 W/m^2, hence having a warming influence on climate, and similar estimates for primary OC particles are –0.01 to –0.06 W/m^2 causing a cooling effect on climate. As global averages, these values, especially BC forcing, are significant relative to the average CO_2 forcing of about +1.5 W/m^2. Some studies suggest that regional aerosol forcings can be an order of magnitude greater than GHG forcings (Ramanathan and Carmichael, 2008). Carbonaceous aerosols are mainly produced during incomplete combustion of fossil fuels and biofuels, as well as open biomass burning. It has been estimated that global annual emissions in 1996 were 8.0 Mt for BC and 33.9 Mt for OC (Bond et al., 2004). The contributions of fossil fuel, biofuel, and open biomass burning are estimated at 38%, 20%, and 42% respectively for BC, and 7%, 19%, and 74% respectively for OC (Bond et al., 2004). Emissions of BC and OC have increased steadily over the past century. Global anthropogenic BC emissions increased from 2200 kilotonnes (kt) in 1900 to 4400 kt in 2000, and OC emissions increased from 5800 kt to 8700 kt during the same period (Bond et al., 2007).

Among 'contained' combustion sources (fossil fuel and biofuel), significant contributors to BC include the transportation, industry, and residential sectors, which account for 20%, 10%, and 25% respectively (Bond et al., 2004). Transportation is the most significant contributor to BC in developed regions, such as North America and Europe, with on-road and off-road diesels having approximately equal contributions. On the other hand, in developing regions like China, India, and Africa, the residential sector contributes the most to BC, though industry (e.g., coke making and brick kilns) and the transportation sector also makes significant contributions. For example, in China the residential and transport sector together comprise 63% and 82% of the total anthropogenic emissions respectively for BC and OC (Zhang et al., 2009). As a consequence of the poorer combustion in small devices, residential solid fuels (biofuel and coal) dominate 'contained' OC emissions in all regions except the Middle East and the Pacific. It is also estimated that residential solid fuels and transport contribute 20% and 4% to the global budget of OC respectively, if one considers all sources (e.g., open biomass burning (Bond et al., 2004)). The regional analyses for Asia presented in Zhang et al. (2009) and Klimont et al. (2009) highlight the dominant role of domestic combustion in OC emissions.

3.2.2 Climate Change and Energy Systems

The world's energy systems constitute an extremely important driver of climate change. This section reviews the current state of knowledge of climate change on consideration of energy system related emissions of GHGs and air pollutants.

3.2.2.1 Long-term Climate Change and Energy Systems

Key to understanding the physical mechanisms of climate change is the concept of energy balance and radiative forcing (RF) in the Earth's atmosphere (see Box 3.1). For the Earth's GMT to remain at an average of 15°C, the net incoming flux of solar radiation at the top of the atmosphere must equal the flux of long-wave radiation out to space. The chief physical mechanism by which the radiation imbalance arises as a consequence of human interference in the climate system is through increases in the atmospheric concentrations of long-lived GHGs. Long-lived GHGs, i.e., those gases that persist for periods of time ranging from decades to centuries, include CO_2, N_2O, and halocarbons. Other atmospheric trace gases are also crucial in determining the energy balance, including stratospheric O_3, which decreases RF (see Box 3.1); CH_4 and tropospheric O_3, which increase it; and aerosols, which on aggregate also decrease RF (IPCC, 2007a). The Intergovermental Panel on Climate Change (IPCC, 2007a) (see Box 3.2) estimates that the combined net RF

Box 3.1 | Radiative Forcing, Climate Sensitivity, and Carbon Dioxide Equivalent

Radiative Forcing (RF)

Radiative forcing (RF) can be defined as the net change in the energy balance between the Earth and space (i.e., the difference in incoming solar radiation less outgoing terrestrial or long-wave radiation) at the tropopause. It is quantified as the rate of energy change per unit area of the globe as measured at the top of the atmosphere and is expressed in units of 'watts per square meter' (W/m^2). Radiative forcing is used to assess and compare the anthropogenic and natural drivers of climate change (IPCC, 2007) and can be linearly related to the global mean equilibrium surface temperature (GMT) change (ΔGMTs); $\Delta GMT = \lambda RF$, where λ is the climate sensitivity parameter (e.g., Ramaswamy et al., 2001).

Climate Sensitivity (λ)

Climate sensitivity (λ) is a measure of the responsiveness of equilibrated global mean surface temperature (GMT) to a change in the radiative forcing equivalent to a doubling of the atmospheric equivalent CO_2 concentration (CO_2-eq) (IPCC, 2007a). Climate sensitivity (λ) is hard to predict, since it needs to incorporate various couplings, feedbacks (particularly those related to clouds, sea ice, and water vapor), and interactions that occur within the climate system in response to any changes within the system.

Carbon Dioxide Equivalent (CO_2-eq)

Carbon dioxide equivalent (CO_2-eq) is a universal unit of measurement used to indicate the GWP of one unit of CO_2 over a 100-year time horizon. It is used to evaluate the releasing of different GHGs against a common basis. Thus, for methane (CH_4) the GWP is 25, and for nitrous oxide (N_2O) the GWP is 296 (IPCC, 2007a).

for all anthropogenic agents is +1.6 W/m^2 (with a 0.6–2.4 W/m^2 90% confidence range) indicating that, since 1750, it is extremely likely that humans have exerted a substantial warming influence on climate.

The contributions from CO_2 and CH_4 to this RF are 1.66 W/m^2 (with a range of ±0.17 W/m^2) and 0.48 W/m^2 (with a range of ±0.05 W/m^2) respectively. The energy sector is important in determining emissions of both these GHGs. Energy systems are the predominant source of CO_2 emissions, accounting for 84% of total global CO_2 emissions in 2005 and for 64% of global GHG emissions related to human activities (IEA, 2009).

Observations of climate change in response to these anthropogenic increases in radiative forcers are now clearly being recorded (IPCC, 2007a). Observations show GMT to have risen by 0.74°C ± 0.18°C when estimated by a linear trend over the past 100 years (1906–2005), with the rate of warming over the past 50 years almost double that of the past 100 years (IPCC, 2007a; see also Figure 3.2). This has lead to changes in Earth system climate. For example, long-term trends in precipitation amounts from 1900 to 2005 have been observed across many large regions, with precipitation significantly increasing in the eastern parts of North and South America, northern Europe, and northern and central Asia. In contrast, drying has been observed in the Sahel, the Mediterranean, southern Africa, and parts of southern Asia. Substantial increases in heavy precipitation events have been observed (IPCC, 2007a). In addition, during the 1961–2003 period the average rate of global mean sea-level rise was estimated to be 1.8 ± 0.5 mm/yr (IPCC, 2007a).

The contemporary climate has moved out of the envelope of Holocene variability, sharply increasing the risk of dangerous climate change. Observations of a climate transition include a rapid retreat of summer sea ice in the Arctic Ocean (Johannessen, 2008), the retreat of mountain glaciers around the world (IPCC, 2007a), the loss of mass from the Greenland and West Antarctic ice sheets (Cazenave, 2006), an increased rate of sea-level rise in the last 10–15 years (Church and White, 2006), a 4° latitude pole-ward shift of subtropical regions (Seidel and Randel, 2006), increased bleaching and mortality in coral reefs (Bellwood et al., 2004; Stone, 2007), a rise in the number of large floods (Milly et al., 2002; MEA, 2005b), and the activation of slow feedback processes like the weakening of the oceanic carbon sink (Le Quéré et al., 2007).

Box 3.2 | Scientific Assessments of Climate Change and the IPCC

The main source of scientific knowledge on climate change is contained in the assessment reports of the Intergovernmental Panel on Climate Change (IPCC). The IPCC was established in 1988 by two United Nations Organizations, the World Meteorological Organization (WMO) and the United Nations Environment Programme (UNEP), to assess "the scientific, technical and socioeconomic information relevant for the understanding of the risk of human-induced climate change." The First Assessment Report, or FAR (IPCC, 1990), informed the intergovernmental negotiations that led to the United Nations Framework Convention on Climate Change (UNFCCC). The Second Assessment Report, or SAR (IPCC, 1995a), informed the negotiations leading to the Kyoto Protocol in 1997. The Third Assessment Report, or TAR (IPCC, 2001), and the Fourth Assessment Report, or AR4 (IPCC, 2007), informed the process leading up to the 2009 United Nations Climate Change Conference in Copenhagen (COP-15), which was intended to create an extended or new regime in anticipation of the 2012 expiration of the first commitment period of the Kyoto Protocol. Each Assessment Report consists of three volumes, from Working Group I on the science of climate change, Working Group II on impacts and adaptation, and Working Group III on mitigation.

IPCC has also produced a series of Special Reports, including the Special Report on Emissions Scenarios (SRES) in 2000 (IPCC, 2000a), the Special Report on Methodological and Technological Issues in Technology Transfer, also in 2000 (IPCC, 2000b), and the Special Report on Carbon Dioxide Capture and Storage (SRCCS) in 2005 (IPCC, 2005).

Each of the IPCC Reports is peer-reviewed and assesses a vast number of scientific publications, and is the most authoritative assessment available. IPCC has recently been subject to criticism due to a few mistakes in the AR4. These mistakes have not affected the overall conclusions or their soundness.

How climate will change in the future under anthropogenic pressures will depend to a large extent on future GHG emissions, changes to the biosphere, and feedbacks in the Earth system. Even if emissions of all anthropogenic RF agents were to remain constant at today's levels, the Earth's climate system would continue to change. This is often referred to as 'committed warming,' and is largely due to the thermal inertia of the oceans and ice sheets and their long time-scales for adjustment. For example, the IPCC (2007a) estimates that committed climate change due to atmospheric composition in the year 2000 corresponds to a warming trend of about 0.1°C per decade over the next two decades, in the absence of large changes in volcanic or solar forcing. By 2050, about a quarter of the 1.3–1.7°C warming relative to 1980–1999 estimated using Special Report on Emission Scenerios, often referred to as the IPCC SRES 'marker Scenarios' (Nakicenovic et al., 2000; see also Box 3.2), would be due to committed climate change if all RF agents were to be stabilized at today's concentration levels.

It is extremely unlikely that RF agents will be held constant, as evidenced by the continued rise in GHG emissions. In order to assess the likely future trends in our climate, the IPCC (2007a) has assessed global climate change projected from six SRES scenarios of emissions of RF agents (see Figure 3.3). These scenarios represent a range of plausible future trajectories of population, economic growth, and technology change, in the absence of policies to specifically reduce emissions in order to address climate change. The assessment of climate change under these scenarios was made using a number of climate models of varying levels of complexity (and hence capable of incorporating different aspects of climate sensitivity; see Box 3.1), from simple climate models to those that include ocean-atmosphere general circulation models and feedbacks between climate change and the carbon cycle (Betts et al., 2011). The IPCC (2007a) concluded that GMTs are likely to increase by between 1.1–6.4°C by the end of the 21st century relative to the 1980–1999 average. A key question is, What are these projected increases in GMT likely to mean for impacts associated with climate change? A related question is, How is this likely to affect our ability to stabilize GHG concentrations so as to "*prevent dangerous anthropogenic interference of the climate system,*" as referred to in Article 2 of the United Nations Framework Convention on Climate Change (UNFCCC, 1992)? One of the core objectives of GEA is to answer these questions by assessing the implied constraints on future energy-related emissions of GHGs that would fulfill the stated objective of the UNFCCC (1992).

3.2.2.2 Impacts of Climate Change in the Future

How will climate change influence Earth systems, and what risks are involved? This has been continually assessed in the four IPCC Assessment Reports (IPCC, 1991a; 1995b; 2001a; 2007a) (see Box 3.2). Increases in GMT of the magnitude projected for 2100 as described in Figure 3.3 would be expected to have substantial global consequences both for near-term climate change and throughout the 21st century. Such consequences would include continued sea-level rise, changes in the cryosphere, decreases in snow cover, changes in global and regional patterns of temperature and precipitation, changes in extreme weather events such as heat-waves and drought, changes in the number and intensity of tropical cyclones, loss of genetic species and ecosystem

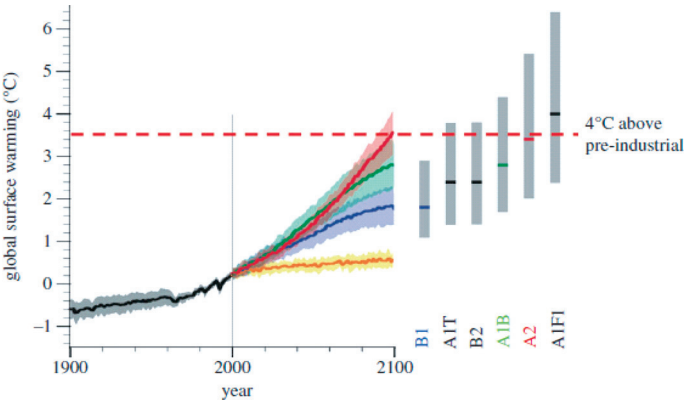

Figure 3.3 | Past changes in global mean surface temperature (GMT) (black curve), and projected future changes resulting from the IPCC SRES (Nakicenovic et al., 2000) 'marker scenarios' of GHG and aerosol emissions (colored curves and gray bars), relative to the 1980–1999 mean (Meehl et al., 2007). Climate changes under the A2, A1B, and B1 scenarios were projected with general circulation models (red, green, and blue lines, with plumes showing 5–95% range of model projections without uncertainties in climate-carbon cycle feedbacks). The full set of 'marker scenarios,' including a range of strengths of climate-carbon cycle feedbacks, were examined with simple climate models. Gray bars show the likely range of warming at 2090–2099 for each scenario, from expert assessments based on all available evidence from general circulation models, simple climate models, and observational constraints. The red dashed line marks warming of 3.5°C relative to 1980–1999, which represents 4°C relative to pre-industrial levels. Red line, A2; green line, A1B; blue line, B1; orange line, year 2000 constant concentrations; black line, 20th century. Source: IPCC, 2007a.

diversity, acidification of the oceans, and, perhaps most importantly, dangers of crossing tipping points that could lead to catastrophic ecological consequences (Schellnhuber et al., 2009). The uncertainties in assessments of these projections in climate change are many, and the IPCC process summarizes these uncertainties in its reports.

The IPCC (2001b) summarized an extensive analysis of the impacts of climate change. The IPCC identified 'reasons for concern' (RFCs), describing them in what has since become known as the 'burning embers' diagram. The diagram aimed to characterize the extent of the level of threat or risk associated with future projected anthropogenic climate change, defined as a change from 1990 levels of GMT.

The 'burning embers' diagram (IPCC, 2001b), as described in Smith et al. (2001), is shown in Figure 3.4, together with data updated by Smith et al. (2009). The comparison of the two diagrams suggests that the temperature range from which a consensus definition of dangerous anthropogenic interference might be drawn is getting lower, a result of advancements in our scientific insights regarding the functioning of the Earth system. There has been a growing consensus toward adopting a '2°C guardrail' approach, shown as a black dashed line in Figure 3.4 (Hare and Meinshausen, 2006). This approach has been adopted by the 'Copenhagen Accord' and the European Commission (United Nations Conference of the Parties, 2009). The 2°C barrier is based on recommendations by numerous scientific studies (Schneider and Mastrandrea, 2005; Fisher et al., 2007; Nakicenovic and Riahi, 2007; Hansen et al., 2008; Schellnhuber, 2008; Kriegler et al., 2009; Meinshausen et al., 2009; Rockström et al., 2009), which suggest that global warming in excess of 2°C from pre-industrial times could trigger several climate tipping elements and lead to unmanageable changes (Smith et al., 2009). This target represents a clear guiding principle for acceptable limits of climate change. However, it has been recognized that establishing how the target will be met is rather complicated, since uncertainties associated with our knowledge of climate sensitivity, particularly the carbon cycle and climate response (see Box 3.1), complicate efforts to estimate the GHG emission reductions that would be necessary to remain below this warming target. Figure 3.4 indicates that even if this rather ambitious target is met, three out of the five 'reasons for concern' would still be at high risk of manifestation.

It is also worth emphasizing that significant risks of adverse climate impacts for society and the environment will have to be faced even if the 2°C line can be held (see also IPCC, 2007b; Richardson et al., 2009; WGBU, 2009). In view of this fact, it is possible that the 2°C barrier will be revised to lower values; efforts to make the target more stringent may be renewed as our understanding of regional consequences of climate change improves (Schneider and Mastrandrea, 2005; Hansen et al., 2008; Kriegler et al., 2009; Rockström et al., 2009).

3.2.2.3 Emission Scenario Requirements to Remain Below the 2°C 'Guardrail'

The UNFCCC Conference of the Parties (COP) in Copenhagen (COP 15) in December 2009 and the UNFCCC COP 16 in Cancun in December 2010 did not arrive at a legally binding agreement on how to proceed after the first commitment period of the Kyoto Protocol ends in 2012. However, the three-page "Copenhagen Accord," which was offered by a subgroup of Parties and taken note of by the COP, provides a consensus, however limited, on defining a 2°C GMT increase as a global 'guardrail' for human-induced climate change. This is the nearest expression of how to interpret dangerous climate change and of the level of mitigation desired. It is therefore taken as the normative goal for energy systems development and used to define the global sustainability criteria used in this GEA assessment (see Chapter 17).

The IPCC (Fischer et al., 2007) addressed the question of what the GHG emission reductions might need to be in order to provide a chance of stabilizing GMT below the 2°C 'guardrail.' The left-hand graph in Figure 3.5 shows the emission paths that are consistent with various stabilization levels, and the right-hand graph indicates that staying below a 2°C 'guardrail' with a 50% probability would require long-term GHG stabilization at around 440–450 ppm CO_2-eq. Figure 3.5 also indicates the uncertainties in climate-sensitivity estimates. For example, to increase the probability to around 90% would require stabilization below 400 ppm CO_2-eq, or essentially the maintenance of current concentrations throughout the century. Basically, global emissions need to decline almost immediately (within the next decade) to keep the goal of stabilizing at 2°C within reach. The higher the 'overshoot' of emissions,

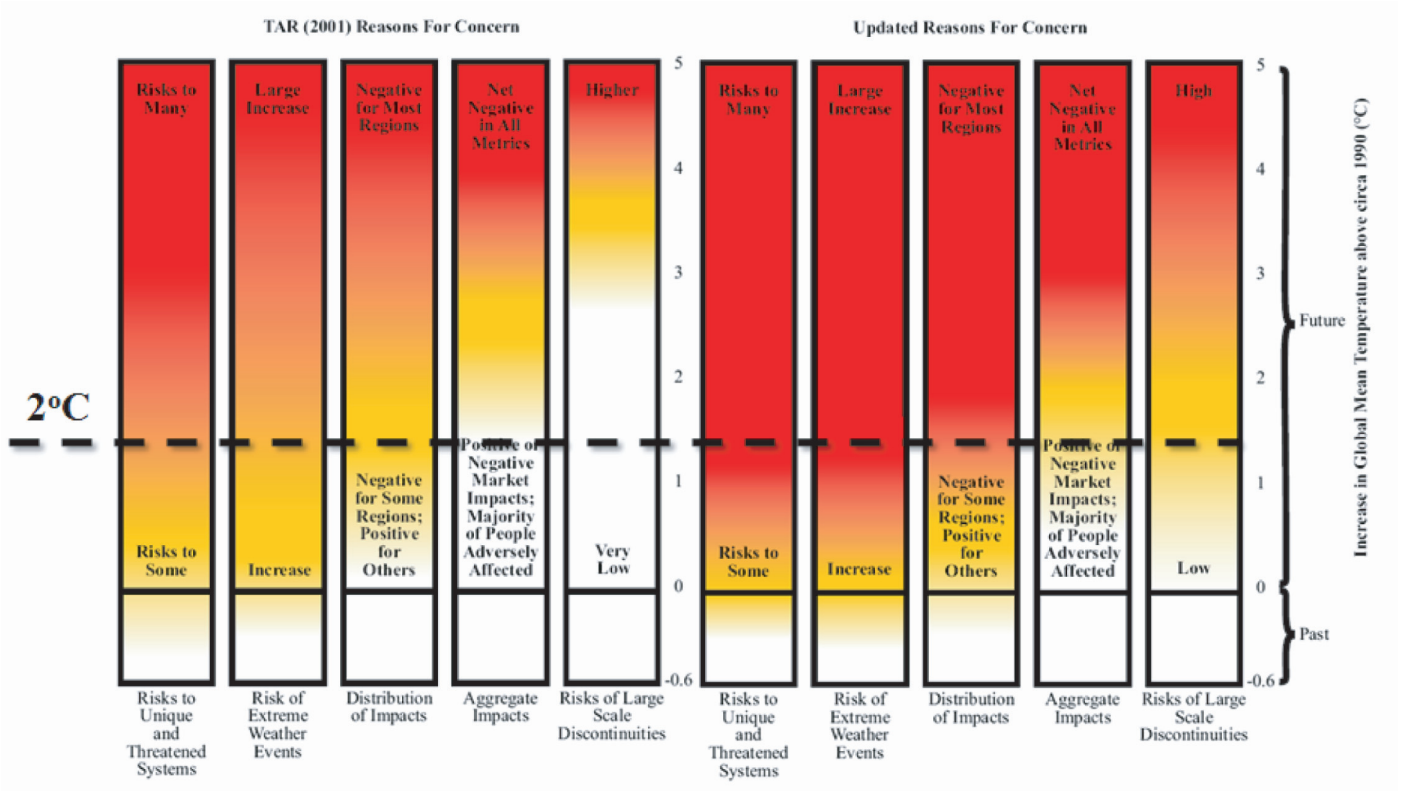

Figure 3.4 | Risks from climate change, by 'reason for concern' (Smith et al., 2001), compared with updated data (Smith et al., 2009). Climate change consequences are plotted against increases in GMT after 1990. The pre-industrial temperature level is also indicated. Each column corresponds to a specific reason for concern and represents additional outcomes associated with increasing GMT. The color scheme represents progressively increasing levels of risk. Both figures suggest that all stabilization levels, including the current atmospheric concentrations of GHGs, can be considered to be in principle dangerous, but it is important to note that the level of concern increases significantly with higher stabilization levels. Source: Smith et al., 2009.

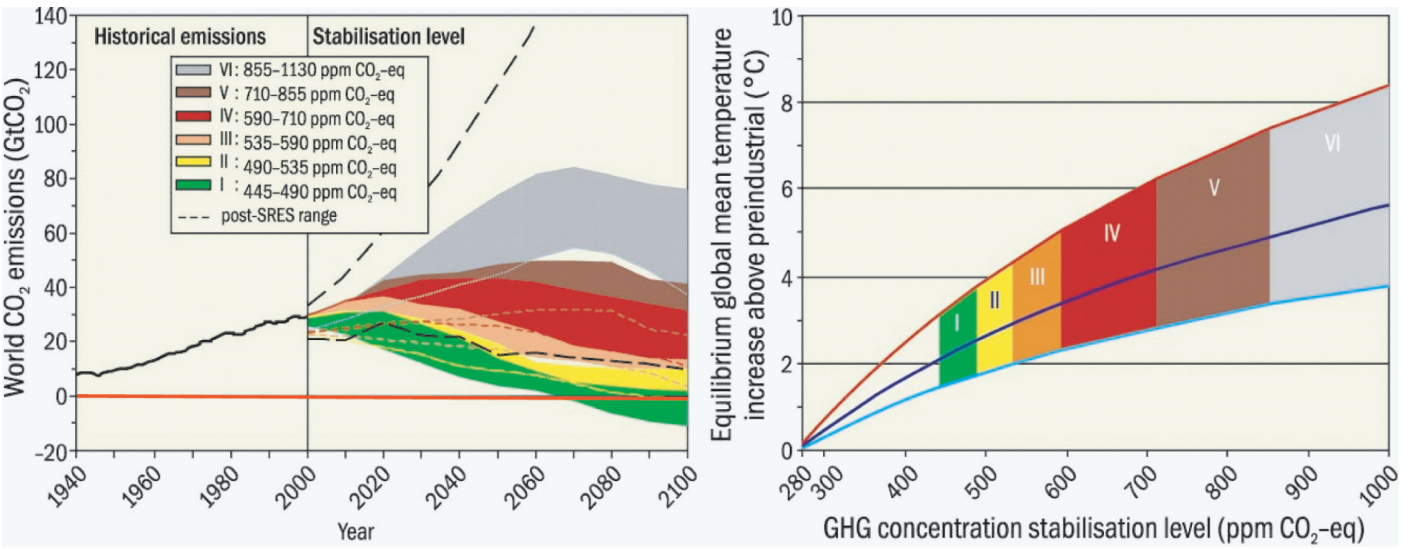

Figure 3.5 | The graph on the left shows the ranges of future emissions pathways for reaching different GHG emissions concentrations, expressed in terms of $GtCO_2$-eq. For example, the green range indicates the emissions trajectories that would lead to stabilization levels between 445–490 ppm $GtCO_2$-eq (as shown in the box within the figure). Note the need for net negative emissions post-2060 in case of the most stringent (green) trajectory. The graph on the right shows the equilibrium GMT increase above pre-industrial levels as a function of GHG stabilization level (ppm CO_2-eq). The middle black line indicates the most likely climate sensitivity, which is the most likely temperature increase at a certain GHG stabilization level. The red and blue lines indicate higher and lower climate sensitivity, that is higher or lower temperature increases for a given GHG stabilization level. Source: IPCC, 2007b.

the steeper the decline needs to be thereafter. At the moment, global GHG emissions are continuing to increase at close to historical rates without a sign of a reversal. A possible decline is being pushed further and further into the future with the recent failure to reach a 'global deal' in Copenhagen during the recent UNFCCC COP 15 (United Nations Conference of the Parties, 2009).

The temperature increase is in the first approximation a function of cumulative emissions. So far, humanity has emitted about 1000 $GtCO_2$-eq into the atmosphere, which has resulted in CO_2 concentrations increasing from about 280 to some 400 ppm today. In the case of lower stabilization levels, the remaining emissions 'endowment' is smaller than the cumulative historical emissions. Meinshausen et al. (2009) estimate that future cumulative emissions will be substantially lower than 1000 $GtCO_2$-eq. The exact amount will depend on the climate sensitivity to future emissions (which is not known with complete certainty) and the desired likelihood of not exceeding a particular stabilization level, say of 2°C. According to the German Advisory Council on Global Change (2009), the cumulative CO_2 emissions from 2010 to 2050 must not exceed 750 $GtCO_2$-eq in order to stay below a 2°C temperature increase with 67% probability. This assumes that there will not be any 'negative' emissions after 2050 to offset the excess emissions of the next several decades. Most of the 2°C stabilization scenarios do actually assume the possibility of negative emissions in the second half of the century (e.g., Fujino et al., 2006, Riahi et al., 2007; Van Vuuren et al., 2007; Wise et al., 2009).

The necessity of adopting such stringent emission reductions is evident, given the facts that a growing body of evidence suggests that the climate is changing more quickly than previously projected by the IPCC Assessment Reports (Jackson, 2009); that substantial climate impacts are occurring at lower GMTs (Smith et al., 2009); and that temperature changes may well be greater during this century than had been previously projected (Sokolov et al., 2009).

3.2.2.4 Near-term Changes of Radiative Forcing

Recent scientific studies indicate that short-term changes of RF play a significant role in climate change. For example, forcing of BC, a short-term radiative forcer, has been estimated to be 20–50% of CO_2 forcing, making it the second or third largest contributor to global warming (Wallack and Ramanathan, 2009). Black carbon and other short-term radiative forcers (e.g., O_3) will enhance warming, and therefore their mitigation would help prevent climate change. In the atmosphere, these short-term radiative forcers often co-occur with other short-lived pollutants such as sulphates, nitrates, OC, and other aerosols. These pollutants cool the climate through scattering and reflection of incoming solar radiation, and hence their mitigation would actually lead to a warming of the climate. These mixtures of anthropogenic particles and gases are sometimes referred to as atmospheric brown clouds (ABCs), especially when they occur in regions that particularly suffer from visible pollution. Such pollution may, for example, result from enhanced biomass burning, such as that occurring in south and southeast Asia (see also Box 3.3 and Ramanathan and Feng, 2008).

The realization of the substantial effect that these short-lived forcers can have on climate has led to a growing consensus regarding the need not only to mitigate those atmospheric agents responsible for long-term climate change, but also to manage the magnitude and rate of change of emissions of near-term radiative forcers and hence their RF (Ramanathan and Xu, 2010). Such mitigation of near-term climate change involves different pollutants, which often arise from different

Box 3.3 | Atmospheric Brown Clouds (ABCs)

What are ABCs

Atmospheric brown clouds (ABCs) are regional scale plumes of air pollution that consist of copious amounts of aerosols (tiny particles of BC, OC, sulphates, nitrates, fly ash) as well as many other pollutants including tropospheric O_3. The brownish color of ABCs is due to the absorption and scattering of solar radiation by BC, OC, fly ash, soil dust particles, and NO_2 gas. Typical background concentrations of aerosols are usually in the range of 100–300 particles/cm^3, in polluted continental regions suffering ABCs, aerosol concentrations are in the range of 1000–10,000 particles/cm^3.

ABCs start as indoor and outdoor air pollution consisting of particles (referred to as primary aerosols) and pollutant gases, such as NO_x, CO, SO_2, NH_3, and hundreds of organic gases and acids. These pollutants are emitted from anthropogenic sources, such as fossil fuel combustion, biofuel cooking, and biomass burning. Gases, such as NO_x, CO, and many VOCs, are important precursors of O_3 which is both an air pollutant and a strong GHG. Gases such as SO_2, NH_3, NOx, and referred to as aerosol precursor gases. These gases – over a period of a day or more – are converted to aerosols through the so-called gas-to-particle conversion process. Aerosols that are formed from gases through chemical changes (oxidation) in the air are referred to as secondary aerosols (Ramanathan et al., 2008).

Impacts of ABCs

Radiative forcing: Some components of ABCs, such as sulphate and nitrate aerosols, have a cooling effect on the climate system through reflection and scattering of incoming solar radiation. Others, such as BC, have a warming effect through absorption of solar radiation, which can lead to warming of the atmosphere or, where the BC is deposited on reflective snow- and ice-covered surfaces, can lead to surface warming and melting with implications for hydrological flows.

Glacial melting: ABCs solar heating (by BC) of the atmosphere is suggested to be as important as GHG warming in accounting for the anomalously larger warming trend observed in the elevated regions. In addition to the heating effect, deposition of BC on snow or ice can reduce the surface albedo and accelerate melting. Scientific studies suggest that ABC is one of the major contributing factors in glacier and sea-ice melting.

Water budget: ABCs change the cloud properties (cloud droplet numbers, size, albedo) and produce brighter clouds that are less efficient at releasing precipitation. Together, these effects can cause localised dimming (reduction of solar radiation reaching the Earth's surface) and lead to a alterations of the hydrological cycle.'

Human health: A large fraction of the aerosol particles that make up ABCs originate from emissions at the Earth's surface caused by the incomplete combustion of fossil fuels and biofuels. Humans are exposed to these particles both indoors and outdoors. Available information about the adverse health effects of airborne fine particles from studies conducted in many areas of the world suggests that ABC exposure is very likely associated with significant adverse health effects.

In summary, ABCs cause perturbations to regional climates, due to their comprising RF species. They also affect human health and agricultural productivity directly, through impacts resulting from the air pollution component (aerosols and ground-level O_3) of ABCs but also (particularly in the case of hydrology and agriculture) indirectly through their mediation of local climate. ABCs therefore represent a striking example of the interactions between climate change and air pollution, not only in relation to commonality in the atmospheric species causing both these environmental problems, but also in relation to the processes by which impacts are propagated. Hence, important lessons can be learned in relation to understanding, with a view to ultimately controlling, the adverse impacts associated with ABCs.

source activities compared with their long-term counterparts. This situation was eloquently described by Jackson (2009), who explored the contributions from near- and long-term climate forcers to climate change over a 20-year time frame, showing the relative contributions to RF from past emissions and from a variety of different pollutants (Figure 3.6). These pollutants are all sourced, albeit to varying extents, through energy-related processes.

Figure 3.6 highlights two important issues. The first is that positive RF resulting from the next 20 years of unrestrained human activity would exceed positive RF remaining from historical human activity after a couple of decades. The second issue is that short-lived pollutants (in particular BC, O_3, and CH_4) account for more than half (57–60%) of the positive RF generated in years 1 to 20.

Jackson also identified the 'top 10' pollutant-generating activities contributing to net RF, taking into account multiple pollutants from each source activity (Figure 3.7, see also Koch et al., 2007). From this information it is argued that the seven sources that appear on the left side (purple bars) would be overlooked by mitigation strategies focusing exclusively on long-lived pollutants. There is therefore an urgent need for integrated mitigation strategies that include both the long- and short-term changes of RF; of these, gas and coal production and residential biofuel combustion are the categories which Jackson believed could be addressed by changes in future energy use and supply.

Raes and Seinfeld (2009) describe the current policy conundrum associated with these short-lived climate forcers. This relates to the fact that in addition to being radiative forcers, these species also play a role in air pollution, causing impacts on both human health (see Chapter 4) and ecosystems (see Section 3.2.3). To prevent and control these air pollutants, particularly in relation to human health, policies are already in place to reduce some of these pollutants (especially those classified as PM which include BC, OC, and other aerosols). These policies do not distinguish between positive or negative radiative forcers. Therefore, they may not improve the situation for climate change, or even actually enhance RF by reducing atmospheric concentrations of the negative forcers more effectively than the positive forcing species. The reality of this situation has been recently investigated by Penner et al. (2010), who argue that the short-term climate forcers need to be brought under

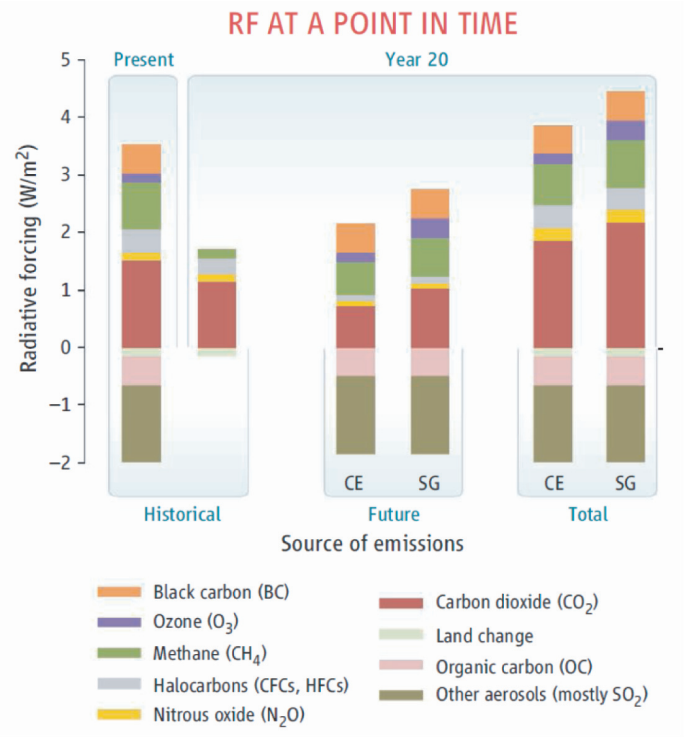

Figure 3.6 | Global radiative forcing (RF). The left-most bar shows RF attributable to historical human emissions (1750–2000), with the next bar representing historical RF that would remain after 20 years of atmospheric decay with zero additional human emissions. The next two bars represent 'future' RF in year 2020 resulting from human emissions. The two scenarios depicted are: emissions remain constant at year 2000 levels (CE), or emissions grow steadily at current rates (SG). The right-most columns show total RF experienced in year 2020 (historical + future emissions), again for both scenarios. For further details, see Jackson, 2009.

control within a few decades, and that the effect of this control on atmospheric composition and climate sensitivity needs to be monitored to provide an understanding of the warming and cooling contributions from CO_2 and short-lived air pollutants. Only with this information will it be possible to identify mitigation options that will afford the largest benefits in the alleviation of climate change while also addressing impacts on human health and ecosystems; a first attempt at identifying such options on a global scale has been achieved by a UNEP/WMO commissioned assessment on Black Carbon and Ozone (UNEP/WMO, 2011). This study found that considerable human health and crop productivity benefits could be realized through a number of technical and non-technical measures to limit emissions of BC and O_3 precursors and that these measures also provide a chance of constraining temperature increases below the 2°C, and even the 1.5°C, threshold if implemented in the very near future. This study helps to highlight that, especially in relation to energy systems, the most obvious policy option would seem to be identifying mitigation measures that would reduce both CO_2 and short-lived climate forcers that would otherwise lead to a warming of the climate systems.

3.2.3 Air Pollution and Energy Systems

As described previously, GHGs and RF agents that are produced from our energy systems can cause impacts other than climate change. Atmospheric emissions of SO_2, NO_x, and O_3 precursors are associated with eutrophication, acidification, and other types of direct ecosystem damage (Fowler et al., 2009). Much of the information describing these various air pollution impacts provided in the following sections is set within the context of an effects-based concept developed by the United Nations Economic Commission for Europe (UNECE) Convention

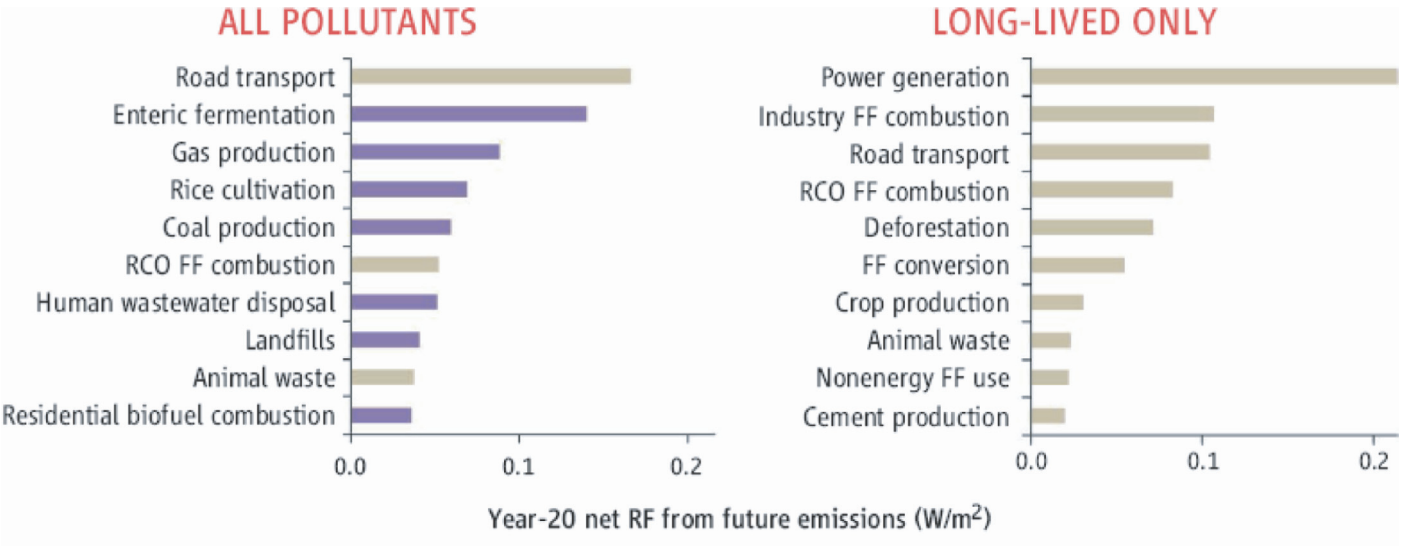

Figure 3.7 | Top-10 global sources of year 20 net radiative forcing (RF). Note: Long-lived pollutants (CO_2, N_2O) have only positive RF, whereas pollutants that are not long-lived have both positive RF (BC, O_3) and negative RF (OC, SO_2). Hence, a source may show a different RF on the left-hand versus the right-hand graph. See Jackson (2009) for further details.

on Long-Range Transboundary Air Pollutants (LRTAP). This approach has been successfully applied at the regional level in Europe to set critical limits below which ecosystems are unaffected by air pollution according to current knowledge (see Sliggers and Kakebeeke, 2004). These limits, which are referred to as critical loads and levels, have been established for different pollutants and impacts and have been used to define national and international air-quality guidelines (e.g., WHO, 2006a). They have also been used in European regional integrated assessment models to optimize air pollution mitigation policies, so that maximum benefits can be achieved at minimum cost (Schopp et al., 1999).

The following sections describe the processes by which these air pollutants impact ecosystems. The focus is on impacts by pollutants acting individually. However it is recognized, though poorly understood, that in reality these pollutants act together. For example, the potential for these pollutants to cause feedbacks on climate systems through perturbations to the terrestrial carbon sink strength has been identified as a major uncertainty which affects our ability to quantify the carbon cycle. Understanding interactions between pollutants is especially important here, given that impacts can both increase or decrease carbon sequestration.

3.2.3.1 Acidification of Soils and Freshwater

It is well documented in Europe and North America that sulphur(S) and nitrogen (N) deposition, predominantly from fossil fuel use, have caused widespread acidification of terrestrial and aquatic ecosystems. Acidic deposition has been linked to serious losses of fish stocks and other sensitive aquatic species, and it has been implicated as a potential cause of symptoms of forest decline (Rodhe et al., 1995; Menz and Seip, 2004) and effects on biodiversity (Bobbink et al., 1998). As emissions and deposition of S and N compounds increase in other parts of the world, particularly in Asia (see Section 3.2.4.4), there is a risk that acidification problems will become more widespread. However, the type and severity of acidification problems depend on many environmental factors, and evidence to date suggests that acidification problems in other parts of the world may not be as serious as they were in Europe (Hicks et al., 2008). It is also known that the reduction of atmospheric emissions of S and N to safe levels will not result in the immediate recovery of impacted ecosystems (e.g., Bishop and Hultberg, 1995), though there is evidence of recovery in European ecosystems (e.g., Vanguelova et al., 2010), where acidic deposition has been reduced significantly since the 1980s (Nakicenovic and Riahi, 2007; Vestreng et al., 2007).

3.2.3.2 Eutrophication

Increased release of reactive nitrogen (Nr) to the environment resulting from energy use is due mainly to increased NO_x emissions from fossil-fuel combustion processes that provide energy for transport, power generation, and industry. However, in terms of the total amount of Nr emitted to the atmosphere, an equal or even greater amount is emitted from agricultural sources in the form of ammonia. Furthermore, Nr losses to ground and surface waters, mainly as nitrates, are dominated by agricultural activity; for example, in Europe, agriculture contributes 60% of these ground and surface water Nr losses, with the remainder largely made up of discharges from sewage and waste water treatment systems. As such, although the atmospheric emission of NO_x from fossil fuel combustion contributes to the eutrophication effects described below, these emissions can be dwarfed by agricultural flows depending on the location of the sensitive systems (Galloway et al., 2008, ENA, 2011).

Nitrogen is an essential nutrient that limits growth in many ecosystems; however, when applied in excess, it can cause eutrophication of terrestrial and aquatic ecosystems. Eutrophication can result in excessive plant growth such as algal blooms in aquatic systems. It can also cause changes in biodiversity. The eutrophying effect of N pollution at the global level is of particular concern (Gruber and Galloway, 2008). Molecular nitrogen (N_2) in the atmosphere is not usable by most organisms; it is only when it is fixed into reactive compounds (i.e., Nr) that it causes environmental impacts. Before the 20th century, the fixation of Nr occurred predominantly via a limited group of microorganisms and by lightning. This was sufficient until the demand for food, driven by rapid population growth, led to new ways of converting nonreactive gaseous N_2 into reactive forms for agricultural purposes, mainly through industrial production of fertilizers. Such Nr fixation requires substantial amounts of energy to break the strong triple bond of N_2; hence, increased anthropogenic Nr fixation became possible through increased access to fossil fuels. This has led to an increase in the use of inorganic fertilizers in agriculture and associated increases in Nr leaching and eutrophication when fertilizer is applied in excess of agricultural system requirements (Smith et al., 1997). A recent study on energy use in the fertilizer industry also showed that despite significant energy-efficiency improvements in fertilizer manufacture, these improvements have not been sufficient to offset growing energy demand, due to rising fertilizer consumption (Ramírez and Worrell, 2006).

At the global level, current Nr emission scenarios project that most regions will have increased rates of atmospheric N deposition by 2030 (Dentener et al., 2006), which may cause significant impacts to global plant biodiversity in sensitive ecosystems (Vitousek et al., 1997; Sala et al., 2000; Phoenix et al., 2006). A significant proportion of these emissions will be related to air pollution from energy sources (Galloway et al., 2008). In addition to the acidification effects of atmospheric Nr loading described above, deposits of Nr compounds act as a fertilizer to increase the productivity of terrestrial and aquatic ecosystems. However, if the supply of Nr continues to increase, a complex series of alterations to soil and biogeochemistry may affect productivity, competition, and microbial community structure (Bobbink et al., 2010). Many of the European arctic, boreal, and temperate terrestrial ecosystems have already been allocated effect thresholds or empirical critical N loads under the LRTAP Convention in the UNECE region, but there is a lack of information on impacts in other parts of the world. Bobbink et al. (2010) conclude that reductions in plant diversity as a result of

increased atmospheric N deposition may be more widespread than first thought. They show that vulnerable regions outside Europe and North America include eastern and southern Asia (China, India), an important part of the Mediterranean ecosystems (California, southern Europe), and several subtropical and tropical parts of Latin America and Africa. However, to date the effects of N deposition on biodiversity are mostly only quantified for plant richness and diversity, and the impacts on animals and other groups are barely studied. Freshwater ecosystems are also affected, for example, across most of Europe nitrate levels in freshwaters greatly exceed a threshold above which water bodies may suffer biodiversity loss (ENA, 2011).

Nitrogen pollution is now considered to be the biggest pollution problem in coastal waters (Howarth et al., 2000; NRC, 2000; Rabalais, 2002), due to algal blooms and hypoxia (Levin et al., 2009) predominantly resulting from Nr fertilizer runoff. Human activities have severely altered many coastal ecosystems by increasing the input of anthropogenic Nr through sources such as rivers and groundwater, direct discharges from wastewater treatment, and atmospheric deposition, resulting in increasing eutrophication (Duce et al. 2008). In addition to runoff from land, atmospheric anthropogenic fixed Nr can enter the open ocean. Duce et al. (2008) found that this could account for approximately one third of the ocean's external (non-recycled) Nr supply and up to 3% of the annual new marine biological production.

In addition to impacts on biodiversity, N deposition and eutrophication in general will also have significant impacts on ecosystem services. Potential impacts include human health impacts of high nitrate levels in drinking water, carbon sequestration, GHG fluxes from soils, pollination, and cultural aspects, such as the loss of treasured species (MEA, 2005; GBO-3, 2010; NEA, 2011). Studies on the significance of these aspects are only just beginning in earnest around the world.

3.2.3.3 Vegetation Damage from Ground-level Ozone (O_3)

Tropospheric O_3 is a naturally occurring atmospheric trace gas. Historically, pre-industrial levels of the pollutant were in the region of 15–20 parts per billion (ppb) (Vingarzan et al., 2004). However, concentrations increased following the advent of industrialization and the burning of fossil fuels for transport, industry, and power generation. This increase was largely the result of increasing NO_x emissions, coupled with increases in NMVOC emissions from industry; these precursor pollutants combine under the action of sunlight through photochemically driven processes to form O_3. Heavily polluted regions can experience frequent occurrences of O_3 concentrations of approximately 40–50 ppb, especially during the summer periods, when the photochemical activity that drives the O_3 formation reactions is high (Royal Society, 2008).

Ozone concentrations vary locally, regionally, and seasonally across the globe (see Figure 3.8). Ozone concentrations can be high in both urban and rural locations (downwind from precursor pollutant sources).

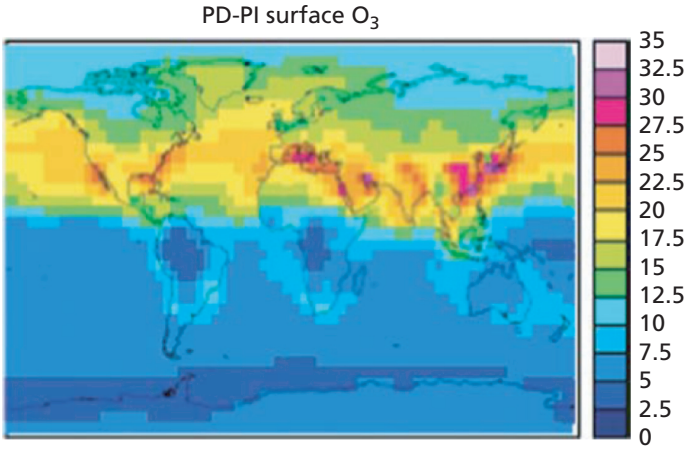

Figure 3.8 | Modelled global increase in surface ozone (O_3) concentrations between pre-industrial times and the present day (PD-PI). Source: Royal Society, 2008.

However, in urban areas, episodes tend to be short-lived, as O_3 reacts with other chemical pollutants, namely nitric oxide (NO). In contrast, rural episodes of elevated O_3 tend to have an enhanced longevity, as the pollutants that destroy O_3 are not so prevalent. This makes O_3 an extremely important rural pollutant, which is heightened by the fact that it is strongly phytotoxic and capable of causing a wide variety of damage to various ecosystems; most notable are decreases in agricultural crop yields (Fuhrer 2003; Fuhrer and Booker, 2003), reductions in forest biomass (Matyssek and Sandermann, 2003), and changes in species composition of seminatural vegetation communities (Davison and Barnes, 1998; Ashmore, 2005). Ground-level O_3 also impacts human health through damage to the respiratory system, with reduced lung function and lung irritation among the most commonly experienced respiratory impairments; these issues are discussed in more detail in Chapter 4.

Although tropospheric O_3 is a relatively short-lived pollutant, with an average tropospheric lifetime of 22 (±2) days (Stevenson et al., 2006), attention has been drawn recently to the phenomenon of hemispheric transport of this air pollutant. This phenomenon is important, since it means that geographical regions (e.g., Europe, Asia, North America) are not in complete control of the air pollution load they experience (UNECE Task Force on Hemispheric Transport of Air Pollution, 2007). This concern is a result of the complex atmospheric chemistry associated with O_3, which can result in formation from precursors long after they have been emitted (Stevenson et al., 2006).

The changes in mean global O_3 concentration between pre-industrial times to the present day, shown in Figure 3.8, emphasise the historical importance of fossil fuel-based energy use and supply as the major source of anthropogenic O_3 precursor emissions, both in industrialized and developing countries. This is reflected in the distribution of the global 'hotspots' of elevated O_3 concentrations (in the United States, Europe, south asia, and east Asia) in regions that have experienced rapid industrialization over the past 200 or so years.

3.2.3.4 Combined Effects of Air Pollutants

Since fossil fuel combustion is an important source of N and S pollution and O_3 precursors, these chemicals will have a tendency to occur as a mix of pollutants in the atmosphere. This has consequences for impacts on receptor ecosystems, since damage by a single pollutant can be altered by the presence of other pollutants, frequently with synergistic (i.e., more than additive) effects. However, calculating response functions for each pollutant in the presence of others is extremely complex (Bell, 1985; Bender and Weigel, 1993). Additionally, the impacts on net primary productivity caused by these pollutants will also affect terrestrial carbon sequestration and hence create feedbacks to climate change.

Perhaps the best-studied of such feedbacks are climate change interactions with the nitrogen cycle. There is growing evidence that the increase in N deposition since industrialization may have been responsible for maintaining at least part of the current terrestrial carbon sink (Magnani et al., 2007; de Vries et al., 2008; Reay et al., 2008; Janssen and Luyssaert, 2009). The natural nitrogen cycle may also have been accelerated by climate change thereby increasing N availability to ecosystems. Nitrogen deposition can also lead to increased emissions of the potent GHG N_2O from soils and can increase soil emissions of NO, one of the important chemical precursors for O_3 formation (Prather et al., 1995). Nitrogen deposition can also enhance the growth rates of Nr-limited forests (Hungate et al., 2009), resulting in enhanced uptake/sequestration of carbon in terrestrial ecosystems where Nr is the limiting nutrient. As atmospheric CO_2 concentrations increase, such Nr limitation may become more common. However, where N deposition exceeds critical loads, adverse effects on growth and carbon sequestration can occur.

There is some evidence that a long-term trend of increased productivity in European forests is associated with such environmental factors, that including N deposition, as well as increased CO_2, and climate change, (Nabuurs et al., 2003), and is not simply due to improved management as is sometimes suggested. These factors can also ameliorate the resilience of trees to O_3. However, O_3 itself is considered a factor potentially capable of reducing the 'benefits' of CO_2 and nitrogen fertilization (King et al., 2005; Magnani et al., 2007). Seminatural grasslands are often limited by nutrients such as Nr or phosphorous. Alleviating such constraints, for instance by the addition of Nr, could decrease the sensitivity of the plant community to O_3 through increasing biochemical detoxification capacity, or increase the sensitivity though increased stomatal conductance. However, to date, evidence of these effects is limited and contradictory. Research into the nitrogen cycle is relatively less well developed than for the carbon cycle. Several authors have evaluated the effect of including C-N coupling in carbon and or climate models (Sokolov et al. 2008; Xu-Ri and Prentice, 2008). These studies suggest that the likelihood of greatly enhanced global CO_2 sequestration resulting from future changes in N deposition is low (Dolman et al., 2010).

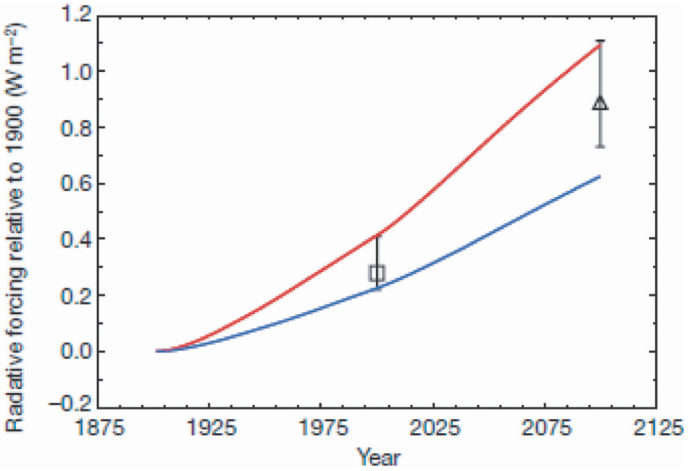

Figure 3.9 | Temporal changes in indirect radiative forcing (RF) due to O_3 for 'high' (red) and 'low' (blue) plant sensitivities to O_3. These results are diagnosed from model simulations using a fixed pre-industrial CO_2 concentration. For comparison, estimates of the direct RF forcing due to O_3 increases are shown by the bars. For further details, see Sitch et al. (2007).

The impact of tropospheric O_3 on ecosystem net primary productivity has also recently been used to estimate the indirect RF that would occur through O_3-induced alterations to carbon sequestration (see Figure 3.9). These estimates suggest that the indirect forcing by O_3 by 2100 would be 0.62 W/m^2 and 1.09 W/m^2 for 'low' and 'high' plant O_3 sensitivity respectively. This compares with a mean direct RF, estimated from 11 atmospheric chemistry models, of 0.89 W/m^2, highlighting the extreme importance of air pollution-dependant ecosystem feedbacks in relation to our understanding of how climate forcing is likely to change in the future.

3.2.4 Regional Impacts of Climate Change and Air Pollution

Energy systems are a significant contributor to climate change and atmospheric pollution in most parts of the world. In this section, the current state of environmental impacts that are related to atmospheric pollution across a number of regions (Europe, the Americas, Asia, Africa, and the polar regions) are discussed in detail. Climate change-related impacts have already been reviewed in great detail in the IPCC 2007 assessment, therefore only a short summary of these impacts is provided here. A more detailed account of relevant air quality impacts is given, since these tend to be less considered compared to climate change impacts, though they cause serious environmental degradation on a regional scale. Here we limit the discussion to environmental impacts; other critical issues, such as health-related impacts of outdoor and household air pollution, are discussed in other chapters, including Chapter 4 and Chapter 17.

3.2.4.1 Europe

Europe has a history of environmental policies that have targeted air quality, dating back to the 1950s. Following the region's increase in economic wealth, industrial activity, and use of fossil fuels, emissions of harmful air pollutants increased significantly in Europe, from the beginning of industrialization to the 1980s (see, for example, historical SO_2 emissions in Figure 3.10). However, the long-term growth trend of emissions reversed after the 1980s, triggered by public concern about the detrimental impacts of urban air pollution on public health, the dieback of forests in Central Europe, and the disappearance of fish and aquatic life in Scandinavia (UNECE, 2004). In numerous international agreements for harmonized emission reductions under the LRTAP Convention and the European Union, countries have agreed to substantially reduce their emissions. As of 2010, emissions of SO_2 and NO_x had declined by 70% and 50%, respectively, since their peaks, due to widespread application of dedicated end-of-pipe pollution-control equipment, as well as improved energy intensities of the European economies and changes in the composition of fuel consumption.

Polices to reduce emissions of GHGs to prevent climate change have only been recently established, even though the European Union (EU) prides itself on having been a driving force behind the international negotiations that led to the establishment of the UNFCCC in 1992 and the Kyoto Protocol in 1997. For the latter, the 15 EU member states signed up to reduce emissions in the 2008–2012 period to 8% below 1990 levels, a target that currently looks achievable. European Union leaders have also endorsed an integrated approach to climate and energy policy to make a transition to an energy-efficient, low-carbon economy. They have made a unilateral commitment in the 'Climate and Energy package', adopted in 2008. By adopting this strategy, the 27 nations of the EU-27 (Austria, Belgium, Bulgaria, Cyprus, Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Latvia, Lithuania, Luxemburg, Malta, the Netherlands, Poland, Portugal, Romania, Slovakia, Slovenia, Spain, Sweden, and the United Kingdom) pledged to reduce overall emissions to at least 20% below their 1990 levels by 2020. The EU pledges that this emission reduction would be increased to 30% by 2020, if other major emitting countries in the developed and developing worlds take similar action.

However, there is ample and robust scientific evidence that even at present rates, Europe's emissions to the atmosphere pose a significant threat to human health, ecosystems, and the global climate (UNECE, 2007). Discussed below are some of the main environmental impacts associated with climate change and air pollution in Europe.

Climate change environmental impacts in Europe

Wide-ranging climate change impacts have been observed in Europe through warming trends (Jones and Moberg, 2003) and spatially variable changes in

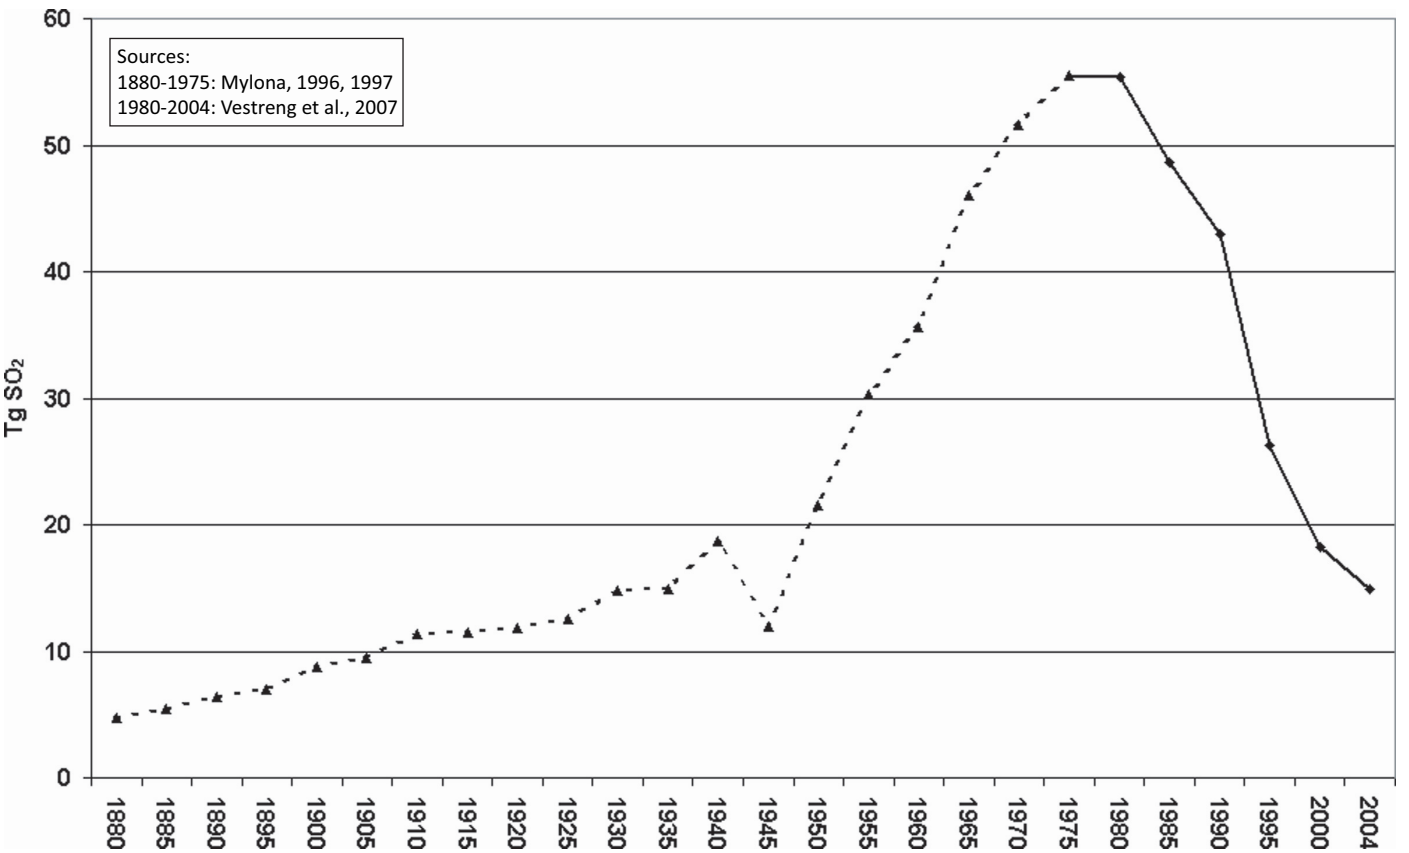

Figure 3.10 | Historical development of sulphur dioxide (SO_2) emissions in Europe (Unit: $MtSO_2$). Source: Mylona, 1996; 1998; Vestreng et al., 2007.

rainfall (Klein Tank et al., 2002). These impacts have affected the cryosphere, as seen in the retreat of glaciers (Hoelzl et al., 2003) and changes in the extent of permafrost (Frauenfeld et al., 2004). They have also impacted natural and managed ecosystems, as evidenced by changes in growing season length (Menzel et al., 2006) and species distribution (e.g., Walther et al., 2005), which have implications for biodiversity. Europe is considered most sensitive to climate change that causes extreme seasons, especially hot, dry summers and mild winters; the former would lead to more frequent and prolonged droughts (Schär et al., 2004) as well as to a longer fire season, especially in the Mediterranean (Moriondo et al.,2006). Climate-change projections indicate greater warming during winter in the north and during summer in the south. These projected changes have implications for crop suitability and production and for forest expansion and biomass growth, both of which are likely to increase in northern Europe and decrease in southern Europe (Olesen et al., 2007; Shiyatov et al., 2005; Metzger et al., 2004). The northward expansion of forests may reduce the extent of tundra regions (White et al., 2000). These changes may be accompanied by a shift in peak electricity demand from winter to summer, as demand for heating decreases and demand for cooling increases (Hanson et al., 2006). Water stress is projected to increase over central and southern Europe. This has important implications for energy supply, since the hydropower potential of Europe is expected to decline on average by 6% by the 2070s, and by 20–50% in the Mediterranean region (Lehner et al., 2005). The important role that water abstraction plays in energy supply is also evident from the fact that 31% of total water withdrawals from 30 European countries are used as cooling water in power stations (Flörke and Alcamo, 2005). Short-duration climate events such as windstorms and heavy rains may also increase in frequency, causing problems such as flooding (Christensen and Christensen, 2003). Longer-term changes in climate will also place considerable pressure on coastal areas through sea-level rise (Devoy et al., 2007). Further details of the observed and projected climate change impacts for Europe are provided by the IPCC in Alcamo et al. (2007).

Air Quality Environmental Impacts in Europe

Eutrophication in Europe

Many plant species are endangered as a result of eutrophication in terrestrial ecosystems (WHO, 2006a). Ecosystems that include meadows, forests, and bogs that are characterized by low nutrient content and species-rich, slowly growing vegetation adapted to lower nutrient levels are overgrown by faster growing and more competitive species-poor vegetation, like tall grasses, that can take advantage of unnaturally elevated Nr levels. As a result, certain habitats may be changed beyond recognition, and vulnerable species may be lost (Hettelingh et al., 2007); for example, the majority of orchid species in Europe are considered at risk from eutrophication (WHO, 2006a). For the year 2000, it was estimated that N deposition had significantly exceeded thresholds that would guarantee ecological sustainability (i.e., critical loads) in most of the European forests and grassland areas (Figure 3.11). It should be noted that energy-related NOx emissions in Europe only account for about half of the total N deposition, with the rest coming from agricultural sources, in particular intensive livestock rearing (Stigliani and Shaw, 1990).

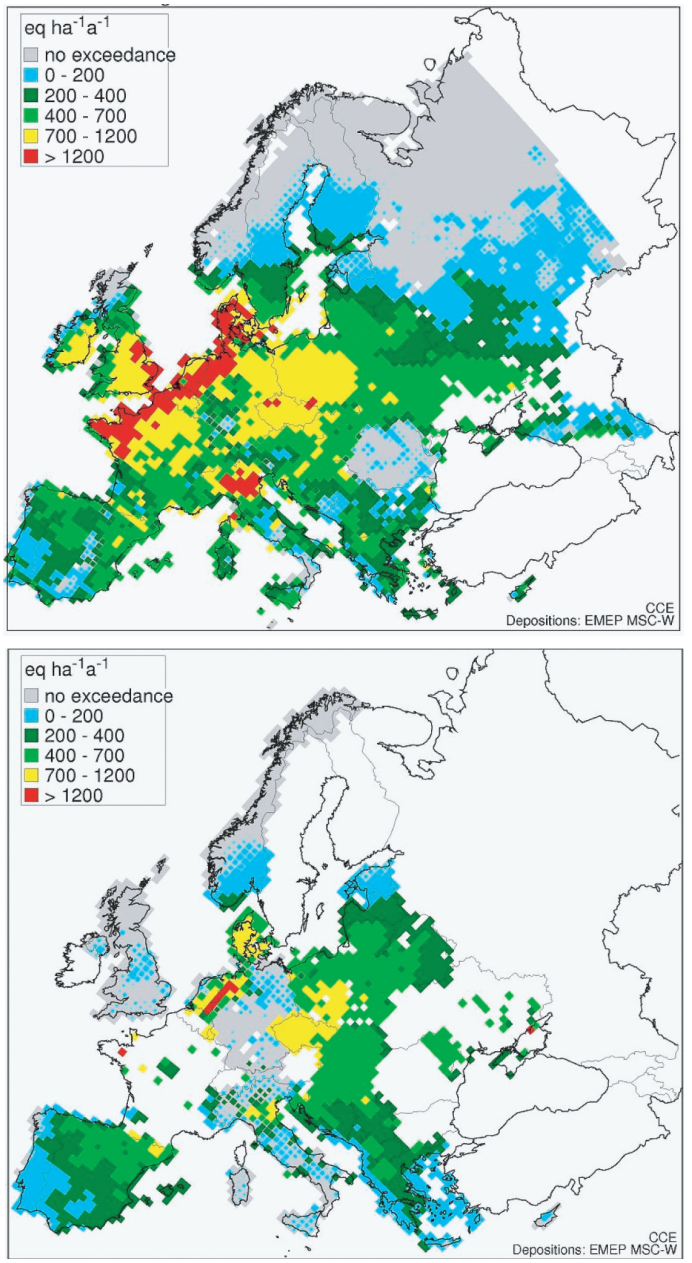

Figure 3.11 | Exceedance of critical loads for eutrophication for forest soils (top panel) and seminatural vegetation (grasslands, shrubs, etc., bottom panel) in the year 2000. The size of a colored grid cell is proportional to the fraction of the ecosystem area in the cell where critical loads are exceeded. Source: Hettelingh et al., 2008.

Methods have recently been developed that can be used to quantify the impacts, rather than merely identifying areas in exceedance, of excess N deposition on plant-species diversity (Hettelingh et al., 2008). These have estimated that current levels of Nr significantly degrade the species richness in many European ecosystems, leading to losses of up to 20% of the species in forests in northwest Europe (Figure 3.12).

Under the Natura 2000 program, the EU declared specific nature reserve areas to maintain and restore natural habitats. Among other stresses (e.g., from the fragmentation of habitats), ecosystems are under pressure

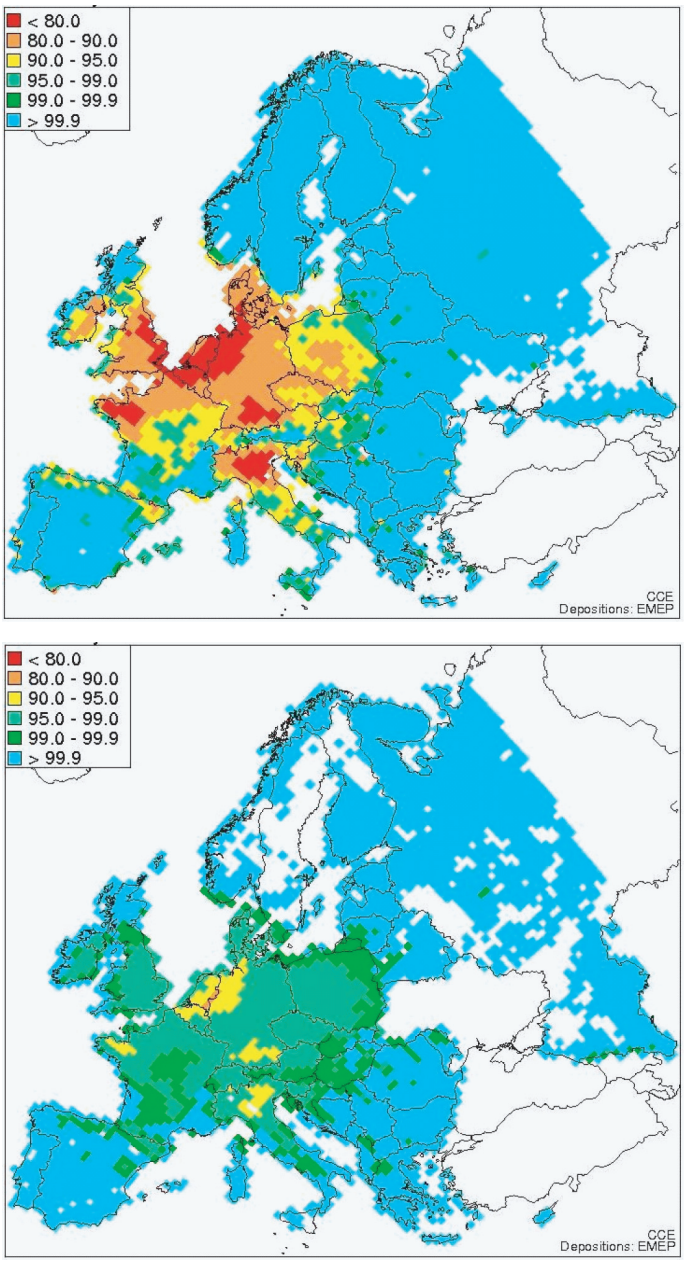

Figure 3.12 | Percentage of species richness in forests in Europe (top panel) and semi-natural vegetation (bottom panel) in the year 2000. Red-shaded areas indicate that the estimated biodiversity indicator percentages are lower than 80%, while green shadings indicate areas where this percentage is between 95–100%. Source: Hettelingh et al., 2008.

from excess deposition of atmospheric pollutants that affect plant species diversity and soil chemistry. For the year 2000, overly high deposition of N compounds constituted an important stress factor to Natura 2000 areas in Germany, the Netherlands, France, Poland, the Czech Republic, and Bulgaria, where deposition exceeded the tolerable levels of input (Figure 3.13).

Acidification in Europe

In the second half of the 20th century, the health of European forests, lakes, and rivers was heavily compromised by high acid deposition resulting from emissions of SO_2, NO_x, and NH_3. As a consequence, soils in forests and freshwater catchment areas, as well as lakes in Scandinavia, experienced strong acidification that led to plant damage and the disappearance of fish and other aquatic fauna. Since then, steep reductions in SO_2 and NO_x emissions have reduced deposition levels considerably, and many areas are now gradually recovering from past acidification. Nevertheless, current deposition rates are still exceeding sustainable levels for large forest areas in central Europe and freshwater catchments in Scandinavia and the United Kingdom (Figure 3.14). It is also clear that the full recovery of acidified soils will require deposition to be below critical-load thresholds for a substantial period of time in order to replenish the buffering capacity of soils, which has been depleted over the last decades. Thus, full recovery of acidified ecosystems in Europe would require SO_2 and NO_2 emissions to decline by 80–90% below current levels.

Ground-level Ozone (O_3)

In Europe, ground-level O_3 has been found to cause impacts to agricultural crops. These impacts include visible injury, (particularly important for leafy salad crop species (Emberson et al., 2003); declines in yields of arable crops (Mills et al., 2007); and alterations to quality of crop yields, for example the nitrogen content of harvestable products (Pleijel et al., 1999).

Exposure to ground-level O_3 also causes negative effects on sensitive forest trees, including reduced photosynthesis, premature leaf shedding, and growth reductions (Skarby et al., 1998). Ozone-sensitive forest tree species, including birch, beech, Norway spruce, Sessile oak, Holm oak, and Aleppo pine, are present across large areas of Europe (Karlsson et al., 2007). Ozone effects on these species have important negative consequences for carbon sequestration, biodiversity, and other ecosystem services that are provided by forest trees. Such services include reducing soil erosion and decreasing flooding and avalanches.

By impacting growth, seed production, and environmental stress tolerance, O_3 also affects the vitality and balance of seminatural vegetation ecosystems and the ecosystem services they provide. These services include carbon storage, water storage, and biodiversity (Fuhrer et al., 2009). The floral diversity of this vegetation type makes it more difficult to generalize about effects and to establish critical levels applicable across Europe. Widespread effects on *Trifolium* (clover species), an important component of productive pasture, have been found in O_3-exposure experiments (Mills et al., 2011). Effects include reductions in biomass, forage quality, and reproductive ability at ambient and near-ambient concentrations in many parts of Europe.

In recent years, research has focused on identifying appropriate indicators to quantify the risk of vegetation damage from O_3 (Emberson et al., 2007). Originally, risks for damage have been associated in Europe with the AOT40 (accumulated O_3 exposure over a threshold of 40 parts per billion) indicator, which measures O_3 concentrations during daylight hours that exceed a 40 ppb threshold, accumulated over the entire vegetation period (Fuhrer et al., 1997). This indicator suggests that for the year 2000 the largest risk to forest trees was in the Mediterranean countries (Figure 3.15).

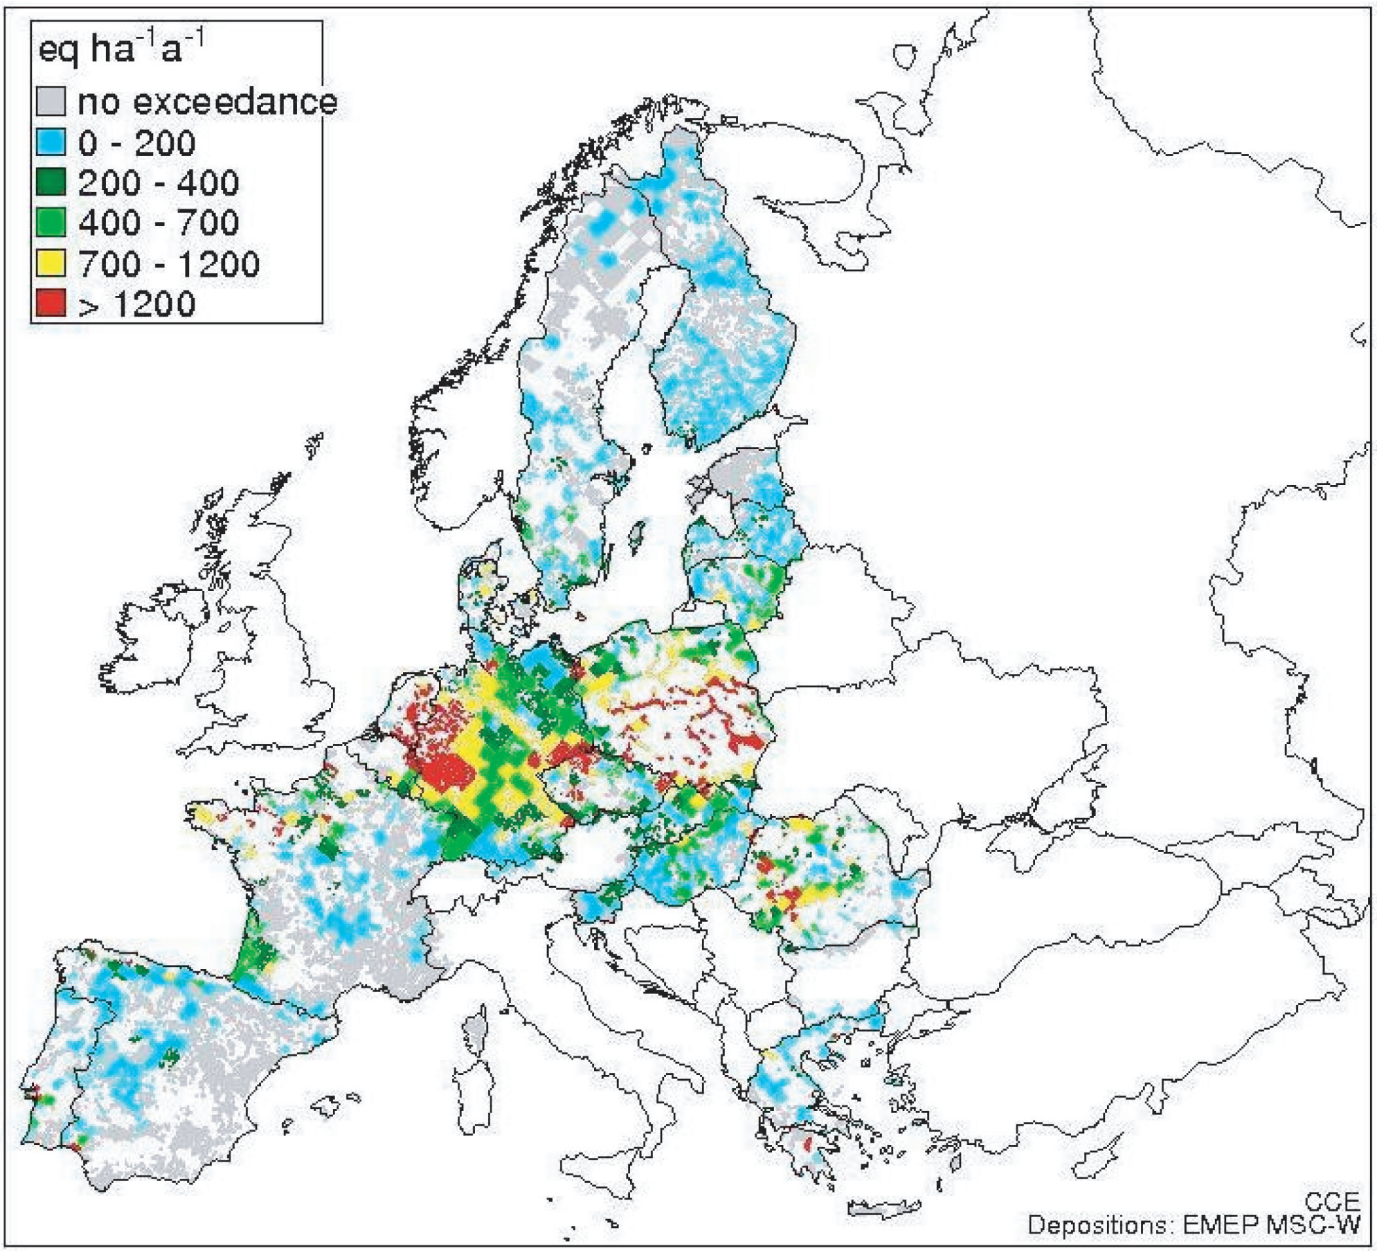

Figure 3.13 | Excess nitrogen deposition (Nr-eq/ha/yr) in Natura 2000 nature protection areas in 2000. Source: Hettelingh et al., 2008.

However, more recent work that associates actual vegetation damage with the O_3 dose that is absorbed by plants (often termed the 'ozone flux' approach) shows higher risks of O_3 in central Europe than indicated by AOT40. The areas at risk identified using this flux-based approach also bear a closer relation to those areas where vegetation damage has actually been found 'on the ground' (Mills et al., 2011).

Reductions in European precursor emissions of ground-level O_3 will certainly alleviate the pressure on vegetation. However, there is growing evidence of an increasing trend in hemispheric background concentrations of O_3 that could counteract the positive effects of measures within Europe (Royal Society, 2008). Effective response strategies that seek to eliminate the risk of vegetation damage from O_3 will therefore need to address not only sources in Europe, but also sources from other continents that may well be contributing to these increasing background concentrations.

3.2.4.2 The Americas

North, Central, and South American countries suffer the full range of environmental threats due to atmospheric emissions to which energy systems remain a major contributor. Problems exist in both rural and urban areas, including increased human morbidity and mortality plus agricultural, forest, water, visibility, and other welfare damage. Air-

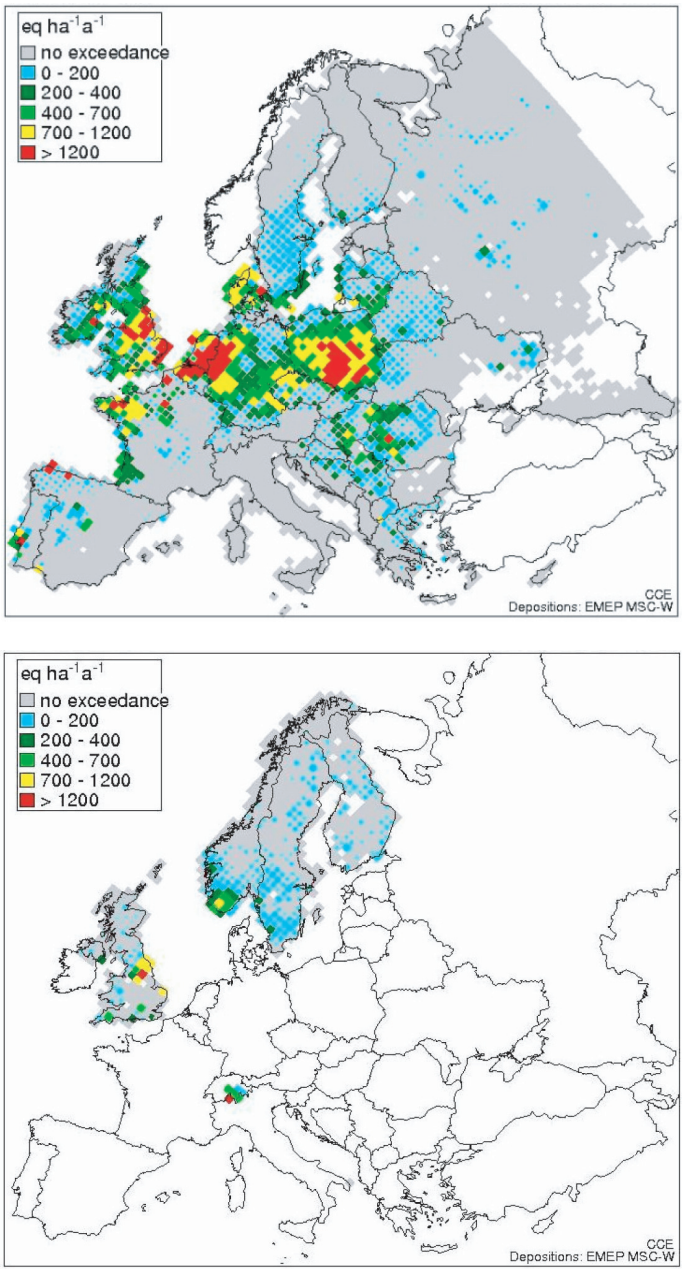

Figure 3.14 | Exceedance of critical loads of acidification (N-eq/ha/yr) in the year 2000 for forest soils (top panel) and freshwater catchment areas (bottom panel). The size of a colored grid cell is proportional to the fraction of the ecosystem area in the cell in which critical loads are exceeded. Source: Hettelingh et al., 2008.

quality deterioration in North American urban areas was initially noted in the first half of the 20th century, which resulted in the establishment of air-quality management programs in a number of the larger urban areas in the United States by 1950. Such programs were extended to Canada in the 1970s and to Mexico after 1980. Regional and global environmental threats were recognized in the late 1970s, when acid deposition was established as a significant problem in the northeastern part of the United States and in eastern Canada. By the 1980s, the potential threat of global climate change was recognized, along with the impacts from the release of toxic materials in all parts of North America. The Clean Air Act was established in 1970 to foster the growth of a strong American economy and industry while improving human health and the environment. Over the last 20 years, total emissions of the six principal air pollutants (also known as 'common' or 'criteria' pollutants) – PM, ground-level O_3, CO, sulphur oxides (SO_x), NO_x, and lead – have decreased by more than 41%. During the same period, GDP has increased by more than 64%.

Although significant progress has been made in improving the quality of the air in most US cities and communities, there is more to be done over the next 40 years. The development and use of energy in North America has been, and still remains, the prime source of environmental degradation. According to the Commission for Environmental Cooperation (CEC) in North America, there is a total of 3.17×10^{10} kilograms of criteria-related emissions emitted by the industrial sector in North America. Of these, 60% of the emissions are released by industrial sources in the United States, 26% by industrial sources in Mexico, and 14% by industrial sources in Canada (CEC, 2009).

Climate Change Environmental Impacts in the Americas

The Fourth Assessment Report of the IPCC states that there is high confidence that North America has experienced locally severe economic damage, plus substantial ecosystem, social, and cultural disruption from recent weather-related extremes, including hurricanes, other severe storms, floods, droughts, heat-waves, and wildfires (Field et al., 2007). There is also high confidence that climatic variability and extreme events have been severely affecting the Latin America region over recent years (Magrin et al., 2007).

Many coastal areas in North America are exposed to storm-surge flooding (Titus, 2005), especially those areas below sea-level. The breaching of New Orleans floodwalls following Hurricane Katrina in 2005 and storm-wave breaching of a dike in Delta, British Columbia, in 2006 demonstrate this vulnerability. Under El Niño conditions, high water levels combined with changes in winter storms along the Pacific coast have produced severe coastal flooding and storm impacts (e.g., Walker and Barrie, 2006). Significant impacts of projected climate change and sea-level rise are also expected for 2050–2080 on the Latin American coastal areas. With most of their population, economic activities, and infrastructure located at or near sea-level, coastal areas will be very likely to suffer floods and erosion, with high impacts on people, resources, and economic activities.

Changes in precipitation and increases in temperature are constraining over-allocated water resources, increasing competition among agricultural, municipal, industrial, and ecological uses across the Americas. In Latin America during the last decades, significant changes in precipitation and increases in temperature have been observed. Increases in rainfall in southeast Brazil, Paraguay, Uruguay, the Argentinean Pampas, and some parts of Bolivia have had impacts on land-use and crop yields, and have increased flood frequency and

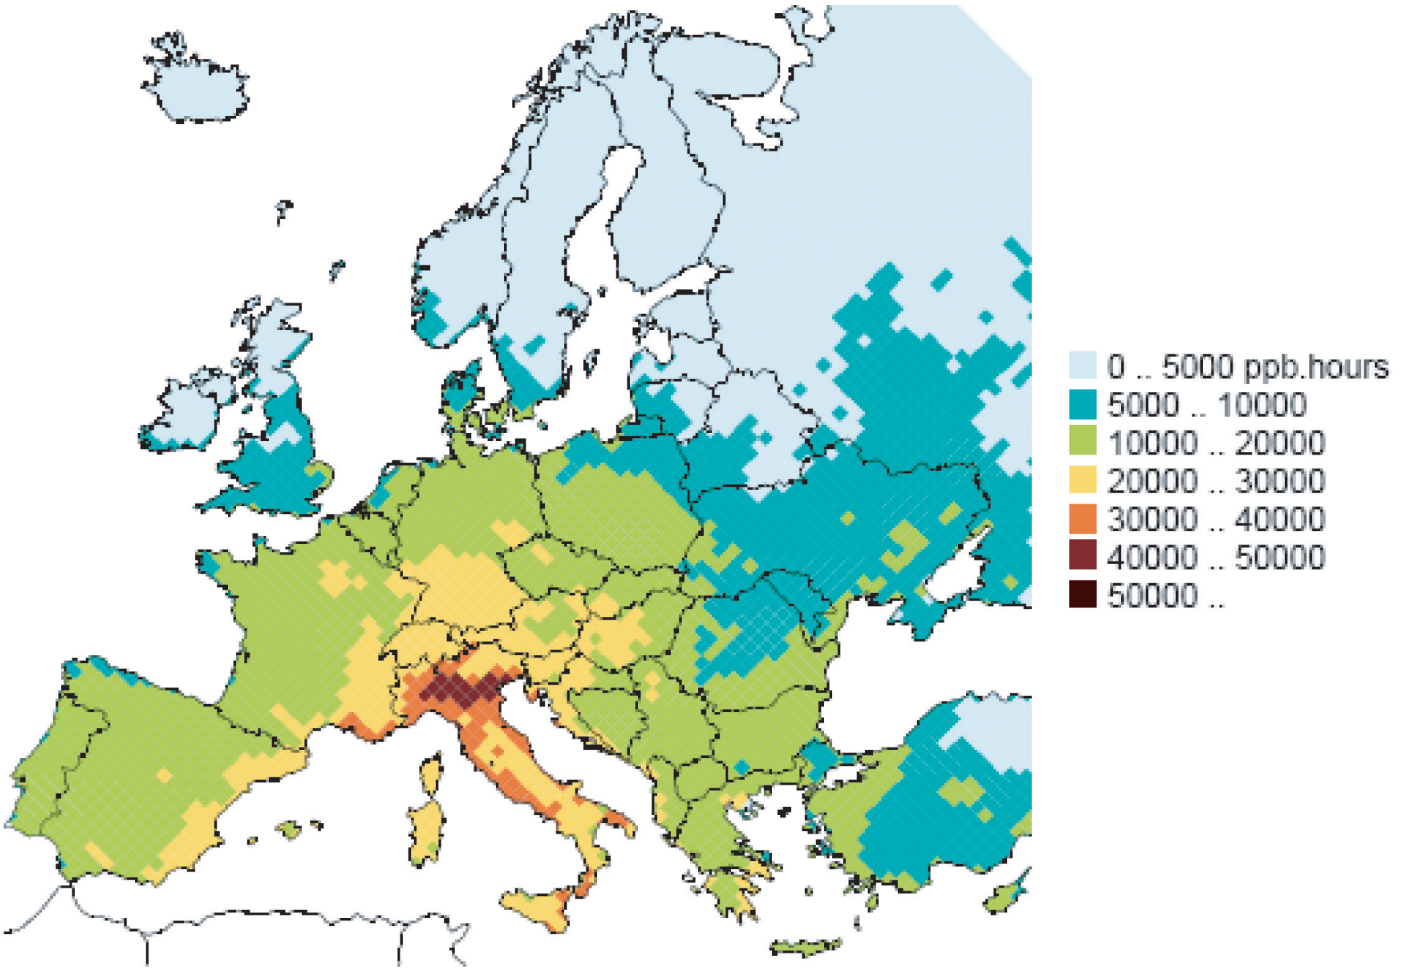

Figure 3.15 | An indicator of ozone damage to forest trees (AOT40) calculated for 2000. Source: Amann et al., 2011.

intensity. On the other hand, a declining trend in precipitation has been observed in southern Chile, southwest Argentina, southern Peru, and western Central America. As a consequence of temperature increases, the trend in glacier retreat is accelerating, with recent studies indicating that the volumes of most of the South American glaciers from Colombia to Chile and Argentina are decreasing at an accelerated rate (e.g., Leiva, 2006). During the next 15 years, intertropical glaciers are very likely to disappear, affecting water availability and hydropower generation. Hydropower production is known to be sensitive to total runoff, the timing of runoff, and to reservoir levels in North America. For example, during the 1990s, water levels in the Great Lakes fell as a result of a lengthy drought, and in 1999 hydropower production was down significantly both at Niagara and Sault St. Marie (CCME, 2003).

Climate change causes a risk of significant species extinctions in many areas of tropical Latin America. Up to 40% of the Amazonian forests could react drastically to even a slight reduction in precipitation. The tropical vegetation, hydrology, and climate system in South America could rapidly change to another steady state (Rowell and Moore, 2000). It is more probable that forests will be replaced by ecosystems that have more resistance to multiple stresses caused by temperature increases, droughts, and fires, such as tropical savannas. The replacement of tropical forest by savannas is expected in eastern Amazonia and the tropical forests of central and southern Mexico, along with the replacement of semiarid vegetation by arid vegetation in parts of northeast Brazil and most of central and northern Mexico, due to the synergistic effects of both land-use and climate changes (Magrin et al., 2007). By 2050, desertification and salinization will affect 50% of agricultural lands in Latin America and the Caribbean zone (FAO, 2004). Over the 21st century, pressure on species to shift north and to higher elevations will fundamentally rearrange North American ecosystems. Differential capacities for range shifts and constraints from development, habitat fragmentation, invasive species, and broken ecological connections will alter ecosystem structure, function, and services (Field et al., 2007).

Further details of the observed and projected climate change impacts for North America and Latin America and the Caribbean are provided by the IPCC in Field et al. (2007) and Magrin et al. (2007), respectively.

Air Quality Environmental Impacts in the Americas

Eutrophication

Although eutrophication was identified as an issue in North America in the 1970s, the problem is not ranked particularly highly within national environmental protection agencies. Nevertheless, the World Resource Institute, which carried out an assessment of eutrophication in North American coastal areas, found 131 areas that show symptoms of eutrophication (WRI et al., 2008).

Various studies in western North America (e.g., US EPA, 2008) demonstrate that some aquatic and terrestrial plant and microbial communities may be significantly altered by N deposition. For example, an accumulating weight of evidence has led some researchers to conclude that high-altitude watersheds in the Colorado Front Range show symptoms of ecological impacts, even at current N deposition levels. These effects include changes in alpine plant communities, elevated surface water nitrate concentrations, and changes in lake algal species communities. Further west, levels of stream water and groundwater nitrate in the San Gabriel and San Bernardino Mountains have been found to be strongly linked to the magnitude of N deposition in watersheds throughout the region. Stream water nitrate concentrations at Devil's Canyon in the San Bernardino Mountains and in chaparral watersheds with high smog exposure in the San Gabriel Mountains northeast of Los Angeles are the highest in North America for forested watersheds. Chronic N deposition and nitrate export from these watersheds contribute to the groundwater nitrate problems in the eastern San Gabriel Basin, where levels often exceed the federal drinking water standard.

A significant amount of research has been conducted since 1990 on the effects of N deposition on terrestrial ecosystems in the Los Angeles air basin in southern California (Fenn et al., 2003). Researchers have found that Nr enrichment, in combination with O_3 exposure, causes major changes in tree health by reducing fine root biomass and carbon allocation below ground and by greatly decreasing the life span of pine foliage. Nitrogen enrichment results in greater leaf growth, while O_3 causes premature leaf loss at the end of the growing season. The net result of these pollutant interactions is significant litter accumulation on the forest floor. Nitrogen cycling rates in soil are also stimulated by the high N inputs, resulting in large leachate losses of nitrate from these watersheds and elevated fluxes of NO gas from soil. Greenhouse and field studies indicate that N deposition may be one factor promoting the invasion of exotic annual grasses into coastal sage ecosystems occurring in low-elevation sites in the region.

One of the main adverse ecological effects resulting from N deposition, particularly in the Mid-Atlantic region of the United States, is the effect associated with nutrient enrichment in estuarine (Bricker et al., 2007) and coastal (Valigura et al., 2001) waters. Eutrophication in such ecosystems is associated with a range of adverse ecological effects, including low dissolved oxygen, harmful algal blooms, loss of submerged aquatic vegetation, and low water clarity. These changes disrupt aquatic habitats; cause stress to fish and shellfish (which in the short term can lead to episodic fish kills, and in the long-term can damage growth in fish and shellfish populations); and cause aesthetic impairments to estuaries. A recent assessment of 141 estuaries in the United States by the National Oceanic and Atmospheric Administration concluded that 64 estuaries (45%) suffered from moderately high or high levels of eutrophication due to excessive inputs of both Nr and phosphorus, with a majority of these estuaries being located in the coastal area from North Carolina to Massachusetts (Bricker et al., 2007). For estuaries in the Mid-Atlantic region, the contribution of atmospheric distribution to total Nr loads is estimated to range between 10% and 58% (Valigura et al., 2001).

Acidification and Visibility

Acid deposition and visibility reduction were noted as significant issues in the United States in the 1980s. In 1990, the US Clean Air Act was amended to specifically address these issues. The US program to address acid rain, which began in 1995, required US power plants to reduce SO_x emissions. A second phase of the SO_x reduction program began in 2000. Overall, the goal of the program has been to reduce SO_x emissions by 10 Mt/yr and cap emission levels from power plants at 8.95 Mt/yr in 2010. In addition to the requirement to reduce SO_x emissions, the US Environmental Protection Agency (US EPA) was required to adopt programs to reduce NO_x emissions by 2 Mt/yr beyond levels projected to occur without the program. Figure 3.16 indicates the emission reductions in NO_x and SO_2 in the United States between 1990 and 2009 (US EPA, 2010b) in relation to changes in electricity generation and retail price.

The success of the US program to address acid rain can be seen in monitoring data collected by the National Atmospheric Deposition Program/National Deposition Trends Network, or NADP/NTN (US EPA, 2010b). The data show significant improvements in the deposition of S and N across the United States (Figure 3.17). Reductions in N deposition recorded since the early 1990s have been less pronounced than those for sulphur.

Eastern Canada also suffers from acid deposition similar to that found in the northeastern United States. More than half of the acid rain in eastern Canada comes from emissions in the United States (Environmental Canada, 2010). It is estimated that 68% of the Canadian emissions are from industrial sources, while 67% of the US emissions are from electric power plants. In Mexico, there is concern that acid deposition is damaging the ancient Maya ruins that can be found in many parts of the country (Bravo et al., 2006).

Acidification Impacts on Aquatic Ecosystems

Acid deposition resulting from SO_2 and NO_x emissions is one of many large-scale anthropogenic impacts that negatively affect the health of lakes and streams in the United States (US EPA, 2010b). Surface-water chemistry provides direct indicators of the potential effects of acidic deposition on the overall health of aquatic ecosystems. Long-term surface water monitoring networks provide information on the chemistry of lakes and streams and on how water bodies are responding to changes in emissions. Since the 1980s, scientists measuring changes in a number

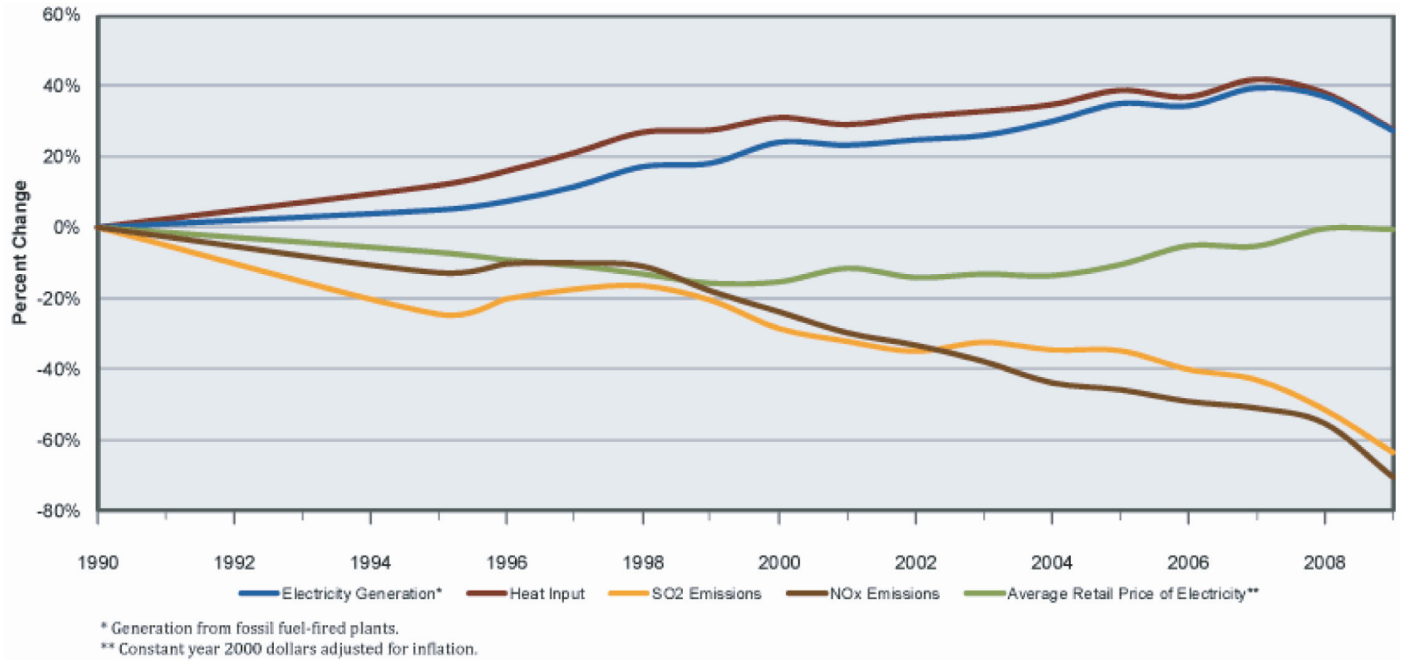

Figure 3.16 | Trends in SO_2 and NO_x emissions in relation to electricity generation and retail price from 1990 to 2009. Source: US EPA, 2010b.

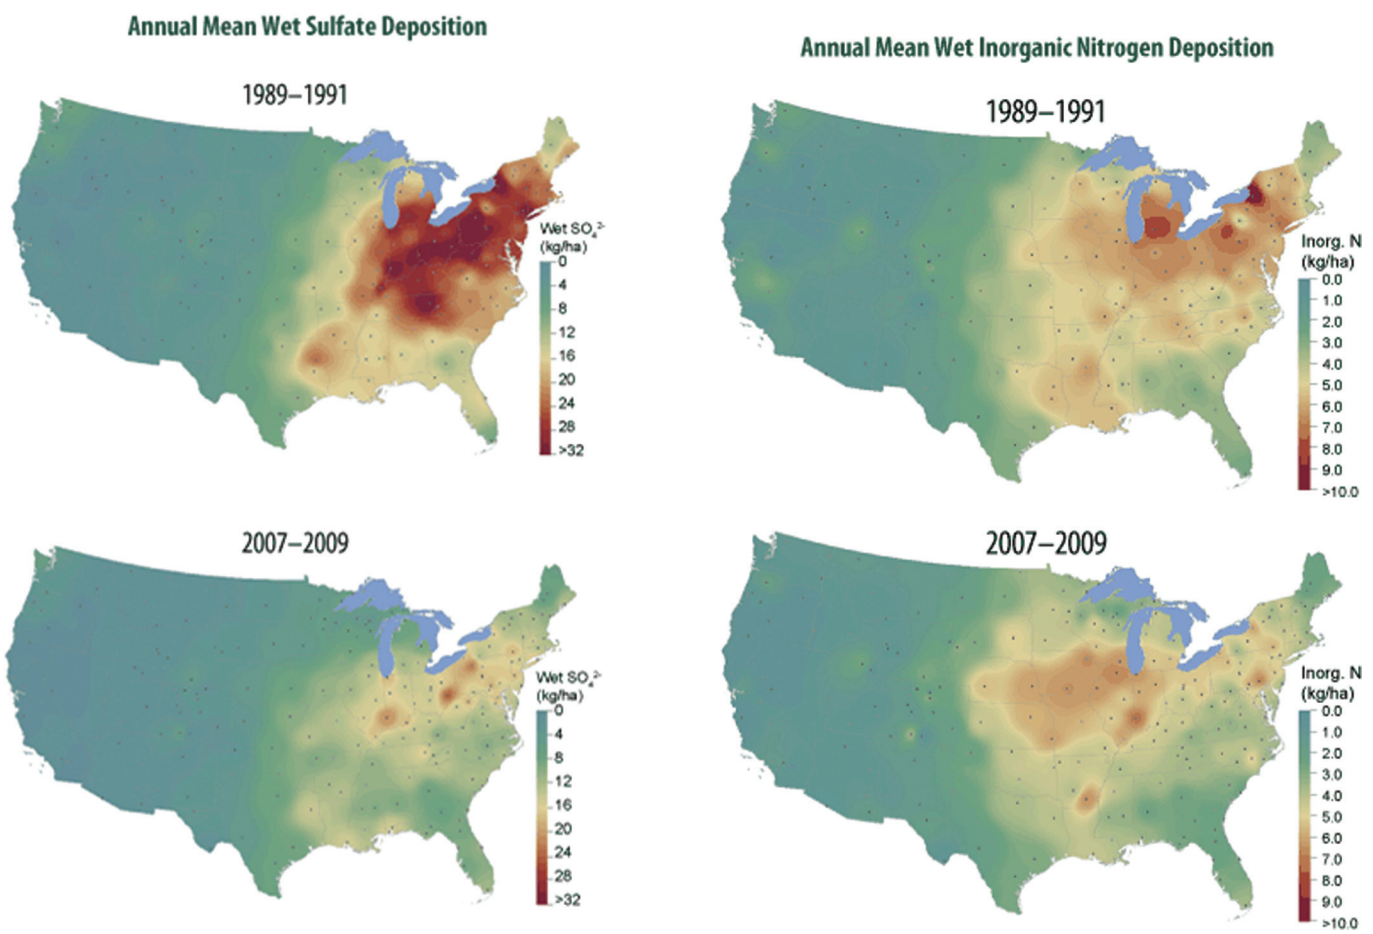

Figure 3.17 | Reductions in sulphate and nitrogen deposition in the United States between 1989 and 1991. Source: NADP/NTN monitoring data, US EPA, 2010b.

of lakes and streams in the eastern United States have found signs of recovery in many, but not all, of those bodies of water. These positive signs are a result of emission reductions that have occurred since the early 1990s (US EPA, 2010b).

The Long-Term Monitoring (LTM) program provides information on the effects of acid rain on aquatic systems. This program was designed to track the success of the 1990 Clean Air Act Amendments in reducing the acidity of surface waters in four regions: New England, the Adirondack Mountains, the Northern Appalachian Plateau, and the Central Appalachians (the Ridge and Valley and Blue Ridge Provinces). The surface-water chemistry trend data in the four regions monitored by the Long-Term Monitoring program (US EPA, 2010b) is essential for tracking the ecological response to emission reductions. One major finding of the program was that sulphate concentrations are declining at most sites in the Northeast (New England, Adirondacks, and the Catskills/Northern Appalachian Plateau). However, in the Central Appalachians, sulphate concentrations in some streams (21%) are increasing as a result of a decreasing proportion of the deposited sulphate being retained in the soil and an increasing proportion being exported to surface waters. Another important finding was that nitrate concentrations are decreasing in some of the sites in all four regions, but several lakes and streams indicate flat or slightly increasing nitrate trends. This trend does not appear to reflect changes in atmospheric pollutant deposition in these areas and is likely a result of ecosystem factors. A third finding was that acid-neutralizing capacity, as measured in surface waters, is increasing in many of the sites in the Adirondack and Catskills/Northern Appalachian Plateau regions, which can be attributed in part to declining sulphate deposition.

The critical load concept, which was first developed in Europe under the LRTAP Convention to assess the effects of acidification (see Section 3.2.3), has been used in Canada since the 1980s. The concept is currently being considered for use in the United States. The most recent analysis of the status of North American ecosystems with respect to acidification uses this critical load concept. This analysis is found in the Progress Report of the United States and Canada Air Quality Agreement, known as AQA (IJC, 2010). This report shows that in Canada, lakes that are highly acid-sensitive exist throughout northern Manitoba and Saskatchewan. Critical loads were set to protect 95% of the lake ecosystems. Critical-load exceedance occurs close to the base metal smelters in Manitoba and downwind of the oil sands operations in western Alberta. The exceedances were almost entirely due to sulphate deposition. Nitrogen inputs to the lakes, while significant, were virtually entirely retained within their catchments (lake water nitrate levels were below analytical detection in most cases), meaning that at present, N deposition is not an acidifying factor. It is estimated that lakes having critical loads as low as those observed in northern Manitoba and Saskatchewan will be threatened by long-term acid inputs. However, they do not presently exhibit obvious symptoms of chemical damage from anthropogenic acidic deposition (i.e., low pH and/or reduced alkalinity). Hence, there is still time to protect them from the acidification effects observed in many eastern Canadian lakes.

In the United States, the critical load approach is not yet officially accepted for ecosystem protection. For example, language specifically requiring a critical load approach does not exist in the Clean Air Act. Nevertheless, several federal agencies are now employing critical load approaches to protect and manage sensitive ecosystems. Modelling studies (US EPA, 2008) show that for the period 1989–1991, 56% of modelled lakes and streams received acid deposition greater than their estimated critical load, compared to approximately 36% in the 2006–2008 period. However, there are still regions where exceedances of critical loads occur. Areas with the greatest concentration of lakes in which acid deposition currently is greater than – or exceeds – estimated critical loads include the Adirondack Mountain region in New York; southern New Hampshire and Vermont; northern Massachusetts; northeast Pennsylvania; and the central Appalachian Mountains of Virginia and West Virginia (US EPA, 2008). Therefore, even though there has been improvement in acidic deposition rates over the past decade (US EPA, 2010b) (see Figure 3.17) application of the critical load concept and estimates from the scientific literature indicate that acid-sensitive ecosystems in the northeastern United States are still at risk of acidification at current deposition levels. As a result, additional reductions in acidic deposition from current levels might be necessary to protect these aquatic ecosystems (US EPA, 2008).

Acidification Impacts on Terrestrial Ecosystems

Certain ecosystems in the continental United States are potentially sensitive to terrestrial acidification, which is the greatest concern regarding N and S deposition (US EPA, 2008). Figure 3.18 depicts the areas across the United States that are potentially sensitive to terrestrial acidification. Current understanding of the effects of acid deposition on forest ecosystems has increasingly focused on the biogeochemical processes that affect plant uptake, retention, and cycling of nutrients within forested ecosystems. Research conducted during the 1990s indicated that decreases in base cations (e.g., calcium, magnesium, and potassium) from soils are at least partially attributable to acid deposition in the northeastern and southeastern United States (US EPA, 2008).

Ground-level Ozone (O_3)

Across North America, the approaches to establishing air quality guidelines for O_3 differ. In Canada, the federal government sets National Ambient Air Quality Objectives (NAAQOs) on the basis of recommendations from the National Advisory Committee and Working Group on Air Quality Objectives and Guidelines. Currently, 'desirable' and 'acceptable' NAAQOs for O_3 are defined as 50 ppb and 80 ppb respectively, expressed as an average O_3 concentration over a one-hour period. Provincial governments have the option of adopting these either as objectives or as enforceable standards, according to their legislation (Environment Canada, 2010).

In the United States, the US EPA is responsible for setting National Ambient Air Quality Standards (NAAQs), which are legally enforced. A revision of the NAAQs is currently ongoing as of 2011, and includes the possibility of introducing a more stringent secondary standard in addition to the primary standard that is designed to protect human health.

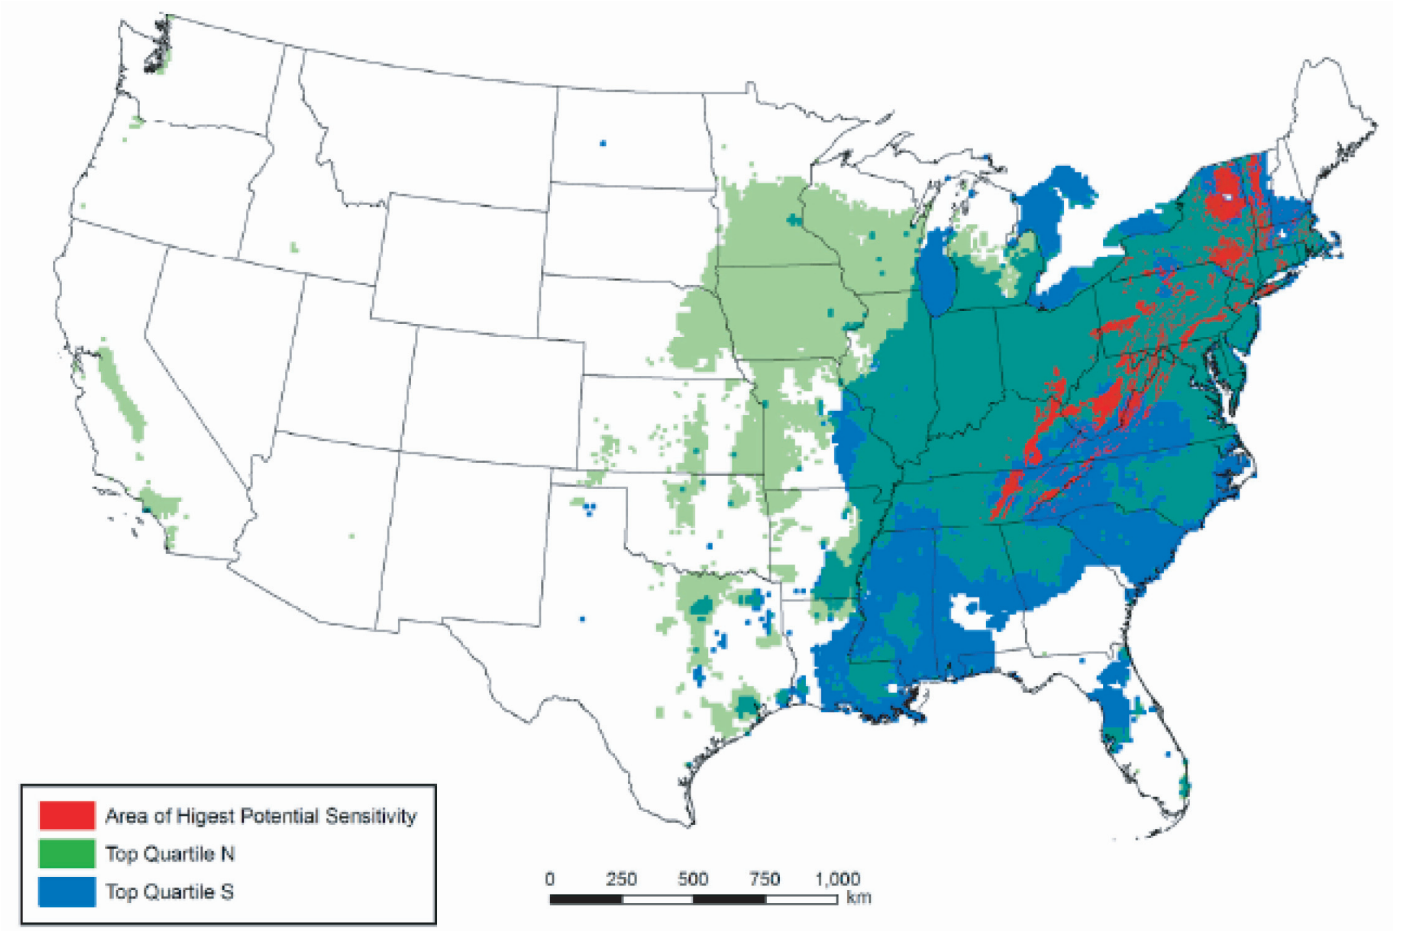

Figure 3.18 | Areas potentially sensitive to terrestrial acidification. Source: US EPA, 2011c.

The secondary standard protects against welfare effects (e.g., impacts on vegetation, crops, ecosystems, visibility, climate, man-made materials, etc.). Currently, the primary standard is 75 ppb averaged over an eight-hour period, or 120 ppb averaged over a one-hour period, with the secondary standard the same as the primary standard (US EPA, 2011a). Long-term trends in O_3 concentrations across the United States reflect notable decreases of approximately 29% in the second highest one-hour O_3 concentrations from 1980–2003, and of about 21% in the fourth highest eight-hour O_3 concentration during the same time period (see Figure 3.19). However, the effects of rising background O_3 concentrations (Vingarzen et al., 2004) and worsening chronic O_3 concentrations are uncertain in relation to ecosystem effects, since most experimental studies have used fumigation profiles that mimic episodic O_3 peaks.

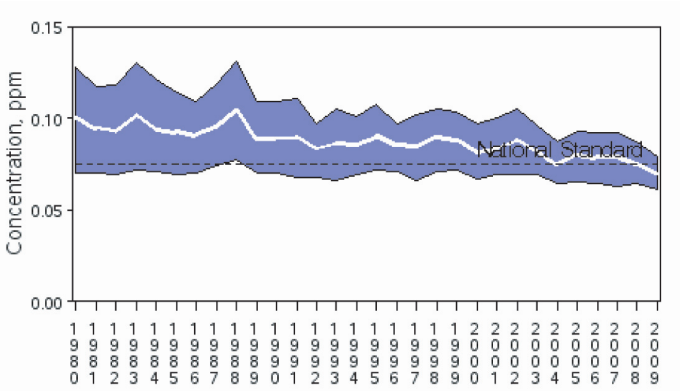

Figure 3.19 | Long-term trends in O_3 concentrations for the United States (1980–2003), based on 255 sites, represented as the fourth highest eight-hour O_3 concentration, with a 30% decrease in national average. Source: US EPA, 2011a.

The ecological effects of O_3 appear to be widespread across North America, based on biomonitoring studies and forest health surveys (US EPA, 2011b). The majority of existing experimental evidence comes from biomonitoring and Open Top Chamber studies that were conducted in North America under the National Crop Loss Assessment Network Programme (Heck et al., 1988). In recent decades, there has been a shift from chamber-based studies to field-based approaches to assess O_3 impacts. In the United States, such studies have investigated forest trees (aspen, maple, and birch) in Wisconsin (Karnosky et al., 2005) and crops (soybeans) in Illinois (Morgan et al., 2006). These studies tend to confirm the detrimental effects of O_3 exposure on vegetation that were found in chamber studies (King et al., 2005; Long et al., 2005).

Extrapolation of data provided by these site-specific studies to the entire United States suggests serious risk to crops and forests from O_3 pollution. The 'cornbelt' in the United States produces 40% of the world's corn and soybean crops, and this region is already potentially losing 10% of its soybean production to O_3 (Tong et al., 2007). In the United States as a whole, agronomic crop loss to O_3 is estimated to range from 5–15%, with an approximate cost of $3–5 billion annually (Fiscus et al., 2005; US EPA, 2006). Despite the overwhelming evidence that current O_3 concentrations are causing yield losses, new O_3-tolerant crop cultivars are not being developed for a future world that could be characterized by higher levels of O_3 (Ainsworth et al., 2008). In addition to regional-scale O_3 risk assessment based on site-specific experimental data, epidemiologic methods have also been used for crop-loss assessments (Fishman et al., 2010). These studies have found that the influence of O_3 can be detected in regional-level production statistics and field trial data, though damage estimates have been found to differ from those obtained from risk assessments performed using empirically derived dose-response relationships. This may be due to the fact that these methods are most effective in those regions characterized by higher average O_3 concentrations (Fishman et al., 2010), where the ozone signal is strong enough to overcome the influence of confounding variables affecting yield.

For forest trees, O_3 has been shown to cause visible foliar injury, accelerate leaf senescence, reduce photosynthesis, alter carbon allocation, and reduce growth and productivity (Karnosky et al., 2007). These effects vary by forest tree species and genotype (Karnosky and Steiner, 1981). Since the mid 1950s, the San Bernardino mixed coniferous forest in southern California has been exposed to some of the highest O_3 concentrations in North America. This exposure has affected such species as ponderosa and Jeffrey Pines. When concentrations were at their height in the 1970s, annual tree mortalities of between 2–2.5% were being reported (Miller and McBride, 1999). Extrapolation of site-specific experimental data in order to perform regional assessments in the United States provides estimates of annual yield losses equivalent to US$80 million (Muller and Mendelsohn, 2007). Finally, although few experimental studies have been conducted investigating the effects of O_3 on seminatural ecosystems in the United States, those that do exist have highlighted O_3 impacts on the nutritive quality of forage crops (Krupa et al., 2004).

Unlike in North America, in South America there have been relatively few studies on the impact of O_3 on vegetation. There is also a dearth of observational evidence on the subject. The most notable exceptions are studies conducted in Mexico in the vicinity of Mexico City. These studies have found evidence of visible foliar injury occurring on forest species, especially in the Valley of Mexico and in Desierto de los Leones National Park (Hernandez and de Bauer, 1984; Hernandez and de Bauer, 1986).

3.2.4.3 Africa

Energy supply and demand in Africa is extremely heterogeneous. For example, northern Africa is a major supplier of oil and gas, while in sub-Saharan Africa more than 70% of the energy demand is met by biomass, mostly from wood and charcoal. (see Chapters 19 and 23 for discussions on energy access issues in Africa). Wood, including charcoal, is the most environmentally detrimental biomass energy source, as it leads to considerable deforestation (Okello, 2001), which is one of the most pressing environmental problems faced by many African nations. Forests cover about 22% of the region, but they are disappearing faster than anywhere else in the world (FAO, 2005). Many sub-Saharan African countries have suffered depletion of more than three quarters of their forest cover (Energy Information Administration, 2000). Africa lost 10.5 % of its forests during the 1980s. It is estimated that if current trends continue, many areas, especially those in the Sudano-Sahelian belt, will experience a severe shortage of fuelwood by 2025 (Energy Information Administration, 2000). It should also be noted that producing and using charcoal is less efficient than using fuelwood directly and leads to forest depletion in rural areas providing fuel to cities (WHO, 2002). Deforestation also causes other problems, such as increased erosion and loss of biodiversity, and has contributed to desertification. Other environmental impacts directly associated with energy systems in Africa include atmospheric emissions from gas 'flaring' and impacts of large-scale hydropower.

Climate Change Environmental Impacts

Although Africa's contribution to global GHG emissions is only about 3%, the continent is more vulnerable than many of the world's regions to the impacts of climate change (Davidson et al., 2007). This vulnerability stems from the fact that, on average, Africa is hotter and drier than most other regions of the world and has less dependable rainfall. Moreover, Huang et al. (2009) show a large-scale effect of aerosols on precipitation in the West African monsoon region. They report a statistically significant precipitation reduction associated with high aerosol concentrations near the coast of the Gulf of Guinea from late boreal autumn to winter. Aerosols originate from various African sources. For example, large quantities of desert dust and biomass-burning smoke are emitted during much of the year across the African continent.

Climate change and variability have the potential to impose additional pressures on water availability, water accessibility, and water demand in Africa (Boko et al., 2007). The population at risk of increased water stress due to climate change is projected to be 75–250 million and 350–600 million people by the 2020s and 2050s, respectively (Arnell, 2004). The impact on water resources is likely to be greatest in northern and southern Africa. In eastern and western Africa, however, more people will be likely to experience a reduction in water stress (Arnell, 2006). In the future, climate change may become a contributing factor to conflicts, particularly those concerning water scarcity (Fiki and Lee, 2004).

It has been estimated by Mendelsohn et al. (2000) that by 2100, parts of the Sahara are likely to emerge as the most vulnerable to climate change, showing likely agricultural losses of between 2–7% of GDP. Western and central Africa are also vulnerable, with impacts ranging from 2–4% of GDP. By contrast, it's estimated that northern and southern Africa will experience losses of 0.4–1.3% GDP.

It is predicted that a significant decrease in the extent of suitable rain-fed land and production potentials for cereals will occur by the 2080s as a result of climate change. Furthermore, for the same projection and time horizon, the area of semiarid land in Africa could increase by 5–8%. southern Africa would be likely to experience a notable reduction in maize production under possible increased El Niño/La Niña-Southern Oscillation (ENSO) conditions (Stige et al., 2006). In some countries, additional risks that could be exacerbated by climate change include greater erosion, deficiencies in yields from rain-fed agriculture of up to 50% during the 2000–2020 period, and reductions in the length of the crop-growing season (Agoumi, 2003). Other agricultural activities could also be affected by climate change and variability, including changes in the onset of rainy days and the variability of dry spells (Reason et al., 2005).

It has been suggested that climate change will have a range of impacts on terrestrial and aquatic ecosystems. For example, two climatic-change scenarios used to assess the sensitivity of African mammals in 141 national parks in sub-Saharan Africa suggest that climate change will have an impact on species diversity. Assuming no migration of species, Boko et al. (2007) projected that 10–15% of the species will fall within the International Union for Conservation of Nature (IUCN) Critically Endangered or Extinct categories by 2050, a figure that will increase to 25–40% by 2080. Assuming unlimited species migration, the results were less extreme, with these percentages dropping to approximately 10–20% by 2080.

In Africa, highly productive ecosystems (mangroves, estuaries, deltas, lagoons, and coral reefs), which form the basis for important economic activities such as tourism and fisheries, are located in the coastal zone. The projected rise in sea-level will have significant impacts on the coastal megacities of Africa because of the concentration of poor populations in areas that are especially vulnerable to such changes (Klein et al., 2002; Nicholls, 2004). By 2080, across a range of SRES scenarios and climate change projections, three of the five regions shown to be at risk of flooding in coastal and deltaic areas of the world are located in Africa (Nicholls and Tol, 2006). Sea-level rise, combined with increases or decreases in rainfall, will alter the penetration of salt water into estuaries and could induce overtopping and even destruction of the low barrier beaches that limit the coastal lagoons, while changes in precipitation could affect the discharges of rivers feeding them. These changes could also affect lagoonal fisheries and aquaculture (République de Côte d'Ivoire, 2000).

The Indian Ocean islands could also be threatened by potential changes in the location, frequency, and intensity of cyclones, while East African coasts could be affected by potential changes in the frequency and intensity of ENSO events and coral bleaching (Klein et al., 2002). Coastal agriculture (e.g., plantations of palm oil and coconuts in Benin and Côte d'Ivoire, shallots in Ghana) could be at risk of inundation and soil salinization. In Kenya, losses for three crops (mangoes, cashew nuts, and coconuts) could cost almost US$500 million for a 1 meter sea-level rise (Republic of Kenya, 2002). In Guinea, between 130–235 km^2 of rice fields (17–30% of the existing rice field area) could be lost as a result of permanent flooding, depending on the inundation level considered (between 5–6 m) by 2050 (République de Guinée, 2002). In Eritrea, a 1 meter rise in sea-level could cost over US$250 million, as a result of the submergence of infrastructure and other economic installations in Massawa, one of the country's two port cities (State of Eritrea, 2001). These results confirm previous studies stressing the great socioeconomic and physical vulnerability of settlements located in marginal areas.

Initial assessments show that several regions in Africa may be affected by different impacts of climate change (Figure 3.20). Such impacts may further constrain attainment of the Millennium Development Goals in Africa.

Air Quality Environmental Impacts

Increased activities in key social and economic sectors (see Table 3.1) are contributing significantly to air pollution in Africa. Unsustainable patterns of use and supply of energy resources by industry, transport, and household sectors have been particularly important as sources of indoor and outdoor air pollutants. Generally, emission levels of NO_2 and SO_2 have increased significantly in many African countries due to the region's industrial activity. In addition, about 1.8 $MtSO_2$/yr are emitted from electricity generation alone (UNEP, 2006). However, Table 3.1 also shows the significant contribution to PM, NMVOCs, NO_x, and CH_4 pollution resulting from agricultural activities (i.e., not associated with energy systems).

Africa's rate of urbanization is the highest in the world. The rate is increasing rapidly, with urbanization rates in sub-Saharan Africa generally in excess of 4% (Clancy, 2008). This results in rapidly increasing energy use and pollutant emissions from industry, motor vehicles, and households, including SO_x, CO_2, and NO_x, as well as PM and other organic compounds (UNEP, 2006). The transportation sector is increasingly being recognized as the highest polluter in key African cities such as Cairo, Nairobi, Johannesburg, Cape Town, Lagos, and Dakar (UNEP, 2006). The transport systems in these cities are emitting tonnes of air pollutants, mainly NO_x, PM, and VOCs. Some of the challenges related to transportation are the use of old vehicles without emission controls; rapidly increasing fleets; an increase in two- and three-wheeler vehicles with 'dirtier' two-stroke engines; absent or improper vehicle maintenance; lack of cleaner burning fuels; and absent or poor regulatory frameworks for vehicle emissions and their enforcement (Schwela, et al., 2007). In addition, inadequate urban planning and poor road networks have led to traffic congestion in most African cities, with impacts on fuel wastage and air pollution. Traditional cooking is also a significant emitter of CO_2, CO, and NO_x (UNEP, 2006). Charcoal production emits significant levels of CH_4, CO, and other products of incomplete combustion and PM (UNEP, 2006).

However, most African countries do not have monitoring networks to measure air pollutants. Therefore, no comparisons of air quality can be made at the subregional level. Recognizing such limitations, the Air Pollution Information Network for Africa (APINA) has identified the lack of reliable emission inventories, the lack of experience in the use of atmospheric models, and the lack of data on measured impacts as important

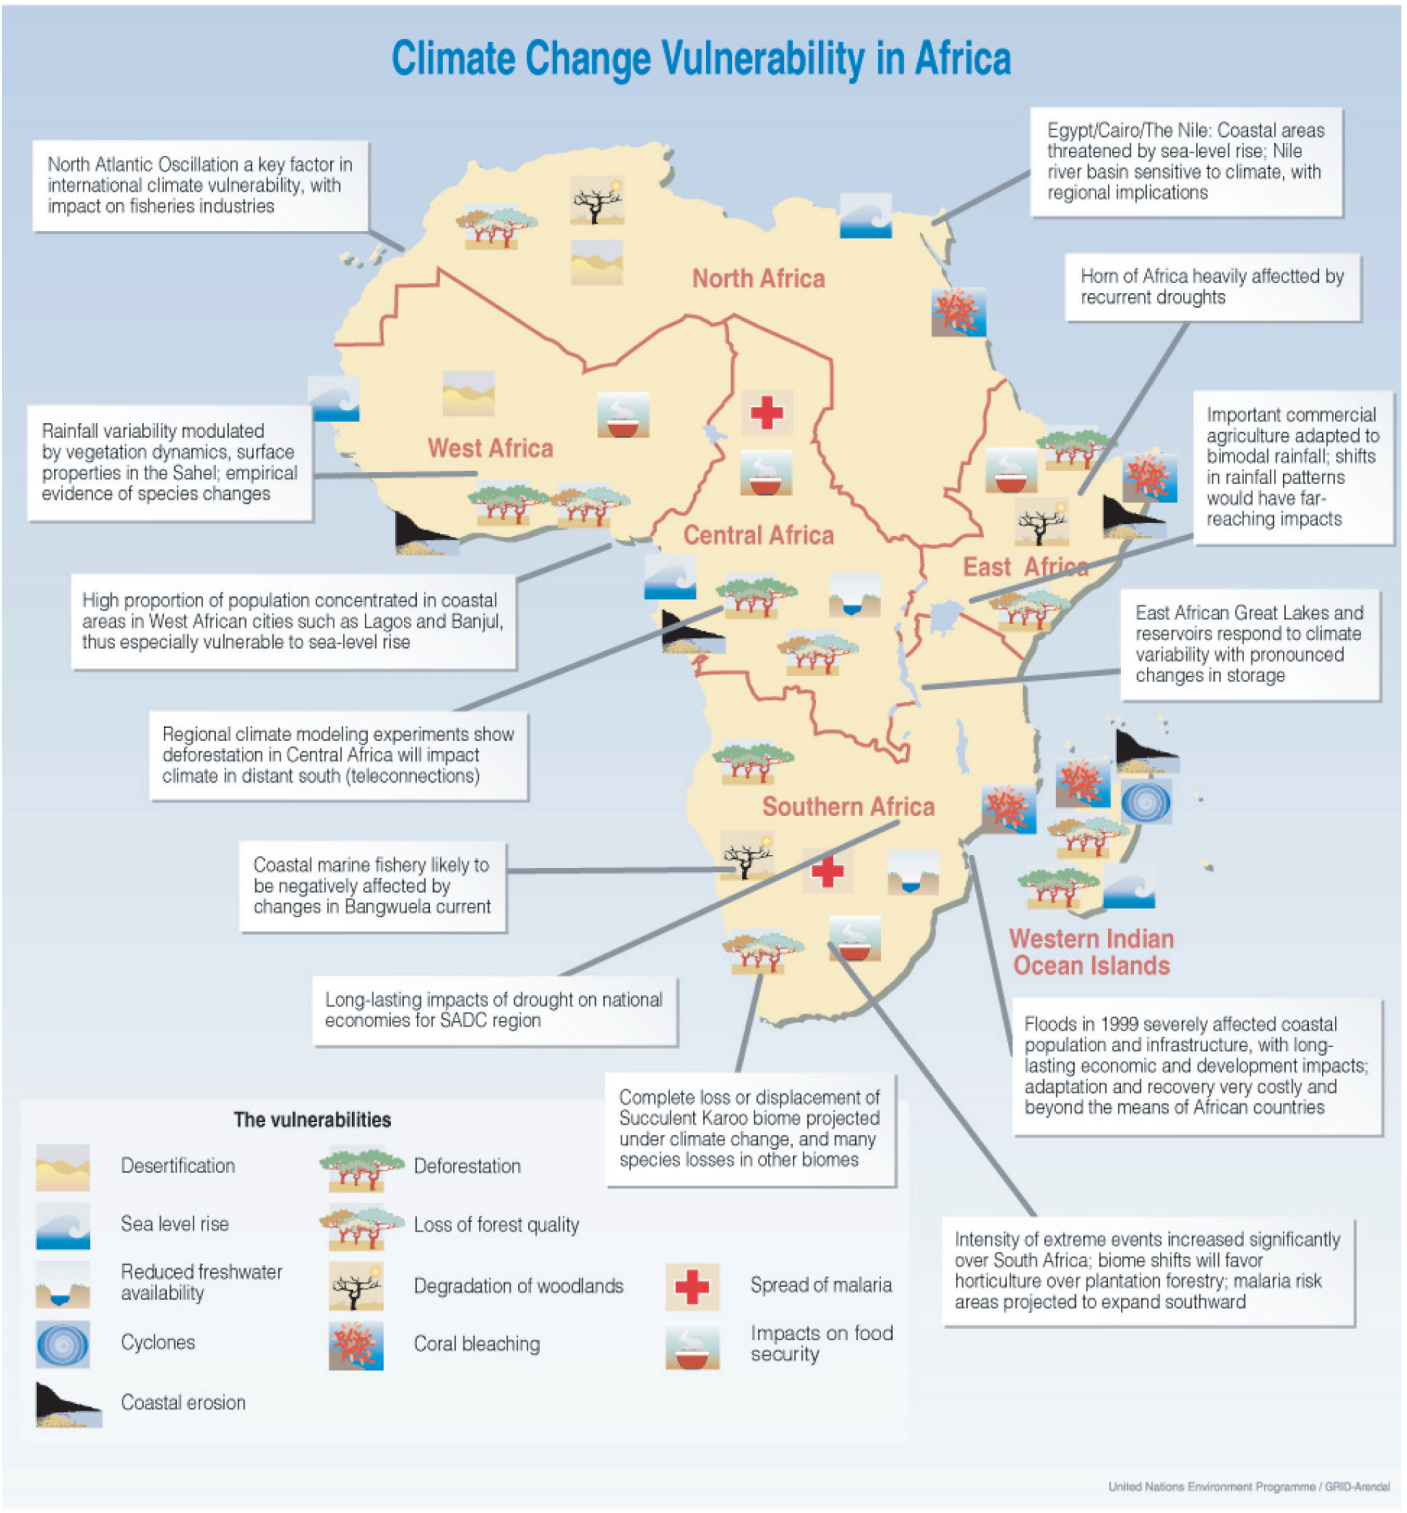

Figure 3.20 | The vulnerability of different African regions to the multiple stresses likely to result from climate change. These impacts include desertification, sea-level rise, reduced freshwater availability, cyclones, coastal erosion, deforestation, loss of forest quality, woodland degradation, coral bleaching, the spread of malaria, and impacts on food security. knowledge gaps to understanding the status of air quality across Africa (UNEP, 2006). Other challenges include weak national energy policies as well as the lack of local air-pollution exposure data. Such data would be necessary to establish air-quality standards that could be used to drive policy making targeted at reducing emissions. At the regional level, APINA and UNEP, together with other global air pollution institutions, have facilitated subregional agreements on air pollution that include the Lusaka Agreement (2008) – Southern African Development Community Regional Policy Framework on Air Pollution; the Eastern Africa Regional Framework Agreement on Air Pollution (Nairobi Agreement–2008); and the West and Central Africa Regional Framework Agreement on Air Pollution (Abidjan Agreement–2009). These agreements detail the actions that are required to reduce air pollution, including emissions from energy use, but the financial means and political will to implement them are still limited. Such policy processes will be important, given the variety of the proved energy potential that exists in Africa. At the global level, most African countries are signatories to the UNFCCC and produce national communications that are GHG inventories. However, they do not produce inventories for the other pollutants.

Acidification and Eutrophication

Africa has many ecosystems with a very high biodiversity value and which provide important ecosystems services. There is potential for sensitive ecosystems to be detrimentally affected by acidifying and eutrophying deposition. However, further research is required in this area to assess the full extent of ecosystem damage.

Acidification is potentially a problem for sensitive terrestrial and aquatic ecosystems downwind of major emission sources of SO_x and NO_x. One such sensitive ecosystem is in Mpumalanga on the Highveld of South Africa, where there are eight coal-fired power stations (Josipovic et al., 2010). A concentration, distribution, and critical level exceedance assessment of SO_2, NO_2, and O_3 in South Africa (Josipovic et al., 2010) shows that some critical levels for vegetation are only exceeded in the central area of the South African industrial Highveld where emission sources are high. Pollutant concentrations are below the critical thresholds for environmental damage in remote areas, including the sensitive forested regions of the Drakensberg escarpment. However, it is possible that critical loads for acidification may be exceeded in areas with sensitive soils and higher rates of total deposition (Fey and Dodds, 1998). There are also soils that are potentially sensitive to acidic deposition across western and central Africa, but deposition levels of S and N are still relatively low in these areas (Kuylenstierna et al. 2001), although they are projected to increase by 2030 (Dentener et al., 2006).

It is thought that between 2000 and 2030, deposition levels in Africa are likely to increase, in part due to increased intensity in the use of fossil fuel to meet increasing energy demand; NO_x emissions in sub-Saharan Africa resulting from fossil fuel combustion are already estimated to be 14 Mt/yr (Selman and Greenhalgh, 2009). Such enhanced deposition may seriously affect the integrity of protected areas, especially those in west and central Africa.

Ground-level Ozone (O_3)

Sunlight and heat stimulate O_3 formation. Therefore, the potential for elevated O_3 is high in many areas of Africa because of the combination of solar radiation and the high emission of precursors such as NO_x and VOCs, from both human activities and natural sources. There is a sharp increase of O_3 with altitude in the tropics, leading to a risk of vegetation damage in high mountainous regions (UNEP, 2006).

Studies in Africa have shown that current-day ambient air pollution concentrations can significantly damage human health, crops, local vegetation, and other materials. Ozone injury to turnips has been

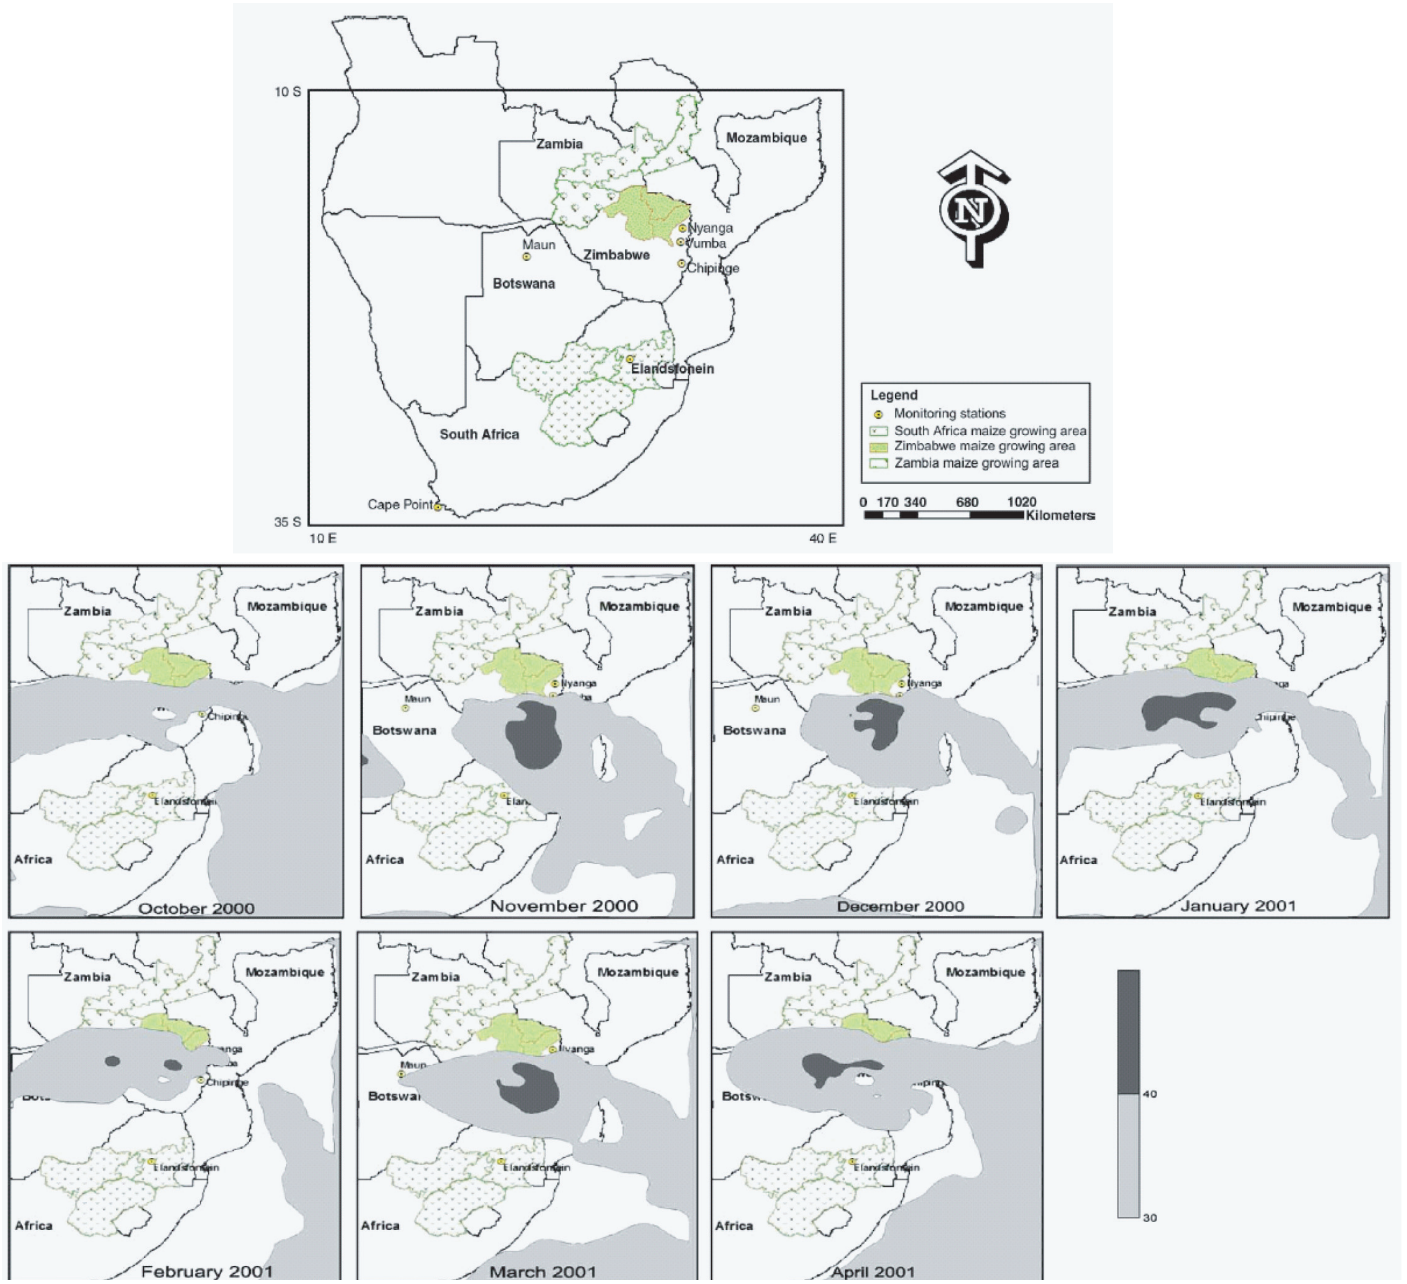

Figure 3.21 | Map of southern Africa showing the modelling domain, maize-growing regions, and locations of O_3-monitoring sites; the series of maps shows average daylight O_3 concentrations in ppb over the main maize-growing area in southern Africa for a five-day period (10th-14th) in each of the months from October 2000 to April 2001. Source: van Tienhoven et al., 2006.

reported in Egypt (Hassan et al., 1995). In parts of Africa, predicted increases in global background concentrations of O_3 combined with trends of increased emissions of O_3 precursors suggest that current and future O_3 impacts on crops and forests in these areas may be significant (Ashmore, 2005). Modelling studies based on 'current legislation' emission projections performed by the Royal Society (2008) suggest that O_3 concentrations are likely to increase in many regions by the year 2050, particularly over landmasses in the tropics, Asia, and Africa, largely because of climate change.

Even under current-day conditions, O_3 may be posing a threat to ecosystems across Africa. For example, photochemical modelling studies have suggested that levels of O_3 concentration that have resulted in impacts in Europe may be occurring in parts of Botswana, South Africa, and Zimbabwe in southern Africa (Figure 3.21). In addition, the maize-growing areas at risk from drought are similar to those modelled to be at risk from elevated O_3 concentrations (USAID, 2002). Therefore, maize may be suffering multiple stresses resulting from O_3 and drought, which may compromise crop productivity. Such stress may be magnified in the

future, as increased air pollutant emissions lead to higher and more persistent O_3 concentrations. Additional studies are required to fully understand the potential threat posed by these combinations of stress.

3.2.4.4 Asia

Asia is experiencing rapid population growth. China and India alone account for approximately 2.5 billion of the global population; according to UN estimates (2008), this figure will have risen to over 3 billion by 2030. This population growth has been closely matched by strengthening economies in many of the most rapidly developing Asian nations. For example, over the past five years (2005–2010), China's annual GDP growth rate has been between 9–13%, while India's growth rate has fluctuated between 5–9 % (UN, 2011). This growth has in part been made possible by increased access and utilization of fossil fuels (van Ardenne et al., 1999), as evidenced by the present energy mix for the Centrally Planned Asia and South Asia regions. In these regions, approximately 85% of energy demand is met by fossil fuels, with coal being the principle energy source (summarized from the GEA database).

This heavy reliance on coal and other fossil fuels translates into substantial CO_2 emissions, with over 1600 MtC/year under current day (2005) conditions (as estimated from the GEA database). Such coal use also results in substantial emissions of SO_2. For example, in 2005 China emitted 25.5 $GtSO_2$, reversing a decreasing trend in SO_2 emissions that was evident prior to 2002 (Chan and Yao, 2008); this has implications for acidification across many parts of the country. In addition to increases in CO_2 and SO_2 emissions, NO_x emissions have also increased, due to combustion of fossil and biomass fuels, especially in the transport, industrial, and power-generation sectors (van Ardenne, 1999). The resulting increases in atmospheric NO_x concentrations will hasten environmental degradation caused by acid deposition, eutrophication, and ground-level O_3. The resulting high levels of air pollution across the Asian region are not a new phenomenon; atmospheric emissions have been steadily increasing over the past few decades, as countries in the region have experienced rapid industrialization and economic growth (Ohara et al., 2007). Even with this increase in economic growth in many Asian countries, large sectors of the population remain deprived of basic facilities and amenities. For example, around 500 million people still do not have access to electricity, and many more lack access to clean drinking water and modern energy fuels like liquid petroleum gas (LPG) and kerosene to meet their domestic cooking and lighting needs. This state of affairs has consequences for both indoor and outdoor pollution and human health (WHO, 2006b; for more information, see Chapter 4). Additionally, many poor people are reliant on agriculture for their livelihoods, and hence are also at risk from the threat of air pollutants that reduce the quality and quantity of crops as well as from droughts that are becoming more frequent with the onset of climate change.

Climate Change Environmental Impacts in Asia

The IPCC Fourth Assessment reported the increasing intensity and frequency of extreme weather events in Asia over the last century and into the 21st century (Cruz et al., 2007). It is likely that climate change will impinge on the sustainable development of most of the developing countries of Asia, as it compounds the pressures on natural resources and the environment associated with rapid urbanization, industrialization, and economic development.

Climate change is expected to affect forest expansion and migration, and exacerbate threats to biodiversity resulting from land-use, cover change, and population pressure in most of Asia (Cruz et al., 2007). Increased risk of extinction for many flora and fauna species in Asia is likely as a result of the synergistic effects of climate change and habitat fragmentation. In North Asia, forest growth and a northward shift in the extent of boreal forest is probable; the frequency and extent of forest fires in North Asia may well increase in the future. In southeast Asia, extreme weather events associated with El Niño were reported to be more frequent and intense in the past 20 years (Cruz et al., 2007). Significantly longer heat-wave duration has been observed in many countries of Asia, as indicated by pronounced warming trends and several cases of severe heat-waves. Generally, the frequency of occurrence of more intense rainfall events in many parts of Asia has increased, causing severe floods, landslides, and debris and mud flows, while the number of rainy days and the total annual amount of precipitation has decreased. However, there are reports that the frequency of extreme rainfall in some countries has exhibited a decreasing tendency. Increasing frequency and intensity of droughts in many parts of Asia are attributed largely to a rise in temperature, particularly during the summer and normally drier months, and during ENSO events. Recent studies indicate that the frequency and intensity of tropical cyclones originating in the Pacific have increased over the last few decades. In contrast, cyclones originating from the Bay of Bengal and Arabian Sea have decreased since 1970, but their intensity has increased. Damage caused by intense cyclones originating in both areas has risen significantly, particularly in India, China, Philippines, Japan, Vietnam, Cambodia, Iran, and the Tibetan Plateau.

Marine and coastal ecosystems in Asia may well be affected by sea-level rise and temperature increases (Cruz et al., 2007). Projected sea-level rise is very likely to result in significant losses of coastal ecosystems, and a million or so people along the coasts of south and southeast Asia may be at risk from flooding. Sea-water intrusion due to sea-level rise and declining river runoff is likely to increase the habitat of brackish water fisheries. Coastal inundation could seriously affect the aquaculture industry and infrastructure, particularly in heavily populated megadeltas. The stability of wetlands, mangroves, and coral reefs around Asia is likely to be increasingly threatened. Risk analysis of coral reefs suggests that 24–30% of the reefs in Asia may be lost during the next 10–30 years (Wilkinson, 2004), unless the stresses are removed and relatively large areas are protected.

Rapid thawing of permafrost and a decrease in the depths of frozen soils, due largely to rising temperatures, have threatened many cities and human settlements. They have led to an increase in the frequency of landslides, a degeneration of some forest ecosystems, and an increase in lake-water levels in the permafrost region of Asia (Cruz et al., 2007). In

drier parts of Asia, melting glaciers account for over 10% of freshwater supplies. Glaciers in Asia are melting faster in recent years than before, as reported in Central Asia, Western Mongolia, and Northwest China, particularly the Zerafshan glacier, the Abramov glacier, and the glaciers on the Tibetan Plateau (Pu et al., 2004). Mudflows and avalanches have increased as a result of the rapid melting of glaciers, glacial runoff, and the frequency of glacial lake outbursts (WWF, 2005). A recent study in northern Pakistan, however, suggests that glaciers in the Indus Valley region may be expanding, due to increases in winter precipitation over western Himalayas over the past 40 years (Archer and Fowler, 2004).

The production of rice, maize, and wheat during the past few decades has declined in many parts of Asia, due to increasing water stress. This stress can be attributed in part to increasing temperatures, the increasing frequency of El Niño, and a reduction in the number of rainy days. In a study at the International Rice Research Institute, the yield of rice was observed to decrease by 10% for every 1°C increase in growing-season minimum temperature (Peng et al., 2004). A decline in potentially good agricultural land in East Asia and substantial increases in suitable areas and production potentials in currently cultivated land in Central Asia have also been reported (Fischer et al., 2002). Climate change could make it more difficult to step up agricultural production to meet the growing demands in Russia and other developing countries in Asia.

In Asia, water shortages have been attributed to rapid urbanization and industrialization, population growth, and inefficient water use, which are aggravated by changing climate and its adverse impacts on demand, supply, and water quality (Cruz et al., 2007). Overexploitation of groundwater in many countries of Asia has resulted in a drop in its level, leading to ingress of sea water in coastal areas, making the subsurface water saline. India, China, and Bangladesh are especially susceptible to increasing salinity of their groundwater as well as surface water resources, especially along the coast, due to increases in sea-level as a direct impact of global warming. Increasing sea-level by 0.4–1.0 m can induce saltwater intrusion 1–3 km farther inland in the Zhujiang estuary. Increasing frequency and intensity of droughts in the catchment area will lead to more serious and frequent salt-water intrusion in the estuary and thus deteriorate surface and groundwater quality.

Air Quality Environmental Impacts in Asia

Eutrophication

Recent global modeling studies suggest that N deposition related to NO_x and NH_3 emissions are now as high in some parts of south, southeast, and southern East Asia as they are in Europe and North America (Figure 3.22), with much of the NH_3 emission coming from agricultural sources such as cattle rearing. There is growing scientific consensus that eutrophication impacts will be considerable in Asia, although local evidence is only just starting to emerge (Phoenix et al., 2006). For example, in China, manipulation experiments suggest that N deposition has the potential to influence the species richness of the understory of temperate and tropical forests. The UN Convention on Biological Diversity has identified N deposition as an indicator of a threat to biodiversity in many Asian countries. In addition, effects on biodiversity have been linked to the type of forest decline that has occurred in some areas of China. This decline is the result of the direct effects of SO_2, via extremely acidic mist or rain events, and the effects of soil acidification, which is caused by S and N deposition as discussed in more detail in the following sectors.

Acidification

The extensive use of coal as a primary energy source across Asia has led to concerns over environmental degradation resulting from acidification. The main sectors contributing to SO_2 emissions are coal-fired electricity production and industry, which are responsible for approximately 45% and 36%, respectively, of SO_2 emissions (Hicks et al., 2008). However, other pollutants, especially NO_x and NH_3, are also involved in acidification via their transformations in the atmosphere and soil. Acid deposition is mainly a problem in the southern and southwestern regions of East Asia, where neutralization by alkaline desert dust in the atmosphere is relatively low. These acidifying emissions have resulted in parts of East Asia being identified as the third largest acid rain-prone region in the world. The variability in susceptibility to acid rain evident across this East Asian region would appear to exist across the whole of Asia, with modelling studies indicating that soil acidification effects are unlikely to be widespread, due to the insensitivity of soils and high concentrations of alkaline dust in the atmosphere. According to Hicks et al. (2008), areas at risk of acidification effects over the next 50 years are mainly restricted to areas of southern East and southeast Asia (Figure 3.23).

Various attempts have been made to estimate the societal costs of air pollution and acid rain in China. In 2004, the former Chinese State Environmental Protection Administration estimated the economic loss due to negative effects of acid rain on crops to be US$4.6 billion (World Bank, 2007). Although such estimates are highly uncertain, they make clear that the economic benefits of tackling acid rain may be considerable.

Policies to control SO_2 emissions in East Asia began in the early 1990s, when the concept of acid rain control zones was developed as the main framework for setting priorities on acid rain reduction policy (Shi et al., 2008). Mitigation actions focused on establishing emissions standards for coal- and oil-fired power plants, targeting the use of low-sulphur coals, the relocation of coal-fired power plants to rural areas, the installation of de-sulphurization technologies, increased chimney stack height, the closing of small coal-fired generating units and polluting industries, and the shifting to cleaner energy sources (Cofala and Syri, 1998). Intergovernmental cooperation has also been established through the Acid Deposition Monitoring Network in East Asia, or EANET (Tsunehiko et al., 2001). These measures, along with the economic recession of the late 1990s, resulted in significant decreases in SO_2 emissions. However, coal consumption continued to increase in East Asia, largely due to the continued expansion of electricity generation and heat provisioning coal-fired power plants (e.g., Fang et al., 2008).

Ground-level Ozone (O_3) and Food Security

The air pollutant that is arguably of greatest concern due to its occurrence at elevated concentrations across large parts of rural Asia is ground-level O_3 (Emberson et al., 2009). Experimental evidence collected in Asia over the past few decades provides a strong indication of the threat posed by O_3 to agricultural production, with staples such as wheat, rice, and beans commonly showing substantial yield losses of 10–30% under ambient pollution concentrations (Emberson et al., 2009). Modelling studies provide an indication of the magnitude and geographical extent of O_3 risk to crop production. These studies indicate that the Indo-Gangetic Plain, one of the most important agricultural regions in the world, is particularly at risk from high O_3 concentrations. This potentially has important implications for agricultural production (Van Dingenen et al., 2009). For example, it is possible that O_3 may be a significant contributing factor to the yield gap that currently exists across much of Asia. It is also possible that O_3 may have played a role in recent reductions in the growth rate in yield of key staple crops, which have recently been a cause for concern across much of south Asia (Emberson et al., 2009).

Economic loss estimates that have been conducted across Asia suggest substantial effects due to yield losses caused by O_3. Estimates from East Asia suggest annual losses of US$5 billion, based on four key crops – wheat, rice, soybean, and maize (Wang and Mauzerall, 2004). A global modelling study that translated production losses (see Figure 3.24, which shows global production loss estimates for wheat) into total global economic damage for the same four commodities, using world market prices for the year 2000, estimated an economic loss of US$16–30 billion per year. About 40% of this damage was found to occur in parts of China and India. For those Asian countries with economies largely based on agriculture, the O_3-induced damage was estimated to offset a significant portion (20–80%) of the increase in GDP in the year 2000 (Van Dingenen et al., 2009).

These modelling studies have relied on North American or European dose-response relationships to assess the yield losses caused by O_3, since equivalent Asian relationships do not exist. However, recent comparisons of Asian and North American O_3-response data strongly suggest that Asian crops (in this instance wheat, rice, and beans) and cultivars may well be more sensitive to O_3 concentrations when growing under Asian conditions (i.e., under Asian climates, on Asian soils, and under Asian management practices). This implies that current economic loss estimates may have substantially underestimated the yield, and subsequent production losses, in the region (Emberson et al., 2009).

The indirect effects that air pollutants may have on the climate system should also be considered within the context of agriculture. Work that

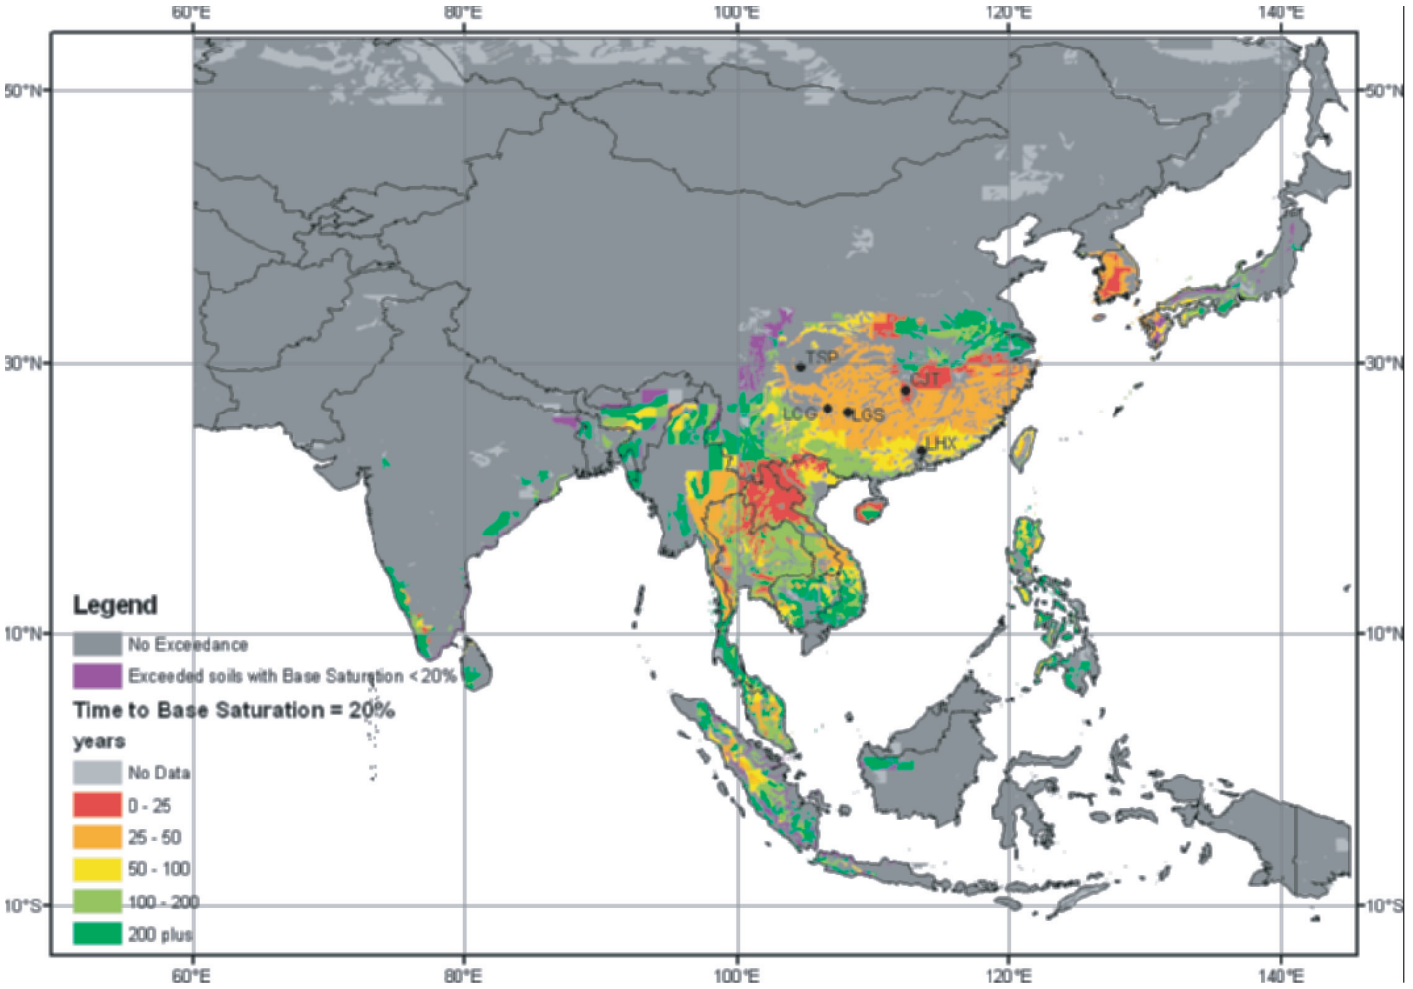

Figure 3.23 | Time development of soil acidification damage according to a modelling study for Asia using the best available data for soil and deposition parameters and deposition estimates obtained using a more pessimistic emission scenario (IPCC SRES A2) for 2030. The model calculates the time it takes for the neutralizing capacity of the soil (expressed as base saturation) to be reduced to a level where acidification effects are observed (i.e., approximately 20% base saturation). Source: Hicks et al., 2008.

has focused on understanding the role of ABCs on climate provides a particularly good example of such effects. The surface dimming (reduction in sunlight reaching the Earth's surface) associated with ABCs, described earlier in this chapter, is thought to impact agricultural yields in Asia, with estimates suggesting that 70% of the crops grown in China may have their yields suppressed by 5–30%. In addition, yields may be impacted through alterations to monsoon rainfall (UNEP, 2008). In particular, BC may play an important role in causing monsoonal shifts, as it dims the surface and warms the lower atmosphere, producing effects on the vertical atmospheric temperature profile, evaporation, atmospheric stability, and strength of convection. These changes in precipitation will also impact agricultural management and productivity across the region.

3.2.4.5 Polar Regions

The Earth's polar regions, the areas of the globe surrounding the North and South Pole, are dominated by polar ice caps. The fact that both of these polar regions are so remote from large-scale industrial activities might suggest that they would remain as pristine environmental strongholds. However, over recent decades the particular sensitivity of these regions to environmental degradation and global environmental change has been striking. Examples of such degradation have involved the global-scale transport and accumulation of persistent organic pollutants (POPs) within ecosystems, the depletion of the stratospheric O_3 layer, the transport of radionuclide material and, most recently, observations of the occurrence of enhanced climate change above the global mean. In addition, the lack of obvious sovereignty of the Arctic region, coupled with this region's wealth of natural resources, threatens to lead to further exploitation of a region that is unprotected by international treaty. Here, the potential of the Arctic as a supply of fossil fuels and the increased demand for energy is of particular relevance. These issues are discussed in the following sections to highlight the possible consequences of unrestrained energy supply and demand for these sensitive regions.

The Sensitivity of the Polar Regions

In recent decades, the particular sensitivity of the polar regions has become worryingly apparent. One of the best examples of this is the

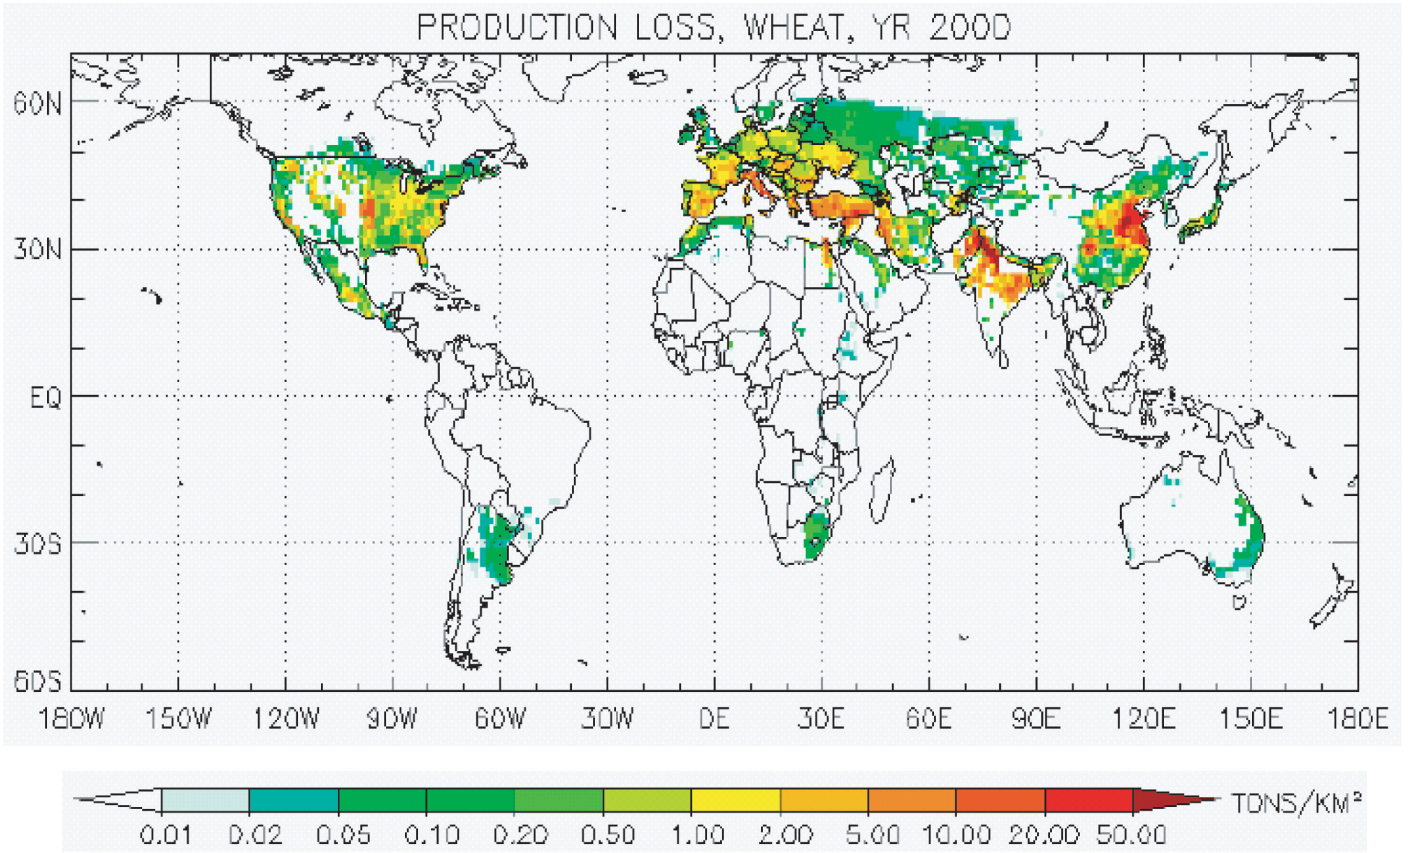

Figure 3.24 | Average wheat crop production losses due to O_3 estimated for the year 2000 using European and North American concentration-based exposure-response relationships. Source: Van Dingenen et al., 2009.

bioaccumulation and biomagnification of POPs in species and ecosystems of these regions. These processes refer to the accumulation of certain long-lived substances such as pesticides or heavy metals as they move up the food chain through a combination of ecosystem contamination and predation, concentrating the substances in tissues or internal organs. The first evidence of the occurrence of these processes was the measurement of the pesticide DDT and its derivatives in Adélie penguins in Antarctica in the 1960s (Sladen et al., 1964). This provided one of the first demonstrations of how human-made substances could spread and affect ecosystems on a global scale. The polar regions are particularly vulnerable to such processes, since their cold climate prevents the breakdown of contaminants, exacerbating their effects.

Another example of polar region sensitivity is that posed by the potential of ozone-depleting substances (ODS) to deplete the stratospheric O_3 layer, which was first recognized in 1974 (Molina and Rowland, 1974). Stratospheric O_3 depletion is important, because the O_3 layer in the stratosphere keeps 95–99% of the sun's ultraviolet-B radiation (UV-B) from striking the Earth. Consequences of increased levels of UV-B include genetic damage, eye damage, and damage to marine life. A decade after identification of the problem in the mid-1980s, the discovery of the O_3 hole over Antarctica (Farman et al., 1985) and the subsequent attribution to ODS (Soloman et al., 1986) further heightened concern for the O_3 layer. This scientific evidence resulted in the establishment of the Montreal Protocol in 1987, which has led to successful restrictions on ODS. These restrictions have meant that net ODS production, consumption, and subsequent emissions have decreased. However, the long atmospheric lifetimes of many ODSs, particularly the chlorofluoro carbons, mean that the mixing ratios of ODS in the stratosphere are decreasing relatively slowly (Velders et al., 2007). Once again, the particular vulnerability of the polar regions is a consequence of their climatic characteristics. Atmospheric circulation patterns, coupled with the absence of solar radiation during the polar winter, allow the buildup of reservoirs of chemical species in the atmosphere. The reintroduction of solar radiation and the concurrent increases in temperature kick-start the photochemical processes that are able to act on the large reservoir of chemicals, allowing rapid destruction of the stratospheric O_3 layer.

Another example of polar sensitivity is that of radionuclide contamination. The Arctic Monitoring and Assessment Programme (AMAP, 2010) reported radionuclide transport to the Arctic, which could be traced back to the nuclear reprocessing facility at Sellafield in the United Kingdom. Discharges of radioactive substances such as Technetium-99 (^{99}Tc), a long-lived product of uranium fission, were found to have been transported by the Atlantic currents to the Norwegian Sea, continuing northwards along the Norwegian coastline to the Barents Sea by the

Norwegian Coastal Current. The Sellafield-to-Barents Sea transport is estimated to take four to five years. In an attempt to avoid similar contamination in the southern polar region, the Antarctic Treaty has declared the region a nuclear-free zone, where nuclear explosions and radioactive waste disposal are forbidden.

The fact that contaminants in water, air, and ecosystems that originate from outside the polar regions can be observed and measured within the region is a critical reminder of the impossibility of confining emissions and their impacts to source regions, regardless of the remoteness of the impacted environment. This points to the need to consider environmental change, and the limits to such change, at the planetary level. In recent years the particular threat posed to the polar regions by climate change has been recognized, as once again these regions seem particularly sensitive when compared to the global mean. The following section describes climate change in the polar regions in more detail, highlighting the physical, socioeconomic, and political considerations that are particularly relevant when considering the sustainability of future global energy systems.

Climate Change in the Polar Regions

Arctic mean temperatures were found to be rising at almost twice the rate of the rest of the Earth. Many parts of the Arctic have seen warming of 2–3°C in the last 50 years alone. In comparison, over the last century GMTs have increased by only 0.6°C (ACIA, 2004).

By 2100, climatologists project an additional mean temperature increase of 5–7°C, with regions closest to the North Pole projected to reach 10–12°C above their current temperatures in the winter months (ACIA, 2004).

Similarly, a number of stations in the Antarctic Peninsula have experienced a major warming over the last 50 years, with temperatures at Faraday/Vernadsky station having increased at a statistically significant rate of 0.56°C/decade over the year and 1.09°C/decade during the winter. Overlapping 30-year-trends of annual mean temperatures also indicate a strong tendency for the warming trend to be greater during the 1961–1990 period compared with 1971–2000 (Turner et al., 2005).

This 'polar amplification,' whereby the rate of regional temperature change far outpaces global changes, is related to a powerful set of thermodynamic and dynamic factors. A driver of this phenomenon is the ice-albedo feedback mechanism, whereby the melting of sea ice in the Arctic caused by warming associated with climate change exposes dark open water or melt ponds on top of ice. This can decrease the albedo (reflectivity of the surface) to between 0.2 for dark melt ponds to 0.6–0.7 for melting multiyear ice, with such effects occurring during the summer, when warming is most acute. In comparison, the albedo of unaffected multiyear ice is high at 0.8–0.9 (Perovich, 2002). The mechanism is a 'positive feedback,' since the absorbed energy resulting from the lower albedo raises the sea and air temperatures, thereby melting even more ice and slowing down the winter refreeze. A phenomenon known as the Arctic haze (see next section) will also contribute to this enhanced warming of the North Polar Region.

Quantitative assessments of the extent of sea-ice melt suggest that sea-ice in September 2007 was half the typical ice extent in the same month between the 1950s-1970s (Stroeve et al., 2008). This area was 23% smaller than the previous ice extent minimum reached in 2005. Arctic ice also has an increased tendency to be younger and weaker. For example, while in 1987 ice older than five years comprised 57% of the central Arctic basin, now it has all but disappeared from this area (Maslanik et al., 2007). In addition, ice thickness has declined by 25% over the last two decades. This appears to be a critical parameter determining sea-ice extent, with evidence suggesting that a threshold may exist below which summer melt potential is greatly enhanced (Holland et al., 2006). The rapid melt of sea ice that has been observed in the Arctic has led some experts to predict that a 'tipping point' will be crossed, resulting in a seasonally ice-free Arctic. Based on observations of the 2007 ice melt, Stroeve et al. (2008) revised earlier projections, suggesting that rapid ice decays in Arctic sea-ice, caused by increases in ocean heat transport to the region, could, with a high degree of probability, realize a seasonally ice-free Arctic Ocean as early as 2030.

The Arctic Haze

The Arctic haze, a visible reddish-brown haze found in the atmosphere at high latitudes, results from the long-range transport of air pollution to the polar regions. This pollution remains in the polar atmosphere due to the slow rate of removal of pollutants in the cold polar air (Shaw, 1995). It was first observed in the 1950s by flight crews on weather reconnaissance missions, but only became public knowledge when Raatz (1984) reanalyzed and published data from these missions (known as the Ptarmigan flights). This reanalysis found that the most frequent reports of the Arctic haze occurred at about 75–80°N during late winter, under clear-sky conditions (Shaw, 1995).

Practically all pollution contributing to the Arctic haze originates from more southerly latitudes (Law and Stohl, 2007); with local pollution sources being small and limited to areas near the Arctic circle. These local pollution sources include volcanic emissions; anthropogenic emissions from urban centers, e.g., Murmansk; and industrial emissions, particularly in the northern parts of Russia, and emissions from the oil industry and shipping (AMAP, 2006). In terms of the long-range transported pollutants, Eurasian emissions are more important than those from North America, due to the closer proximity of Eurasian sources, atmospheric circulation patterns, and the extended distribution of the haze over Eurasia (Law and Stohl, 2007). Some studies have even suggested that Asian dust may be contributing to the Alaskan Arctic haze (Rahn et al., 1981), though this claim has been disputed (Stohl, 2006).

The Arctic haze is important, since it changes the short- and long-term radiation balance in the Arctic. Because large areas are affected, this can have significant effects, even though the concentrations of aerosols found in the Arctic are approximately an order of magnitude lower than

those found in polluted and industrial locations (AMAP, 2006). These aerosols can also affect the physical properties of clouds, which will affect the radiation balance (Garrett et al., 2002). Black carbon will also cause heating in the haze layers (Quinn et al., 2007) and, on deposition to snow and ice, will result in a reduction in surface albedo. The resulting warming may lead to the melting of ice and may be contributing to earlier snowmelts on tundra in Siberia, Alaska, Canada, and Scandinavia (Foster et al., 1992).

In terms of future trends for this pollutant haze, there is evidence that ship traffic is already affecting the summertime Arctic atmosphere; increases have been seen in the deposition of BC from increased shipping following reductions in summer sea-ice (Corbett et al., 2010). The warming of northern latitudes could also cause boreal forest fires to become more frequent, thus increasing pollution transport to the Arctic (Stocks et al., 1998). Finally, the polar dome, which currently presents a barrier to pollution transport in the Arctic, may weaken in the future, as the Arctic continues to warm relatively faster than lower latitudes, allowing more efficient pollution import into the Arctic (Eckhardt et al., 2003).

Energy Issues in the Arctic

The physical changes in the Arctic environment will cause substantial impacts on the regions human populations and ecosystems. However, perhaps more worrying, at least from the point of view of enhancement of the level and rate with which impacts are occurring in the Arctic, are the economic and political implications of these physical changes. Importantly, the physical feedback of ice-melt has realized the potential for transport routes (with the apparent opening of the North West Passage for ice-free navigation which would substantially reduce shipping distance from Europe to Asia) and hence improved accessibility to energy sources (Powell, 2008). Johnson (2010) describes this situation as 'accumulation by degradation' where the previous combustion of fossil fuels generates geophysical changes that are exploited in order to identify, extract, and combust additional hydrocarbons that fuel development and lead to future CO_2 emissions and additional climate change; this process will lead to self-amplifying feedbacks of the geophysical world.

Fuelling the likelihood of such a feedback process are the claims of undiscovered hydrocarbon reserves in the Arctic region. There are estimates that as much as 25% of the World's undiscovered oil and gas lie in the Arctic (AMAP, 2007) though this figure has been contested (Powell, 2010). The US Geological Survey recently completed its first probabilistic assessment of all undiscovered oil and gas deposits of the Arctic Circle. It estimated that of the world's undiscovered resources the region holds 30% of natural gas, 20% of natural gas liquids and 13% of oil (US GS, 2008).

The potential hydrocarbon gains, coupled with climate change-driven ice melt, could substantially reduce the costs associated with hydrocarbon exploration and exploitation, including deep-water exploration and the transport of cargo, drilling equipment, and petroleum, and extend the seasonal period during which such operations are feasible. These activities themselves will cause environmental degradation of the region by increasing the likelihood of oil spills and pollution (Casper et al., 2009).

3.3 Land-use and Energy Systems

Renewable energy sources often require more land than the fossil energy sources that they replace, which means that making energy systems more sustainable can place additional pressures on land-use. The transition towards sustainable energy thus tends to increase land pressures due in part to the fact that current energy systems to some extent substitute nonrenewable resources – fossil and nuclear – for land. It is clear that a critical component of a sustainable energy path – and indeed the sustainable use of natural resources in general – is to use land more effectively in the future, with the recognition that some of that land will have to substitute for the fossil resources that will no longer be available at acceptable levels of economic and environmental costs. Renewable resources that occur on water (e.g., tidal power) or land that is difficult to use for other human needs (e.g., mountain tops) will naturally also become more valuable in the sustainability transition.

In this section, we provide a brief overview on the *quantity* of land associated with energy systems, while of course recognizing that the quality of land-use is just as important, if not more important, than the quantity *per se*. The reason for focusing on the quantity of land required is to provide some rough idea of how priorities might be set where land-use pressures are a key concern. Some explanation and/or examples are also given here, in instances where there are significant qualitative land-use impacts that are obscured by simple quantitative comparisons.

3.3.1 Land-use Changes

Land is essentially always transformed in the initial establishment of any energy system. This transformation can be significant, in that the effects are not easily reversed. In the case of coal, hundreds of years may be needed for recovery or reclamation from the toxic effects of coal mining. In the case of nuclear power, the consequences of a serious accident result in land-use transformation that requires tens of thousands of years for recovery. Consequently, changes in land-use from toxic, nonrenewable resource uses should not be directly compared to land-use changes associated with biological or natural resources.

Indeed, the term 'land-use change' has a special meaning within the context of natural resources and climate, in that it refers to the transition from one type of land-use such as forestry to another, such as agriculture. Although also representing a transformation and involving energy use and GHG emissions, these land-use changes are qualitatively quite different from fossil or nuclear land-use impacts, in that there are generally no toxic effects and the land could potentially be converted back

Table 3.2 | Land-use intensity (LUIs) for various electric power production systems.

Type	Reference capacity (for energy conversion)	Land-use intensity for installed power (km^2/GW)		Land-use intensity for electricity generation (km^2/TWh/yr)		Assumptions and/or type of impact
		low	high	low	high	
Coal	85%	18.6	126.6	2.5	17	Area disturbed by mining
Hydropower	44%	62.2	354.8	16.1	92.1	Area submerged by lake
Biomass electricity	75%	2844	4294	432.9	653.6	Area for growing woody feedstock (willow)
Geothermal	85%	7.5	103.6	1.0	13.9	Area covered by plant and access infrastructure, fragmented habitat
Solar thermal	29%	25.9	51.8	10.2	20.4	Area covered by plant and access infrastructure, fragmented habitat
Solar photovoltaic (PV)	28%	51.8	129.5	21.1	52.8	Area covered by plant and access infrastructure, fragmented habitat
Onshore wind	35%	199.4	242.8	65.0	79.2	Area covered by turbine and access infrastructure, fragmented habitat
Nuclear	91%	3.02	4.78	1.9	2.8	Area covered by plant, as well as area for uranium mining and waste storage

Source: adapted from McDonald et al., 2009.

to its previous use or to some other use, especially if the previous uses were agricultural. In this respect, the impacts of the sheer quantity of land-use change associated with agriculture or bioenergy are tempered somewhat by the fact that they can be reversed in some cases without extensive damage. However, there can also be serious and irreversible losses when land of high carbon stock or land with high biodiversity value is converted for food, fiber, energy, or other commercial uses. The complexity and dynamic nature of land-use change places it beyond the scope of this brief review, which focuses mainly on the quantity of land required by energy systems.

3.3.2 Land-use Intensity

Land-use intensity (LUI) is a static measure of the land needed for continuous operation and that which is unavailable or otherwise impacted with respect to other uses. The LUIs of energy systems vary by several orders of magnitude. Nuclear and fossil fuels have fairly low land-use intensities, while renewable energy systems exhibit much more variation, ranging from modest requirements for geothermal and solar photovoltaics (PVs) to extremely high requirements for some types of biomass to electricity systems. The high value for biomass electricity is also partly due to the fact that biomass is most efficiently used and optimized for heat production in combination with electricity.

The land-use intensity of energy systems provides some first-order indication of the types of land-use pressures associated with the transition to sustainable energy systems. Land-use impacts are based on the amount of land that is rendered unavailable for other uses for at least the duration of the lifetime of the energy systems. It is important to note that such calculations include only the energy system in use and do not include land-use impacts due to accidents, which could be quite serious in the case of nuclear power and could contaminate land for thousands of years. Accidents in most renewable energy facilities would generally not be serious, as there are very few potentially toxic elements and those that are used could not spread over large areas.

A representative comparison of LUIs with respect to installed power and electricity production in the United States is given in Table 3.2. The systems with the lowest LUI are nuclear, coal, and geothermal. Solar and wind have LUIs that are 1 order of magnitude higher, while biomass has LUIs that are 2 orders of magnitude higher. However, since biomass energy systems normally have coproducts and since the land can often accommodate other uses, the effect of the land impacts can be significantly less. In the case of geothermal energy, there are underground impacts that are not included. There are also some similarities in the land impacts of geothermal energy with those of oil and natural gas. In the case of geothermal energy supply that involve wells, only 5% of the associated impacts are from direct land-use effects; the remaining 95% are due to habitat fragmentation and species-avoidance behavior. Onshore wind has a comparable breakdown, in that 95–97% of the impacts are not due to the land occupied, but rather to fragmentation and the effects on birdlife (McDonald et al., 2009).

3.3.3 Power Density

Another way to compare energy use in relation to area is to use the power density, expressed in watts per square meter (W/m^2) and representing the incident energy that can be delivered. Incident solar energy is typically in the range of 100–200 W/m^2 in Europe, but is much higher in the lower latitudes. The highest delivery of high-quality (electric) renewable energy per unit of land is likely to be from solar PV,

Table 3.3 | Land-use intensity and nitrogen intensity of various energy crops used for biofuel production.

	Land-use intensity (LUI)		Nitrogen intensity		Combined weighted ranking
	(ha/1000 GJ)	rank	(kg N/1000 GJ)	rank	
Sugarcane	2.3	2	110	2	0.02
Willow	5.3	6	90	1	0.03
Miscanthus	4.2	5	210	5	0.03
Sugar beet	1.9	2	460	8	0.03
Oil palm	3.0	4	440	8	0.04
Birch	6.8	8	160	3	0.04
Poplar	7.2	8	160	3	0.04
Switchgrass	6.5	8	300	6	0.05
Corn	4.9	6	490	8	0.05
Sweet sorghum	6.1	8	390	7	0.05
Algae	0.3	1	1100	11	0.05
Grain sorghum	16.2	12	1000	11	0.13
Rapeseed	16.5	12	1400	12	0.15
Soybean	20.2	13	3900	13	0.30

Source: Miller, 2009.

which could capture in the order of 10–20% or roughly 10–40 W/m^2 for European conditions when placed on south-facing surfaces. This might be compared with other energy systems in terms of how much electricity they can deliver, such as wind (2 W/m^2) or tidal (3 W/m^2), again based on conditions common in Europe (MacKay, 2008). The calculation of power density is somewhat more location-specific than the LUI measure used in Table 3.2, because it is based mainly on the energy that can be instantaneously extracted, whereas the LUI includes various land impacts that are then averaged across the power or energy that is available.

3.3.4 Biofuels, Land-use, and Nutrient Demand

The land-use associated with energy crops that are used to make liquid biofuels differ qualitatively from other types of energy supply in that they involve agricultural operations, and therefore other types of land issues arise. A particularly useful metric that can be compared alongside LUI is the nitrogen requirement; by combining this measure with LUI, one obtains a much better indicator for sustainability. Table 3.3 provides an example of such analysis, in which a combined ranking for two criteria was made, with equal weighting given to LUI and nitrogen-use intensity (Miller, 2009). An obvious conclusion from this comparison is that soybean, rapeseed, and grain sorghum are highly inefficient crops for biofuel production compared to almost any other option. Sugarcane scores highest in the initial ranking, and this held true even when sensitivity analysis was conducted for key parameters such as higher heating value (HHV), nitrogen and harvestable yield (Miller, 2009).

3.3.5 Multiple Uses, Hybrid Systems, and Land-use Efficiency

As the demand for food, feed, fiber, energy, and other products requiring significant land-use increases, greater land-use competition will be expected. Furthermore, since land is also valued for recreation, conservation, biodiversity, and many other uses, the 'productive' capacity of land must also be weighed against ecosystem services that are in fact highly productive, but whose value is poorly reflected in our socioeconomic systems. Consequently, the rise in importance of bioenergy has raised concerns that other valuable land-uses will suffer as a result of bioenergy expansion. One approach to reducing the LUI, while also improving the system design, can be hybrid systems that combine biomass with intermittent renewables such as wind. One example is a hybrid wind/biomass system that uses compressed air storage, which was estimated to require 70 m^2/MWh, a LUI that is just a fraction of the range given for biomass in Table 3.2 (Denholm, 2006).

The attention paid to bioenergy systems has also led to increased scrutiny of the land-use efficiency of agricultural and livestock practices. Greater land-use efficiency in agriculture, forestry, and other land-uses could free up some land for the renewable energy options that will be ultimately required to replace fossil and nuclear fuels. Current agricultural practices have tended to be land-intensive, as the low price of rural land in combination with fossil fuel infrastructure led to continual expansion. With precision farming methods and low tillage methods, land can be used more effectively while also reducing GHG impacts from fertilizer use, N_2O, and soil carbon release; this is true regardless of whether the land is used for food, feed, or fuel (Fischer et al., 2010).

Table 3.4 | Principal water uses for various energy systems.

Process requiring water	Type of energy produced	Environmental impacts	Energy eq. produced
Biomass growth	Traditional heat/cooking	Consumptive: less quantity of water for other uses, ecosystem services	36 EJ (traditional)
	Commercial biomass: heat, electricity biofuels	Non-consumptive: water quantity used released back into flow system, sometimes with degraded quality	9 EJ (commercial)
Direct energy generation	Hydropower	Non-consumptive, but can have large impacts on upstream and downstream habitats, depending on water flows affected by hydropower dams Consumptive: (unproductive) evaporation losses from dams, reservoirs	20% of total global electricity
Direct energy generation	Wave and tidal power (sea water)	Non-consumptive	
Energy processing	Thermal power	Non-consumptive	
Energy processing	Fossil fuel and nuclear power stations	Non-consumptive: for cooling; release of cooling water increases local habitat water temperatures

3.4 Water Resources and Energy Systems

Water resources and the flow of freshwater through the biosphere are fundamental to supplying benefits to society, including various forms of energy. Fresh water is a finite global resource, with no substitute in biological processes. On a planetary scale, water stress and water pollution are already reaching alarming levels, though currently concentrated in local and regional 'hot spots.' With increasing demand for energy, the competition for appropriating more water is expected to increase, in particular for hydropower and for the production of bioenergy crops. Mining activities also have implications for water resources, as they can cause pollution and change local water flows with implications for groundwater reservoirs. Impacts on the quality and quantity of water resources often relate to local social, economic, and environmental settings. The decisions on how best to develop energy system strategies and investments therefore need to be made at all levels, from local to national, in a transparent manner and according to best-informed practices.

3.4.1 Water Resources in Energy Systems: Demand and Impacts

Unlike the atmospheric impacts of different energy systems, which can be considered globally or regionally, the impacts of energy systems on water resources are more meaningfully considered at smaller spatial scales, from local to national levels. This is due to the nature of water resources and the boundaries of water flows. The impacts of various energy systems on water resources must be considered in terms of quality as well as quantity, at local and regional scales, in landscapes, catchments, or river basins. There are large differences in the availability of water resources among regions in the world, with ample freshwater in temperate cold regions and humid tropical regions contrasted by water scarcity in arid, semiarid, and sub-humid tropical regions. As a result, assessments of aggregate water resource availability at the global level may exaggerate actual access to water resources in societies and for specific ecosystem purposes.

Water has three key uses in energy systems (see Table 3.4). The first use is biomass production (rainfed and irrigated), including crops, plantations, and seminatural vegetation types, including forests and grasslands. The second use is processing (e.g., sugarcane, coal washing) and cooling to produce energy (e.g., fossil fuel and nuclear power stations). The third use is generating energy (e.g., hydropower, wave power, and tidal power).

3.4.2 Water Embedded in Biomass Production for Energy

A large part of the energy stemming from biomass is used for primary human energy needs such as heating and cooking. Only a small part of biomass is used for secondary energy supply, involving substantial post-harvest processing, sometimes including additional water uses.

All biomass production, be it for crops or primary biomass production for energy, is associated with large consumptive use (water that does not return to the river or groundwater) of freshwater. Biomass production is the single largest freshwater-consuming process on Earth, with large volumes of water used to produce energy (e.g., a range of 60–110 m^3 per gigajoule (GJ), for major bioenergy crops), according to Geerben-Leenes et al. (2009).

The use of wood fuel for basic human needs of heating and cooking will continue to remain dependent on local resources, and thus the water input will depend on the local hydrological conditions prevailing at the source of production, which in this instance will be the same as the site of use and energy supply. Change in energy use, for example cooking facilities with better wood fuel energy conversion, can be translated into a 'water saving,' as less embedded water is used to

Table 3.5 | Water productivity (as actual evapotranspiration per GJ output of electricity for biofuel).

Crop	Biofuel	Energy water footprint (as tonne water per GJ output)
Rapeseed	Biodiesel	100–175
Sugarcane	Ethanol	37–155
Sugar beet	Ethanol	71–188
Corn	Ethanol	73–346
Wheat	Ethanol	40–351
Lignocellulosic crops, including salix, eucalyptus, switchgrass, miscanthus	Ethanol	11–171
Lignocellulosic crops, including salix, eucalyptus, switchgrass, miscanthus	Methanol	10–137
Lignocellulosic crops, including salix, eucalyptus, switchgrass, miscanthus	Hydrogen	10–124
Lignocellulosic crops, including salix, eucalyptus, switchgrass, miscanthus	Electricity	13–195

Source: adapted after Berndes, 2008.

produce the same amount of energy. Although 'water footprints' are a common way of accounting for water use embedded in biomass produce, care should be taken, as water-use efficiency values vary globally and locally, depending on production systems and agroclimatic conditions for the same species. Also, the calculations vary in regard to how the water consumption is related to the supply of energy. For example, is the full crop used for energy supply, or are only crop by-products used for energy supply? A synthesis by Berndes (2008) show large variations in embedded water in different types of energy systems (Table 3.5). Thus, good planning both in terms of location and type of energy can have large local impacts on landscape and river basin water use efficiency.

Practices that will cause changes in land-use, e.g., shifting biomass production systems, are likely to lead to changes in landscape hydrology, which in turn can affect the downstream availability of water. Bioenergy production upstream may thus impact on water-dependent provisioning and supporting or regulating ecosystem services downstream in a catchment or river basin. A meta-analysis of catchment land-use changes shows that transitions from annual crop and/or grassland to more water-demanding woody species can reduce stream flow (e.g., Jackson et al., 2005; Locatelli and Vignola, 2009). Other crops and habitats that depend on certain volumes and the timeliness of river flows may be impacted, with subsequent implications for livelihoods and economies depending on these ecosystem services. These changes in water flow, caused by changes in crop production for bioenergy or other land-use changes, may not be evident at the outset and may be difficult to anticipate (e.g., Gordon et al., 2008).

3.4.3 Impacts on Water Resources by Post-harvest Processing Biomass for Biofuel

Crops (annual or perennial) that are produced for commercial purposes and eventually processed into energy as heat, electricity, or biofuels, may have a production and processing location that is different from the location of consumption. Thus, over extraction or pollution of water resources due to such commercial biomass production or to post-harvest processing is not necessarily co-located with the place of consumption of the end product. Two water-related issues, in addition to the previous discussion about water footprints, have also been documented: degradation of surface and groundwater by agrochemicals, and post-processing of biomass for bioenergy.

Degradation of surface and groundwater by agrochemicals: As with other intensive crop-production systems, biofuel crops have also been associated with pollution due to the intensive use of agrochemicals such as fertilizers, pesticides, and herbicides. These different chemical components have been shown to cause harm to both surface and groundwater resources in areas of intensive, large-scale use, such as maize (corn) in the midwestern United States for ethanol (e.g., Donner and Kucharik, 2008), and sugarcane in various parts of Brazil (e.g., Goldemberg et al., 2008).

A second pressure on water resources can be associated with post-processing of biomass for bioenergy. This water use is non-consumptive, and the water used will eventually be released back into the landscape. However, as has been seen, for example in association with the production of large amounts of sugarcane, the release can be associated with degraded quality, thus affecting downstream users and habitats.

3.4.4 Impacts on Water Resources by Utilization of Water for Cooling

In various energy systems, such as fossil fuelled power stations and nuclear power stations, water is used for cooling purposes. This use is non-consumptive, and water can be used downstream for other purposes. However, local impacts on water-related habitats have been identified, as the returned cooling water has a higher temperature than natural temperature cycles, especially during cold seasons. This can alter local habitats and species (e.g., Teixeira et al., 2009; Yi-Li et al., 2009; Svensson and Wigren-Svensson, 1992).

3.4.5 Impacts on Water Resources by Hydropower Generation

A major impact on global freshwater flows is the construction of dams and reservoirs for hydropower generation. Thus the environmental impacts, in terms of the hydropower energy chain, are almost entirely due to infrastructure construction activities. Although the energy supply is non-consumptive in terms of landscape water flows, several water-related impacts are associated with hydropower generation. The key ecosystem services that are affected by dams are: the change of flow patterns in time and space at site and downstream; the change of aquatic and riparian habitats; and river-system fragmentation.

The most important impact is the fragmentation of river systems (e. g., Nilsson et al., 2005). The construction of large dams and reservoirs change temporal water flow distribution in river systems, affecting downstream habitats and water quality. This has far-reaching impacts on various ecosystem services that benefit human activities, economies, and development. Although the World Commission on Dams (2000) estimated 40–80 million people to be affected by dam constructions, the numbers of people impacted downstream of dams are in the order of 500 million (Richter et al., 2010). The loss of functioning habitats such as wetlands and floodplains often means that benefits, both valued and non-valued, are irreversibly lost. A recent global assessment indicates that of 292 rivers, 172 are already seriously affected and fragmented by dams (Nilsson et al., 2005). The most fragmented rivers systems are also some of the most habitat-rich, biodiverse, and populated river systems of the world. On a global scale, dams and reservoirs have already had a significant impact on freshwater flow-related ecosystem services, and the societies, economies, and population relying on these ecosystem services (Meybeck, 2003). In addition, natural recreational areas may be destroyed by large-scale dam construction.

Sometimes the regulating function of dams is desired. For example, dams may protect valuable infrastructure and settlements from recurrent flooding events. Dams and reservoirs can also ensure the provision of a regular water supply to society and agriculture. However, the net outcome of a holistic assessment of dams and reservoirs is, more often than not, the loss of provisioning, supporting, and regulating ecosystem services that would directly benefit humans in terms of energy, water supply, and water regulation. In some cases, large dams are being deconstructed to restore natural river flows (e.g., Gosnell and Kelly, 2010). In view of the development demands of the world, it is expected that a number of large dams for hydropower purposes will be constructed in many countries in Latin America, Africa, and south Asia in the near future. However, even the World Bank recognizes the limited operational capacity that exists to ensure that ecosystem values are truly accounted for, despite the increased recognition of these values highlighted by the groundbreaking report of the World Commission of Dams in 2000 (World Bank, 2009).

GHG release from large dams and reservoirs: A recently recognized added impact of large manmade dams is the release of CH_4 to the atmosphere. Methane is released as a by-product by anaerobic breakdown of inundated biomass. Methane has GWP 25 times greater than that of CO_2 and thus will have a significant contribution to total effective GHG emissions from large hydropower energy systems (e.g., Chen et al., 2009; Guerin et al., 2006). According to International Rivers (2011), 23% of all manmade CH_4 emissions can be attributed to large dams.

The trapping of sediments in dams: a serious impact of reservoirs and dams is the reduced levels of sediments transported to various parts of the river systems. An earlier estimate suggested that globally, dams in river systems trap 4–5 Gt/yr (Vorosmarty et al., 2003), or approximately 25% of total sediment transport. The environmental issue related to the sediment trapping is the concentration of harmful compounds that are stored in these sediments. Sometimes this has unintended benefits, such as dams acting as storage for harmful substances. Some authors are warning that a restoration or unintended break in these dams would pose serious threats downstream due to the years of built-up polluted sediments.

3.5 Environmental Sustainability in Energy Systems

It is a major challenge, and an absolute necessity, to understand the demands that will be placed on future energy systems to develop means of ensuring that energy can be provided in a sustainable manner. One approach to achieving this is to develop energy systems within globally defined sustainability criteria for critical Earth-system processes.

Defining these criteria requires the inclusion of living and nonliving systems (ecosystems and natural resources) and the consideration of risks of abrupt nonlinear changes, or tipping points/thresholds, as a result of environmental overshoot. Attempts have been made in the past to develop global indicators for sustainability, most famously in the Limits to Growth World3 scenarios in the 1972 Club of Rome report (Meadows et al., 1972). These scenarios, later revised twice (Meadows et al., 1992; 2004), excluded ecosystems and focused on nonrenewable resources and persistent pollution. Later global assessments, such as the Millennium Ecosystem Assessment (MEA, 2005) and the IPCC (2007a), include analyses of environmental states and trends, with partial attempts to also define global sustainability criteria. The IPCC stabilization scenarios come closest to defining such criteria at the global scale for the climate system. These scenarios involve targets of maximum atmospheric CO_2 concentration, but the CO_2 concentrations are not linked to specific thresholds or other features of the climate system. Other atmospheric pollutants that are targeted for their impacts on poor air quality rather than climate change have been addressed at the regional level. Methods such as the effects-based approach developed by the UNECE Convention on Long-Range Transboundary Air Pollution aim to optimize improvements in air quality (see Sliggers and Kakebeeke, 2004) and have defined critical loads and levels for different pollutants to protect

human health, materials, and a range of ecosystems from the impacts of air pollution impacts.

Other approaches to defining global sustainability criteria include the World Wildlife Fund Living Planet Index, which is an indicator of global biodiversity, and the global ecological footprint assessment, which attempts to compare humanity's demand for renewable provisioning ecosystem services (crops, fish, livestock, timber) in relation to the capacity of the planet to regenerate these services (Living Planet Report, 2010). Regulating services from ecosystems, such as climate stability and freshwater supplies, are only partially represented, through estimates of carbon footprints.

Perhaps coming closest to defining appropriate global sustainability criteria for the Anthropocene era are the scientific advancements made in assessing the risks of tipping elements in the climate system (Schellnhuber, 2009), and the 'tolerable windows approach' that has been developed to provide a climate policy guidance framework. In the tolerable windows approach, which was first proposed by the German Advisory Council on Global Change (WBGU, 2009), limits designed to avoid dangerous anthropogenic climate change are set against assessments of tolerability. A key feature of this approach, and most other attempts to develop sustainability criteria, is the compromise between limits set by nature on the one hand, and the demands and the 'tolerable' costs set by society on the other.

A number of modeling tools have also been developed to specifically represent the sustainability impacts of energy systems. These include life-cycle analysis tools that provide quantitative assessments that compare the potential for environmental impacts (GHG emissions, SO_2 emissions, NO_x emissions, direct land requirements) associated with different energy systems at different points along the energy chain (Evans et al., 2009). Other tools include natural resource management; ecologically sustainable development tools, and integrated assessment models. The latter have been specifically developed for research on climate change and air quality (e.g., IPCC, 2007) and incorporate, for example, the full cycle of anthropogenic GHG emissions, the options and costs of their mitigation, the resulting climate change, the impacts of climate change, and the related options and costs of adaptation (Toth, 2003). There is also increasingly a focus in models on the 'triple bottom line,' or sustainability in terms of ecological, sociological, and economic factors (Harris, 2002).

3.5.1 Environmental Sustainability in GEA

The GEA transition pathways (see Chapter 17) build on existing frameworks and use a range of modeling tools. These pathways propose the development of future energy systems under a number of sustainability criteria. Key environmental targets are formulated with respect to climate change and air pollution. These include limiting global mean surface temperature change to 2°C above pre-industrial levels with a likelihood of more than 50% and achieving global compliance with WHO air-quality standards ($PM2.5 < 35\ \mu g/m^3$) by 2030 (see Chapter 17 for more detail). The climate-change target is discussed in Section 3.2.2, while the air-quality target relates to human health and is considered in Chapter 4. Both targets consider current knowledge and policy in developing stringent environmental goals for energy systems.

The stringency of such goals implies significant environmental outcomes of these pathways measured with respect to atmospheric pollutants. As discussed in Chapter 17, the GEA transitions are most comparable to the most stringent IPCC scenarios. In these low pathways, GHG emissions may continue to increase only for a very short period of time (peaking between 2020 and 2030) before they must decline to reach levels at about zero or even negative over the long-term (beyond 2060). These scenarios are compatible with long-term atmospheric CO_2 concentrations stabilizing at below 400 ppm (see Figure 17.35 in Chapter 17).

The GEA pathways indicate that the nature and magnitude of future environmental impacts will greatly depend on the evolution of energy systems and other anthropogenic activities in the coming decades. A major global energy transition in the future as described by the GEA pathways will require on the one hand conditional convergence in incomes across regions, and on the other hand a combination of policies at the local and regional levels, with global availability of energy-efficient technologies and devices (see Chapter 17 for a detailed discussion). Future energy systems are expected to evolve differently across regions under such a major energy transition. In general, one can expect increases in fossil-energy systems equipped with carbon capture and storage (CCS) and increases in renewable energy (wind, solar, bioenergy) across all regions. The exact extent of such changes in energy systems will depend on availability of energy sources and other constraints (see Chapter 17, Section 17.3.4.4 for more regional discussion of energy systems). The changes in the energy system will have a major impact on GHG emissions and air pollutants in the future. In addition to global climate change policies, regional and local policies will play a major role in influencing future environmental impacts. Policies will need to be stringent in order to significantly control future environmental and other impacts. Ensuring universal access to clean cooking fuel and controlling levels of air pollution across all regions through stringent legislation are seen as being essential to ensuring improvements in environmental quality.

As summarized in Figure 3.25, the GEA 'Counterfactual' scenario indicates that in the absence of stringent policies in all regions, GHG emissions can be expected to increase across all regions, while the regional evolution of air pollutants (shown here are SO_2, NO_x, and $PM_{2.5}$) will depend on the effectiveness of currently legislated air-quality controls. While currently planned air quality legislation, as in the GEA Counterfactual scenario, will bring reductions in outdoor air pollution levels across Organisation for Economic Co-operation and Development (OECD) regions, for other regions, in particular Asia and sub-Saharan Africa, increasing populations and rapid expansions in energy systems

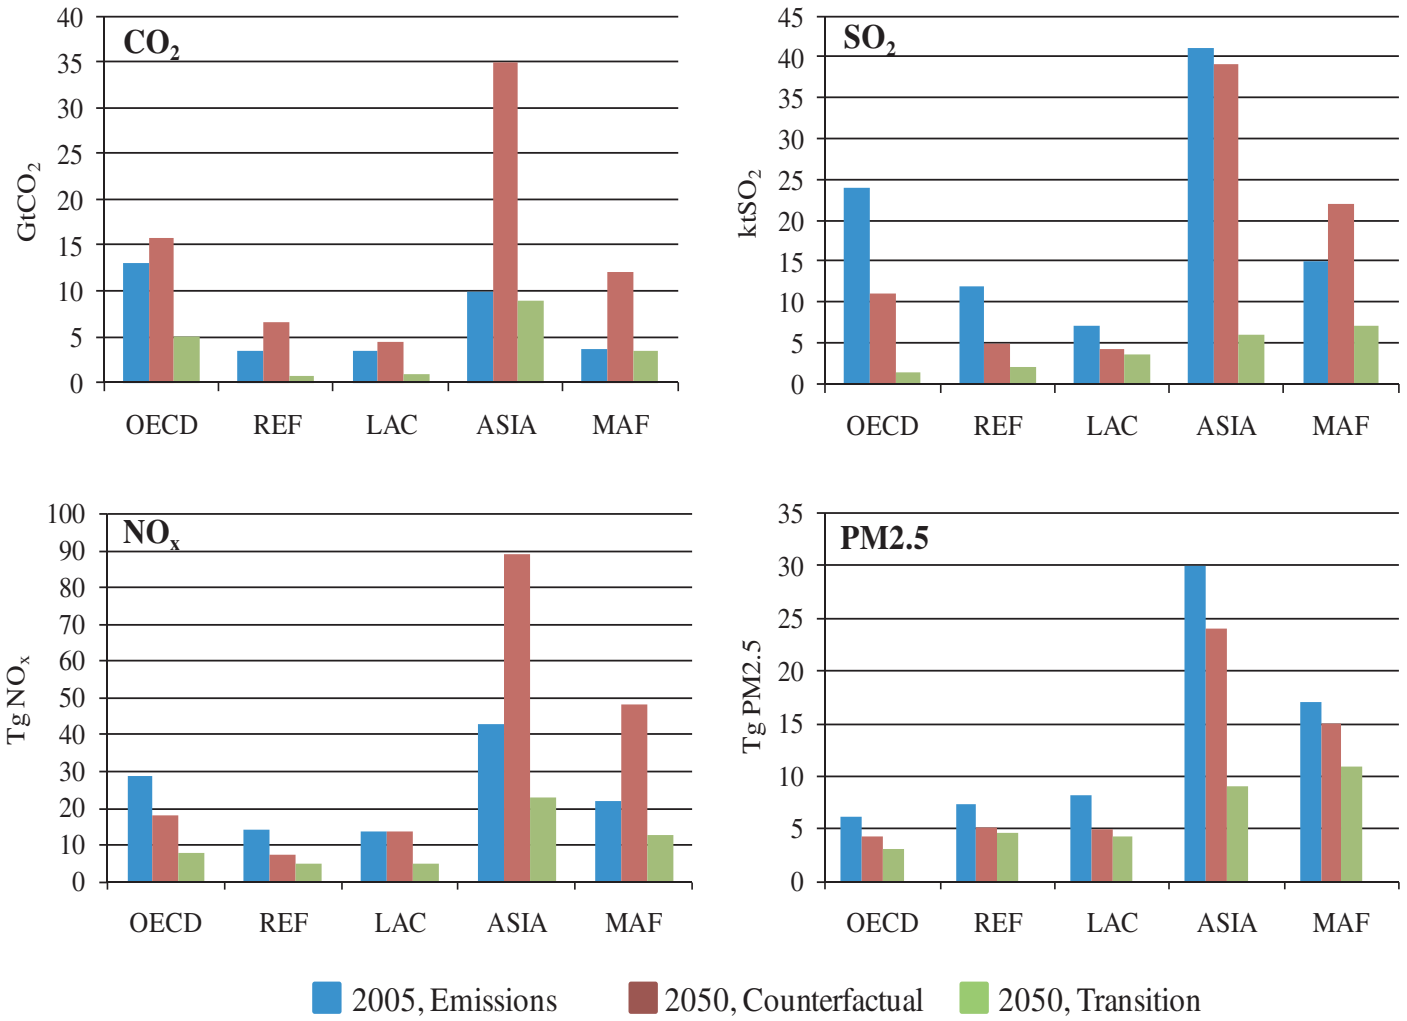

Figure 3.25 | CO_2, SO_2, NO_x, and $PM_{2.5}$ emissions in 2005 and 2050 in GEA Counterfactual and GEA Mix (Transition) Scenarios. Regional definition in Chapter 17.

will mean that emissions continue to increase. The inclusion of sustainability criteria, as in the GEA transition pathways (shown here is the GEA Mix; see Chapter 17 for a full description of pathways), and the subsequent increase in the stringency of policies, lead to significant declines in both GHG and pollution levels across regions.

These emission reductions from anthropogenic systems can be expected to bring significant environmental benefits across regions compared to current levels. While a detailed description of regional environmental impacts is beyond the scope of this discussion, such impacts will extend to a wide range of environmental concerns, as discussed earlier in the regional descriptions. These would include, for example, decreased sea-level rise; decreased frequency of droughts and flooding; decreased impacts of BC-related climate effects, decreased crop losses from O_3-related effects; and decreased acidification and eutrophication. In addition to environmental benefits, significant health-related benefits can be expected as a result of stringent pollution energy access policies (see Chapters 4 and 17 for discussions on the health-related impacts of air pollution).

3.5.2 Proposal for Alternative Framework for Environmental Sustainability of Energy Systems

Our assessment is that global sustainability criteria for the global energy systems in the Anthropocene era must be comprehensive, including all relevant environmental processes (e.g., carbon and nitrogen cycles) and systems on Earth that are affected by our energy systems (e.g., the climate system, the ocean system, and terrestrial and aquatic systems). Such criteria must consider the interactions and risks of abrupt, nonlinear change (tipping points and thresholds). They must also address the ability of systems on Earth to maintain their resilience, and thereby their capacity to remain in desired states conducive to human development in an era of rapid global change. The GEA sustainability indicators provide a systematic approach to defining specific quantitative goals for environmental sustainability with respect to the atmospheric impacts associated with particular scenarios involving air pollution and climate change (see Chapters 4 and 17). This approach will also need to extend to encompass the full range of Earth-system considerations.

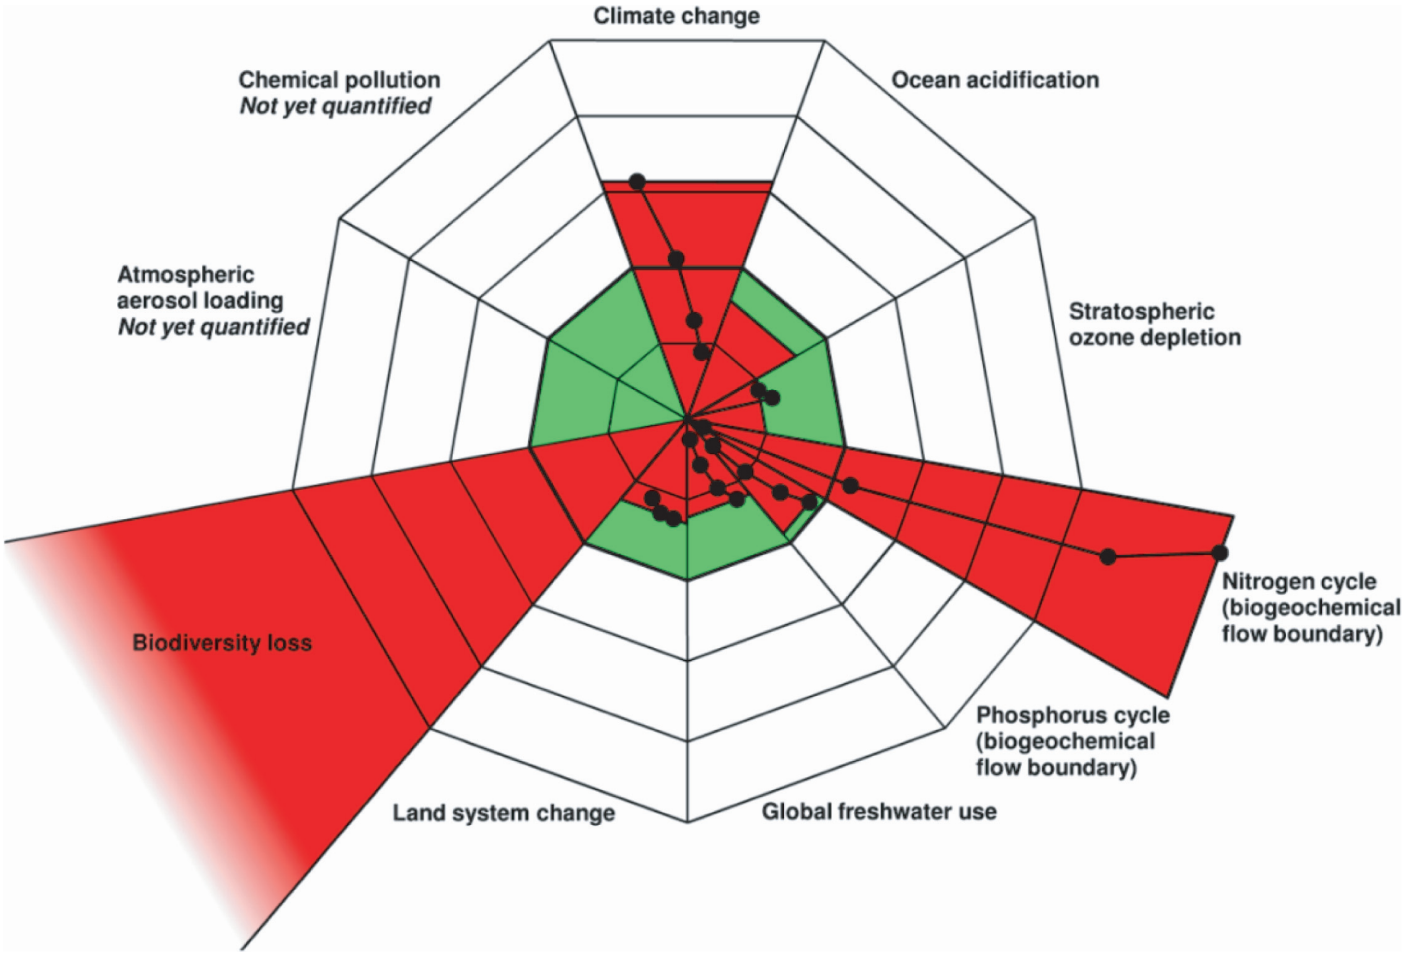

Figure 3.26 | Current global state of the world for the ten proposed planetary boundaries. The green areas denotes a "safe operating space" for human development, and red indicates the current position for each boundary process. The dots indicate evolution by decade from the 1950s.

Based on this conclusion and on the assessment of previous approaches to defining global sustainability criteria, the recently advanced planetary boundaries concept (Rockström et al., 2009) is considered here as a complementary way of framing the assessment of sustainability criteria for global energy systems. This framework, which builds on previous global sustainability approaches, advances in Earth system science, and resilience research, was developed as a means of addressing and establishing global sustainability criteria that recognize the global pressures from human enterprise and the risk of undermining the resilience of major biophysical systems on Earth. It complements existing environmental indicators, such as the critical loads and levels approach, global footprint analysis, and the 'tolerable windows approach,' by addressing the biophysical prerequisites for avoiding abrupt and undesired global change. It is an expansion of the 'guardrail' approach (Hare and Meinshausen, 2006) used to define safe climate-mitigation targets by also addressing other global environmental change processes. The approach is presented in Figure 3.26, which shows the planetary boundaries for nine Earth-system processes, which together define a safe operating space for humanity (indicated by the green area), within which human development stands a good chance of proceeding without large-scale deleterious change. Estimates indicate that the safe levels are approached or in some cases surpassed. Energy systems contribute to humanity's approach to all the planetary boundaries, but in particular climate change, biodiversity loss, land-system change, atmospheric aerosol loading, and chemical pollution.

So how can the planetary boundary framework be redefined to be appropriate for an assessment of our energy systems? First this requires that the main Earth-system processes affected by our energy systems are defined (as already discussed in previous sections) and related to impacts that act at the planetary level. The planetary boundary framework already includes proposed boundary levels appropriate for the prevention of Earth system-threatening climate change (see Rockström et al., 2009). Conceptually, the framework may also facilitate efforts to understand the impacts of the more 'traditional' atmospheric pollutants on ecosystems, since a similar critical limits threshold-driven concept has long been used in scientific research to define loads and levels below which pollution would not threaten perturbations to environmental systems (Sliggers and

Table 3.6 | Summary of proposed global sustainability indicators and target levels for energy systems based on planetary boundaries.

Pressure	Receptor system	Planetary boundary	Indicator target or orientation value
Emission of radiative forcers (e.g., CO_2, PM, aerosols), leading to changes in global and regional climate	Atmosphere	Climate change; Rate of biodiversity loss; Ocean acidification; Atmospheric aerosol loading	350 ppm CO_2 or climate forcing less than 1 W/m^2 above the pre-industrial level, or less than 1000 $GtCO_2$-eq released in the period 2000–2050
			No more than 2°C above pre-industrial of human-induced global warming, with a probability greater than 50%
			Aim for 50% GHG emission reduction by 2030 and subsequent reductions to achieve the target
			Reduce by 2030 and eliminate by 2050 emissions of BC, OC, nitrogen and sulphur, and other PM that contribute to atmospheric aerosol loading, so that radiative forcing remains less than 1 W/m^2.
Emission of air pollutants (e.g., SO_2, No_x, O_3)	Atmosphere	Climate change, Rate of biodiversity loss, Nitrogen cycle, Chemical pollution; Atmospheric aerosol loading	Reduce by 2030 and eliminate by 2050 emissions of BC, OC, nitrogen and sulphur species, and other PM that contribute to atmospheric aerosol loading, so that radiative forcing remains less than 1 W/m^2.
			Reduce by 2030 and eliminate by 2050 emissions of air pollutants that contribute to human health and ecosystem damage – *further research required to define such limits*
Land requirement and degradation	Terrestrial biosphere	Change in land-use; Rate of biodiversity loss; Chemical pollution	No more than 15% of global land cover should be converted to cropland
Water resource requirement and impaired water quality	Freshwater and marine systems	Global freshwater use; Rate of biodiversity loss; Chemical pollution	Limit global freshwater use to no more than 4, 000–6, 000 km^3/yr of consumptive use of accessible river flow

Kakabeeke, 2004). Therefore, for many of the environmental threats related to atmospheric emissions from energy, it might be considered relatively straightforward to use existing indicators and sustainability criteria to assess whether the planetary boundary has been crossed. The actual reality of using these indicators is discussed in more detail below. For the other environmental impacts, which are not directly related to atmospheric emissions (for example, land-use and water resources), different threshold criteria will have to be defined according to a full understanding of the potential impacts, their causes in relation to energy use and supply, and trends and variations within geographical regions.

Discussed below are proposed definitions for planetary boundaries for energy systems that include a range of environmental impacts. They build on earlier analysis by Rockström et al. (2009), and also include boundaries for air pollution, land-use, and water use, based on the summary of current impacts in Sections 3.2, 3.3, and 3.4. The proposal is summarized in Table 3.6.

3.5.2.1 Defining Planetary Boundaries for Climate Change

The planetary boundary GHG concentration-based target proposed by Rockström et al. (2009) calls for limiting concentrations to 350 ppm CO_2, or approximately 400 ppm CO_2-eq, with an uncertainty range of 350–500 ppm CO_2. The climate-change boundary proposed here aims at minimizing the risk of highly nonlinear, possibly abrupt and irreversible, Earth-system responses (National Research Council, or NRC, 2002; IPCC, 2007c). These responses may be related to one or more thresholds, the crossing of which could lead to the disruption of regional climates (Lenton et al., 2008), trigger the collapse of major climate-dynamic patterns such as the thermohaline circulation (Clark et al., 2002), and drive other impacts that would be difficult for society to address, such as rapid sea-level rise. The risk of crossing such thresholds will rise sharply with further anthropogenically driven deviation from the natural variability of the Holocene climate.

This dual approach to defining the planetary boundary for climate change uses both atmospheric CO_2 concentration and RF as global-scale control variables. Boundary values of 350 ppm CO_2 and 1 W/m^2 above pre-industrial levels are suggested. The boundary is based on: an analysis of the equilibrium sensitivity of the climate system to GHG forcing; the behavior of the large polar ice sheets under climates warmer than those of the Holocene (Hansen et al., 2008); and the observed behavior of the climate system at a current CO_2 concentration of about 387 ppm and +1.6 W/m^2 (with a 0.6–2.4 W/m^2 90% confidence range) net RF (IPCC 2007a).

3.5.2.2 Defining Planetary Boundaries for Air Pollution

How do the critical loads and levels currently defined by the UNECE LRTAP Convention relate to the planetary boundary concept? Firstly, it is useful to identify which boundaries presented in Rockström et al. (2009) are relevant for air pollution. Perhaps the most obvious is that for the nitrogen cycle, which proposes a boundary of 35 Mt/year of N_2 removed from the atmosphere for human use. How does this compare with LRTAP Convention critical loads? Current empirical critical loads for nutrient nitrogen (which protect against changes in plant growth, interspecific relationships, and soil-based processes) are provided for a wide variety of different natural and seminatural ecosystem habitats. These include forest

habitats, heathlands, scrubland, tundra, grasslands, mires, bogs, fens, and inland surface water and coastal and marine habitats. The critical loads vary from 5–40 kg N/ha/year, with the range indicating the variability in ecosystem sensitivity to excess Nr input. Considering that there are similar variations in ecosystem sensitivity to acidifying nitrate and to ammonium deposition, which causes soil acidification, the difficulty of defining a single, planetary-scale boundary for N deposition becomes apparent.

The planetary boundary limit on N_2 fixation attempts to reduce Nr at the source, rather than at different points along the nitrogen cascade that will lead to varying types of ecosystem damage defined by Galloway et al. (2003). However, the difficulty comes in using scientific or expert judgment (the latter is necessary where there are gaps in our scientific understanding) to define a threshold for damage for the different processes through which excess Nr causes eutrophication and acidification. This is the case, since unless N_2 fixation rates equal denitrification rates, there will always be excess Nr in the system, which may cause damage. The geographical spatial heterogeneity of atmospheric Nr pollution and deposition as well as ecosystem sensitivity will mean that some ecosystems will be unprotected by a single planetary-scale boundary that is set to avoid stepping outside the resilience of the system as a whole. It is also not possible to exclude the possibility of cumulative impacts caused by steady increases in N deposition that may result in systems crossing tipping points, even under low pollution loads, if they persist for substantial periods of time. Therefore, we propose that the planetary boundary for N_2 fixation provides a useful guide to encourage more efficient use of Nr in our agricultural systems and more efficient combustion of fossil fuels, but that it should be used in concert with regionally based indicators that employ an effects-based approach to limit pollution impacts. Only then will control be sufficient to ensure protection of the most vulnerable systems. Similar arguments can be made for each of the regional-scale air pollutants discussed in this Chapter.

3.5.2.3 Defining Planetary Boundaries for Land-use

The planetary boundary for land-use proposes that no more than 15% of global land cover should be converted to cropland. Given the current level of malnourishment in the world and the expected 50% increase in world population by 2050, the demand for food and animal feed is expected to require a 70% increase in agricultural production by 2050 (FAO, 2006). Even if most of the increase comes through intensification and yield improvements, there remains a chance that land converted to agriculture could surpass 15% by 2050; this chance is increased by the likelihood that an increasing share of agricultural land will also be devoted to production of biofuels. However, with major investments in agricultural research and an emphasis on high-efficiency agricultural and integrated food-energy systems, expansion of land under agriculture could be significantly constrained (Johnson and Virgin, 2010). The conclusion is that expansion of land used for biofuels must accompanied by much greater investment in 'smart agriculture,' both for the sake of reducing land pressures and for improving food and energy security simultaneously.

3.5.2.4 Defining Planetary Boundaries for Water Resources

Actual freshwater availability is manifested at the local catchment or river-basin level. At the same time, there is increasing evidence that humanity faces global freshwater constraints due to the finite nature of freshwater resources, and the coupling of local water balances with the global hydrological cycle. Currently some 30% of the world's population faces water stress, and approximately 25% of the world's rivers dry out before reaching the ocean (Molden, 2007). The global freshwater cycle has entered the Anthropocene era (Meybeck, 2003), where humans now constitute the dominant driving force, altering river flows at the global level (Shiklimanov and Rodda, 2003) and the spatial patterns and seasonal timing of vapor flows (Gordon et al., 2005).

Global freshwater assessments show that the accessible global volume of runoff water (accessible base flow) is in the order of 12,500–15,000 km^3/yr (Postel et al., 1998; deFraiture et al., 2001). Several analyses show that severe water scarcity is experienced on the regional scale when withdrawals of runoff exceed 40–60% of this stable freshwater resource. This provides an uncertainty range of sustainable global freshwater withdrawals of 5000–9000 km^3/yr, beyond which negative implications for human societies are expected. However, not all of these withdrawals constitute consumptive use. Current withdrawals of approximately 4000 km^3/yr (World Water Development Report, 2009), of which less than 3000 km^3/yr is consumptive use. Based on these indicators of sustainability thresholds for freshwater use, a planetary boundary range for global freshwater use has been proposed at 4000–6000 km^3/yr of consumptive use of accessible river flow. Evidence indicates that transgressing this boundary range leads to an overuse of freshwater in catchments and river basins where water-induced thresholds, e.g., the collapse of freshwater dependent ecosystems, can no longer be excluded (Rockström et al., 2009). This freshwater boundary is highly tentative, given the uncertainties associated with aggregating sustainable freshwater use at a global level, but it does provide an indicator of the magnitude of freshwater that can be used for bioenergy and other purposes before serious water-related problems occur.

3.6 Conclusion

The assessment in this chapter confirms earlier scientific findings that a global energy transformation is needed to address the growing risks associated with accelerated global environmental change. Anthropogenic pressures on the planet have reached a level where large-scale deleterious impacts, or even catastrophic ones, can no longer be excluded. Such impacts have the potential to undermine human development. This new global social-environmental predicament is closely associated with energy.

Atmospheric emissions from energy use contribute to multiple environmental impacts. In addition to climate change, atmospheric pollutants may limit net primary productivity of ecosystems, and lead to the acidification and eutrophication of land and seascapes. These impacts

interact, reinforcing impacts on social and environmental systems, in complex ways that are not always well understood. This chapter confirms the necessity for the global energy system, which is the largest source of GHG emissions, to – as a minimum requirement – operate within the 2°C climate guardrail. In fact, based on the latest science, this chapter concludes that 1.5°C may be a more appropriate guardrail. This conclusion is based on the high likelihood that even small increases in global mean surface temperature will have extensive negative impacts on societies and ecosystems. This chapter also concludes that immediate action on reducing BC and tropospheric O_3 should be a high priority for short-term climate mitigation with associated benefits for human health. Action to control BC will particularly aid improvements in indoor air quality in the poor households of the world (see also Chapter 4).

This chapter also confirms the interconnectedness among all regions of the world, in terms of high dependency on fossil-energy sources and negative environmental impacts from the current energy mix. This energy mix generates impacts at the local, regional, and global levels. This chapter also confirms that there are winners and losers on the global energy scene – with the poorest tropical regions in the world being most vulnerable to the environmental impacts of unsustainable energy use, and the lowest energy-using regions, including the poorest developing countries and the polar regions, being highly affected by negative impacts originating from energy use in other regions.

This chapter confirms the intricate link between land and energy. Land is affected through loss or damage to ecosystems from land-use change and contamination from energy-related waste arising from activities such as mining, drilling, and the transport of fossil fuel raw materials. The alternatives to fossil fuel-based energy systems (e.g., nuclear power, hydropower, biomass-derived fuels and solar power) also lead to a variety of adverse environmental impacts on air, land, and water at various stages in the energy chain. In particular, the intensive use of land and fresh water by bioenergy systems has implications for meeting increased global food demands, as assessments increasingly indicate the existence of regional and global limitations to the expansion of agricultural land and water use for biomass production. It is concluded that the expansion of land used for biofuels must be accompanied by greater investment in 'smart agriculture,' both for the sake of reducing land pressures and for improving food and energy security simultaneously.

Water resources and aquatic ecosystems are also adversely impacted by various types of energy systems. Water may be diverted from other uses by biomass crop production or hydropower schemes. Aquatic ecosystems may be damaged by the interruption of hydrological flows (e.g., from dam construction or open-cast mining operations) as well as by contamination during coal and uranium ore mining, oil and gas drilling, fossil fuel-processing and transportation, or thermal pollution from power stations.

Drawing upon the latest science, this chapter confirms earlier assessments (particularly within climate science) that atmospheric emissions, of both GHGs and air pollutants, constitute the core and most immediate environmental challenges within the energy sector. However, it is equally clear that energy impacts the biosphere; this calls for immediate attention to reduce the impacts of energy systems on land and water resources, including the use and flow of nitrogen; biodiversity loss; the toxic effects of tropospheric O_3 and other toxic chemical pollution.

Chapter 3 therefore concludes that there is a need for an integrated approach, in which all environmental impacts from energy use are considered, both in terms of climate and ecosystem change. An energy transformation would bring multiple benefits and would help humanity tunnel out of the current era of rapid global environmental change. Such a transformation would have benefits ranging from averting global climate change to reducing the burden of air pollution and ecosystem degradation. It would also require the integration of policy and development action on climate change, air pollution, and ecosystem management, from local to regional to global levels. Energy systems, climate change, and air pollution are strongly connected, in such a way that integrated decision making, coordinated at an international level, will be absolutely crucial to the development of viable options for mitigating the adverse environmental impacts of our energy needs.

A new framework is therefore needed to guide a global energy transformation. This chapter concludes that there is an urgent need for global sustainability criteria, within which the global energy system can operate and identifies the 'planetary boundary' approach as one means of defining global sustainability criteria that could help establish future sustainable energy pathways.

Executive Summary

Despite providing significant benefits for human health, energy systems also negatively affect global health in major ways today, causing directly perhaps as many as five million premature deaths annually and more than 5% of all ill-health (measured as lost healthy life years). Air pollution from incomplete combustion of fossil fuels and biomass fuels is by far the single major reason that energy systems negatively affect global health, although ash, sulfur, mercury, and other contaminants in fossil fuels also play a role. Effects on workers in energy industries are the second biggest health impact globally.

The largest exposures to energy-related air pollution occur in and around households, particularly in developing countries where unprocessed biomass (wood and agricultural wastes) and coal are used for cooking and heating in simple appliances.

This chapter does not focus on differences in impacts among alternative energy systems that have *minor* impacts on global health; rather, the focus is on the most significant impacts of energy systems on health. The important positive impacts of energy systems on health are mostly addressed in Chapter 2.

Given the importance of avoiding climate change, there is secondary focus on the ways that mitigating climate change through changes in energy systems might achieve important health improvements: co-benefits.

Unless major policy interventions are introduced, energy systems are expected to continue contributing significantly to the global burden of disease for years to come.

Household air pollution: GEA estimates for 2005 put the burden of disease caused by household air pollution at about 2.2 million premature deaths annually. These deaths occur mainly among women and young children in developing countries because they receive the highest exposures to household air pollution from cooking and heating with solid fuels. Although the fraction of households relying on solid fuels is slowly declining, the absolute numbers are still rising among the world's poorest populations.

The only way to ameliorate this health risk is through encouraging as many households as possible to use clean-burning gases and liquids made from biomass or petroleum fuels while initiating widespread promotion of new generations of advanced combustion biomass stoves. These stoves reduce biomass emissions to nearly the level of emissions from clean fuels, by using small blowers and other technical innovations.

Outdoor air pollution: Outdoor air pollution from incomplete combustion and other emissions from fuel use is also an important health risk globally. GEA estimates that it was responsible for some 2.7 million premature deaths in 2005. Outdoor air pollution affects not only urban areas, but many regions between cities, due to long-range transport of pollutants. Dominant sources of outdoor air pollution include combustion of fossil fuels in industry and transportation. In addition, poor household fuel combustion is a significant contributor to outdoor pollution in many parts of the world, for example South Asia and China, which means that the goals for clean household energy and general ambient air pollution are linked. GEA scenarios project the magnitude of the improvement that could be achieved with (1) implementation and enforcement of strict emissions controls, (2) universal access to clean cooking fuels, and (3) shifting of energy to non-combustion energy sources and efficiency.

Occupational health impacts: Occupational injuries and diseases, particularly in biomass and coal harvesting and processing (such as coal mining and transport), are the next most important impact on health from energy systems. Only strict adherence to international norms for worker health and safety can blunt this impact. Despite substantial gains over the past 50 years at some energy-related workplaces, health and safety systems do not exhibit best practices in many countries. The advent of novel nano- and other engineered materials for advanced solar and other energy systems potentially pose risks to workers and the public that need to be carefully investigated before widespread deployment to avert health impacts before they occur.

Nuclear power impacts: Unlike biomass and fossil fuels, nuclear power systems are not a significant source of routine public health impacts globally, although they often garner considerable public and policy concern. This said, reprocessing facilities release significantly larger amounts of radioactivity than power reactors and uranium mining leads to considerable environmental effects and health risks to workers. Average radiation doses to workers in nuclear power industries have generally declined over the past two decades, but tend to be concentrated in workers under less regulatory control. For nuclear power facilities, as with large hydroelectric facilities, the major health risks lie mostly with high-consequence but low-probability accidents. These risks are difficult to compare to the impacts that occur day-to-day. (See Chapter 14 for more discussion of nuclear accidents).

Energy efficiency and health: Although energy efficiency is usually found to be the best overall first strategy to improve the sustainability of energy systems, there can also be downsides if done without care. This has been seen, for example, in programs to improve the energy efficiency of buildings without considering the impacts on indoor air quality of reducing ventilation or use of improper materials.

Climate change, energy, and health: Climate change to date, to which energy systems are a significant contributor, is starting to have an important impact on health, perhaps exceeding 200,000 premature deaths annually by 2005, more than 90% among the poorest populations in the world. It is expected, however, that the health burden due to climate change will rise under current projections of greenhouse gases and other climate-altering pollutants (CAP) and background health conditions in vulnerable populations, which are largely in developing countries. Well over 20 million people along the vulnerable coastal regions of Bangladesh, Egypt, and Nigeria are estimated to be at risk of inundation from a one-meter sea level rise, not accounting for inevitable population growth. Other health impacts from climate change include the effects of extreme weather events, heat waves or sustained periods of extreme heat, malnutrition, spreading infectious diseases, and resource-related conflicts.

Protecting the climate system and improving health: There are a number of opportunities to reduce the current burden of disease while also reducing the pressure on global climate. Some relate simply to reducing energy use and its associated health and climate impacts through efficiency improvements and increased use of non-carbon based fuels, particularly renewable energy sources. Others, however, take advantage of the relatively high health and climate risk per unit emission posed by targeting specific short-lived greenhouse pollutants produced by energy systems, in particular black carbon and the precursors to ozone such as methane. Some of the energy-associated and health-damaging pollutants, such as sulfate and organic carbon particles, however, have cooling characteristics that create potential trade-offs between health and climate goals when controlling certain sources.

Overarching concepts: Per unit of useful energy, the health and climate benefits of emission reduction interventions rise with the fraction of incomplete combustion; and, also per unit of useful energy, the health benefits of emission reduction interventions rise as the combustion is closer to the population, increasing the proportion of emissions inhaled by the population.

From a health standpoint, in addition to reducing risk factors such as air pollution and climate change, there is equal importance to reducing vulnerability by improving background health conditions, particularly among the world's poor. Meeting the Millennium Development Goals (MDGs) as soon as possible will be critical, and bringing modern energy services to the world's people living in poverty is a necessary, if not sufficient, condition in doing so.

4.1 Introduction

Humanity requires energy to bring the benefits of health care, adequate food, education, protection against the elements, and the many other activities of society that enhance population health. On the other hand, dirty, dangerous, and environmentally disruptive energy supplies can lead to disease, injury, and premature death that is significant on local and global scales. Health impacts have thus been a major consideration in the promotion of some types of energy supplies and the avoidance of others.

Energy services provide important direct health benefits; for example, refrigeration preserves food and allows storage of vaccines. Energy for lighting enables health clinics to operate after dark. Energy for heating and cooling helps avoid heat stroke, hypothermia, and other health impacts of extreme conditions. It also improves general quality of life. These benefits are described in detail in Chapter 2. The lack of sufficient energy services, therefore, can be considered a health risk. However, whereas the impacts of lack of energy access are discussed elsewhere in the report, this chapter focuses on the health consequences of the energy society *does* use.

Two principal categories of risk lead to human health impacts associated with energy systems: risks resulting from routine operation (e.g., air pollution, occupational accidents) and risks from low-probability, high-consequence events (e.g., accidents at nuclear power plants and dams). Although the former category has the greatest impact on health year in and year out, the risk of major, if infrequent, events creates uncertainty and unease. Even as society seeks to limit such risks, there is sometimes a disconnect between calculated risk and perceived risk, the latter being influenced by the dread of disastrous, though rare, events associated with energy systems.

In addition to the public at large, many workers in the energy sector, especially in low-income countries, also bear health burdens from the world's energy supply systems. Although the total burden (mortality and morbidity) is larger in the public as a whole, the risk per person is usually greatest among workers, raising equity issues.

Within the general public, the health impacts of energy systems are also distributed inequitably. Not surprisingly, people living in poverty bear a disproportionate burden due to, for example, reliance on poor-quality combustion in households and living in the polluted areas of cities. They suffer more both because of their higher exposures and because of their greater vulnerability and co-risk factors, such as malnutrition and poor access to health care. The health effects of climate change also burden the poorest and most vulnerable populations disproportionately.

As with the environmental impacts presented in Chapter 3, the largest health impacts globally from energy systems are associated with the combustion of carbonaceous fuels, whether fossil or biomass. Chapter 3 presented the patterns of pollutant emissions from energy systems across the world and the resultant ambient air pollution levels. These are inputs into an assessment of health impacts but are insufficient by themselves. Firstly, there are substantially different types and magnitudes of health impacts from different types of pollutants. Secondly, health impacts are not a direct function of emissions or environmental concentrations but of human *exposure* to them. For instance, pollution over the ocean may cause impacts on marine ecosystems and the climate but no appreciable impact on human health because no one is there to breathe it. On the other hand, a relatively small amount of pollution emitted inside households may have major impacts on human health, but a small effect on ambient (outdoor) pollution levels. The exposure implications of different emissions sources has come to be termed the "intake fraction" – that is, the fraction of the material emitted to which the population is actually exposed (Bennett et al., 2002). This can vary by three orders of magnitude among energy systems and thus is crucial when considering health effects. Thus, no one-to-one relationship between the rankings of impacts in Chapter 3 and this chapter exists, even when the same sources and pollutants are considered (see Box 4.1).

In simple combustion situations, such as household stoves and small boilers in developing countries, combustion is far from complete, thus releasing a significant amount of the fuel carbon in products of incomplete combustion (PICs). These include a range of toxic compounds, such as carbon monoxide (CO), polyaromatic hydrocarbons (PAHs), benzene, and formaldehyde. Even when burned under excellent conditions, fossil fuels vary in quality. Some supplies contain significant toxic contaminants, such as sulfur, ash, and mercury, which are released in large amounts unless emissions are controlled after combustion. Finally, even when burned completely without any release of contaminants, carbon dioxide (CO_2) from fossil fuel use is the primary source of greenhouse gas (GHG) emissions, which threaten health through climate change. In general, consideration of climate change aside, health damage of all sorts is greatest with solid fuels, intermediate with liquid fuels, and least with gaseous fuels.

Health impacts from energy supply systems do not stem solely from the final conversion step – the power plant or automobile, for example. A common framework for evaluating the environmental and health implications of energy systems is the fuel cycle, which starts with harvesting of the raw fuel and proceeds through processing, transport, perhaps more than one conversion stage, and through to final waste disposal. In addition, there may be important impacts from the construction as well as the operation of facilities, together called "life-cycle assessment" (LCA) (see Box 4.4). Although the majority of health risk is usually exerted at the final conversion stage, a full understanding and comparison of energy systems requires such LCAs.

There is essentially no human endeavor that does not affect and is not affected by both health and energy in some way. The importance of and knowledge about the connections, however, vary dramatically. Here in the limited space available, we must focus only on the largest and most well understood of these relationships and thus set a fairly conventional system boundary for most of our analysis, i.e., energy supply systems.

As in the World Energy Assessment (Holdren and Smith, 2000) this chapter is organized by spatial scale, starting with what happens inside

Box 4.1 | Intake fraction

Health impacts of airborne and other pollutants depend on the level of exposure to the population of concern, which in turn depends not only on the amount and toxicity of emissions, but also on the proximity of the emissions to the population. Thus, if no one is downwind to breathe it, a pollutant released far from populations may not affect health significantly, while a pollutant released in the direct proximity of people can have a major effect, even if it is released in relatively small amounts. The metric used to compare such situations is called "intake fraction" (iF) which, for airborne pollutants, is simply the amount inhaled by the population divided by the amount released (Bennett et al., 2002). The difference between major categories of pollution can be several orders of magnitude, as illustrated in Figure 4.1.

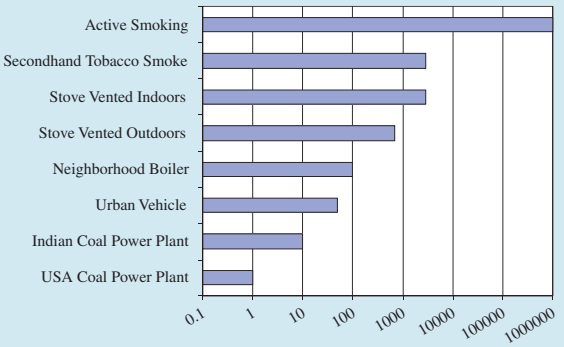

Figure 4.1 | Approximate intake fractions for typical sources of air pollution. Expressed as grams of pollutant inhaled for every tonne emitted. Thus, about one gram per tonne (one in a million emitted) is breathed by someone downwind of a typical power plant in the USA, while about 3000 grams are inhaled per tonne released indoors from a stove. Source: data from Smith et al., 1993.

Note that the iF for active smoking is 1.0 (one million grams inhaled for every million emitted): by definition, all the released pollutant is breathed in. At the other end of the iF spectrum in this figure are remotely sited US power plants, where only one millionth of what is released is breathed by someone. For pollutants released indoors, iFs are a few thousands per million, by comparison, while outdoor neighborhood sources range in between. The iFs vary by local situations, of course; for example, for indoor sources they depend on ventilation (Nazaroff, 2006). In cities, the iF of traffic pollution tends to be larger for bigger cities because the pollution is carried across the breathing zones of more people on its way downwind (Marshall et al., 2005). iF is generally used for primary pollutants, i.e., those actually emitted, and it must be supplemented by other analyses when addressing secondary pollutants, e.g., particles created downwind from sources emitting gases such as sulfur dioxide (SO_2).

The large difference in iFs across pollutant categories goes a long way toward explaining why relatively small amounts of pollution in the form of cigarette smoke or smoke from indoor cookfires can have such significant health impacts compared to the much larger amounts of pollution released from outdoor sources.

households and workplaces, moving to community and regional impacts, and ending with health risks from global changes due to energy use. In addition, we take up some special topics, including the health impacts of the nuclear fuel cycle, emerging technologies, and energy efficiency. Throughout, we start with a summary of what is known about health impacts today and then describe how these might evolve under different pathways of energy supply. As impacts on climate are a central theme throughout GEA, we end with a discussion of the potentials for "co-benefits," i.e., ways in which the evolution of energy systems can be directed to simultaneously achieve climate and health protection.

4.2 Household Energy Systems

4.2.1 Key Messages

- Human exposure to health-damaging air pollution from household combustion of fuels is widespread, affecting about 40% of the world population, and larger fractions in most developing countries.
- Women and children are likely to bear the largest share of the health risk burden from these exposures. According to GEA estimates in Chapter 17, household use of solid fuel for cooking resulted in 2.2 million premature deaths, or 41.6 million DALYs (disability-adjusted life years), in 2005, from exposures around the households.[1]
- Although only gaseous fuels and electricity offer truly clean performance, an emerging set of advanced biomass stove technologies

1 The most authoritative source of such estimates is the international Comparative Risk Assessment (CRA) which is part of the Global Burden of Disease Project. An extensively revised edition of the CRA is planned for publication in 2012, which will have updated authoritative estimates of the use of household solid fuels by region and the associated burden of disease as well as exposures and burdens from outdoor air pollution. These estimates are the most useful available for global policy because they are done across a range of risk factors, both environmental and other, in a consistent fashion. Thus they provide reliable information about the relative importance of interventions to improve health across sectors with minimal concern about differential assessment methods. Unfortunately, the updated CRA results were not available before GEA was completed but are scheduled to be available on the World Health Organization website in 2012: www.who.int/healthinfo/global_burden_disease/en/index.html.

provides intermediate performance that is more affordable and nearly as clean. More research and development is needed, however, to assess the field performance and acceptance of these stoves in different parts of the world, as well as the development of quantitative international standards for performance.

- Poverty and education deficits are likely to further exaggerate exposure potentials for vulnerable groups. To help meet the Millennium Development Goals (MDGs), opportunities to include household fuel and consequent air pollution issues in the mainstream public health agenda should be identified.

4.2.2 Background

A great majority of people living in poverty in developing countries have limited or no access to modern energy services, including access to electricity and modern fuels for cooking. As discussed in Chapter 1, GEA estimates that in 2005 about 2.8 billion people, mostly in the least developed and developing countries, relied on solid fuels such as biomass (wood, agricultural residues, and animal dung), charcoal, and coal for cooking and other household energy needs. Solid fuels in these households are often used in inefficient, poorly vented combustion devices, which results in the bulk of the fuel energy being emitted and wasted as toxic products of incomplete combustion. Further, the use of traditional stoves in small and poorly ventilated kitchens – in close proximity to household members on a daily basis – leads to exposures that are significantly detrimental to the health of family members, particularly to women and children, who spend the most time in or near the kitchen. Very young children are especially at risk, as they receive some of the highest exposures during vulnerable periods of growth. The scale of the exposures (spread across many countries), the complexity of the exposure situation (with multiple household-level determinants influencing frequency, duration, and magnitude of exposure), and the limited availability of data on exposures and health outcomes have resulted in a somewhat belated recognition of this risk factor as a major contributor to the disease burden at the global, regional, and national scales. Health impacts surrounding this risk factor are thus often neglected in global energy discussions.

With persuasive evidence for health impacts from the Comparative Risk Assessment (CRA) exercises conducted by the World Health Organization (WHO) (WHO, 2002), new, revised estimates of the burden of disease are being prepared, and an increasing body of scientific literature indicates substantial co-benefits for health and climate change from household energy interventions. This section provides an overview of patterns of household fuel use across world regions; concentrations and exposures experienced within household micro-environments; linkages between exposures and select health outcomes; and selected intervention options that are available and/or are being evaluated for broader application within countries (Household fuel systems of developed countries are not elaborated in this section but are discussed in Section 4.9 in the context of energy efficiency).

4.2.3 Patterns of Household Fuel Use in Developing Countries

Hundreds of demographic surveys conducted in developing countries, especially over the last decade, have collected information on household fuel use. According to a recent United Nations Development Programme review (UNDP, 2009), some 129 countries have data available on fuel use, including access to modern fuels and fuels used for cooking (see Table 4.1 and Figure 4.2). India and China together account for nearly half the global population that uses solid fuels for cooking (27% and 25%, respectively); sub-Saharan Africa also accounts for a significant share. Wood is the predominant type of solid fuel used, although in many surveys the distinction between wood, woodchips, and agricultural residues is not clearly made. Among developing countries generally, nearly 40% rely on modern fuels; however, in the poorest, least developed countries, gas use is uncommon. Use of other fuels is concentrated in certain countries, e.g., charcoal in sub-Saharan Africa, coal in China, dung in India, kerosene in Djibouti, and electricity in South Africa.

Accurate information on fuel use at the national and regional scales is a critical input for calculating the attributable burden of disease. Traditionally, the risk estimates from epidemiological studies have

Table 4.1 | Number of people relying on solid and modern fuels for cooking for all developing countries, least-developed countries, and sub-Saharan Africa.

	Number of people relying on solid fuels (millions)			Number of people with access to modern fuels (millions)
	Traditional biomass	Coal	Total	
Developing Countries	2564	436	2999	2294
LDCs	703	12	715	74
Sub-Saharan Africa	615	6	621	132

Notes: Based on UNDP's classification of developing countries, and the UN's classification of least developed countries (LDCs). There are 50 LDCs and 45 sub-Saharan African countries, with 31 countries belonging to both categories. Traditional biomass includes wood, charcoal, and dung. Wood includes wood, wood chips, straw, and crop residues. Modern fuels refer to electricity, liquid fuels, and gaseous fuels such as LPG, natural gas, and kerosene.

Source: data estimated by UNDP, 2009 for 2007.

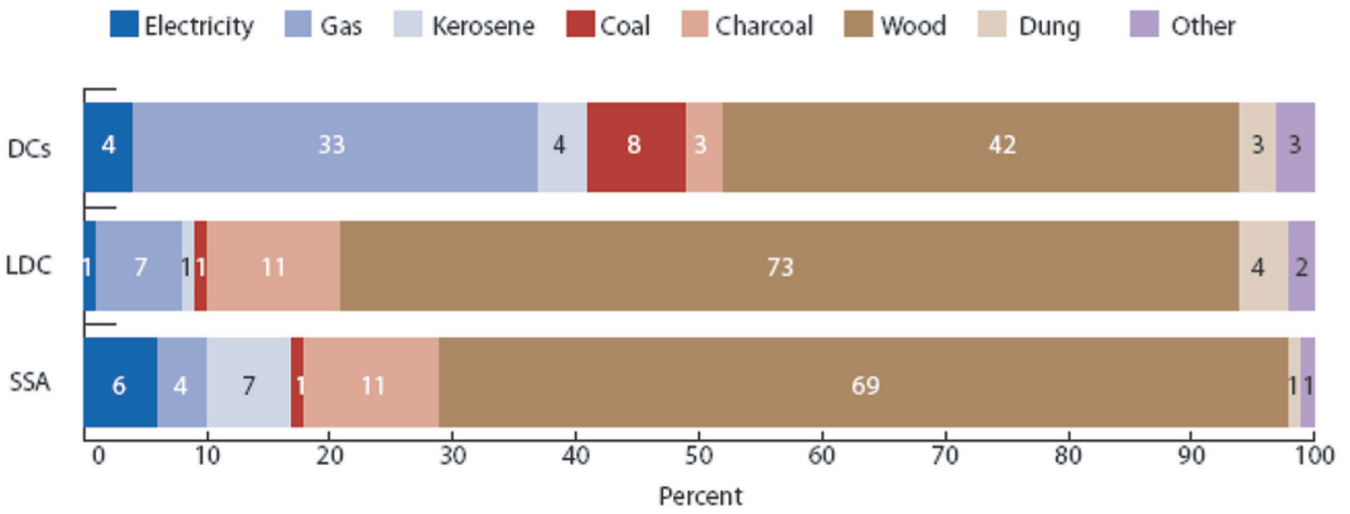

Figure 4.2 | Share of population relying on different types of cooking fuels in all developing countries, least-developed countries, and sub-Saharan Africa. Source: data estimated by UNDP, 2009 for 2007.

Notes: Based on UNDP's classification of developing countries (DCs), and the UN's classification of least developed countries (LDCs). There are 50 LDCs and 45 sub-Saharan countries (SSA), of which 31 countries belong to both categories. Gas includes natural gas, LPG, biogas, and ethanol. Kerosene includes kerosene and paraffin. Coal includes coal dust and lignite. Wood includes wood, wood chips, straw, and crop residues. "Other" includes missing data, "no cooking in the house," and other fuels.

been based on whether solid fuels are used for cooking or heating (WHO, 2002).[2]

Socio-economic factors significantly influence household fuel choice. In most countries with per capita incomes under US$1000, household fuel demands account for more than half of the total primary energy demand for cooking and heating; in contrast, such demands account for less than 2% of total primary energy use in industrialized countries (UNDP, 2000). As per capita incomes increase, households switch to cleaner, more efficient energy systems for their household energy needs, i.e., they move up the "energy ladder" (Hosier and Dowd, 1987; UNDP, 2000). With technological progress, the income levels at which people make the transition to cleaner modern fuels has fallen. However, availability of cleaner fuels at the national level does not guarantee availability of supply in rural areas (Masera et al., 2000), due to issues related to transport, reliability of supply, and socio-cultural preferences. Moreover, in every poor country the income disparities between rural and urban people are large, with most people in rural areas pursuing subsistence livelihoods. Household fuel generation, distribution, and consumption are thus closely related to the overall status of energy, environment, and development in the respective countries.

Several household factors directly influence patterns of human exposure to cooking fuel smoke, which occurs both inside and around households using poor combustion. Fuel type, kitchen location, use and maintenance of stoves, household layout and ventilation, time-activity profiles of individual household members, and behavioral practices (such as where children are located when cooking is being done) have been shown to influence pollution levels and individual exposures. Countries with low gross domestic product (GDP) also typically experience greater gender inequities in terms of income, education, access to health care, social position, and socio-cultural preferences, all of which could potentially influence exposures for vulnerable groups, such as women and children.

Geographic variables can also significantly affect pollution intensity and duration. Extreme temperature differentials between seasons, rainfall, altitude, and even meteorological factors (such as wind speed, wind direction, and relative humidity) could determine whether fuels are used for both cooking and heating, as well as whether they are affecting aerosol dispersion and/or deposition. Patterns of vegetation (e.g., tropical rain forests vs. scrub) could contribute to household decisions on seeking alternative energy sources. Easy availability of wood or other biomass at little or no cost is likely to encourage continued use, especially among people living in poverty.

Although the available literature does not allow a detailed attribution of exposures to each of these variables, these can be expected to make varying contributions and should be considered while creating local or regional profiles of the exposure situation. A schematic showing the potential determinants is shown in Figure 4.3.

2 Only recently has it also been possible to estimate the exposure-response relationships for a few important diseases at exposure levels typical for populations using solid fuels for cooking. In addition, estimates of household exposures across major populations have been done. These will be available in the new CRA. See Footnote 1. The estimates in GEA, however, are based on the traditional approach: yes-no epidemiological relationships in which the average difference in disease between people living in polluted and less polluted households has been determined based on cookfuel type.

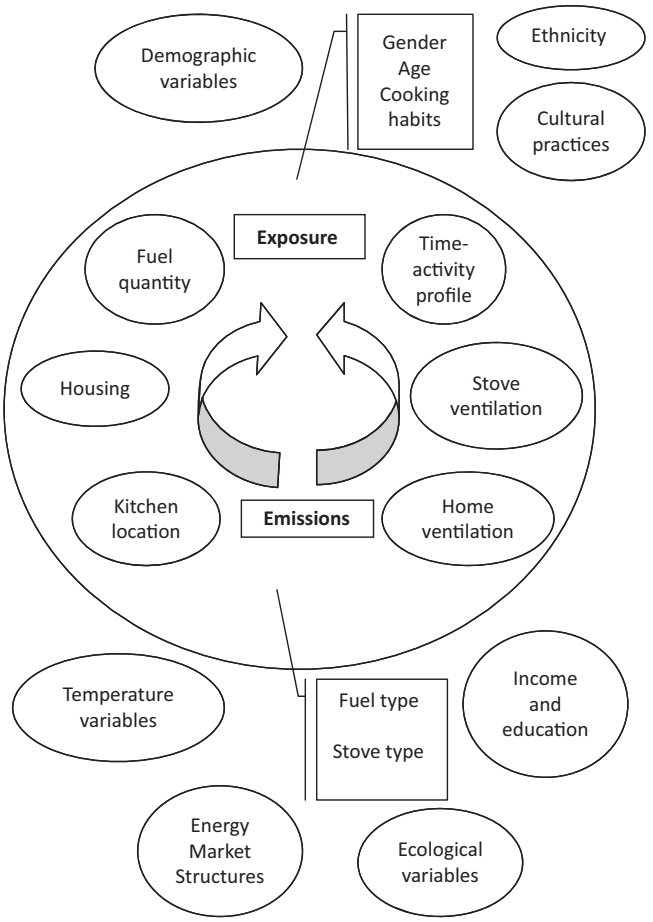

Figure 4.3 | Macro and micro-environmental determinants of exposure to solid fuel smoke.

4.2.4 Emissions from Combustion of Household Fuels

A majority of households in developing countries using solid fuels for cooking burn them in poorly functioning mud or metal stoves or use open pits, usually without a chimney or other arrangement to vent the smoke from the area. Under ideal conditions, complete combustion of carbon would produce only CO_2 and water. However, virtually all traditional ways of burning household biomass fuel emit substantial quantities of PICs, since conditions for the efficient combustion of these fuels are difficult to achieve in typical household stoves. PICs include: small respirable particles, gases such as carbon monoxide and nitrogen, phenols, quinones/semiquinones, chlorinated acids such as methylene chloride, and dioxins. Combustion of coal may release, in addition to the above pollutants, sulfur oxides, heavy metal contaminants, arsenic, and fluorine. On average, a typical solid fuel stove converts 6–20% of the fuel into toxic substances. At least 28 pollutants present in smoke from solid fuel use have been shown to be toxic in animal studies; some 14 carcinogenic compounds and four cancer-promoting agents have been identified (Table 4.2).

In a recently concluded assessment by the International Agency for Research on Cancer, emissions from household combustion of coal have been classified as being "carcinogenic to humans" (Group 1 carcinogen, based on sufficient human and experimental evidence), while indoor emissions from household combustion of biomass fuel (mainly wood) has been classified as "probably carcinogenic to humans" (Group 2A carcinogen, on the basis of limited evidence of carcinogenicity of biomass combustion emissions, mainly from wood, in humans and experimental animals; sufficient evidence of carcinogenicity of wood-smoke extracts in experimental animals; and strong evidence of mutagenicity) (IARC, 2010).

4.2.5 Exposures to Health-Damaging Pollutants from Combustion of Household Fuels

Well over 100 studies over the last two decades have assessed levels of indoor air pollutants in households using solid fuels. The methods employed range from the collection of questionnaire-based information to quantitative measurements of household-level exposures. A global database documenting results from these measurements across some 70 studies in the developing countries of Asia, Latin America, Africa, and China (if reported in English) is available from WHO (2005). Although a great majority of studies have performed single-pollutant measurements on a cross-sectional sample of households, select studies have examined temporal, spatial, or multi-pollutant patterns, in addition to day-to-day or seasonal variability in concentrations and exposures (Saksena et al., 1992; Ezzati et al., 2000; Balakrishnan et al., 2002; He et al., 2005). A few have also developed models to examine the differential contributions of household determinants and validate the use of simpler household indicators (that are relatively easy to collect) as a proxy for actual household exposures (Balakrishnan et al., 2004; Bruce et al., 2004).

Data from more than 70 studies are available in the global indoor air pollution databases (Saksena et al., 2003), with some 30 new studies added in a recent update. Nearly one-third of the studies are from South Asia; Latin America, Africa, East Asia, and Eastern Mediterranean are also well represented. On a country-by-country basis, India reported the most studies (27), followed by China (13), Guatemala (10), and Mexico (10). Other countries generally reported fewer than five studies. While most studies reported results from rural areas, 34 studies reported on urban households, indicating a substantial use of solid fuels in urban settings of developing countries. These measurements cover approximately 13,000 households worldwide.

Wood was the most commonly reported solid fuel, with many studies reporting wood, wood chips, and agricultural residues in aggregate or as "mixed fuels." Similarly, gaseous and liquid fuels were often reported as "mixed clean fuels" rather than individually. Prior to 2000, most studies reported measurements from households using traditional solid fuel stoves, while more recently nearly 30 studies have reported results from households using self-styled "improved (solid fuel) stoves."

Table 4.2 | Toxic pollutants from incomplete biomass combustion.

Pollutant	**Known Toxicological Characteristics**
Particulates (PM_{10}, $PM_{2.5}$)	Bronchial irritation, inflammation increased reactivity, reduced mucociliary clearance, reduced macrophage response
Carbon monoxide	Reduced oxygen delivery to tissues due to formation of carboxyhemoglobin
Nitrogen dioxide (relatively small amounts from low temperature combustion)	Bronchial reactivity, increased susceptibility to bacterial and viral lung infections
Sulfur dioxide (relatively small amount from most biomass)	Bronchial reactivity (other toxic end points common to particulate fractions)
Organic air pollutants	
Formaldehyde 1,3 butadiene Benzene Acetaldehyde Phenols Pyrene, Benzopyrene Benzo(a)pyrene Dibenzopyrenes Dibenzocarbazoles Cresols	Carcinogenicity Co-carcinogenicity Mucus coagulation, cilia toxicity Increased allergic sensitization Increased airway reactivity

Mixed Liquid/ Gaseous fuel	76	376	398	149

Notes: Data include all size fractions and sampling durations.

Source: author's calculations based on data from 108 studies in the revised WHO Global Indoor Air Pollution Database (WHO, 2005).

Particulate matter of various sizes was the most commonly measured pollutant, followed by carbon monoxide. Other air toxics were seldom reported. While earlier studies measured total suspended particulate matter (TSP) over short sampling times (e.g., during cooking), many recent studies report results of PM_{10} or $PM_{2.5}$ over 24-hour periods. Table 4.3 shows the distribution of measured values across studies that used alternative fuels.[3]

Median values in households using liquid or gaseous fuel are observed to be 5- to 10-fold lower than those reported for households using solid fuel. When compared with more carefully done studies, however, the levels in households using gaseous fuel is often 10- to 20-fold lower. Peak values in dung- and coal-using households have occasionally been observed to be 100-fold higher than levels in corresponding gas-using households.

Households using solid fuels experience indoor concentrations many times higher than WHO Air Quality Guidelines (AQG) for PM_{10} and $PM_{2.5}$ (WHO, 2006). Even gas-using households in rural areas barely meet the strictest AQG values, presumably due to a high background

3 It should be noted that PM_{10} and $PM_{2.5}$ are generic particle classes defined simply by the upper limit of the particle diameters contained within that class (i.e., 10 or 2.5 micrometers). These metrics encompass particles of any chemical composition whose aerodynamic diameters fall below the respective size, potentially including sulfates, nitrates, metals, elemental and organic carbons.

Table 4.4 | Mortality and morbidity attributable to indoor air pollution from solid fuel use, by global region, 2004.

	Attributable deaths per year		Attributable DALYs per year	
	Number ('000)	Per 1 million population	Number (in millions)	Per 1 million population
Developing countries	1,994	378	40.5	7,878
LDCs	577	771	18.4	24,606
Sub-Saharan Africa	551	781	18	25,590
South Asia	662	423	14.2	9,075
Arab States	35	114	1.1	3,489

of outdoor air pollution resulting from the venting and dispersion of solid fuel smoke from neighboring households.[4]

Collectively, the evidence from these studies shows that rural women, children, and men in households using solid fuels experience extremely high levels of exposure to particulate matter and toxic gases. Often these exposures are an order of magnitude or even higher than levels generally considered safe. Further, some emissions from coal combustion (e.g., arsenic and fluorine) have additional, non-inhalational exposure routes (such as deposition on food and contamination of drinking water sources), compounding health effects (He et al., 2005).

4.2.6 Health Effects Associated with Household Fuel Combustion

The amount of disease resulting from the use of solid fuels has been estimated (Smith et al., 2004) as part of WHO's CRA (WHO, 2002; Ezzati et al., 2004). The burden of disease is calculated by combining information on the increased risk of a disease resulting from exposure with information on how widespread the exposure is in the population (in this case, the percentage of people using solid fuels). This allows for the calculation of the "population attributable fraction" (PAF), which is the fraction of the disease seen in a given population that can be attributed to a particular exposure – in this case, solid fuel use. Applying this fraction to the total burden of disease (e.g., child pneumonia expressed as deaths or DALYs), gives the total number of deaths and DALYs that result from use of solid fuels.

For computing disease burdens associated with solid fuel use, estimates of relative risk obtained from all published epidemiological studies have been combined together in a process called meta-analysis into a single best estimate of the risk. In the 2004 CRA, three diseases were felt to have sufficient evidence bases to be included in the final estimate of the health burden of solid fuel use: pneumonia in children aged under five years, chronic obstructive pulmonary disease (COPD), and lung cancer (only for use of coal). The 2004 WHO-led CRA exercise estimated that annually about 1.6 million deaths and over 38.5 million lost healthy life years (also measured in DALYs) were attributable from household solid fuel use in 2000 (Table 4.4) (Smith et al., 2004).[5] Cooking with solid fuels is thus responsible for a significant proportion, about 3%, of the global burden of disease. In many poor countries, such as India, solid fuel use was found to be the third most important risk factor for ill health, exceeded only by malnutrition and unsafe water and sanitation (Smith and Ezzati, 2005).

The regional or national burden of disease attributable to solid fuel use varies considerably and is based not only on differences in fuel use but also on underlying disease rates. For example, among developing countries, attributable deaths from COPD are greater in India and China as compared to least developed countries (LDCs) and sub-Saharan Africa, while attributable deaths from child pneumonia are highest in the latter because of different patterns of background disease rates. It is to be emphasized that child pneumonia accounts for some 75% of DALYs attributable to solid fuel use in developing countries overall (compared with less than half of all premature deaths) and an even greater share of DALYs in the LDCs and sub-Saharan Africa. In India, for example, pneumonia accounts for more than half of all DALYs attributable to solid fuel use, but only about a third of premature deaths. Because the DALY measure captures the many years of life lost due to deaths from child pneumonia, it shows an even stronger impact of solid fuel use on health in the poorest countries, where pneumonia is a major cause of death in children under five years of age. As expected, the poorest are at the greatest risk of exposures and disease burdens wherever they are found.

At the time of the preparation of the CRA (~2002), the evidence for attributable disease burden was sufficient only for the three health outcomes

4 The completed global indoor air pollution measurement database is expected to be available on the WHO website in 2012: www.who.int/indoorair/health_impacts/databases_iap/en/

5 As noted in Footnote 1, a completely revised update will be available on the WHO website in 2012.

mentioned above (i.e., child pneumonia, COPD, and lung cancer). An emerging body of evidence, however, indicates additional burdens from other diseases and conditions, including new studies on cataracts, low birth-weight, and tuberculosis, as well as lung cancer associated with biomass fuel use (Lin et al., 2007; Pope et al., 2010; Hosgood III et al., 2011). Although not yet conclusive, there is also growing evidence of other cancers and burns related to biomass fuel use. Evidence on the original health outcomes is growing as well; see Dherani et al. (2008) for information on pneumonia, Kurmi et al. (2010) on COPD, and the IARC (2010) on lung cancer from coal. In addition, results will soon be available from the first randomized controlled trial for an intervention related to solid fuel use, through the use of chimney stoves in Guatemala (Smith et al., forthcoming). Although there have not been any studies of heart disease in these settings, substantial evidence from other exposures to combustion particles (outdoor air pollution, environmental tobacco smoke, and active smoking) together provide strong, although indirect, evidence of a probable major impact from household fuels as well (Pope et al., 2009; Smith and Peel, 2010).[6]

For the future scenarios used in GEA, a simplified health assessment was conducted using the same relative risks published in the 2004 CRA, as well as new relative risks for ischemic heart disease published in Wilkinson et al. (2009),but with changing exposures as advanced stoves and fuels come into use in the next decades (in line with GEA assumptions). GEA estimated premature mortality from household fuels in 2005 using this approach was 2.2 million, which is somewhat higher than what was found for 2000 in the CRA. The methods used are discussed in detail in Chapter 17.[7]

4.2.7 Intervention Effectiveness

Household energy interventions to date have largely centered on improving fuel efficiency, either by using better fuels and stoves or using improved stoves with the same fuels (Barnes et al., 1994). Considerable evidence is available to indicate that households using gaseous (liquified petroleum gas or biogas) or liquid fuels experience considerably lower pollution levels as compared to homes using solid fuels (Albalak et al., 2001; Balakrishnan et al., 2002; Balakrishnan et al., 2004). A limited number of studies have also shown significant reductions with the use of electricity (Rollin et al., 2004). Improved biomass stoves, which burn more efficiently and vent emissions outside the home, have been an intervention option for more than two decades. Improved stove programs have been implemented in many countries, most notably in India and China. Although designed to conserve fuel, these programs have had some impacts on reducing household emissions of health-damaging pollutants and CAPs (US EPA, 2000; Edwards et al., 2004).

Somewhat lower indoor concentrations using stove models equipped with chimneys have also been documented in many regions, including China (Sinton et al., 2004), India (Smith et al., 1983; Ramakrishna et al., 1989), Nepal (Reid et al., 1986; Pandey et al., 1990), Latin America (Brauer and Bartlett, 1996; Albalak et al., 2001; Bruce et al., 2004), Mexico (Riojas-Rodríguz et al., 2001), and sub-Saharan Africa (UNDP, 2009). Interventions that reduce exposures either through behavioral interventions or through improved ventilation have also been described (Barnes et al., 2004; UNDP, 2009).

More recently, advanced combustion stoves – using traditional woodfuel but burning much more cleanly – have become available. One promising approach involves so-called "gasifier" stoves that achieve very high combustion efficiency through designs that facilitate two-stage combustion. The most reliable of these use small electric blowers to stabilize the combustion. Where there is no reliable electricity available, inexpensive thermal-electric generators (TEGs) are now being incorporated into stoves to generate the needed power from the stove heat itself.

Although programs promoting the use of improved stoves have not always proved successful, some have achieved remarkable penetration. For example, the Chinese National Improved Stove Programme was able to provide stoves to some 180 million rural households during the 1980s and 1990s (Barnes et al., 1993; Smith et al., 1993; Sinton et al., 2004). Several programs are underway in India that attempt to promote penetration of improved stoves using market-based approaches, in contrast with earlier, government-subsidized efforts. While substantial reductions in emissions have been achieved with many of these improved stove models, the residual levels of pollutants are still high compared to WHO's health-based AQGs. More recent programs increasingly emphasize not only the provision of stoves, but also support for installation and routine maintenance, training and education, and use of market mechanisms to continuously assess user preferences. These innovations are expected to expand coverage and improve performance, leading to further sustained exposure reductions across large populations.

Some evidence suggests that health benefits can accrue even with modest reductions in exposures. In the trial with chimney stoves in Guatemala, a 50% reduction in smoke exposures resulted in an 18% reduction in physician-diagnosed childhood pneumonia (Bruce et al., 2007; Smith et al., forthcoming). To achieve this, however, required nearly a 90% reduction in indoor levels, which is difficult to achieve reliably in practice without advanced combustion stoves. In those households achieving a 90% reduction in exposure, on the other hand, children had only half as much pneumonia, an improvement greater than achieved by available vaccines and nutrition supplements, which are the other major interventions for this major killer of children. To obtain this much reduction, however, will require extremely clean burning stoves used regularly over long periods.

6 See Footnote 2.

7 As noted in Footnote 1, readers interested in the burden of disease attributable to household air pollution or outdoor air pollution in 2005 or 2010 are advised to refer to the updated CRA on the WHO website, as it is part of a larger consensus assessment in which fair comparisons were made across risk factors. Please note that the CRA does not attempt to project changes in burden of disease over future years as does GEA in Chapter 17.

Table 4.5 | Health benefits of the Indian Improved Stove Program, 2010–2020 (estimated).

	Deaths from ALRI	Deaths from COPD	Deaths from IHD	Total DALYs for these diseases
Avoided in 2020 (%)	30.2	28.2	5.8	17.4
Annual number in 2020 without stoves ($x10^6$)	0.14	1.00	1.77	63.0
Total avoided 2010–20 ($x10^6$)	0.24	1.27	0.56	55.5

Note: ALRI = acute lower respiratory infections. COPD = chronic obstructive pulmonary disease. IHD = ischaemic heart disease. DALY = disability-adjusted life year.

Source: Wilkinson et al., 2009.

In a striking set of analyses, simulations to estimate percent use of improved stoves under baseline and assumed enhanced rates of dissemination for the case of India have shown that nearly 12,500 DALYs could be avoided annually per million people. The national burden of disease (DALYs) in 2020 from these three major diseases is estimated to be about a sixth lower than it would have been without the stove program, which is equivalent to the elimination of nearly half the entire cancer burden in India in 2020 (Table 4.5 and Wilkinson et al., 2009). What is not well understood yet, however, is how well such advanced stoves actually perform in field conditions and how well they are accepted by large populations.[8]

4.2.8 Conclusion

The UNDP report of 2009 assesses that while many developing countries have clear targets for providing access to electricity, only a handful (17 for access to modern cooking fuels and 11 for provision of improved stoves) have set targets to reduce household solid fuel use. Evidence of health benefits from incremental improvements could be expected to provide relevant cost-effectiveness information to policy makers, greatly facilitating the acceleration of intervention efforts. To effectively implement stoves that truly lower exposures, however, there is a need to define more quantitatively what is meant by various levels of "improvement," probably separately in terms of expected emissions/exposure and fuel use per meal. In the past, unfortunately, almost any new stove could be claimed to be "improved" when many actually did little. Fortunately, the WHO has embarked on the process to develop formal health-based guidelines, slated for publication in 2012.[9] Another factor stove programs need to address directly is adoption/usage – it does no good to disseminate a high-performance stove that no one uses, something that has happened in many past programs. New monitoring technologies, however, are making it possible to keep track of actual household usage inexpensively (Ruiz-Mercado et al., 2011). This will allow programs to better understand the stove designs, training, and incentives that enhance usage.

8 In 2010, a number of non-governmental organizations; foundations; international, bilateral, and national agencies and companies announced the formation of Global Alliance for Clean Cookstoves. Its goal is to engender the introduction of 100 million clean-burning cookstoves globally by 2020. See http://cleancookstoves.org/the-alliance/.

4.3 Occupational Health Effects of Energy Systems

4.3.1 Key Messages

- Energy systems involve a large number of workers, particularly in low- and middle-income countries, and entail significant occupational health problems.
- Solid fuel systems (i.e., biomass and coal) tend to have higher occupational risks, in both absolute and per-worker terms.
- Despite substantial gains over the past 50 years at some energy-related workplaces, health and safety systems do not exhibit best practices in many countries. Health risks could be reduced with the adoption of modern occupational health management and prevention programs, in accordance with international conventions and guidance from the International Labour Organization (ILO).
- Renewable energy systems, such as hydropower, wind power, and photovoltaic power, likely involve lower occupational health risks. These risks occur mainly during construction work.
- Occupational health hazards for each type of energy source need to be assessed at the local level, followed by the creation of a plan for effective health protection. Such assessments should also include analysis of occupational health co-benefits of changing to more renewable energy sources.

4.3.2 Background

Energy production, processing, transport, waste disposal, and end use involves millions of workers around the world. In addition, the construction work required to build the energy supply units requires large numbers of additional workers. The health hazards they are exposed to during work activities are important concerns for the energy industry. Many of these jobs are hazardous, with particular risks of injuries, dust diseases, poisoning, noise/induced hearing loss, heat stroke, and radiation effects.

Energy-related work for rural and urban people living in poverty primarily involves the collection of biomass fuel for daily household

cooking and heating needs. Their work involves injury risks, heavy load bearing and heat exposure in bright sun during the hot season, the latter being exacerbated by global climate change. In some areas, risks of physical violence, snake bite, and leeches accompany biomass collection for women. Biomass fuel collection may also occur in dumps and landfill sites, which increases the risks of injuries and chemical exposures for the collectors. Much of the work needed for household energy supply in the developing countries is carried out as a household task that does not figure in the national statistics as an "occupational" issue.

Coal as an energy source involves coal mining, one of the most hazardous occupations on Earth. Miners are exposed to collapsing mine shafts, fire and explosion risks, toxic gases (carbon monoxide), lung-damaging dusts (coal and silica), and hot work environments, as well as injury and ergonomics hazards. Coal also requires major transport arrangements for coal and waste that create health hazards. Oil and gas workers face injury risks, particularly during drilling and emergency situations and work on offshore platforms, as well as exposure to toxic materials at refineries. The Gulf of Mexico oil platform disaster in 2010 is an example of the extreme hazards involved.

Hydropower electricity production on a large scale requires major dam, tunnel, and building construction, which also entails high injury risks and exposure to noise and heat. Mini- and micro-hydro schemes do not require such major infrastructure.

Wind power, photovoltaic solar power, and solar water heating involve more limited occupational hazards during construction and are associated with risks of manufacturing steel, cement, and other materials, while nuclear power has its own special hazards associated with potential radiation exposure and the disposal of radioactive waste (see Sections 4.7 and 4.8).

This section will analyze the health issues based on the type of energy source and give examples of how the effects have been documented in different countries. The ILO Encyclopedia of Occupational Safety and Health (ILO, 1998) was published more than 10 years ago but is still a very useful source of information on occupational health aspects of energy systems. This section therefore refers to "older" sources from that period, but that does not mean that the health information is out of date. Ideally, there would be data on the occupational health impacts of different energy sources expressed as "burden of disease and injury per megawatt-hour of energy supply," but these are not yet available.

The analysis of occupational health impacts of different energy systems should include a full life-cycle analysis of the extraction, transport, and processing of raw materials; the production of machinery and buildings required; and the transportation and disposal of waste from the process, as well as the actual energy medium (see Box 4.4 (p 205)).

4.3.3 Biomass

Wood, agricultural plant waste, cow dung, etc., are common sources of cooking and heating energy in poor households in developing countries. Wood is still also widely used in developed countries for space heating, in some cases promoted in the interest of reducing CAP emissions (UNDP, 2000). Biomass constitutes approximately 9% of the global primary energy supply. A detailed review of the occupational health and safety issues of forestry can be found in Poschen (1998a). Additional and updated information can be searched, for instance, on the website "Atlantic Network for Research in Forestry Occupational Health, Safety and Ergonomics."[10]

The majority of wood and agricultural waste, etc. is collected by women and children in local fields and forests (Sims, 1994). This is a part of the daily survival activities, which also include water hauling, food processing, and cooking. An analysis of time use for these activities in four developing countries (Reddy et al., 1997) showed that women spent 9–12 hours per week doing this, whereas men spent 5–8 hours. Women's role in firewood collection was most prominent in Nepal (2.4 hours for women and 0.8 hours for men). Updated similar information about sub-Saharan Africa is now available (Blackden and Wodon, 2006). Firewood collection may be combined with harvesting of wood for local use in construction and small-scale cottage industry manufacturing. This is subsistence work, often seasonal, unpaid, and unrecorded in national economic accounts. Globally, about 16 million people were involved in forestry in the 1990s (Poschen, 1998b), more than 14 million of them in developing countries and 12.8 million of them in subsistence forestry (UNDP, 2000).

A number of health hazards are associated with the basic conditions of the forest. The workers have a high risk of suffering from insect and snake bites, stings from poisonous plants, cuts, falls, and drowning. In tropical countries, the heat and humidity create great strain on the body (Wasterlund, 1998; Kjellstrom et al., 2009), whereas in temperate countries the effect of cold climate is a potential hazard. The work is outside, and, in low-latitude countries, high levels of ultraviolet radiation can be another health hazard, as it increases the risk of skin cancer and cataracts (WHO, 1994). All forestry work is hard physical labor, often causing repetitive stress injuries, such as painful backs and joints, as well as fatigue, which in turn increases the risk of injuries from falls, falling trees, or equipment (Poschen, 1998b). Women and children carrying very heavy loads of firewood are a common sight in areas with subsistence forestry (Sims, 1994). Children may also drop out of school due to the need to help with family forestry work. In addition, the living conditions of forestry workers are often poor quality, and workers may be spending long periods in simple huts in the forest with limited protection against the weather and poor sanitary facilities (UNDP, 2000).

Urbanization leads to the development of a commercial market for firewood and larger-scale production of firewood from logs or from smaller waste material left over after the logs have been harvested. Energy forestry then becomes more mechanized and the workers are exposed to additional

10 www.safetynet.mun.ca/forestry/index.htm

hazards associated with commercial forestry (Poschen, 1998b). Motorized hand tools (e.g., the chain saw) become more commonly used, which leads to high injury risk, as well as noise-induced hearing loss and "white finger disease" caused by vibration of the hands. In addition, synthetic fertilizer and pesticides become a part of the production system, with the potential for pesticide poisoning of workers (UNDP, 2000).

As the development of forestry progresses, more and more of the logging becomes mechanized with very large machinery involved, which reduces the direct contact between worker and materials. Workers in highly mechanized forestry have only 15% of the injury risk of highly skilled forestry workers using chainsaws (Poschen, 1998b). However, firewood production remains a hazardous operation because it requires manual handling of the product close to cutting tools (UNDP, 2000).

Another health aspect of wood-based energy is the risk of burning wood that has been treated against insect damage with copper-arsenic compounds or painted with lead paint. Such wood may be more difficult to sell, and may therefore be used to a greater extent by the firewood production workers themselves in stoves and open fires. When burnt, poisonous arsenic and lead compounds, as well as dioxins and furans, are emitted with the smoke and can lead to ill-health when inhaled (UNDP, 2000; Tame et al., 2007).

4.3.4 Coal

Coal is a major energy source, constituting approximately 25% of total primary energy (see Chapter 1). Coal can be produced through surface mining ("open cast") or underground mining. Both operations are inherently dangerous to workers. About 1% of the global workforce is engaged in mining, but they account for 8% of the global fatal occupational accidents (about 15,000 per year) (Jennings, 1998). Since 1900, over 100,000 people have been killed in coal mining accidents in the United States, and in China, underground mining accidents cause 3,800–6,000 deaths annually (Epstein et al., 2011). A detailed review of occupational health and safety issues in coal mining and other mining is available in Armstrong and Menon (1998).

Underground coal miners are exposed to the hazards of excavating and transporting materials underground. This includes injuries from falling rocks and falls into mine shafts, as well as injuries from machinery used in the mine. There are no reliable global data on injuries of this type from developing countries (Jennings, 1998), but in developed countries miners have some of the highest rates of compensation for injuries. The situation is likely to be worse in developing countries. In addition, much of the excavation involves drilling into silica-based rock, which creates high levels of silica dust inside the mine. Occupational lung disease (silicosis) is therefore a common health effect in coal miners (Jennings, 1998). In addition, coal miners have an increased risk of lung cancer (Donoghue, 2004).

Other health hazards specific for underground coal mining include the coal dust, which can cause "coal workers' pneumoconiosis" or anthracosis (black lung disease), often combined with silicosis (Ross and Murray, 2004). Since 1900, coal workers' pneumoconiosis has killed over 200,000 people in the United States; in the 1990s alone, over 10,000 former US miners died from the disease. The prevalence has more than doubled since 1995 (Epstein et al., 2011).

The coal dust is explosive, and explosions in underground coal mines are an ever-present danger for coal miners. Coal is also inherently a material that burns, and fires in coal mines are not uncommon. Once such a fire has started it may be almost impossible to extinguish it. Apart from the danger of burns, the production of smoke and toxic fumes will create great health risks for the miners. Even without fires, the coal material will produce toxic gases, such as carbon monoxide, carbon dioxide, and methane, when it is disturbed (Weeks, 1998). Carbon monoxide is extremely toxic, as it binds to hemoglobin in the blood, blocks oxygen transport, and causes "chemical suffocation" (WHO, 2000). It is a colorless and odorless gas, giving no warning before symptoms such as drowsiness, dizziness, headache, and unconsciousness occur. Carbon dioxide can sometimes displace oxygen in the underground air and can cause suffocation. Another health hazard in mining is exhaust fumes from diesel engines used in machinery or transport vehicles underground. These exhausts contain very fine particles, nitrogen oxides, and carbon monoxide, all of which can create serious health hazards (WHO, 2000).

Work in coal mines is also uncomfortably hot during the warmer seasons of the year (Kampmann and Piekarski, 2005). In both Germany and South Africa, heat impacts on mine workers increase during and just after the summer season. Ongoing climate change is expected to increase the occupational health risks related to coal mining.

Surface coal mining avoids the hazards of working underground but does still involve injury risk from machinery, falls, and falling rocks. In addition, coal mining is very physically intensive work, and heat, humidity, and other weather factors can affect workers' health (Kjellstrom, 2009). The machinery used is noisy and hearing loss is a common effect in miners (Armstrong and Menon, 1998). Another health hazard is the often squalid conditions under which many coal workers in developing countries live, creating particular risk for the diseases of poverty (Jennings, 1998). In addition, many modern coal mines involve mountaintop removal and strip mining, which adds to ecological damage, causes mental stress among nearby communities, leads to ammonia releases, and contaminates water sources with waste emissions (Epstein et al., 2011).

After extraction the coal needs to be processed and transported to the sites where it will be used, including residential areas, power stations, and factories. This creates other types of occupational hazards (Armstrong and Menon, 1998). For instance, coal for residential use is often ground and formed into briquettes. This work involves high levels of coal dust, as well as noise hazards. Loading, transportation, and

offloading of large amounts of coal involves ergonomic hazards, noise, and injury hazards (UNDP, 2000).

The use of coal on a large scale in power stations or industry creates yet more hazards. One of the more specific hazards is the conversion of coal to coke in steel production. This process, though not entirely associated with energy supply, distills off a large number of volatile polycyclic aromatic hydrocarbons in coal, the so-called "coal tar pitch volatiles" (Moffit, 1998). Coke oven workers have twice the lung cancer risk of the general population (IARC, 1984). Additional health hazards for workers are created when the large amounts of ash produced in power stations or by industry need to be transported and deposited. The health hazards of power generation workers have been reviewed by Crane (1998).

4.3.5 Oil and Gas

Oil and gas exploration, drilling, extraction, processing, and transportation involve a number of hazards, including heavy physical labor, ergonomic hazards, injury risk, noise, vibration, and chemical exposures (Kraus, 1998). This type of work is often carried out in isolated geographic areas with inclement weather conditions. Long-distance commuting may cause fatigue, stress, and traffic accident risks (UNDP, 2000).

The ergonomic hazards lead to risk of back pain and joint pain. Injuries include burns and those caused by explosions. Skin damage from exposure to the oil itself and from chemicals used in the drilling processes creates a need for well-designed protective clothing (Kraus, 1998). In addition, many oil and gas installations have used asbestos in insulating cladding on pipes and equipment. This creates the hazard of inhaling asbestos dust during the installation and repair of such equipment. This in turn creates a risk of lung cancer, asbestosis and mesothelioma (WHO, 1998).

Much exploration and drilling for oil and gas now occurs offshore. The Gulf of Mexico catastrophe in 2010 highlighted the hazards involved, including underwater diving work, which is inherently dangerous. In addition, the weather-related exposures can be extreme, particularly as the work often requires continuous, around-the-clock operations (Kraus, 1998). Transport to and from the oil rig is another hazard (Gardner, 2003).The work is also stressful due to its shift-work character, characterized by long work shifts and extended periods in cramped, crowded living conditions (Knutsson, 2003).

4.3.6 Hydropower

This type of energy generation has its own set of occupational health hazards (McManus, 1998). Constructing a hydroelectric power station usually means building a large dam, excavating underground water channels, and erecting large structures to house the electricity generator. McManus (1998) lists 28 different hazards involved in the construction and operation of these power stations, including chemical exposures from paints, oils, and polycholrinated biphenyls (PCBs); asbestos exposure; diesel fumes; welding fumes; work in confined spaces or awkward positions; drowning; electrocution; noise; heat; electromagnetic fields; and vibration (UNDP, 2000).

Much of the construction of new hydropower stations occurs in low- and middle-income countries (see International Energy Agency databases), where occupational health management and prevention may be laxer than in high-income countries. Thus, expanded use of hydropower, as an element of policies to reduce GHG emissions, must entail the application of up-to-date occupational health standards.

4.3.7 Nuclear

Nuclear power generation has its own particular hazards due to the radiation hazards involved in mining, processing, and transporting uranium, as well as the radiation present in the power station itself. These hazards are addressed in Section 4.7 below.

4.3.8 Other Electricity (Wind, Solar, Waste)

The manufacture of equipment used in the wind power and solar power industries involves the hazards typical of manufacturing industries, including injuries, noise, and chemical exposures. In addition, the technologies for solar electricity generation involve new chemical compounds, some based on rare metals, with poorly understood toxic properties. These risks are discussed in Section 4.8 below.

4.3.9 Number of Workers and Quantitative Health Effects Comparisons

Much of the comparative analysis of the human impacts of various energy systems has been carried out as economic analysis (e.g., Pearce, 2001). Energy policy analysis often assesses "externalities" of different types, but occupational health issues are not always included and the "life-cycle" approach mentioned earlier (Sorensen, 2003) is not always applied. A comparison of wind and coal as energy sources in the United States (Jacobson and Masters, 2001) concluded that wind was at a great advantage, with one key rationale being the high occupational mortality in coal mining. Another more comprehensive analysis (Rabl and Dreicer, 2002) highlighted the lower health and economic impacts of renewable energy systems compared to coal.

Comparisons of the occupational health aspects of energy systems require data on the number of workers involved, as well as the level of occupational health risks in each system and the different elements of the lifecycle of that system. The number of people necessary for each type of energy system to meet the energy requirements of a community is difficult to estimate accurately. As mentioned earlier, much of the work done to supply the energy needs within the poorest communities is carried out by family

members, particularly women, who are not employed in the formal sense. In addition, much of this work is carried out by small enterprises, and is not always recorded in national employment statistics.

In the ILO Encyclopedia on Occupational Health (Hamilton, 1998) a summary table outlines the occupational health and general public health impacts of selected energy systems used in electricity generation (Table 4.6). Each of these systems has important occupational health effects; it is unfortunate that a comparison with renewable energy sources was not included.

Mining is a particularly dangerous occupation and miners are a large occupational group in the international statistics (e.g., the UN Demographic Yearbooks and the Laborsta database at the International Labor Organization). They represent up to 2% of the economically active population in certain developing countries (Kjellstrom, 1994), but the breakdown by different types of mining work is not always reported. Coal mining is, however, a common type of mining in certain developing countries.

Table 4.7 highlights the high occupational mortality rates in mining in the official statistics of a number of countries. It is likely that in some developing countries a number of occupational deaths are excluded from these statistics due to the limited scope of reporting and assembling statistical information. The table also shows that workers in the electricity (and other infrastructure occupations) have a higher mortality rate than the country averages.

It should be emphasized that these risk estimates are based on the current situation and the risks in many countries and for several energy systems can be significantly reduced if appropriate occupational health

Table 4.6 | Significant health effects of technologies for generating electricity.

Technology	Occupational Health	Public Health
Biomass	Trauma from accidents during gathering and processing Exposure to hazardous chemical and biological agents	Air pollution health effects Diseases from exposure to pathogens Trauma from house fires
Coal	Black lung disease Trauma from mining accidents Trauma from transport accidents	Air pollution health effects Trauma form transport accidents
Oil	Trauma from drilling accidents Cancer from to refinery organics	Air pollution health effects Trauma from explosions and fires
Oil shale	Brown lung disease Cancer from exposure to retorting emissions Trauma from mining accidents	Cancer from exposure to retorting emissions Air pollution health effects
Natural gas	Trauma from drilling accidents Cancer from exposure to refinery emissions	Air pollution health effects Trauma from explosions and fires
Tar sands	Trauma from mining accidents	Air pollution health effects Trauma from explosions and fires

Source: Hamilton, 1998.

Table 4.7 | Fatal occupational injury rates per 100,000 workers; crude rates for all occupations and rate ratio between mining and all occupations.

Country	Crude Occupational Mortality Rate, all occupations (per 100,000 workers)	Rate Ratio, mining workers vs. all occupations
Argentina	15	3
Nicaragua	10	6
El Salvador	10	4.5
South Korea	12	12
Hong Kong	7.5	11
Zimbabwe	7	3.5
Japan	2	8
Sweden	1.5	6
United Kingdom	0.7	13

Notes: Based on rates per 100,000 insured workers or rates per million work hours and 2000 hours per worker and year. Recent years, 2006 or average of five recent years until 2006, approximate figures, men and women combined. These data most likely underestimate the true rates and should be seen as indicative, of the additional risks in mining. The rates for electricity workers are in a number of countries similar to the rates for mining. Most countries provide incomplete information to ILOs website.

Source: ILO website, Laborsta, 2009.

standards are applied. The differences in mining mortality risks in Table 4.7 between countries such as Sweden or Japan and the other countries, even developed countries, are likely to indicate the impacts of good preventive occupational health programs.

4.3.10 Conclusion

Biomass and fossil fuel systems have a number of occupational health problems and involve very large numbers of workers, particularly in low- and middle-income countries. Major successful efforts to reduce occupational risks in the energy supply chain can be demonstrated during the last 50 years, but in many mines, construction sites, and power stations, the health and safety systems are not commensurate with best practice. The health risks can be further reduced if modern occupational health management and prevention programs are applied in all countries and all energy supply sites. International conventions and guidelines from the ILO can be used as a basis for such applications.

Renewable energy systems such as hydropower, wind power, and photovoltaic solar power most likely involve less occupational health risks, while nuclear power has special hazards with low probability but enormous health impact if a major accident occurs. Further comparative analysis of the occupational health risks in different energy systems would be of great value.

Each energy investment project should include a detailed occupational health and safety impact assessment as well as a strategy and program to implement prevention. This program should identify the initial and ongoing costs for maintenance of the program, and these should be included in future budgeting.

4.4 Community Effects of Energy Systems

4.4.1 Key Messages

- Air pollution emissions from fuel combustion is a major risk factor for morbidity and mortality in communities, particularly for people living in poverty, who often rely on low-quality energy sources and technologies. Within and across communities, vulnerability to pollution-related health risks varies as a function of age and income.
- Community air quality is relatively good and improving in most developed countries, and relatively poor and deteriorating in many developing countries.
- Exposure to outdoor particle air pollution, largely due to fuel combustion, is estimated by GEA to have been responsible for about 2.7 million premature deaths in 2005.[11]
- In developed-world communities, transportation emissions are a particularly important cause of health burdens, due both to the nature of the emitted pollutants and the close proximity of emissions to vulnerable populations. Energy use in buildings also makes a significant contribution.
- In developing-world communities, the situation is more complex, with contributions from vehicles, industry, trash burning, household biomass fuels, agricultural burning, and other sources. Health burdens associated with community energy use are largest in developing-world cities, especially in China and India.
- Experiences from developed countries indicate that outdoor pollution levels can be greatly reduced through the application of control technologies on combustion and shifts to non-combustion sources of energy.

4.4.2 Background

Communities are residential groupings of people ranging in size from small rural villages to large, densely populated megacities. Patterns of energy use and resulting health impacts vary with size, and also with economic development. Within communities, vulnerability to pollution exposures and health impacts varies considerably across the population, with the young, old and those living in poverty often at greatest risk. Community-scale use of energy and associated environmental health consequences will increase in importance as populations continue to concentrate in urban areas, particularly in developing countries.

For the purposes of this section, the wide spectrum of communities measured on scales of density and economic development has been simplified to three representative categories: large developing-world cities, large developed-world cities, and low-density, peri-urban communities in the developed world. This simplification helps to organize the discussions that follow. However, it should be recognized that tremendous heterogeneity exists within these categories. Where particularly relevant, variations within categories are highlighted. (We exclude the category of rural villages in developing countries because energy use in this setting is usually dominated by solid fuel combustion for cooking, an issue dealt with in Section 4.2.)

Energy-related health impacts can arise in community settings either when fuel storage, processing, or combustion occurs within the community itself (e.g., due to exposures to fuel or combustion products), or when it occurs someplace else (e.g., due to transported pollutants). In this section, we focus primarily on the former situation. Section 4.5 addresses regional scale energy use and health impacts.

Large, developing-world cities are often characterized by rapid growth, increasing traffic congestion, the intermingling of industrial, commercial, agricultural and residential zones, and often inadequate sanitary

11 See Footnote 1 (p 263).

and solid waste disposal systems. In the absence of technology interventions, urbanization in this setting typically leads to higher outdoor air pollution concentrations (Smith and Ezzati, 2005), a substantial portion of which could be attributed to increasing energy use in buildings, transport, and industry as population and consumption rise. At the same time, household energy use for cooking and space heating may shift towards cleaner fuels and technologies, reducing indoor exposures from those sources. Depending on climate, development level, and fuel availability, building-related energy use for heating, cooling, lighting, and cooking ranges widely across and within cities in the developing world (Kandlikar and Ramachandran, 2000).

Income inequalities within developing-world cities may lead to large variations in exposures to, and resulting health impacts of, energy use for transport, buildings, or industrial production. Asthma and other chronic disease rates are on the rise worldwide, adding to vulnerability. In addition, children may be at special risk due to their activity patterns and developing respiratory systems (Selevan et al., 2000). Over coming decades, rapid population growth is likely to continue as people seek economic opportunities in cities. Technological interventions that reduce emissions per unit of energy used will be needed to avoid worsening health impacts. Recent successes in reducing transport emissions in Delhi and Dhaka serve as useful examples.

Most large cities in developed countries have relatively stable populations, adequate infrastructure for transport and waste disposal, and relatively stable or declining air pollution levels. Improvements in air quality are due in part to emissions controls and in part to slow economic and population growth rates. Per capita energy use in developed-world cities is high compared with developing cities, but low compared with the peri-urban communities that surround them. For example, a 2005 energy use survey reported that urban households use on average less than 80% of the energy used by suburban households in the United States (US EIA, 2005). Transportation and the heating and cooling of buildings are the two major categories of local energy use. In contrast to the situation in developing cities, industrial production is usually not a major energy sector in developed cities. Per capita transport energy demand varies considerably depending on urban density and the availability of public transportation. While pollution emissions per unit of energy used may be relatively low, population exposures can be elevated owing to high population density and the proximity of people to emissions sources, especially motor vehicles. High and increasing rates of asthma result in a large pool of vulnerable people. In the next few decades, continuing efforts to reduce energy use and pollution emissions have the potential to accelerate improvements in environmental health in large cities in the developed world.

Low-density, peri-urban communities (i.e., "suburbs") have been growing rapidly in developed countries for many decades (Frumkin et al., 2004). Residents of many such communities depend almost completely on automobiles for moving people between home, work, school, and commercial services. Thus peri-urban communities tend to have high per capita energy use for transportation. Because dwellings and other buildings are typically large, detached, and surrounded by high-maintenance landscapes, these communities also have relatively high per capita building-related energy use. Accordingly, emissions of pollutants from fuel combustion may be high on a per capita basis, but relatively low per unit of land area, resulting in lower ambient air pollution levels than in nearby cities. Local air pollution hot-spots may still occur where high-traffic roadways pass close to residences, schools, or other places where people congregate.

4.4.3 Community Health Risks From Energy-Related Air Pollutants

Fuels (including wood, coal, oil, gasoline and diesel, liquified petroleum gas, and natural gas) may be combusted in communities to supply energy for transportation, to heat and cool buildings, and for waste processing and disposal. Fuels may also be burned to produce electricity for lighting, though this combustion often occurs outside of city limits. In addition, solid fuels (e.g., dung, wood, charcoal, coal) are often used for cooking in developing-world cities. While the household impacts of solid fuel use for cooking are discussed above (see Section 4.2), here we consider the implications of solid fuel combustion for ambient air quality in urban areas.

Depending on the fuel used and the way it is burned, combustion may produce a wide spectrum of solid and gaseous pollutants that can impact community air quality. It is useful to distinguish between primary and secondary pollutants. Primary pollutants are emitted directly at the source and thus have the potential for very local air pollution health impacts. Secondary pollutants form via reactions of primary pollutants in the atmosphere and thus have the potential for wider, more regional impacts. Pollutants emitted within communities will be experienced by community members mainly as primary pollutants; communities downwind of the source are more likely to experience them as transformed secondary pollutants. Thus, isolated communities (i.e., those not downwind from many other communities) will be exposed mainly to primary pollutants generated locally. On the other hand, communities that are downwind of many other communities will experience both locally generated primary pollutants and transported secondary pollutants. As population and economic activity rise, the relative importance of secondary pollutants is likely to rise. Indeed, a relatively easy way to reduce local primary pollution impacts is to build taller smokestacks on industrial and power facilities, though secondary pollutant impacts in downwind communities may increase.

Primary pollutants emitted by fuel combustion include many of the "criteria" pollutants that are often measured and regulated (i.e., SO_2, NO_2, CO, and some of PM_{10} and $PM_{2.5}$, including lead if used as a gasoline additive), as well as many other less-familiar or less-measured "non-criteria" pollutants such as trace metals, elemental carbon, and a wide range of solid and vapor-phase organic compounds. Secondary pollutants include

ozone, some components of PM_{10} and $PM_{2.5}$, and organic vapors. Among secondary particles, sulfates, nitrates, and organic and elemental carbon represent important components. The levels and character of the pollutants emitted from fuel combustion depend greatly on the type of fuel used, the conditions of combustion, and on any post-combustion pollutant capture technologies. Across these dimensions, communities tend to utilize cleaner options as economic development advances, which is likely an important reason for the trend towards lower community-scale emissions as one moves up the economic development scale (Smith and Ezzati, 2005).

Available knowledge regarding the effects on human health of the pollutants that derive from fuel combustion is robust for only a subset of these pollutants (Kunzli et al., 2010). The knowledge base is most extensive for the criteria pollutants, owing to their widespread measurement in developed countries. In developed-world cities, scientific evidence for health impacts at observed concentrations levels suggests that particulate matter (either PM_{10} or $PM_{2.5}$) and ozone remain of greatest concern among the criteria pollutants.

Laboratory studies have shown that ozone can cause acute, reversible drops in lung function, increases in non-specific bronchial responsiveness, and pulmonary inflammation (Kim et al., 2011). In addition, epidemiology studies demonstrate associations with worsened asthma, emergency room visits, hospital admissions, and deaths. In particular, time-series analyses have shown that ozone is associated with an increased risk of premature mortality. Daily changes in ambient ozone concentrations have been found to be significantly associated with daily changes in the number of deaths, on average, across 98 US communities. Any anthropogenic contribution to ambient ozone, however slight, presents an increased risk for premature mortality (Smith et al., 2009). NO_x, CO, or volatile organic compounds (VOCs) emissions can contribute to ozone concentration both near and far from emission sources. Populations most at risk include children and adults who are active outdoors, especially those with asthma.

Epidemiology studies addressing health effects of PM_{10} and $PM_{2.5}$ have reported associations with both acute and chronic mortality in urban areas, as well as increases in hospitalizations and respiratory symptoms and decreases in lung function. Long-term studies in the United States have found strong associations between human exposure to fine particulate matter and adverse impacts on human health, including lung cancer and deaths from cardiopulmonary disease (Pope et al., 2002). Time-series studies have found similar concentration-response relationships in the developing countries of Asia (HEI, 2010). Because recent research indicates there is no well-defined threshold below which adverse health impacts from PM do not occur (Schwartz et al., 2008), incremental increases in PM concentration can increase rates of premature death in relatively clean communities as well as polluted ones. Populations at greatest risk of PM effects include the elderly and those with pre-existing cardiopulmonary disease. Not yet clear from the available evidence is whether specific chemical components of PM are more important than others in the observed health effects.

Assessing health risks associated with energy-related air pollution emissions in communities is challenging. First, there are many relevant pollutants that cause adverse health impacts, and choices must be made as to which to include in the analysis. A common approach, particularly in developing-country settings, is to use particulate matter as a proxy for the entire mix of pollutants. This is a reasonable strategy, given the strong evidence base for premature mortality effects of PM. Another key challenge in developing countries is the limited availability of data – including air pollution exposures, baseline health statistics, and the exposure-response relationship linking pollution to health risk– for use in risk assessments. Also, not all air pollution in communities arises from energy use, so it can be challenging to parse out the energy-related component of health risk.

WHO tackled many of these challenges in its analysis of the adverse health burden related to urban air pollution for world cities with populations of 100,000 or more in the year 2000 (Cohen et al., 2004). This assessment used particulate matter to represent all urban air pollution, and estimated the numbers of deaths associated with $PM_{2.5}$ levels in each city as compared to a reference concentration of 7.5 ug/m^3. It focused on three categories of cause of death: cardiopulmonary and lung cancer deaths among adults, and acute respiratory infections in children from birth to age four. The largest mortality burden was estimated to occur in the more polluted, rapidly growing cities of the developing world. On a global basis, it was estimated that urban PM caused approximately 3% of mortality due to cardiopulmonary disease, about 5% of mortality from lung cancer, and about 1% of mortality from acute respiratory infections.[12]

Adult mortality attributable to $PM_{2.5}$ was estimated using a concentration-response function derived from the US-based American Cancer Society epidemiologic study (Pope et al., 2002). Since the effect of PM pollution was not well known above 50 ug/m^3 $PM_{2.5}$, mortality impacts were truncated at that level. In spite of these uncertainties, this work provided a valuable snapshot of the total health burden in 2000 attributed to urban air pollution, which totaled 0.8 million premature deaths annually. Note that not all outdoor fine particle pollution is due to the operation of energy systems; they are, however, probably responsible for about 85% globally.

As part of the current GEA effort, estimates of the global burden of years of life lost and DALYs due to ambient particulate matter in 2005 are calculated based on the WHO (2004) (Cohen et al., 2004) methodology using estimated exposures and most recent baseline mortality and DALYs from WHO (2008). Globally, there were 23 million DALYs and 2.75 million premature deaths due to outdoor air pollution from energy

12 As noted previously, this WHO assessment is being extensively revised for 2012 publication.

systems. These new estimates are higher than those reported earlier in the WHO work discussed above, due in part to higher pollution concentration estimates in China and India, but also because all exposures, urban and rural, were included. The reader is referred to Chapter 17 for a full description of this assessment. The distribution of estimated $PM_{2.5}$ levels is shown in Figure 17.45.

It is also worth noting that, when monetary values are assigned to the health damage caused by air pollution, the economic benefits of air quality improvements can be very substantial. Nemet et al. (2010) and colleagues reported that air pollution-related health co-benefits can substantially offset control costs for GHG emissions reductions.

4.4.4 Exposure vs. Emissions

An important consideration in assessing the potential health significance of air pollutants emitted by fuel combustion is the temporal-spatial relationship between pollutant concentrations and the people living in those communities. No matter how much pollution is emitted, people must breathe air pollution of sufficient concentrations for sufficient periods of time to elicit adverse health effects (see Box 4.1). Digging deeper, we may examine this question for population subgroups of potentially greater vulnerabilities, including the young, the old, and those with pre-existing diseases. Although clear understanding of which levels produce how much ill health in each population is not yet available, exposures that are higher and/or longer will be of greater health significance.

Spatial relationships between source and receptor can vary widely for different types of fuel combustion sources. Also, human activity patterns play an important role in determining the extent to which individuals encounter air pollution. In developing-world cities, for example, poor individuals often live in more polluted locations, and are more likely to commute by walking or cycling along congested roadways. People living in poverty are thereby exposed to elevated levels of air pollution, while also experiencing high lung doses due to enhanced activity and breathing rates. This is particularly true for children, who have higher metabolic rates than adults (Selevan et al., 2000). Wealthier individuals often live in cleaner neighborhoods and are more likely to commute by car, and their pollution doses may be lower due to less time spent on the roads and slower resting breathing rates. In developed-world cities and suburbs, similar patterns are seen, although a far greater proportion of the population commutes in vehicles. Housing design and climate factors influence the extent of penetration of ambient air pollution indoors. The intake fraction (Box 4.1) is a metric to integrate over these domains and provides a relative ranking of human impacts of different sources per unit of emissions. Kandlikar and Ramachandran (2000) estimated values of a related metric, exposure efficiency, for a range of sources across the development gradient. Exposure efficiency ranges from 100 Exposure Units [EU = (ug/m^3)-person-year] per tonne for a US power plant to 100,000–200,000 EU/tonne for indoor combustion in urban India.

4.4.5 Building-Related Air Pollution Emissions

Residential and commercial buildings are an important source of energy-related air pollution emissions in communities, due to the combustion of fuels for heating, cooling, and cooking. The nature and magnitude of the impacts on air quality vary with the type and amount of fuel used, how it is burned, the density of buildings, and local topographic and meteorological features. Emissions and local concentrations generally diminish as one moves from coal and wood to oil and to natural gas. Major air pollution episodes such as London's killer Great Smog of December 1952 have been attributed to dense, urban household coal combustion combined with stagnant "inverted" meteorological conditions, favoring the buildup of particulate matter and other pollutants in the lower atmosphere. Transition to oil and other clean fuels for household heating led to substantial improvements in air quality in London and other developed-world cities in the 20th century, essentially eliminating the periodic mortality peaks that had previously been observed. In Dublin, Clancy et al. (2002) documented a 10% drop in cardiovascular deaths and a 15% drop in respiratory deaths in the years following the 1990 elimination of household coal combustion. Black smoke concentrations in Dublin fell by about two-thirds following the coal ban. Oil is far cleaner than coal, and more refined grades of oil are cleaner than residual oil. Recent studies in New York have highlighted the pollution impacts of residual oil combustion for heating of buildings in winter and for hot water and steam generation throughout the year (Peltier and Lippmann, 2009). Peltier et al. (2008) show that commercial burning of residual fuel oil, mainly for space heating, leads to high concentrations of trace metals (e.g., nickel) that may have particular health significance.

In addition to fuel switching, technology improvements can lower emissions while also reducing energy use and GHG emissions. Many cities are developing GHG emissions inventories, and the building sector can be a dominant source of such emissions. For example, the 2005 New York City emissions inventory found that over 60% of CO_2-equivalent emissions were from residential, commercial, and institutional buildings (City of New York, 2007; Bloomberg and Aggarwala, 2008). Substantial health co-benefits can be achieved via technology strategies whose primary objective is to reduce GHG emissions, because they reduce air pollution emissions (Wilkinson et al., 2009). The monetary value of these health benefits could partially or completely compensate for the costs of the new technologies.

In developing-world cities, emissions from cooking with solid fuels like wood, dung, and charcoal contribute significantly to urban air pollution. The proportional use of wood and dung is usually lower in urban than in rural areas (Kandlikar and Ramachandran, 2000), but the density of emissions is far higher. In Africa, charcoal often becomes the dominant cooking fuel in urban areas. Though emitting fewer particles at the stove than wood, the production of charcoal in low-technology kilns is highly polluting, although fortunately usually occurring outside cities.

4.4.6 Transportation Emissions

Energy use for transport is a major source of air pollutants in all communities, but with wide variations depending on vehicle densities, congestion, fuels, and engine technologies. Vehicle emissions have special significance from a human health perspective because they occur in close proximity to people, enhancing the fraction of emissions that is inhaled. In developed cities, where industrial and uncontrolled point source combustion is relatively rare, vehicle emissions can be the dominant local air pollution source (Qin et al., 2006). The situation in developing cities is far more complicated, with much higher levels of air pollution emissions overall, from a wide range of sources. However, vehicles play an important and probably increasing role in urban air pollution in developing cities Kinney et al. (2011). In a study of four Indian megacities, Chowdhury et al. (2007) found that gasoline and diesel vehicle emissions together represented 20–50% of $PM_{2.5}$ concentrations, depending on the city and season.

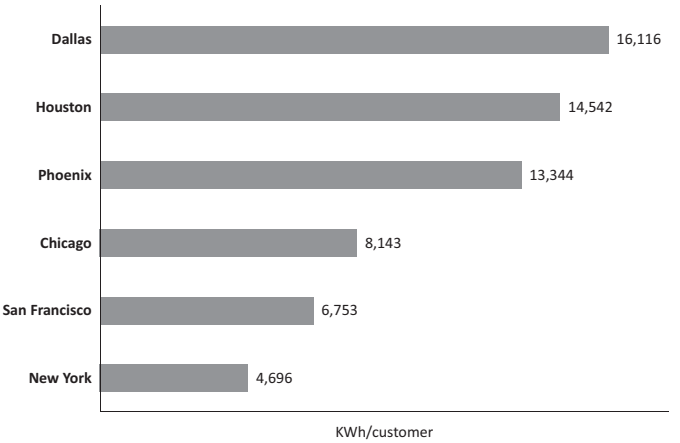

Figure 4.4 | Average annual residential electricity usage by city, 2000–2005. Source: adapted from City of New York, 2007.

Though there are few reliable data on vehicle emissions in developing cities, emissions per kilometer are estimated to be at least an order of magnitude higher than in developed cities, and perhaps far higher (Kandlikar and Ramachandran, 2000). Reasons for higher per vehicle emissions in developing countries include higher proportions of diesel vehicles, adulteration of fuels with inexpensive alternatives like kerosene, and the lack of catalytic control of engine emissions. Several large developing-world cities have achieved major air quality improvements by enacting laws requiring the use of cleaner fuels in commercial vehicle fleets (Chelani and Devotta, 2007; Begum et al., 2008; Reynolds and Kandlikar, 2008).

Reducing per vehicle emissions, either through fuel or technology interventions, is a relatively fast and economical approach for achieving significant improvements in urban air quality. Another challenging but ultimately more sustainable solution is to address growing road congestion by providing public transportation options. This has the potential to reduce the rapid rise in private vehicle use being seen in many developing cities, which is far outpacing road infrastructure (see Table 4.8). Many developing-world cities are examining urban transport reform, with some success stories (e.g., Brazil or Bangkok). Dedicated lanes for bus rapid transit can reduce both congestion and air pollution levels, while also providing affordable transportation for urban residents. Developed cities (e.g., London, Milan) have been successful at reducing congestion by imposing automated congestion fees within the downtown zone. While many developed cities are dependent on private vehicles for workforce commuting, there are wide variations even within countries. For example, the proportion of commuters using public transportation in six US cities ranges from 5% to over 50% (Figure 4.4).

Vehicles can affect air quality in other ways besides their engine emissions. Road dust can be a serious nuisance in developing-world cities, and often carries health risks due to toxic materials re-suspended with the dust, including asbestos from brake linings, lead from tire weights, and oil from leaking tanks.

Table 4.8 | Composition of vehicle population in India.

Year end March	Mopeds, Motorcycles etc.	Cars, Jeeps etc.	Buses	Goods Vehicle	Others	Total (Million)
	(as % age of total vehicle population)					
1951	8.8	52.0	11.1	26.8	1.3	0.31
1961	13.2	46.6	8.6	25.3	6.3	0.66

4.4.7 Community Impacts of Transported Regional Pollutants Related to Energy Supply

As described below in Section 4.5, community air quality can be impacted by pollutants transported from other regions. In fact, upwind sources may often dominate local sources as contributors to community air quality, particularly for communities that are downwind of major source regions, such as cities in the northeastern United States, and those downwind of the industrial heart of China, such as Hong Kong. The scale over which pollution can be transported may be hundreds or even thousands of kilometers.

4.4.8 Energy-Related Pollutants in Water and Soils

Health can also be negatively impacted by energy-related pollutants in water and soils. Spills are common near oil drilling and handling operations. Spills from ageing or sabotaged pipelines have increased in Arctic Russia, the Niger Delta, and the northwestern Amazon, leading to contaminated drinking water supplies, fishing areas, and agricultural fields (Jernelov, 2010). In a preliminary analysis of health impacts in the months after the BP oil spill in the Gulf of Mexico, Solomon and Janssen (2010) report that 300 people sought treatment in Louisiana for symptoms typical of hydrocarbon and/or hydrogen sulfide exposures, including nausea, vomiting, cough, and respiratory distress. Mining has been associated with offsite contamination of domestic groundwater supplies, even after mine-site reclamation (Palmer et al., 2010). Exposure can also come from contact with surface water (Besser et al., 1996) or re-suspended dust (Ghose and Majee, 2007). Hazardous compounds in dust were elevated near surface coalmining operations in India (Ghose and Majee, 2007). Elevated rates of cardiac, pulmonary and kidney diseases, and hypertension were observed in the general population living near coal mining operations in the US state of West Virginia (Hendryx and Ahern, 2008). Health damage from fossil fuel extraction processes can be reduced through improved mining practices, but also by efforts targeting energy demand, such as improved energy efficiency and use of renewable sources.

4.4.9 Other Sources

Other energy-related sources that can play an important role in community air quality include electric utility facilities (as well as smaller distributed energy sources), industrial operations, port facilities, and uncontrolled combustion of solid waste. The latter is a widespread source of toxic pollutants in developing cities. Though not strictly an energy issue, the energy contained in solid waste could be utilized for energy supply while at the same time improving air quality and health. Waste-to-energy facilities may represent a long-term solution to this growing problem.

Electric utilities and small power generators often are sited in or near urban areas. Depending on the fuel burned, stack height, and emission control technology employed, emissions and local impacts vary widely. Peak energy loads during summer hot spells are often supplied by diesel generators, with higher impacts than plants fired by natural gas. Large electric utilities require large amounts of water for their routine operations, and can adversely impact downstream water quality.

Industrial operations have been largely eliminated from developed cities but still remain significant sources of air pollution in many developing cities (Kandlikar and Ramachandran, 2000; He et al., 2002). While moving dirty industries away from populated areas would be the most sustainable solution, improved fuels and emissions control technologies can provide important short-term gains. There is also growing recognition of the air quality impacts on local communities of emissions from port operations (e.g., Newark, New Jersey; Los Angeles).

4.4.10 Conclusions

Air pollution emissions from fuel combustion are a major risk factor for morbidity and mortality in communities. Key energy-related emissions sectors include transportation, building heating, cooling and cooking, electricity generation, industrial processes, and waste combustion. Transportation emissions are particularly influential in health burdens, due both to the nature of the emitted pollutants and to the close proximity of emissions and vulnerable populations. Within and across communities, vulnerability to pollution-related health risks varies as a function of age and income. While health burdens due to community air pollution exist everywhere, these burdens are largest and in developing-world cities, particularly in China and India.

4.5 Regional and Transboundary Impacts

4.5.1 Key Messages

- Air pollutants can be transported long distances before being removed from the atmosphere and thus health impacts from emissions can occur locally, regionally, and even globally, following intercontinental

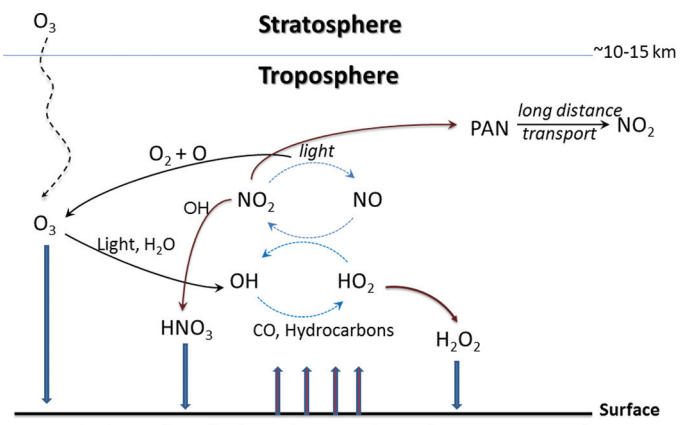

Figure 4.5 | Ozone production in the troposphere.

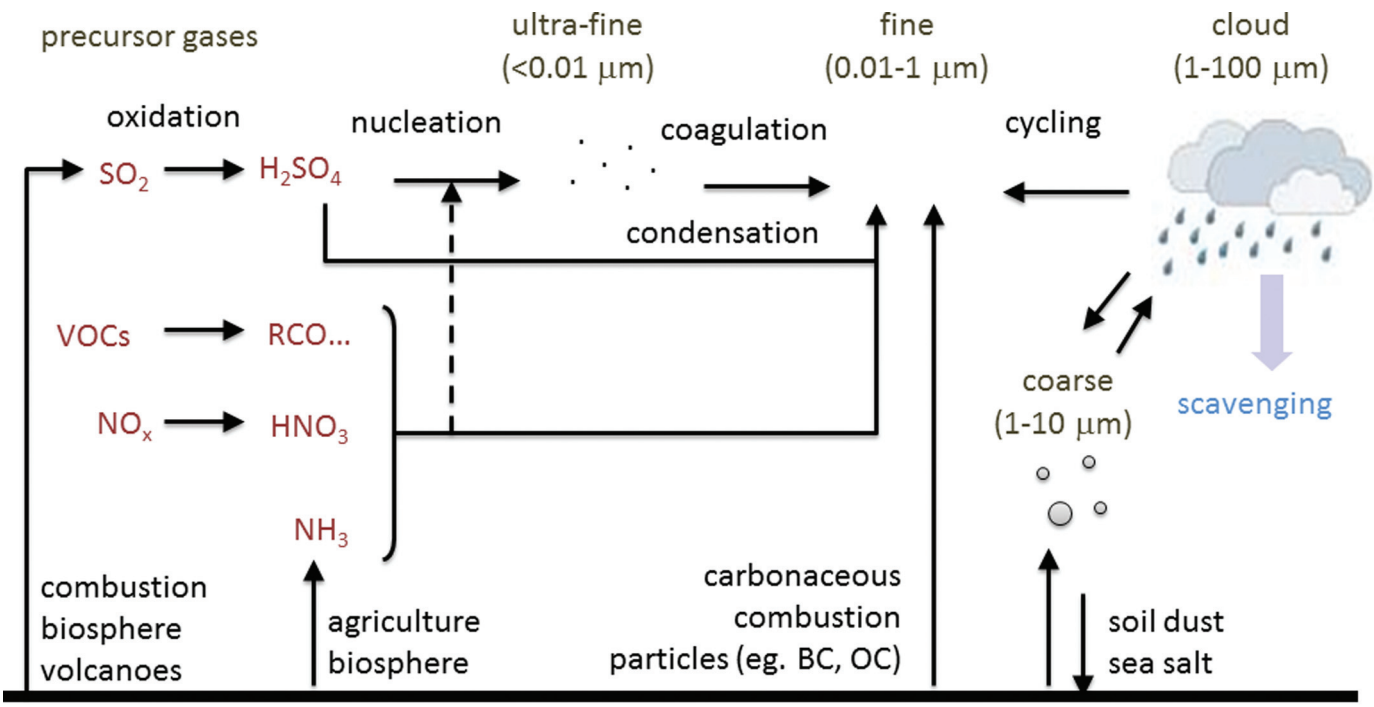

Figure 4.6 | Particulate matter (PM) sources and processes.

transport. In general, health damage due to ambient air pollution from the combustion of fossil and biomass fuels is greatest close to the source of emissions and within population centers.

- Emissions of particulate air pollutants have a significant effect on climate change. Externally mixed sulfate aerosols decrease radiative forcing, while black carbon (BC) aerosols increase it. Hence, although reductions in particle concentrations benefit public health, reductions in emissions of sulfur dioxide (the precursor to sulfate) will likely warm climate and reductions in the emissions of BC will likely cool climate.

- Long-range transport can bring black carbon to glaciers and snow-covered regions (Kopacz et al., 2011) where it may increase melting rates, affecting water supplies and health.

4.5.2 Contribution of Energy Systems to Air Pollution

Combustion of both fossil fuels and biomass releases a myriad of gaseous and particulate air pollutants in large quantities that have direct adverse impacts on public health. These pollutants include nitrogen oxides (NO_x); VOCs including methane, carbon monoxide (CO), sulfur dioxide (SO_2); and black carbon and organic carbon (OC) particulates. In addition, a variety of persistent organic pollutants (POPs) and heavy metals, including mercury (Hg), are also emitted. The reaction of some of these compounds in the atmosphere in the presence of sunlight forms secondary pollutants. In particular, NO_x, CO, and VOCs can react to form ozone (O_3) (see Figure 4.5). Sulfur dioxide and nitrogen oxides can form aerosols. (See Figure 4.6 for a summary of the sources and processes of particulate matter.)

The lifetime of air pollutants varies from hours (NO_x) to days/weeks (aerosols, VOCs) to months (O_3, CO, and Hg) and even years (POPs). The lifetime of the pollutant has a large influence on the distance it can travel before being removed from the atmosphere. Methane –produced by both natural and anthropogenic sources is released by the incomplete combustion of fossil fuels and, in larger amounts, as leaks from oil refineries, pipelines, coal mines, and other parts of energy systems – has a lifetime of approximately 12 years. As a result, it is relatively well mixed in the atmosphere. Oxidation of methane contributes to the production of tropospheric ozone. However, due to methane's long lifetime in the atmosphere, ozone may be produced far from the source of methane emissions, contributing to the observed rise in global background ozone levels (Fiore et al., 2008).

4.5.3 Mechanisms of Regional and Intercontinental Transport

Historically, air pollution was viewed as an urban problem. The Great London Smog of December 1952, caused by the combustion of coal, mainly for residential heating, during an atmospheric inversion that trapped the pollutants close to the surface, caused the death of thousands of people. This resulted in increased recognition of the toxic effects of air pollution on the urban scale.

In the 1970s, several studies confirmed that acid deposition could occur hundreds of miles from where SO_2 was emitted as a result of the oxidation of SO_2 to sulfuric acid (H_2SO_4) and sulfate. Starting in the 1980s, there was increasing recognition that other pollutants can be transported hundreds of miles and affect air quality far downwind of emission sources. The Long Range Transboundary Air Pollution Convention and its protocols (www.unece.org/env/irtap) were signed and ratified by nations of Europe and North America in the 1980s and 1990s to control emissions of sulfur, nitrogen oxides, VOCs, heavy metals, and POPs, and to abate acidification, eutrophication, and ground-level ozone concentrations. The Convention was the first international effort at coordinated abatement of air pollutant emissions.

In the late 1990s, efforts began in the United States to develop interstate emission controls on NO_x in order to reduce the long-range transport of ozone. NO_x emitted in cities and then transported to rural areas can react with VOCs emitted from vegetation to form ozone on a regional scale (see Figure 4.5). Elevated ozone concentrations can impact human health, ecosystems, and agriculture on a regional to global scale (Bell et al., 2004; Mauzerall and Wang, 2001).

Transport of air pollutants across the North American or European continent takes approximately one week, while circumpolar transport of pollution at northern mid-latitudes takes approximately one month. Mixing between the tropics and the high latitudes of the northern hemisphere requires approximately three months. Starting in the late 1990s, intercontinental transport of air pollutants, particularly ozone, mercury, and POPs, was recognized by the research community as potentially affecting the ability of some regions to meet their own air quality goals (Fiore et al., 2002).

Although aerosol transport from Asia to the United States has been observed by satellite as taking less than one week, average transport time is calculated to be two to three weeks (Liu and Mauzerall, 2005). Pollutants with lifetimes of a few days or less tend to remain within a limited area, while those with lifetimes of several weeks or more can cross oceans and influence air quality on downwind continents. Pollutants with lifetimes less than several years, however, have their largest concentrations close to the source of emission.

Intercontinental transport also influences surface ozone concentrations. Ozone has a lifetime of days in the continental boundary layer (the surface to approximately 2 km) but several weeks in the free troposphere (approximately 2–10 km above the surface). Ozone can be transported in the free troposphere and then subside to the surface, where it has adverse effects on human health, ecosystems, and agriculture. Observations at northern mid-latitudes have shown background ozone concentrations to be rising from preindustrial concentrations of approximately 10 ppbv (parts per billion by volume) (Marenco and Gouget, 1994). Model simulations define background ozone concentrations to be the ozone that results when emissions of ozone precursors from one region are turned off while emissions from the rest of the world are maintained at current levels. Present background concentrations in the United States are in the range 20–40 ppbv, at least half of which is of anthropogenic origin (Fiore et al., 2002). Rapid increases in combustion of fossil fuels for industry and vehicles in Asia has led to large increases in the emission of NO_x (Ohara et al., 2007) and resulting increases in hemispheric background concentrations of ozone, despite simultaneous decreases in NO_x emissions in the United States and Europe.

4.5.4 Implications of the Lack of a Threshold below which Air Pollutants No Longer Damage Health

As noted in Section 4.4, there is good evidence of health effects of small particles, even at low levels. In addition, both observational and modeling studies show that concentrations are influenced by long-range transport, as well as by local anthropogenic and natural emissions (Jaffe et al., 1999; Park et al., 2004). As a result, even relatively modest increases in PM concentration due to regional and intercontinental transport can increase rates of premature mortality in both polluted and relatively clean regions. A recent evaluation of the global health impact of intercontinental transport of fine aerosols found that nearly 380,000 premature deaths globally of adults age 30 and older are associated with exposure to particulates originating from foreign continents, with approximately 90,000 of these deaths attributable to fine, non-dust aerosols (Liu et al., 2009).

4.5.5 Effect of Ozone on Agricultural Yields

Episodes of elevated ozone are frequently observed in suburban and rural regions due to NO_x outflow from urban centers reacting with hydrocarbons from local vegetation. Elevated ozone concentrations can reduce agricultural yields (Mauzerall and Wang, 2001). Surface ozone in East Asia in 1990 is estimated to have reduced agricultural production of wheat, rice, and corn in China, Korea, and Japan by 1–9% and of soybeans by 23–27% (Wang and Mauzerall, 2004). In 2020, assuming no change in agricultural production practices, grain loss due to increased levels of ozone pollution is projected to increase to 2–16% for wheat, rice and corn and to 28–35% for soybeans (Wang and Mauzerall, 2004). More recent studies have examined the global impact of ozone on agricultural crop yields in the years 2000 and 2030 (van Dingenen et al., 2009; Avnery et al., 2011a; Avnery et al., 2011b), and found 2000 global relative yield reductions to be approximately 9–14% for soybean, 4–15% for wheat, and 2–6% for maize; in 2030, the projected yield losses were 5–26% for wheat, 15–19% for soybean, and 4–9% for maize. Similar results were obtained by van Dingenen (2009). Developing countries are likely to experience simultaneous increases in population and in

emissions of ozone precursors, with resulting reductions in agricultural yields. This will have an indirect effect on health via escalating commodity prices, hunger, and malnutrition in some parts of the world.

4.5.6 Mercury Emissions: Transport and Intake that Affects Health

Mercury, largely emitted from coal combustion, has long been recognized as a global pollutant by the scientific community (Selin, 2005). Mercury is largely emitted in the elemental form Hg(0), which is oxidized in the atmosphere to Hg(II) and subsequently deposited. The atmospheric residence time of Hg(0) is about a year, which permits its global transport (Selin et al., 2007). Microbiological action converts Hg(II) into methylmercury (MeHg), an organic form of mercury. MeHg is highly toxic and can accumulate up the food chain in aquatic systems, leading to high concentrations in predatory fish. Consumption of contaminated fish is the major source of human exposure to MeHg in the United States. Fetal exposure via fish consumption by pregnant women can pose neurodevelopmental risks (NAS, 2000).

4.5.7 Effects of Air Quality on Climate Change and Vice Versa: Resulting Effects on Health

Some air pollutants have a significant effect on climate. As shown in Figure 4.7, tropospheric ozone and black carbon together have a positive global radiative forcing larger than methane, the second most important CAP (Forster and Ramaswamy, 2007). In contrast, sulfate and organic carbon have a negative radiative forcing due to both direct effects (reflection of incoming solar radiation) and indirect effects on clouds (smaller droplets and hence whiter clouds with higher albedo) (Forster and Ramaswamy, 2007). Table 4.9 summarizes the climate, health, and environmental issues associated with emissions leading to sulfate and BC (see also Box 4.2).

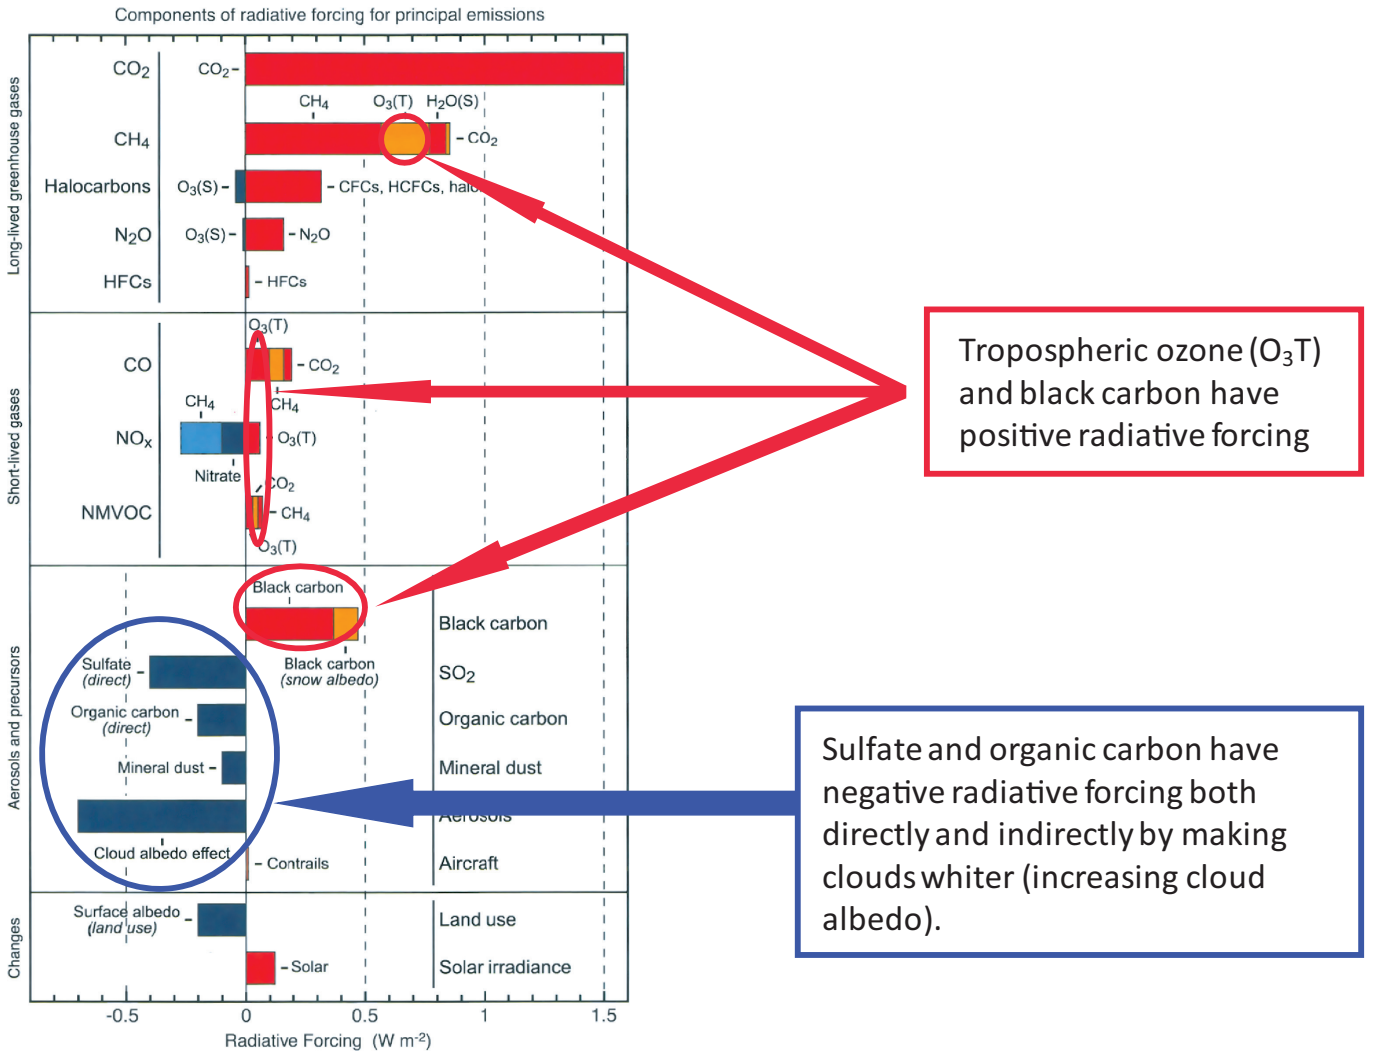

Figure 4.7 | Global radiative forcings due to emissions changes, 1750–2005: important contributions of air pollutants. Source: adapted from Forster and Ramaswamy, 2007.

Table 4.9 | Summary of sulfate and black carbon, climate, health, and environment issues.

	Source	*Measurement*	*Health*	*Climate*	*Environment*	*Confounders*
Sulfate	Mainly power and industry, but also transport	Little uncertainty although emissions are mainly SO_2 gas, with calculation of transformation to sulfate necessary	May be less damaging than the average PM, but uncertain	Relatively little uncertainty on direct and indirect climate cooling effects, but cloud physics still poorly understood	Acid precipitation – relatively little uncertainty but wide difference in impact by location	Sulfur control can reduce mercury emissions from power plants but has minor interaction with other types of control
Black Carbon	Mainly diesel engines and household fuel	Because BC is co-emitted with other carbonaceous aerosols basic measurement methods and metrics not well characterized	May be more damaging than the average PM, but uncertain	Major uncertainties but high radiative forcing – complicated by location and short lifetime	Major melting impact if falls on ice or snow, particularly in Arctic and Himalayan glaciers. Not well understood	Except for emissions from diesel engines, it's difficult to control BC alone without also reducing organic aerosol emissions, which are generally cooling

Box 4.2 | Health and climate primer for energy-related climate-active pollutants

Long-lived (hundreds of years)

Carbon dioxide (CO_2) poses a low direct health hazard and indeed is also the weakest greenhouse pollutant by mass. However, because of its magnitude of emissions, it is the most important overall. It also has a much longer lifetime in the atmosphere than any of the other energy-related pollutants – most is gone in 100 years or so, but a portion of emissions is thought to remain in the atmosphere for thousands of years. Even without special measures to burn fuels more cleanly, measures that reduce fossil fuel use or increase its efficiency will have co-benefits, through associated reduction of CO_2 emissions and the health-damaging pollutants noted below that accompany fuel burning. About 78% comes from the combustion of fuels.

Medium-lived (tens of years and thus globally mixed)

Methane (CH_4) is the second most important greenhouse pollutant. About one-third of global emissions come directly from energy-related sources, including leakage from oil/gas facilities and coal mines as well as incomplete combustion of biomass and fossil fuels. Its main sources, however, are from agriculture and poor management of wastes. Although not directly health-damaging, methane is a primary precursor to the global rise in tropospheric ozone levels. Although methane has a shorter atmospheric lifetime than carbon dioxide, a tonne of methane will have a much bigger warming impact than a tonne of CO_2 for the first few decades after emission, because of its large direct and indirect impacts on warming.

Short-lived (days to weeks, and thus effects depend on local conditions)

- Carbon monoxide (CO) is mainly a product of incomplete combustion. Although it does not have a direct climate effect, it acts to sweep up hydroxyl (OH) radicals in the atmosphere, thus effectively increasing the lifetime of methane and adding to tropospheric ozone. The impacts of CO on methane and tropospheric ozone are both potentially climate warming. About two-thirds comes from the energy sector, the rest from forest/savannah/agricultural fires.

- Non-methane volatile organic compounds (NMVOCs) come from several human-generated sources, including incomplete combustion and evaporation from fuels. They also have primarily indirect rather than direct impacts on climate. They play an important role in urban ozone formation as well. NMVOC emissions reduce the oxidizing capacity of the troposphere, increasing the lifetime of methane and adding to tropospheric ozone. Many of these compounds also have direct health effects on humans. About one-third is due to human energy use.

- Nitrogen oxides (NO_x) derive from fuel combustion and have a complex relationship with and indirect impact on both climate warming and cooling by affecting ozone, methane, and particle levels. NO_x emissions act to decrease the oxidizing capacity of the troposphere and

increase the lifetime of methane, but also are a major precursor to tropospheric ozone. Nitrate particles, like those of sulfate, are lighter colored and thus generally cooling. There also seems to be a small increase in carbon capture in natural ecosystems due to the eutrophication from deposited nitrate. About half comes from the energy system.

- Sulfur oxides (SO_x), which derive mainly from combustion of fuels, partly convert to sulfate (SO_4^{2-}) aerosols in the atmosphere, which although potentially health-damaging, are generally thought to exert a net cooling effect on the climate. Along with organic carbon (OC, see below), can sometimes be coated with black carbon (BC, see below) to create "brown carbon" with warming potential. Essentially all human emissions derive from fuel use (see Figure 4.10).
- Black carbon (BC), which is fine particulate matter of dark color containing a large fraction of elemental carbon, is derived exclusively from incomplete combustion. They are strongly warming in the atmosphere and increase heat absorption if deposited on ice and snow, such as on Himalayan glaciers or in the Arctic. About two-thirds of human emissions come from energy systems (Figure 4.10).
- Organic carbon (OC) aerosol, which is less dark carbonaceous particulate matter produced, like BC, largely from incomplete combustion, but also from secondary processes involving biogenic VOCs. Although not well characterized and sometimes coated around BC, it is thought generally to produce a net cooling effect globally, although with much local variation. It is a major form of health-damaging small particles globally. About half comes from energy systems.

Very short lived (hours)

- Tropospheric ozone (O_3): is a secondary pollutant formed through complex photochemical reactions involving nitrogen oxides and volatile organic compounds including methane in the presence of sunlight. Worldwide, background ozone has more than doubled since pre-industrial times and continues to rise (Unger et al., 2008). Although plants and other natural sources such as forest fires contribute to ozone levels, the major sources are the rise in methane emissions and burning of fuels with subsequent increased emissions of nitrogen oxides and VOCs. In the Intergovernmental Panel on Climate Change (IPCC) assessments, as shown in Figure 4.7, taken all together, ozone is the third most important greenhouse gas (after carbon dioxide and methane), although itself created from other gases. Stratospheric ozone generally has different sources and, although also warming, protects Earth's surface from health- and ecosystem-damaging ultraviolet radiation.

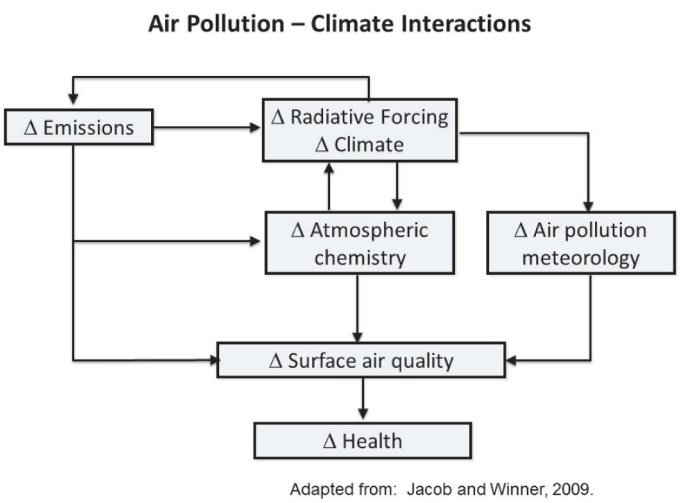

Figure 4.8 | Overview of air pollution – climate interactions from emissions to surface air quality to health. Source: adapted from Jacob and Winner, 2009.

Figure 4.8 summarizes interactions and feedbacks of air pollution, climate change, and health, which are in general poorly understood. Changes in emissions of CAPs affect radiative forcing and climate change (ozone, PM, methane), which in turn influences atmospheric chemistry, surface air quality (ozone and PM), and public health. Climate change affects meteorology and hence transport and mixing of air pollutants and natural emissions (biosphere, dust, fires, lightning) with implications for surface air quality (Jacob and Winner, 2009), health, and agricultural and ecosystem impacts. A recent study concluded that, "[c]oupled GCM (General Circulation Model]–CTM (Chemical Tracer Model] studies find that climate change alone will increase summertime surface ozone in polluted regions by 1–10 ppb over the coming decades, with the largest effects in urban areas and during pollution episodes" (Jacob and Winner, 2009). This climate penalty means additional impacts on public health unless stronger emission controls are implemented.

Sulfate, BC, and OC all contribute to suspended particulate matter less than 2.5 micrometers in diameter ($PM_{2.5}$). Figure 4.6 describes the

sources and processes for forming, coagulating, and scavenging PM from the atmosphere (see also Box 4.2).

BC is emitted during the incomplete combustion of fossil fuel and biomass. BC is generally co-emitted with OC, another type of carbonaceous (carbon-based) aerosol. Because OC has a cooling effect on climate, the net warming effect of carbonaceous aerosol emissions decreases as their OC:BC ratio increases (Kopp and Mauzerall, 2010). This ratio is relatively high for biomass combustion and quite low for diesel engines. The warming effect of BC varies among source types and regions due to differences in co-emitted aerosols, transport, and deposition location. In addition to causing warming when lofted in the atmosphere, BC also enhances melting rates when it is deposited onto snow and ice. It thus contributes significantly to the warming of the Arctic, where it accelerates melting of sea and land ice. When it is emitted from South and East Asia, a major source area, it accelerates Himalayan glacier and snowpack melting, with resulting impacts on water supplies.

BC predominantly falls within the PM_{10} category (particulate matter with a diameter less than 1 micrometer). Both diffuse and concentrated BC particles, like all fine particles, have adverse impacts on human health, including premature mortality. There is a perception that particles from diesel engines, elemental, and organic carbon are the "most toxic" constituents of $PM_{2.5}$ (Cooke et al., 2007). The few long-term studies, however, do not indicate that BC particles are significantly more toxic than the "average" ambient particle (Smith et al., 2009).

As long as the BC/OC ratio is sufficiently high, reduction in emissions of combustion particles will result in rapid, short-term reductions in radiative forcing, hence slowing warming significantly in the near term while simultaneously improving public health (UNEP, 2011).

4.5.8 Conclusion

Poor combustion of both fossil and biomass fuels releases gaseous and particulate air pollutants in large quantities, nearly all of which have adverse impacts on public health. Pollutants with lifetimes of a few days or less tend to remain within a limited area, while those with lifetimes of several weeks or more can cross oceans and influence air quality on downwind continents. Because research indicates that there is no threshold of health effects at ambient concentrations of fine particulates, incremental increases in particle concentration due to regional and intercontinental transport can increase rates of premature mortality in both polluted and relatively clean regions. The secondary formation of ozone has direct adverse health impacts and also decreases agricultural yields, hence reducing food availability in some regions. Long-range transport of BC to glaciers may increase melting rates, thus influencing water supplies and health.

4.6 Global Health Impacts from Climate Change

4.6.1 Key Messages

- Of the many impacts of climate change on human health, most will be adverse and will particularly affect the world's people living in poverty and otherwise vulnerable populations. These health impacts will occur largely by exacerbating existing health problems. This will impede efforts to reduce longstanding public health impacts, particularly in low-income countries. Climate change will also confer some benefits to health in some populations, at least in the early stage of the process.

- There is broad agreement among researchers that, as climate change progresses, indirect effects on health are likely to account for the largest population health burden, compared to events with direct impacts such as heat waves. These indirect effects include the risks of malnutrition, altered patterns of infectious diseases, and the consequences of conflict, disruptions, and displacement due to climate-exacerbated resource shortages.

- The WHO's estimate of the burden of disease attributable to incipient climate change in the year 2000 identified malnutrition as the preeminent component of health loss. Most of that loss (i.e., premature deaths, stunting, and susceptibility to infection) was in young children in developing countries.

- The existing systems for managing public health problems should provide a foundation for CAP dealing with most of the health impacts of climate change. Therefore, it is likely that most of the required public health adaptations will entail incremental and complementary changes in those systems.

- Actions taken by governments and communities to reduce emissions should, in general, confer localized health benefits as a bonus (i.e., "health co-benefits"). This adds further incentive to undertake those mitigation actions.

4.6.2 Background

The science of climate change, including the influence of human use of energy, is now robust (see Chapter 3) and provides a base for anticipating and estimating human health consequences. Climate change affects social institutions, economic activities, and human health both directly and indirectly. Many major health problems in populations around the world, particularly in the poorer and more geographically vulnerable regions, are climate-sensitive. Hence, a change in climatic conditions will inevitably affect the rates and patterns of those diseases and disorders, including diarrheal disease, malaria, and under-nutrition – all

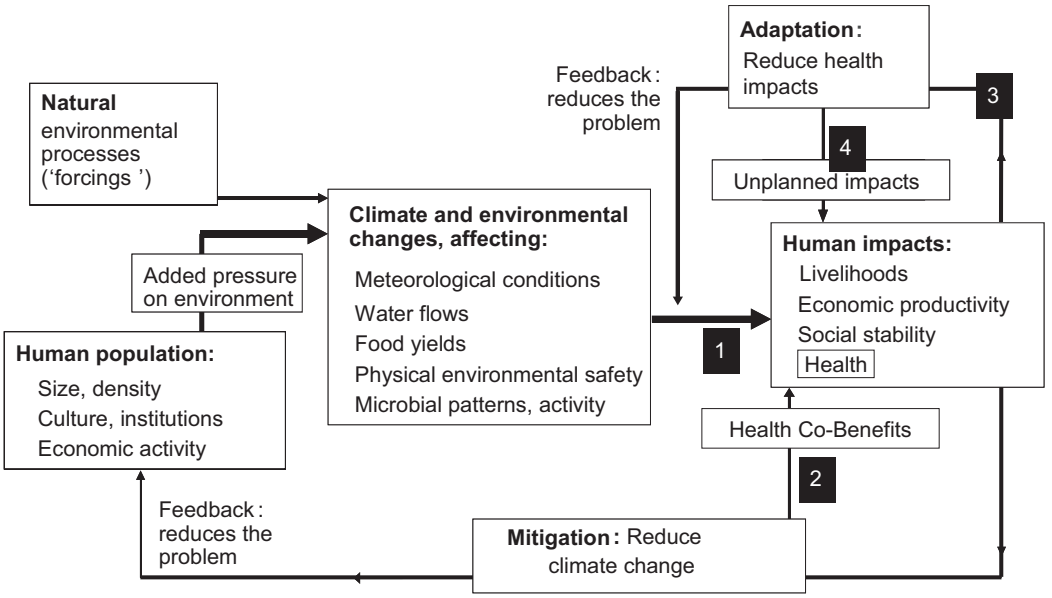

Figure 4.9 | Major pathways leading to impacts on population health associated with climate change and social responses. The four numbered paths refer to major, distinct, areas of research enquiry: 1 = identifying and estimating risks to health from climate change; 2 = estimating the collateral health benefits to local populations as they take action to mitigate climate change (mostly to reduce greenhouse emissions); 3 = research on the effectiveness and equity of adaptive strategies to protect population health against adverse climate change impacts; 4 = monitoring and estimating the collateral impacts of adaptive strategies on (mostly local) population health.

major killers of infants and young children in most low-income countries (Akachi et al., 2009).

Substantial inequalities in material and social conditions, and hence in health status and life expectancy, persist between subgroups, national populations, and geographic regions (Commission for the Social Determinants of Health, 2008). Many of these existing health inequities will be exacerbated by the environmental and social consequences of climate change. Climate-related exposures often impinge with differing intensity between locations (Kesavan and Swaminathan, 2006), and the resultant variations in adverse impacts on well-being, health, and survival will often be compounded by differences in human and financial resources, coping capacity, and social resilience.

The Fourth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) summarized the published scientific evidence, both direct and inferential, of current and future risks to human health from climate change (Confalonieri et al., 2007). It is not yet possible to confirm and quantify all of the many potential impacts of climate change on health. Those with limited available evidence include the risks to health from heightened (especially local/regional) food shortage and food insecurity, from sea level rise, and from population displacement and conflict. Further, climate change may cause widespread economic disruption, leading to severe health consequences – again, especially in poor and vulnerable populations (see also Costello et al., 2009).

Emerging evidence strongly suggests that some health impacts that are reasonably attributable to climate change have already occurred (Costello et al., 2009; McMichael and Bertollini, 2011). This evidence includes reports of an uptrend over recent decades in deaths, injuries, and other adverse health impacts from cyclones, storms, wildfires, and flooding; an increase in annual deaths from heat waves in several countries; shifts in the range and seasonality of some climate-sensitive infectious diseases; adverse mental health consequences in farming communities affected by drying; and impairment of food yields (and hence increased risk of malnutrition) in some already food-insecure populations. These are discussed in more detail below.

Recognition of the risks to human health strengthens the rationale for the rapid abatement of human-driven climate change (see Section 4.6). That is, those risks, properly understood, signal that climate change is beginning to weaken and disrupt nature's life support systems – the systems that are prerequisite for the attaining and sustaining of high levels of human population health (Raven, 2002; McMichael, 2009a). Meanwhile, appreciation of the range and likely ubiquity of these health risks provides an evidence base for adaptive interventions to protect population health against those climate change-related risks that already exist or are apparently unavoidable, given the as-yet-unrealized climate change from extant emissions.

4.6.3 Diverse Health Risks; Multiple Causal Pathways

Weather variations and changes in climatic conditions affect human well-being, safety, health, and survival in many ways (see Figure 4.9). Some health impacts are direct-acting, familiar, and easily understood in relation to future climate change. This category includes the diverse health consequences of weather disasters (which will typically increase in frequency and intensity under climate change) and the health consequences of heat extremes within both the general community and segments of the workforce. Other health impacts are less immediate, occur via more complex pathways, and may be less obvious and more difficult to attribute (Butler and Harley, 2010). This category includes the changes in patterns of various infectious diseases, especially those transmitted via vector organisms, and the nutritional consequences of impairments in regional food availability, in part due to alterations in pests, aflatoxin contamination, and crop diseases (Butler, 2010). Climate change also harms ocean acidity (Doney et al., 2009), phytoplankton production (Boyce et al., 2010), and corals (Hoegh-Guldberg and Bruno, 2010).

Further, since climate change is part of a larger set of contemporary, human-induced global environmental changes, most of them of unprecedented scale, many of the health impacts of climate change will be modulated, and often amplified, by these other coexistent environmental changes. A ready example is that of food yields and human nutrition. In many parts of the world, the productivity of food systems is being jeopardized by the combination of soil exhaustion, chemicalization, diminished supplies of fresh water, local losses of biodiversity (e.g., pollinating organisms), coastal salination (rising sea level), and climate change (McIntyre et al., 2007).

Climate change entails a complex of environmental, ecological, and social changes. It is therefore not some new and distinctive "risk factor," nor is it likely to generate *new* diseases or health disorders. Instead, via that complex of changes, many existing population health problems will be exacerbated. It is important, in a policy context, to note that this threat of exacerbation heightens the already strong practical and moral rationale for reducing pre-existing disease rates as quickly as possible – something that the world is striving to achieve via the MDGs. An obvious focus of efforts to protect population health against further incursions by climate change is that of childhood malnutrition and infection, especially acute respiratory infection and diarrheal diseases, which currently kill around nine million children annually.

The following subsections consider first the health impacts of climate change that occur via apparently direct, relatively simple, pathways, followed by a discussion of those health impacts that arise via less direct, and often diffuse and deferred, causal pathways.

4.6.4 Direct Health Impacts: Temperature Extremes, Weather Disasters, and Health Impacts

Heat waves (extreme temperature events relative to local average, and of, typically, around three to seven days duration) will become more frequent and more severe as background temperatures rise and weather variability increases. It is well established that heat waves can kill people and increase the incidence of heart attacks and strokes, especially in the elderly, the frail, and those with underlying chronic diseases (Kovats and Hajat, 2008).

Temperature extremes that exceed physiological coping capacity also affect bodily functioning, mood, and behavior (Kjellstrom, 2009). This usually happens at temperatures above 30°C, depending on humidity, wind movement, and heat radiation. This has particular relevance to segments of the workforce exposed to extreme thermal stress. Poor people without access to household or workplace cooling devices are likely to be most affected, in hot, high-income countries as well as in hot, low- and middle-income countries. This climate change impact will primarily affect adults 20–60 years of age. Heat also affects other daily physical activities that are unrelated to work for all age groups.

Physically active workers in low- and middle-income tropical countries are particularly vulnerable, since many are engaged in heavy physical work, outdoors or indoors, without effective cooling. If high work intensity is maintained in excessively hot workplaces, serious health effects can occur, including heat stroke, organ damage, and death. Meanwhile, depending on the type of occupation, the required work intensity, and the level of heat stress, as temperature extremes rise over time, working people will need to work more slowly to reduce internal body heat production and the risk of heat stroke. Hence, without preventive interventions to reduce heat stress on workers, both their individual health and economic productivity will be impaired (Kjellstrom et al., 2009).

Hotter weather also increases the formation and concentration of various noxious ambient air pollutants, especially ozone, in large, motorized, industrial cities. Ozone is a well-established risk factor for respiratory tract damage and cardiovascular disease. Much of the huge mortality excess caused by the August 2003 heat wave in Western Europe may have been due to the coexistent high levels of ozone in and around some of the big cities – high levels that, indeed, may have been partly attributable to the unusually high temperatures (Dear et al., 2005; Kinney, 2008).

Weather disasters – such as the cyclones that have struck vulnerable, mostly poor, coastal populations of Myanmar, Haiti, and Viet Nam in recent years – kill, injure, dispossess, impoverish, and cause mental health burdens. They also predispose people to outbreaks of infectious diseases and cause damage to crops. Among vulnerable populations, droughts variously cause hunger, loss of farming jobs, impoverishment, population displacement, and misery; suicide rates may rise in response to these hardships.

4.6.5 Direct Health Impacts: Sea Level Rise

The average global rate of sea level rise is now approximately 3 mm/year (Rahmstorf et al., 2007; Allison et al., 2009) – that is, approximately 50% higher than in the 1980s. A growing proportion of the rise is due

to the melting of polar ice and (less certainly) alpine glaciers, on top of the contribution from the ongoing thermal expansion of ocean water. Increasingly, scientists expect that the sea level may rise by a meter or more this century (Hansen, 2007; Allison et al., 2009) – a figure that is noticeably higher than the cautious forecast contained in the IPCC's Fourth Assessment Report in 2007 (IPCC, 2007b). Well over 20 million people along the vulnerable coastal regions of Bangladesh, Egypt, and Nigeria are estimated to be at risk of inundation from a one-meter sea level rise, without also factoring in the inevitable population growth (Perch-Nielsen et al., 2008).

Sea level rise is already endangering food yields, freshwater supplies, and physical safety in several low-lying small island states (Barnett and Adger, 2003; Kelman, 2006; White et al., 2007). In some cases, these problems are exacerbated by high population density and continuing high fertility rates (Ware, 2005). India, with its low-lying and densely populated coastline extending for over 7000 km, is highly vulnerable to sea level rise. This includes the threat of inundation and salinization of many coastal paddy fields (Kesavan and Swaminathan, 2006). Various less direct risks to health (physical and psychological) will result from likely displacement of populations and the breakup of families and communities due to sea level rise.

4.6.6 Indirect Pathways

The health of human populations depends fundamentally on various environmental and ecological systems and processes that determine the cycling and flow of water, food yields, and the natural geographic and seasonal constraints on infectious agents. As human-induced climate change progresses, these essentially indirect pathways are likely to account for an increasing and substantial proportion of the population health burden attributable to climate change (Confalonieri et al., 2007; Costello et al., 2009; Butler and Harley, 2010). These impacts will occur particularly via increased malnutrition, altered range and seasonality of infectious disease, and the consequences of conflict, social disruptions, and displacement due to resource shortages.

4.6.6.1 Water Insecurity

Climate change will exacerbate water insecurity in many regions, via alterations in the seasonality and intensity of rainfall, via geographic shifts in rainfall systems, and by increased rates of evaporation. As is evident in the paleoclimatic record, global warming displaces rainfall systems in subtropical regions towards the poles. Such displacement appears to have emerged recently in southern Australia, southern Africa, southern Canada, southern Spain, and Italy, for example. Further, stratospheric ozone depletion, as a concomitant global environmental change, also contributes to such displacement of rainfall systems (Cai, 2006).

By 2050, the projected changes, from medium-to-high scenarios of climate change, in rainfall, surface runoff, and depleted flows from reduced glacier masses will expose an estimated additional 2–3 billion people to severe water stress (IPCC, 2007a). Water scarcity poses multiple risks to health, including water-borne infectious diseases (e.g., cholera, other diarrheal organisms, cryptosporidium, etc.), vector-borne diseases associated with water storage, exposure to higher concentrations of salt and chemical contaminants in water, and impaired food yields. Sufficient water also reduces the risk of water-washed diseases, including diarrhea (Curtis and Cairncross, 2003), trachoma (Mecaskey et al., 2003), and scabies. Water stress seriously constrains sustainable development, particularly in savannah regions, which represent two-fifths of the world's land area. It may also lead to conflict over diminishing supplies, as well as the many adverse health consequences that flow from conflict, property loss, bereavement, and population displacement (McMichael and Bertollini, 2011).

4.6.6.2 Food Yields, Food Insecurity, and Health

Many aspects of climate change and its environmental consequences affect food yields, on land and at sea. Impairment of food yields by climate change, including the impacts of an increase in extreme weather events and heightened risks of infestations and infectious diseases, pose a great threat to population health. Meanwhile, food insecurity persists widely, and appears to have increased in absolute numbers over the past decade. In 2009, over one billion persons were classified as undernourished (FAO, 2009), representing around a one-fifth increase on the corresponding estimate at the start of the decade (Butler, 2009).

During 2008, as food prices escalated and shortages emerged, concerns were expressed about contributory climatic influences on food yields (Sheeran, 2008). Indeed, climate change is increasingly viewed as a likely contributor to altered food yields in many regions (Lobell and Field, 2007; Lobell et al., 2008; Battisti and Naylor, 2009). This superimposed threat to food supplies from climate change looms greatest in food-insecure regions where high levels of malnutrition and child stunting already exist (Lobell and Field, 2007).

Modeling studies consistently project that climate change will, overall, have a negative impact on global food yields (Nelson et al., 2009). However, those impacts will occur unevenly; some temperate regions may benefit, particularly where the soil is fertile. In general, countries in the tropics and subtropics, where both warming and reduced rainfall are likely to occur, are at greatest risk. Many studies indicate that South Asia is particularly vulnerable, and likely to experience declines in total cereal grain yields of the order of 10–20% by later this century (Fischer et al., 2005). In temperate regions and at high latitudes, agricultural productivity could initially increase, but elsewhere smallholder and subsistence farmers, especially in the tropics, are at particular risk (Morton, 2007).

Many such model-based estimates are likely to be conservative, particularly since they are unable to take into account the episodic, perhaps "surprise," events that will greatly increase the damage to yields and harvests. Extreme weather events (storms, floods, fires, etc.) can wreak disaster. This happened in 2010 with the extreme wildfires in Russia, which, in combination with preceding prolonged drought, resulted in the loss of almost one-third of the nation's annual wheat crop. Climatic conditions also affect the probability of damage by plant and livestock pests and pathogens. The northern movement of the blue-tongue virus in Southern Europe, in association with warming over the past decade, has extended the region of an economically catastrophic threat to cattle and sheep populations (Purse et al., 2005). Warming affects a range of pests; flooding favors fungal growth, whereas drought encourages aphids, whiteflies, and locusts.

It is clear from the above that estimating the current and future contributions of climate change to local or regional food availability per capita is necessarily an inexact and incomplete science. There are further methodological difficulties in translating food availability into an estimation of the actual burden of disease and functional impairment (including intellectual development in children) due to malnutrition. One major reason is the considerable variation in the role of climatic conditions as direct determinants of food availability, as well as other factors in the causation of stunting and wasting, such as diarrhea, tropical enteropathy (Humphrey, 2009), and other infections.

In remote and food-insecure regions, climate-related downturns in yields of crops and pastures can quickly result in hunger, under-nutrition, starvation and, on occasion, conflict. For example, a field assessment in western Sudan by the United Nations Environment Programme (UNEP) concluded that tensions between traditional farmers and nomadic herders over declining pasture and evaporating water holes, during a protracted period of declining rainfall, may have contributed to recent conflicts (UNEP, 2007). Inevitably, the cause of such conflict is complex (McMichael, 2009a). Other authors have noted the lag of several decades between a stepped decline in rainfall in the region and the outbreak of conflict, and have assigned a primary causal role in the region discrimination against the population of Darfur by the central Sudanese government (Kevane and Gray, 2008).

Concerns over the risk of conflict due to the environmental consequences of climate change should be set against other evidence indicating that genuine cooperation can eliminate conflict (Salehyan, 2008). Indeed, care should be taken to ensure that the implication of environmental factors is not used to evade political responsibility for the occurrence of conflict (Butler, 2007). Nevertheless, many examples from human history suggest that the long-term prospect of conflict arising in part from resource insecurity, both real and perceived, is genuine – especially when a tipping point is exceeded. Unabated climate change will reduce many kinds of resources, including food, fertile coastal land, and habitable areas within low-lying cities. The nurturing of protective human institutions to reduce this threat is vital – but so, too, are the technological developments and the forms of social reorganization that are required to accelerate the energy and sustainability transitions (Walker et al., 2009).

4.6.6.3 Infectious Diseases

Many infectious diseases – whether food-borne, water-borne, or vector-borne – are sensitive to climatic conditions (Dobson, 2009; Wilson, 2009). Various combinations of warmer temperatures, increased rainfall (affecting both humidity and surface water bodies and flows), changes in wind patterns, altered profiles of vegetation, and the aftermath of weather disasters can affect a wide variety of infectious disease agents, vectors, and the pathogen's intermediate (non-human) host species.

The rate at which bacteria multiply in food and in nutrient-loaded water increases as temperature rises. Research in Australia and elsewhere has shown a clear positive relationship between weekly or monthly temperatures and the incidence of (reported) salmonella food poisoning (D'Souza et al., 2004; Kovats et al., 2004). Changes in rainfall can affect local flooding, well-water quality, river flows and general sanitary conditions, thereby affecting the spread of diarrheal diseases, including cholera. Research based on extensive systematic historical records in southern India shows that cholera outbreaks occur most often either when conditions are very dry (and vibrio bacteria are therefore concentrated) or during times of flooding and crowding when person-to-person contact increases and hygienic conditions deteriorate (Ruiz-Moreno et al., 2007). Furthermore, especially in temperate and tropical areas, flooding can lead to increased moulds in and around dwellings, and hence additional respiratory illnesses such as asthma (Rao et al., 2007).

The range and seasonality of many vector-borne infections (diseases transmitted by mosquitoes, other insects, or rodents) are sensitive to temperature, rainfall, humidity, and wind. Pathogens incubating within mosquitoes (e.g., the malaria plasmodium and dengue virus) mature and replicate more rapidly as temperatures rise (within limits – excessive heat is harmful to insects, as it is to humans); and mosquitoes feed more frequently (McMichael, 2009a). Minimum temperature is often particularly important, often as a threshold. As predicted by climate change modeling, minimum daily temperature has been rising more rapidly around the world in recent decades than has maximum daily temperature.

Surface water patterns influence mosquito breeding; humidity and temperature affect mosquito survival. Modeling vector-borne disease transmission shows that a small temperature rise can substantially increase transmission probability. Hence, where the geographic range of malaria has increased alongside gains in climate-determined suitability the geographic range of for transmission – as in parts of eastern Africa recently – it is reasonable to assume that the climate trend partly explains the observed increases in disease (Pascual and Bouma, 2009).

The occurrence of infectious diseases (many of them vector-borne) that spill over sporadically into human populations from animal sources – that is, 'zoonotic' infections – is often influenced by climate-related changes in the population density and geographic range of the "reservoir" animal species (Harley et al., 2011). Examples include: West Nile Fever (now in the United States and Canada: host animal species are birds), bubonic plague (sub-Saharan Africa, western USA, Central America: wild rodent species), Lyme disease (south-eastern Canada: deer), Ross River Virus (Australia: kangaroos and wallabies), and Rift Valley Fever (Kenya: cattle).

In recent years, the geographic range of some vector-borne infectious diseases appears to have increased in association with documented regional warming (Alonso et al., 2011; McMichael and Lindgren, 2011). The explanation for any one, disease-specific observation is usually contestable. However, the overall pattern, across multiple settings and continents, indicates the likely emergence of a climate "signal." This set of changes includes shifts in patterns of occurrence of malaria in some eastern African highlands, tick-borne encephalitis in Sweden and the Czech Republic, and Lyme disease in Canada.

Recent warming in eastern China has been accompanied by the northwards extension of the temperature-limited transmission zone for schistosomiasis (for which the temperature-sensitive water snail is intermediate host), putting an estimated 21 million more persons at risk (Zhou et al., 2008).The first reported outbreaks of dengue in the Himalayan foothills have occurred recently – in Bhutan in 2004 and in Nepal in 2006 (TDR, 2009). Meanwhile, in Europe, there has been recent evidence of warming-induced northwards extensions of the bluetongue virus disease in livestock, and of its midge vector (Purse et al., 2005). In 2006, a further northerly extension occurred, with an outbreak 900 km north of its previous limit (Carpenter et al., 2009).

4.6.7 Social, Economic, and Cultural Disruption and Health

The disruptive effects of climate change on social conditions, relationships, and economic circumstances will affect human health and well-being in many ways. For example, adverse impacts on freshwater supplies and food yields can cause social and economic disruptions. These, in turn, may result in the displacement of people, which then often leads to various health risks, including malnutrition, mental health problems, and exposures to infectious diseases.

These direct and indirect risks to health may be further amplified by accompanying changes to other health-related behaviors, such as the (economic) need to resort to transactional sex, or by increases in the consumption of tobacco, alcohol, and perhaps illicit drugs. An illustration of the complex and sometimes extended pathways by which climate change may increase the burden of disease is in relation to HIV/AIDS (see Figure 4.10).

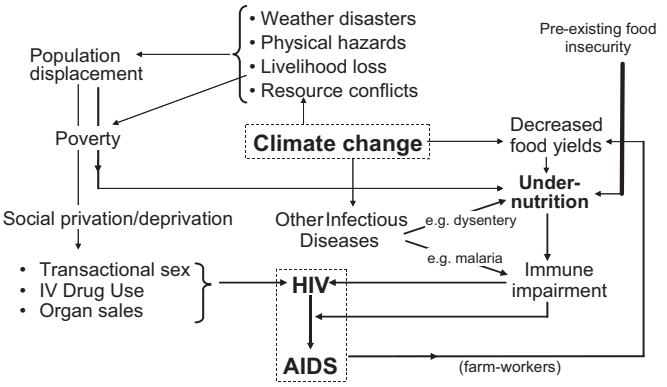

Figure 4.10 | Multiple pathways for impacts of climate change on risks of HIV/AIDS.

This category is also well illustrated by the impacts of the relatively rapid ongoing warming in the Arctic region. The resultant loss of sea ice and permafrost is already adding further stress to already disturbed traditions of living, hunting, and eating patterns in the Inuit communities of northern Canada. One consequence has been a reduction in physical activity, an increased reliance on imported energy-dense processed foods, and hence potentially amplified risks of obesity, cardiovascular disease, and diabetes (Nickels et al., 2005). The mental health consequences of these social and cultural disruptions, and of associated perceptions of future threats, pose an increasingly important risk to health.

4.6.7.1 Population Displacement

In addition to the above-mentioned general health risks associated with population displacement, changes in climate will often intensify the stresses and health risks of displacement and may erode environmental resources at the site of resettlement.

Estimates vary as to the likely number of persons displaced by climate change, with mid-century totals often of the order of several hundred million (McMichael and Bertollini, 2011). Much climate change-related displacement is likely to occur in developing regions where public health resources are lacking or inadequate (Carballo et al., 2008). Increased flooding, water shortages, and drought are likely to amplify rural-to-urban migration in many such countries, yet many poor urban communities are situated in parts of cities that are themselves at high risk for climate change impacts. Hence, people migrating into these settings may face continued environmental and, hence, health threats.

4.6.8 Burden of Human Disease Attributable to Climate Change

The task of risk assessment and risk estimation, in relation to either current or future climate change, is a very heterogeneous one; it depends on type of health outcome, type of population, and the time of interest

(present or future). Some estimations are relatively straightforward; for example, for a given plausible temperature increase, and with no future change in population biomedical profile nor in adaptive circumstances, how will annual age-specific death rates from heat waves change?

Identifying and quantifying the climate-attributable impact on various other specified population health outcomes (e.g., child stunting due to malnutrition) are inherently difficult, especially at the relatively earlier stages of climate change. The often diverse, coexistent non-climate influences, upon the same health outcomes, of cultural attributes, behaviors, and exposures can easily obscure any early real signal of a climate-related health impact. Child stunting is, for example, influenced by many factors other than agricultural production or even food intake. These include co-infection with parasites, caloric demand due to ambient temperature and workload, and the frequency of other infections, including malaria, diarrhea, and tropical enteropathy (Humphrey, 2009).

Another area of difficulty relates to estimating how and how much climate change affects mental health – a health risk in many of Australia's rural communities, for example, who face increased warming, drying, and fires; declining incomes; and possible future relocation. Similarly, inhabitants of low-lying coastal areas and many small island states live with the growing insecurity, somewhat analogous to people who live in river valleys, that they are destined for future inundation (Jackson and Sleigh, 2000).

It is possible, however, to estimate the health impacts of climate change via statistical modeling, given sufficient prior knowledge of exposure-response relationships. Indeed, such an exercise was carried out in the early 2000s as part of a systematic international CRA project. That project estimated and compared portions of disease burdens (globally and regionally) attributable to a nominated list of major risk factors, including climate change. The estimation for climate change (McMichael et al., 2004) was necessarily limited to just the few health outcomes for which there was sufficient direct epidemiological evidence (from at least several geographic regions for each outcome) to derive an estimated average exposure-response relationship. The five such conditions were: diarrheal disease, malaria, malnutrition, deaths due to flooding, and (in developed countries) cardiovascular events and deaths due to thermal stress.

The modeling of attributable disease burdens from those specific health outcomes was carried out both for the year 2000 and for various future years (including 2020 and 2030). The best estimate of the average exposure-response relationship was derived from published literature. That relationship was then applied, using the estimated region-specific level of climate change "exposure" for 2000, and 2030 (from global climate models), to the project-generated estimates of current and future disease burdens from the health outcomes of interest. The modeling thus yielded estimates, at both the global level and by geographic region, of burdens of (chronic/disabling) disease and premature mortality attributable to climate change that had already occurred by 2000 (or was projected to occur). These were expressed and summed as total loss of DALYs.[13]

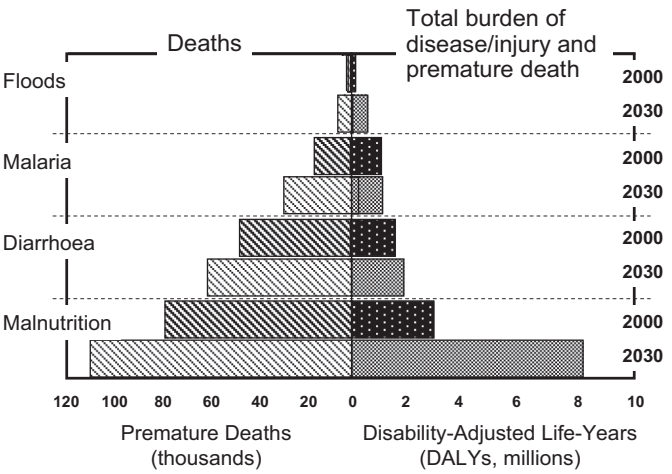

Figure 4.11 | Deaths and total burden of disease/disability/death attributable to climate change for the four selected health outcomes shown, in the years 2000 and (projected) 2030. Climate change is assessed relative to the average (reference) climate during 1961–1990. Estimations were done by major geographic region, in relation to region-specific estimates of climate change (2000 and 2030) and then summed. Estimates for 2030 were based on the projected region-specific disease and death rates for the year 2000. Source: data based on McMichael et al., 2004.

The main results for the global level are summarized for 2000 and 2030 in Figure 4.11. The exercise yielded a modest estimate of the climate change-attributable burden of disease for the year 2000 (~0.4% of DALYs; 0.3% of deaths). Inevitably, that small figure reflected the marginal change in world climate over the course of the preceding several decades. In addition, only a few health outcomes that also had great relevance to the developing world (where the brunt of the impacts from malnutrition, infection, and flooding would be expected) could be included. An estimated 88% of the climate change-attributable loss of DALYs worldwide (and more than 85% of deaths) was in children under age five in poor countries. In 2000, the climate change-attributable burden of disease was estimated to increase by around 35%, compared to 2000, with a global population increase of only 25%. Malnutrition was considered to be responsible for the largest fraction of this burden, and also to have the greatest proportional increase. Beyond that time, population growth will further slow but the impact of climate change is likely to be disproportionately more, perhaps 40–50% greater than in 2000. Many synergies are likely; for example, heavier rainfall events that cause flooding, drowning, injury, and psychological trauma also contribute to diarrhea, reduced harvests (and resultant food prices rises), social disruption, and outbreaks of vector-borne diseases, including malaria, in some locations. Poor communities are likely to have the highest burden of disease, but high-income countries will not be fully spared.

13 The DALY was developed for this international assessment as a universally applicable metric enabling the project to provide the first-ever systematic assessment of disease burdens, within which comparisons could be made across risk factors, ages, sexes, and regions.

Box 4.3 | Mitigation and adaptation actions: Implications for health risks

If mitigation is to *avoid the unmanageable* (the types of changes and risks to health that would be seriously different, worse and perhaps uncontrollable, compared to current conditions), then adaptation is to *manage the unavoidable* risks to health (i.e., those that have already begun to occur, that are impending and probably unstoppable as further climate change occurs, or are fully realized with the physical, biological, and social environments).

Reducing emissions of climate-active pollutants (i.e., "mitigation") is the first-order task. Many mitigation actions will, in their own right, affect the health of localized populations; encouragingly, most of those consequences should be beneficial, and they are thus sometimes called "co-benefits" (see Section 4.10).

Adaptive strategies are also needed, however, given that no feasible mitigation measures can fully prevent human-caused climate change. Some strategies will entail improving or extending existing policies and practices, such as mosquito control, better sanitation, nutritional supplementation programs, and stronger flood controls. Others will require innovative actions, such as community-wide early warning systems for impending weather extremes (e.g., heat waves, storms, and cyclones), crop substitution, water harvesting, and (if feasible) genetic modification of mosquito populations (McMichael, 2009a).

Unless international cooperation and resultant mitigation actions increase markedly, the need for adaptive responses to lessen the impacts on health will stretch into the distant future. However, any such extended and prolonged reliance on adaptation – particularly if seen as a substitute for mitigation – would increase the moral dilemma, since adaptation will, in general, be more achievable and affordable in the higher-income countries (McMichael, 2009a). To constrain the risks to health (and to other environmental and social assets), to do so in the framework of *sustainability*, and to facilitate the achievement of a more equitable world, mitigation must remain the centerpiece of national and international climate policy.

The above comparative risk assessment exercise is almost a decade old. It may well be that its estimates for future health impacts are too conservative. For example, world food prices reached a fresh peak in 2010. A rising trend of extreme weather events, contributed to by climate change, appears to be a major cause of this peak. Higher food prices inevitably harm the nutrition and health of the poorest on a very wide scale.

4.6.9 Differences in Vulnerability

The adverse health impacts of climate change today primarily affect low-income, poorly resourced, and geographically vulnerable populations – just those who have not contributed historically to GHG emissions (Patz et al., 2007). This pattern will persist as climate change intensifies (Confalonieri et al., 2007; Costello et al., 2009; McMichael and Bertollini, 2011). Many of the low-income countries in tropical and subtropical regions, especially their poor slum-dwelling populations, will be at particular risk. Bangladesh, for example, is vulnerable on multiple counts: widespread poverty and food insecurity, high rates of infectious diseases associated with tropical climates and with poverty and crowding, a low-lying coastal population vulnerable to cyclones and storm surges (Mitchell et al., 2006), and threats to river water flows (Himalayan glacier retreat and the probability of upstream damming and diversion of rivers by China and India).

Higher-income countries also can have marked differences in vulnerability. In the United States, for example, the impacts of the 1995 heat wave in Chicago (Semenza et al., 1996) and the 2005 Hurricane Katrina in New Orleans differed markedly between ethnic and socio-economic groups. In Australia, the population groups considered to be particularly vulnerable to climate change include (McMichael et al., 2009):

- rural communities exposed to long-term drying conditions;
- older and frailer persons, especially in relation to heat waves;
- coastal communities facing storm surges, coastal erosion, and greater risks from cyclones;
- remote indigenous communities facing heat, drying, water shortages and loss of traditional food species; and
- persons living in regions where climate-sensitive infectious diseases may tend to spread, including communities in northern Australia with greater exposure to mosquito-borne infections.

In principle, for reasons of both moral obligation and achievable social benefit, adaptive strategies should be weighted towards high-vulnerability groups and subpopulations. In practice, such interventions could take many forms, depending on the scale (global, regional, local), the type of health risk, the timeframe, and the resources available. This has implications for the ways in which intervention options are selected, and the level of specificity at which they are evaluated.

Meanwhile, human-induced climate change is already occurring and will increase over the coming decades, no matter what action humankind takes today. Therefore, adaptation is required, at least transitionally, to reduce otherwise unavoidable adverse impacts on health. This will be particularly important in populations where underlying disease rates (e.g., child diarrhea, malnutrition) are already high and will therefore rise further due to multiplier effects caused by a change in climate (Smith and Desai, 2002).

Many adaptive strategies to reduce health risks require planning and coordinated action across diverse research disciplines, sectors of government, and community interests. This collaboration extends beyond the skills and experience of the formal health sector – and reflects the fact that a society's ways of building, moving, living, producing, sharing, and consuming are the prime determinants of population health. The typical 'health' sector plays a more limited, focused, and mostly reactive role to states of health and disease. However, in addition to joining the above collaboration, there remains a major distinct role for the health sector in adaptation strategy. Institutions (hospitals, ambulance services, etc.) will need added capacity to cope with impacts of more severe weather disasters. Health professional education and training should incorporate new learning about climate-related health risks likely to apply within any particular population. Public health programs such as vaccination, child nutrition, sanitation, and community education will require further fortification. Primary health care, as the front line of the health, will be important in educating, counseling, and detecting changing health outcome patterns (Smith, 2008).

4.6.10 Climate Change and Health: Attuning Public Health Capacities

Climate change will affect human health by modulating (mostly intensifying and extending) existing climate-related risks to health. Novel health outcomes are unlikely. Therefore, the existing social and public health systems should provide a foundation for the strengthening of adaptive strategies, via incremental and complementary changes in existing health risk management programs (Ebi et al., 2006; McMichael, 2009b). Such changes also include:

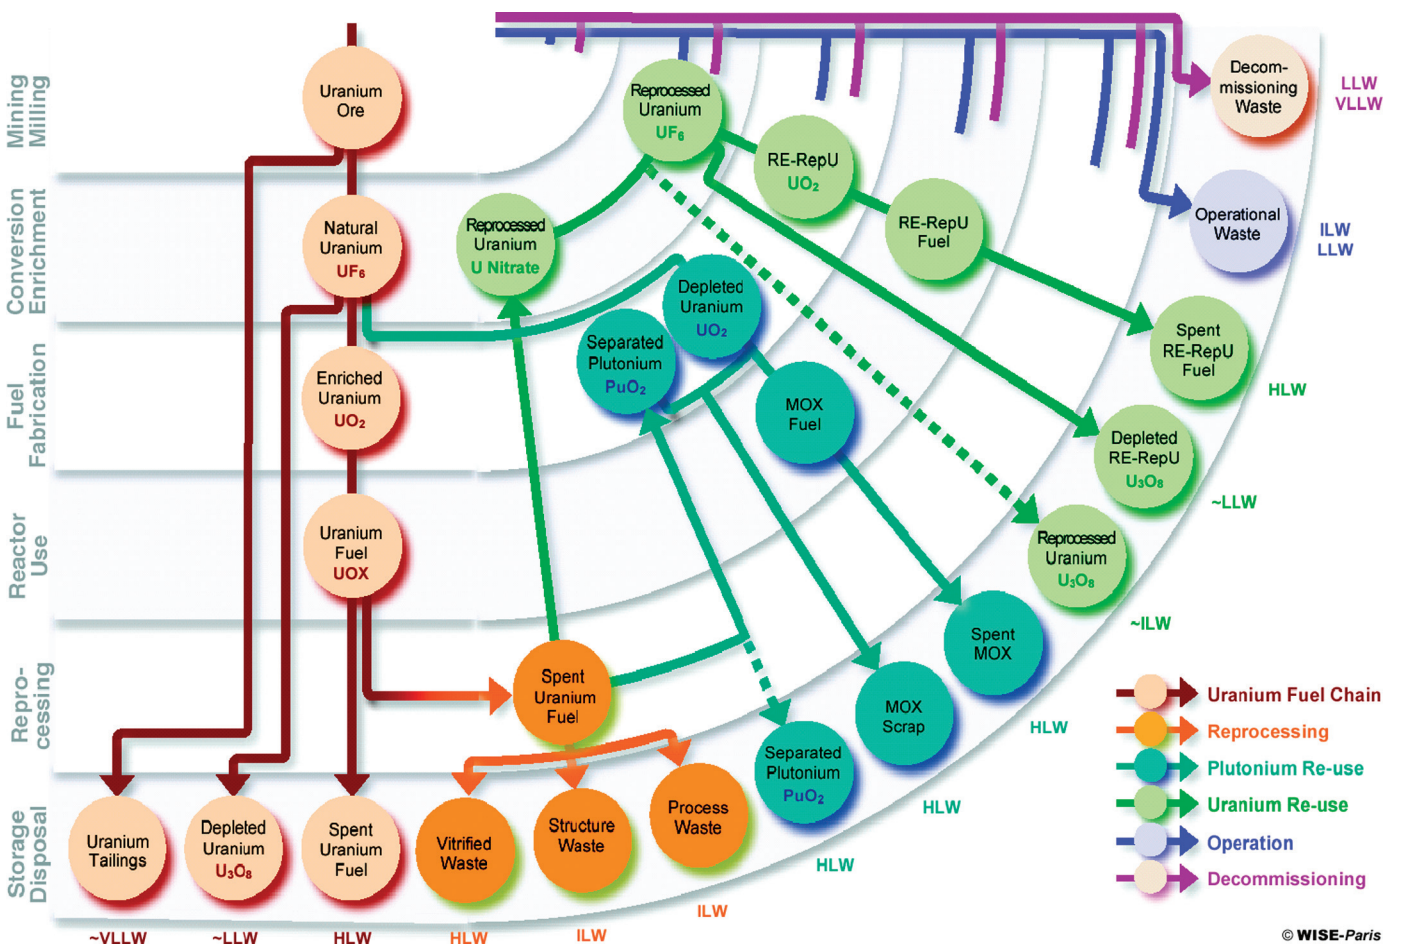

Figure 4.12 | The nuclear fuel chain. Source: WISE-Paris.

- Orienting the existing structure, staffing, knowledge base and awareness of the health system and its infrastructure to the altered and impending risks to health needs (Jackson and Shields, 2008)

- Translation of policies and knowledge from other countries or regions, to address changes in the geographic range of some health risks and diseases

- Restoration and strengthening of surveillance, maintenance and prevention programs that may have been neglected or abandoned

- Development of new policies and strategies to address any apparently new threats to health

4.7 Routine Health Impacts of the Nuclear Power Fuel Chain

4.7.1 Key Messages

- Based on current evidence, the main health effect from routine radiation releases from nuclear power facilities is the increased incidence of childhood leukemia – a rare disease. The resulting burden of disease is small compared to routine operation of fossil fuel facilities, but child cancer garners considerable public and policy concern.

- Radioactive releases from reprocessing plants are greater than from reactors. In addition, concerns exist about the significant environmental effects of uranium mining and milling which are often excluded from assessments of nuclear power.

- Average radiation doses to full-time permanent workers in nuclear power industries have generally declined over the past two decades. An increasing share of the collective dose is received by the workers of subcontractors and operators of fuel chain facilities.

- As with large hydroelectric facilities, there are difficult-to-quantify risks due to high-consequence low-probability accidents that affect workers and the public, which are also difficult to compare with day-to-day impacts (see Chapter 14).

4.7.2 Overview

The nuclear fuel supply system, from uranium mining to radioactive waste disposal, is frequently called the nuclear fuel "cycle." A strategy that leads to the direct disposal of spent fuel is referred to as "open" or "once-through," while a reprocessing strategy that separates plutonium and uranium from fission products and other wastes is called a "closed fuel cycle."

The use of such terminology suggests a circular system that confines most of the materials. In fact, each step in the system leads to specific radioactive and chemical emissions and specific new waste streams. A more accurate term would be the nuclear fuel "chain." In a typical light water reactor, with a direct disposal scheme (i.e., no reprocessing), the uranium is mined and milled before it is converted into uranium hexafluoride (UF6). In this gaseous form, the percentage of the fissile isotope U-235 is increased by diffusion or centrifugation. It is then converted back to uranium oxide, shaped into fuel pellets, and inserted into tubes in nuclear fuel assemblies. After the fuel has undergone fission in a reactor for three to four years, it becomes "spent" and is put into cooling ponds, in most cases, for at least 10 to 20 years. The term "spent" is slightly misleading, as this fuel remains extremely radioactive and dangerous for hundreds of years. The ultimate fate of spent fuel is a vexed issue and remains unresolved at this date. In many countries, spent fuel is being left in cooling ponds for increasingly lengthy periods due to the absence of technical solutions and to political opposition to plans for nuclear waste facilities. This unsafe and unsatisfactory situation poses considerable challenges for future nuclear waste management.

The decision to separate plutonium and uranium from spent fuel in reprocessing plants greatly increases the complexity of the system and its impact on the environment and health (see Figure 4.12). For these reasons, most future plans for nuclear power do not include reprocessing. (See Chapter 14 for more discussion.)

4.7.3 The Nuclear Fuel Chain

This assessment of the health impact of nuclear power systems distinguishes between effects on workers and the public. Average doses to workers in nuclear countries have generally declined over the past two decades. However, a larger share of the collective dose is received by workers of nuclear subcontractors and operators of fuel chain facilities. In France, for example, in 2008 about 31% of the nuclear workers under radiological surveillance belonged to subcontractor companies, but they received around 49% of the collective dose (calculation based on IRSN (2009)).

In 2005, a retrospective study (Cardis et al., 2005) on over 400,000 nuclear industry workers in 15 countries, the largest study of nuclear workers ever conducted, concluded that there were increased risks of solid cancers and leukemia, "even at the low doses and dose rates typically received by nuclear workers in this study" (Cardis et al., 2005). This finding is consistent with other studies of radiation health effects at low doses (NRC, 2006).

4.7.4 Uranium Mining and Milling

Canada, as the world's largest producer of uranium, illustrates issues in these stages of the nuclear fuel chain. After mining, uranium is separated from its ore by acidic leaching, as occurs in many uranium mines around the world. Because the ore usually contains only about 0.1%

uranium, leaching results in extremely large volumes of mine wastes. Canadian mine companies, for example, had accumulated about 213 million tonnes of uranium mine tailings (LLRWMO, 2004) and 109 million tonnes of waste rock, as of the end of 2003. In addition, this process has generated about 400 million cubic meters of contaminated process water. The resulting tailings, waste water, and runoff from waste rock piles contain over 80% of the initial radioactivity in the ore, and thus constitute serious low-level, but long-lived, radioactive hazards.

In addition, as in other types of ore processing, large volumes of sulfuric acid are used to mobilize heavy metals such as copper, zinc, nickel, and lead, which are highly toxic to aquatic and terrestrial wildlife. Severe contamination of groundwater constitutes a permanent risk. The government health ministry, Health Canada, states: "There is a serious possibility that the food chain can be contaminated unless appropriate mitigation is instituted. Fish, wildlife, vegetation, country foods, and drinking water are all at risk should spills or leakages occur. The need to manage the water from waste management areas is important, particularly if there are drinking water sources in the vicinity" (Health Canada, 2004). However, leakages, mostly small, do occur frequently. In the Elliot Lake area in Ontario, for example, over 30 failures of tailings dams have been reported.[14]

Recent research suggests that the health detriments of ingested and inhaled uranium may be greater than previously estimated, mainly because of the likely synergism between the carcinogenic chemical and radiation effects of uranium exposures (UNIDIR, 2008). There is also evidence that, like many other chemicals, uranium may have an endocrine-disrupting function in the body, implying that those exposed should be followed for increased risk of fertility problems and reproductive cancers (Raymond-Whish et al., 2007). As a result of such evidence, the German government recently decided to lower the regulatory limit to 10 micrograms of uranium per liter of drinking water (Associated Press, 2008).

The most significant health impacts from uranium mining probably result from the release of radioactive radon gas, which is particularly significant in underground uranium mines. Various studies have documented significant excesses in lung cancer among uranium miners (e.g., NRC, 1999; Grosche et al., 2006).

4.7.5 Uranium Conversion and Enrichment

The health risks associated with uranium conversion and enrichment are primarily due to the inhalation or ingestion of uranium in various chemical and physical forms. The uranium concentrate from the milling process (U_3O_8), which is termed yellowcake, is converted into uranium hexafluoride (UF_6), a highly volatile and toxic chemical. Airborne UF_6 immediately reacts with water vapor to form hydrofluoric acid, which is extremely toxic and can cause pulmonary irritation, edema, corrosion of the lining of the lungs, seizures, and even death.

The large stockpiles of depleted uranium accumulated as a byproduct of uranium enrichment, over 700,000 tonnes in the United States alone, pose challenges for future safe management. Depleted uranium is presently stored in ageing UF_6 containers at the sites of the enrichment plants, mostly in the United States. The conversion back to more stable uranium oxide involves the same type of risks as the original conversion from oxide to UF_6.

4.7.6 Nuclear Power Reactors and Nuclear Reprocessing Plants

During normal operation, nuclear power reactors routinely release radioactive gases to the atmosphere and radioactive liquids to the sea or rivers. In addition, when reactors are depressurized prior to being opened for refueling, larger gaseous emissions occur over short time periods. The main radioactive releases are tritium (hydrogen-3, half-life of about 12 years), carbon-14 (5,700 years), krypton-85 (11 years), argon-41 (1.8 hours), and a number of iodine isotopes (including iodine-129, 16 million years).

Commercial nuclear fuel reprocessing is carried out primarily in the United Kingdom and France. During reprocessing, spent but still highly radioactive nuclear fuel is cut up and dissolved in boiling nitric acid. Plutonium and uranium isotopes are then separated out from the fission products in the fuel. The recovered plutonium is fissile and can be used in nuclear weapons. Beyond the environmental and safety problems, it therefore constitutes a serious security and proliferation risk and is stored in guarded vaults. Part of the plutonium is mixed with uranium oxide to form mixed oxide (MOX) fuel, which is used in some reactors in Europe. However, the use of this fuel entails several economic, operational, and waste management disadvantages. (See Chapter 14 for more detail.)

The recovered uranium has no commercial value as it is contaminated with isotopes (U-234, U-236) that make further use unattractive. Most of it is currently stored in steel drums in the United Kingdom and France or has been exported to Russia. The remaining fission products, mainly cesium-137 and strontium-90, are stored in solution at high temperatures in dozens of huge tanks. These tanks, containing large unstable quantities of radioactivity, require continuous cooling by various independent cooling systems. Originally, these wastes were to be vitrified online and stored in the safer and more manageable solid form. However, such processes have proved complex and some of these (and future) wastes have remained in liquid form for many years. Again, this situation poses challenges for future nuclear waste management.

Annual nuclide releases from reprocessing plants are several orders of magnitude larger than those from nuclear power stations (European

14 This is not new. Thirty years ago, the Ontario Royal Commission on Electric Power Planning stated that, "The mining and milling of uranium ore produces very large volumes of long-lived, low-level radioactive tailings which have leached into waterways in the vicinity of Elliot Lake, Ontario, thereby posing serious health and environmental problems" (Ontario Royal Commission, 1978).

Parliament, 2001). The main releases are krypton-85, hydrogen-3, carbon-14, and a number of iodine isotopes (European Parliament, 2001). The global collective dose resulting from the discharges of the La Hague reprocessing facility for its remaining years of operational life – truncated[15] at 100,000 years – would cause over 3,000 additional cancer deaths globally, if the linear no-threshold theory of radiation is applied.

Although nuclides are routinely released from nuclear facilities, the health consequences among populations living downwind remain a subject of controversy. In the 1990s, several studies found increased incidences of childhood leukemia near UK nuclear facilities. However, official estimated doses from released nuclides were too low, by two to three orders of magnitude, to explain the increased leukemias. Recent epidemiological studies have reopened the child leukemia debate. Baker and Hoel (2007) carried out a meta-analysis of 136 nuclear sites in the United Kingdom, Canada, France, United States, Germany, Japan, and Spain and found cancer death rates for children were elevated by 5–24% depending on their proximity to nuclear facilities. Hoffmann et al. (2007) found 14 leukemia cases between 1990 and 2005 in children living within 5 km of the Krümmel nuclear plant in Germany, significantly exceeding the 0.45 predicted cases.

Most important, however, is the KiKK study, (*Kinderkrebs in der Umgebung von Kernkraftwerken* = Childhood Cancer in the Vicinity of Nuclear Power Plants) (Kaatsch et al., 2008; Spix et al., 2008) which found a 60% increase in solid cancer risk and a 120% increase in leukemia risk among young children living within 5 km of all German nuclear reactors. The findings are significant because KIKK was a large, scientifically rigorous study: the German government, which commissioned it, has confirmed its findings. The KiKK results are presently the subject of much research and it is too early to provide a firm explanation for the increased cancers although radiation exposures are thought to be involved. One hypothesis (Fairlie, 2009) proposes that infant leukemias are mainly a teratogenic effect from in utero radiation exposures due to radionuclide intakes during pregnancy. Whatever the explanation(s), the epidemiological evidence points to raised cancer risks among children living near nuclear reactors.

In recent years, a number of official reports have been published on the hazards of tritium, the radioactive form of hydrogen that is released in large quantities from all nuclear facilities, in particular from spent fuel reprocessing plants and heavy water reactors. Extremely large amounts of tritium would also be released from any fusion facility, should one ever be operated successfully. In the past, this isotope had been regarded as being only weakly radiotoxic, but this view is now changing among governments and international agencies concerned with radiation exposures. Reports have been published to date by radiation safety agencies in the United Kingdom (AGIR, 2007), Canada (CNSC, 2010a; CNSC, 2010b), and most recently in France. The French Nuclear Safety Authority (ASN, 2010) has published a comprehensive white paper on tritium and the French Institute of Radioprotection and Nuclear Safety (IRSN, 2010a; IRSN, 2010b; IRSN, 2010c; IRSN, 2010d; IRSN, 2010e; IRSN, 2010f) has published six major reports on tritium. These reports draw attention to various hazardous properties of tritium, including its extremely rapid distribution in the environment and its heterogeneous distribution within tissues.

4.7.7 Decommissioning and Waste Management

The collective dose of atmospheric discharges during the decommissioning processes of nuclear facilities in the European Union in 2004 have been estimated to be nearly 100 times less than from the operation of nuclear facilities (European Commission, 2005).[16] In total today, however, both are small by comparison to other human-caused radiation exposures, which are currently dominated by medical procedures and radon in buildings (Culling and Smith, 2010; see also Section 4.9).

Nuclear waste storage and disposal has led to significant environmental pollution in the past. In France, the Centre de Stockage de la Manche (CSM) repository stores 527,000 cubic meters of low- and intermediate-level waste and was filled and closed in 1994. The CSM contains considerable amounts of long-lived radioisotopes, including at the minimum about 100 kg of plutonium and 200,000 kg of uranium. It also contains large amounts of heavy metals, including about 20,000 tonnes of lead and 1,000 kg of mercury. Tritium leaks from the site have polluted the local water tables and streams. Contamination levels measured near the site exceeded six million becquerels per liter in 1983. Similar problems have been raised in Germany concerning the Asse nuclear waste disposal site that, in addition, is struggling with massive water intrusion and structural instability. The Federal Radiation Protection Office has recently recommended taking out all of the 126,000 drums with radioactive waste.

High-level waste (HLW) in the form of spent nuclear fuel or vitrified waste from reprocessing contains more than 90% of the radioactivity in wastes from nuclear electricity generation. However, there is no operating HLW repository in the world, and none is expected in the foreseeable future. This means that estimates of the radiological impacts of HLW disposal remain highly speculative, but HLW still poses the key question of intergenerational liability and justice. Although unlikely to pose health risk to populations approaching that of fossil alternatives, the difficulty of assuring the long-term integrity of HLW disposal sites and the difficulty of siting them due to local opposition is a major bottleneck to expansion of nuclear power in some countries (see Chapter 14).

15 The authors of the present report consider that, while the use of truncated collective doses might be justified in some comparisons, untruncated collective doses are necessary to treat present and future generations equally, a key requirement of the principle of sustainable development. Untruncated doses are of course larger than truncated ones.

16 These collective dose estimates were truncated by the European Commission at 500 years.

4.7.8 Transport

As can be seen from Figure 4.12, the nuclear fuel chain involves many stages, which inevitably results in a great deal of transportation between the various steps. These include uranium ore mining, milling, leaching, yellowcake production, U-235 enrichment, fuel fabrication, reactor operations, defuelling, temporary storage of spent fuel, encapsulation of spent fuel, and final disposal of spent fuel. This is for the direct once-through path; the reprocessing path involves significantly more stages.

Few recent studies have examined the routine health impacts of these transportation stages, as opposed to the health impacts of transport accidents that, by their nature, are not routine. Perhaps the most likely step where radiation doses may be a matter for consideration is the transport of spent nuclear fuel, in particular spent plutonium fuels (MOX fuels) by ship, rail, and road from reactors to reprocessing facilities. Older studies indicate that members of the public can receive small radiation doses from prolonged standing near spent fuel railway flasks. The result has been, at least in the United Kingdom, that railway transports of spent fuel are not allowed to stop in areas to which members of the public may have access or where they may be present.

4.7.9 Summary

Nuclear power facilities have been associated with the risk of some cancers in selected sub-populations, such as workers, but nevertheless do not represent a significant fraction of radiation exposure or the burden of disease in any population. Leaving aside the important potential of weapons-grade material being diverted from commercial nuclear fuel systems and major nuclear accidents, all major studies indicate that well-run modern nuclear power systems pose much less risk than fossil power systems, even modern ones. Nevertheless, because of the character and history of radiation, the risks of nuclear power systems are of particular concern to the public and policy makers and thus do significantly influence energy policy decisions in many countries. In addition, as the size and scale of nuclear facilities expand, such risks may also rise unless careful measures are taken. Finally, as discussed in Chapter 14, the difficult-to-quantify risks of proliferation from some nuclear fuel technologies may overwhelm those from all other parts of the system, including routine operation, accidents, and waste disposal.

4.8 Emerging Energy Systems

4.8.1 Key Messages

- Energy derived at a large scale from sunlight and wind is not free of health and environmental impacts. Issues of land use, maintenance, materials inputs, and energy storage raise concerns about environmental, occupational, and community health impacts.
- The health and environmental impacts of advanced materials such as nanotechnology materials that are used in some advanced energy technologies are not well characterized. There are a number of concerns about both occupational and environmental exposures from the widespread use of these materials and the resulting impact on disease burden

4.8.2 Background

Accessible and affordable energy has facilitated the industrialization, strengthening, and growth of the world economy over the past century. But rising energy use has also brought recognition to the human health and environmental impacts of different systems for producing, transforming, transporting, and consuming energy. As fossil fuel use developed over the last century, a variety of associated health and environmental effects began to appear. To address these problems, ongoing investments have been made in alternative energy sources and technologies, often with an implicit assumption that alternate sources will reduce impacts relative to existing technologies. The flaw in this assumption, however, is that lack of knowledge about impacts is not the same as absence of impact.

Changes from one energy source to another are likely to have different impacts through the whole usage chain (or fuel life cycle), from resource capture through to conversion, distribution, and end use. Moreover, because the full impact burden of extant energy systems has not been adequately characterized, there is no appropriate baseline against which to compare the relative benefits of new systems. Therefore, as world leaders consider options for changing the portfolio of future energy sources, it is important to examine each of the options for associated impacts and strategies to address those impacts.

The history of technology development (e.g., pesticides, vaccines, drugs, nuclear power, transportation, fuel additives) reveals that all technologies have both benefits and drawbacks (health, environmental, financial, and social). Not all benefits and drawbacks can be accurately characterized in advance of technology deployment, but technology assessment has proven useful in avoiding strategic errors that can derail a promising technology. Prior to widespread technology deployment is the time to confront issues such as demands on resources and materials, occupational and environmental health burdens, impacts on water supply and climate, and land-use offsets. As emerging energy technologies move from concept to deployment, there is a need to go beyond a simple current carbon benefit or net energy balance assessment and include other impacts such as human health benefits and impacts.

One tool to evaluate the cumulative impacts of existing technologies and anticipate the impacts of future technologies is lifecycle assessment (LCA). LCA provides a framework for comparing services and products (or product-related emissions) according to their total estimated environmental impact summed over all chemical emissions and activities associated with the product's life cycle. Box 4.4 below illustrates life-cycle impact as it applies to both existing and emerging energy systems.

Box 4.4 | Life-cycle assessment

Life-cycle assessment (LCA) has evolved over the last three decades as an effective strategy for organizing a comprehensive assessment of energy system impacts. The purpose of LCA is to quantify and compare environmental flows of resources and pollutants (to and from the environment) associated with an industrial system, such as an energy supply and use system, over the entire life cycle of the system – from resource extraction to energy use. LCA evaluates a broad range of requirements and impacts for technologies, industrial processes, and products in order to determine their propensity to consume natural resources or generate pollution. The term "life cycle" refers to the need to include all stages of a process – raw material extraction, manufacturing, distribution, use, and disposal, including all intervening transportation steps – so as to provide a balanced and objective assessment of alternatives. In the case of electrical energy, this means tracking the system from resource extraction (i.e., collection of sunlight, extraction of tar sands, collection of wind energy, etc.) through conversions, storage, transmission, and end use. In the case of transportation energy, LCA tracks the system of resource extraction (biofuel production, oil shale extraction, oil well production, etc.) through conversions, storage, and transport to the point of energy release and use in a vehicle (auto, bus, train, airplane, etc.).

An LCA includes three types of activities: collecting life-cycle inventory data on materials and energy flows and processes; conducting a life-cycle impact assessment (LCIA) that provides characterization factors to compare the impacts of different product components; and life-cycle management, which is the integration of all this information into a form that supports decision making. As an illustration of the LCA approach, Figure 4.14 shows a comprehensive LCA for transportation biofuels that addresses cumulative impacts to human health and the environment from all stages, impacts from alternative materials, and impacts from obtaining feedstocks and raw materials.

"To assess human toxicity impact, the LCIA practitioner considers for each chemical involved the cumulative exposure associated with the mass released to a defined (indoor, urban, regional, etc.) environment by multiplying the release amount by a measure of toxic impact to characterize the likelihood of health effects and their potential consequences. The SETAC Life Cycle Impact Assessment (LCIA) Working Group on Human Toxicity (Krewitt et al., 2002) has classified measures of toxic impact into two broad categories: potency-based characterization factors that are used to assess the likelihood of a disease or effect (cancer, death, reproductive failure, etc.) and severity-based characterization factors or damage factors that, in addition to the qualitative or quantitative likelihood of disease, reflect population consequences of the disease in terms of years of life lost or some other measure of societal impact" (McKone et al., 2006).

Below we discuss a set of emerging energy systems, along with the new and/or potentially worrisome health issues surrounding these systems. The health impacts from energy systems include those that can be measured through occupational or community health tracking and those that are estimated using tools such as risk assessment. Most of the health impacts from emerging systems, and many of the health impacts from existing systems, are in the latter category. So, a key challenge of addressing health impacts from emerging systems is the lack of large empirical databases or well-established assessment methods. To address this gap, we first consider the baseline impact from existing systems and then consider how emerging systems will perform to reduce and/or redistribute this burden.

4.8.3 Baseline Impact Assessment

For both transportation fuels and electricity production, an assessment of the current disease impact associated with a base metric, such as 100,000 vehicle km traveled and with a GWe-yr of electricity produced, provides baselines for the comparative assessment of emerging energy systems. It is difficult to obtain accurate and consistent assessments of the disease burden of energy in these terms, but some key studies offer insight regarding the magnitude of the disease burden. In its extensive study of energy externalities, the US National Research Council (NRC) (2010) noted that among alternate approaches employed to address baseline assessments, some are "top-down," others "bottom-up." The top-down approach makes use of morbidity and mortality statistics for a specific population, such as the inhabitants of a country or a population group, and postulates a link to a specific source, such as transportation or power plant emissions or to an activity (smoking). The bottom-up approach begins with hazard identification, defining sources for pollutants of concern and then follows these sources from a point of release into a receptor population to assess exposure and damage. According to the NRC (2010), "Top-down assessments for air pollution have been carried out for many regions such that it is possible to provide a disease burden estimate for air pollution. But allocation to specific energy

Table 4.10 | Examples of the categories of impacts that have been associated with pollutant emissions from energy supply and the specific types of health effects and other damages associated with these pollutants.

Impact Category	Pollutant/Burden	Effects
Human health – mortality	PM_{10}, SO_2, NO_x, O_3	Reduction in life expectancy
	Benzene	Cancers
	Benzo-[a]-pyrene	
	1,3-butadiene	
	Diesel particles	
	Noise	Loss of amenity, impact on health
	Accident Risk	Fatality risk from traffic and workplace accidents
Human health – morbidity	PM_{10}, O_3, SO_2	Respiratory hospital admissions
	PM_{10}, O_3	Restricted activity days
	PM_{10}, CO	Congestive heart failure
	Benzene	
	Benzo-[a]-pyrene	Cancer risk (non-fatal)
	1,3-butadiene	
	Diesel particles	
	O_3	Asthma attacks
		Symptom days
	Noise	Myocardial infarction
		Angina pectoris
		Hypertension
		Sleep disturbance
	Accident Risk	risk of injuries from traffic and workplace accidents
Building material	SO_2 Acid deposition	Ageing of galvanized steel, limestone, mortar, sand-stone, paint, rendering, and zinc for utilitarian buildings
	Combustion particles	Soiling of buildings
Crops	NO_x, SO_2	Yield change for wheat, barley, rye, oats, potato, sugar beet
	O_3	Yield change for wheat, barley, rye, oats, potato, rice, tobacco, sunflower seed
	Acid deposition	Increased need for liming
Global warming	CO_2, CH_4, N_20, N, S	World-wide effects on mortality, morbidity, coastal impacts, agriculture, energy demand, and economic impacts due to temperature change and sea level rise
Amenity losses	Noise	Amenity losses due to noise exposure
Ecosystems	Acid deposition, nitrogen deposition	Acidity and eutrophication (avoidance costs for reducing areas where critical loads are exceeded)

Source: European Commission, 2005.

systems cannot be resolved, because the top-down approach usually lacks the spatial and temporal resolution needed to track impacts to specific technologies." To address the damages associated with specific technologies requires the bottom-up approach such as was used in the comprehensive ORNL/RFF (ORNL/RFF, 1992–1998) and ExternE (European Commission, 2005) studies.

Both the ORNL/RFF and ExternE studies employ a bottom-up approach, in which environmental benefits and costs are determined using a pathway analysis that follows the energy-technology pollutant emissions from the source, then tracking dispersion in air, soil, and water and ultimately to health and environmental impacts. Both ORNL/RFF and ExternE used a life-cycle approach to characterize externalities associated with electricity production from a variety of technology options. In order to permit comparisons across multiple technologies, the ORNL/RFF and ExternE characterized externalities in monetized units, that is dollars of damage per kWh. This involved the use of detailed models to predict the dispersion from energy supplying facilities of primary pollutants as well as the atmospheric formation of secondary pollutants, specifically ozone and fine particulate matter (see Table 4.10). The ExternE study also considered transportation systems. More recently, Hill et al. (2009) assessed life-cycle impacts from air emissions attributable to transportation fuels. They used a life-cycle approach to assess the potential impacts of emerging

Box 4.5 | US National Research Council study on the "hidden costs" of energy

In 2008, the US Congress asked the National Research Council (NRC) of the US National Academy of Science to prepare a report that defined and evaluated "key external costs and benefits – related to health, environment, security, and infrastructure – that are associated with the production, distribution, and use of energy but not reflected in market prices or fully addressed by current government policy." The NRC released this report in late 2009 (NRC, 2009b). To assess damages, the committee used a life-cycle approach with relatively high spatial resolution for characterizing emissions and exposures attributable to energy used in the United States by electricity generation, transportation systems, process heat, and building heating/cooling. They applied these methods to a year close to the present (2005) for which data were available, and also to a future year (2030) so as to gauge the impacts of possible changes in technology. In addition to impacts in the near term (health damages), the committee considered damages in the future attributable to emissions of atmospheric greenhouse gases.

The report found that, in 2005, the unpriced impacts of energy supply amounted to US$120 billion. This amount is due mainly to the negative impact of air pollution on health. Of this amount, US$62 billion was attributable to electricity (mainly coal) and about US$56 billion was attributable to transportation, with the remainder due to process heat and comfort control. The long-term damages from climate change were estimated to be comparable (~US$120 billion) and security costs were not quantified. Coal-fired plants, which produce about half of US electricity, had an impact of about US¢3.2 of "nonclimate" damages for every kilowatt-hour (kWh) generated. In contrast, natural gas electricity had an impact of US¢0.16. In the transportation sector, which accounts for 30% of US energy use, the estimated unpriced health damages of US$56 billion works out to US¢0.7–1 per vehicle km traveled. The estimated air pollution damages associated with electricity generation in 2030 will depend on many factors, such as the future mix of generation technologies, end-use efficiency, air pollution regulations, etc. With regard to transportation impacts, the committee noted that substantially reducing nonclimate damages related to transportation by 2030 would require major breakthroughs, such as cost-effective technologies to create cellulosic biofuels and to capture and store carbon from coal-fired power plants. In addition, great increases in renewable or other forms of electricity generation (for electric vehicles) with lower emissions would be needed. Further enhancements in fuel economy will help, especially for emissions from vehicle operations, although they are only about one-third of the total life-cycle emissions (NRC, 2010).

biofuels relative to gasoline. The impact pathways included in ExternE are listed below.

The NRC (2010) report on the unpriced consequences in the United States considered impacts from all forms of energy supply, distribution, and use. The approach and findings of this report are summarized in Box 4.5. Although these results are most relevant to North America, they provide key insights about the relative magnitude of the health and environmental impacts from existing and emerging energy technologies. This report makes clear that, even for relatively clean energy technologies, the upstream inputs can have a significant impact because they often rely on existing technologies for energy inputs. For example, the production of fuels, whether from biomass or from petroleum, requires a significant amount of energy that could be coming from a coal-fired power plant.

4.8.4 Biofuels

Biofuels have become the focus of both governments and industry efforts to find technically feasible and carbon-neutral fuels for transportation and (to a lesser degree) electricity production. The challenge for biofuels is to compete with fossil-based fuels in terms of cost and impact. The enormous world demand for liquid fuels makes it inevitable that a biofuel economy will involve significant changes in agricultural, fuel-production, and transportation infrastructure. Building and operating this infrastructure will involve many complex technical and policy choices. Addressing these complex choices requires research to anticipate the nature and scale of the supply/demand systems that will arise in large-scale deployment of biofuels (Energy Biosciences Institute, 2010). However, the current methods used to measure, evaluate, and regulate human health impacts and benefits of biofuels suffer from a number of information gaps and have not been fully integrated into an LCA framework. Moreover, the call for biofuels gives rise to environmental and ethical questions regarding the impacts in rural communities from deforestation, food price changes, and loss of ecosystem services that can accrue when monoculture crops replace extant systems.

Ethanol derived from corn or sugarcane as an additive to or substitute for gasoline, along with biodiesel derived from vegetable oils or waste animal fat, are currently the largest and most economically viable biofuels options. However, biofuels can be produced from a wide variety of plant materials and wastes. The biofuel feedstocks receiving the most attention include corn stover (stalks and cobs), perennial grasses (switchgrass and miscanthus), sorgum, algae, trees and dedicated woody crops, and even garbage. Because plants absorb CO_2 during growth and may

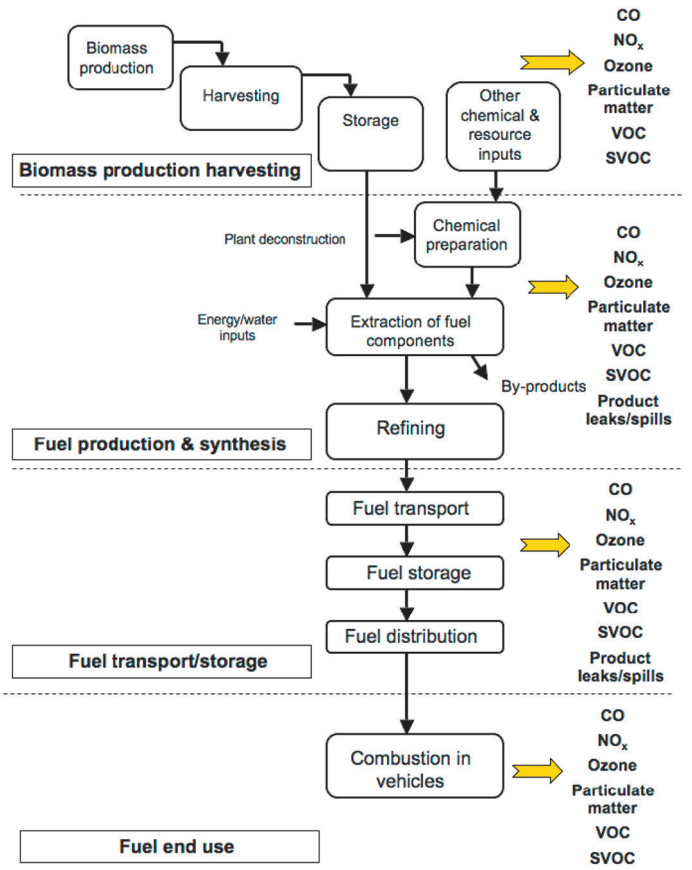

Figure 4.13 | Pollutants associated with biofuel production, transport and use.

increase stores of soil organic carbon (Tilman et al., 2006), biofuels may reduce GHG emissions relative to petroleum-derived fuels. Many studies (see, for example, the review in NRC, 2010) conclude that there are at least small, positive life-cycle GHG benefits from most biofuels. But there continues to be debate concerning the net GHG effects from first-generation biofuels, particularly corn-based ethanol.

In addition to potential reductions in GHG emissions, vehicle tailpipe emissions of many air pollutants harmful to human health will be different and may be lower with biofuels (McCormick, 2007). Questions remain regarding how shifts from petroleum-based fuels to biofuels will affect the combustion-phase emissions of air pollutants. Evidence for lower primary particle emissions must be weighed against evidence for potentially higher VOC emissions, which could increase ozone and secondary particle formation. Whether and how much biofuels reduce human health impacts (see Figure 4.13) relative to fossil fuels depends strongly on how they are produced, distributed, and combusted (Robertson et al., 2008). Energy inputs, fertilizer use, biomass yields, conversion efficiencies, pollution control technologies, and direct and indirect damages to water supplies and land all determine the cumulative impacts on human health from both biofuels and fossil fuels (Hill et al., 2006; Fargione et al., 2008; Searchinger et al., 2008).

In characterizing the life-cycle health impacts associated with liquid transportation fuels from biomass, one needs to consider the emissions generated at each of the following stages (see Figure 4.14):

- production of the feedstock (farm or forest externalities);
- transportation of the feedstock to the processing facility;
- processing of the feedstock into liquid fuels;
- transportation of the fuel to distribution endpoints; and
- downstream effects of using the fuel.

The last two steps are identical to any liquid transportation fuel and, at least for air emissions, have been addressed by air quality studies and models. But these studies have significant uncertainties, so it remains difficult to make an accurate characterization of the overall disease burden from gasoline, much less to project future scenarios. The upstream impacts of biomass feedstock effects will be quite location specific, as different feedstocks will be economically viable in different locations (e.g., corn stover and switchgrass in the corn belt, miscanthus in warmer climates, trees and forestry in the southeast, etc.). In addition, the health impacts associated with any given feedstock are also likely to vary by specific field/watershed within a region (depending on climate, land use history, soils, slope of the land, proximity to water bodies, etc.) and can be attenuated by farming practices (use of conservation tillage, nutrient management of both fertilizer and manure applications, placement of buffers or wetlands, etc.). Finally, transportation of feedstocks to processing facilities is expected to remain expensive, even after technological improvements, so that numerous, small processing facilities located throughout the landscape is a likely configuration of the industry. This means that health impacts associated with production and transportation of the feedstock and liquid fuels will be both site-specific and widespread.

Hill et al. (2009) estimated that for "each billion ethanol-equivalent gallons of fuel produced and combusted in the USA, the combined climate-change and health costs are US$469 million for gasoline, US$472–952 million for corn ethanol depending on biorefinery heat source (natural gas, corn stover, or coal) and technology, but only US$123–208 million for cellulosic ethanol depending on feedstock (prairie biomass, miscanthus, corn stover, or switchgrass)." However, their analysis does not distinguish mortality from morbidity or define the equivalent disease burden associated with these numbers. Moreover, their approach focuses on air emissions and excludes the impacts of toxic air pollutants and releases to soil and water. Future life-cycle assessments are needed to address a full range of air emissions, as well as emissions to surface water, soil, and groundwater, which have complex and significant pathways from release to human intake (e.g., food pathways).

The debate concerning the net GHG effects of biofuels centers on indirect land use changes. Indirect land use refers to crop allocation changes occurring indirectly as a result of biofuels policies and the effect of such

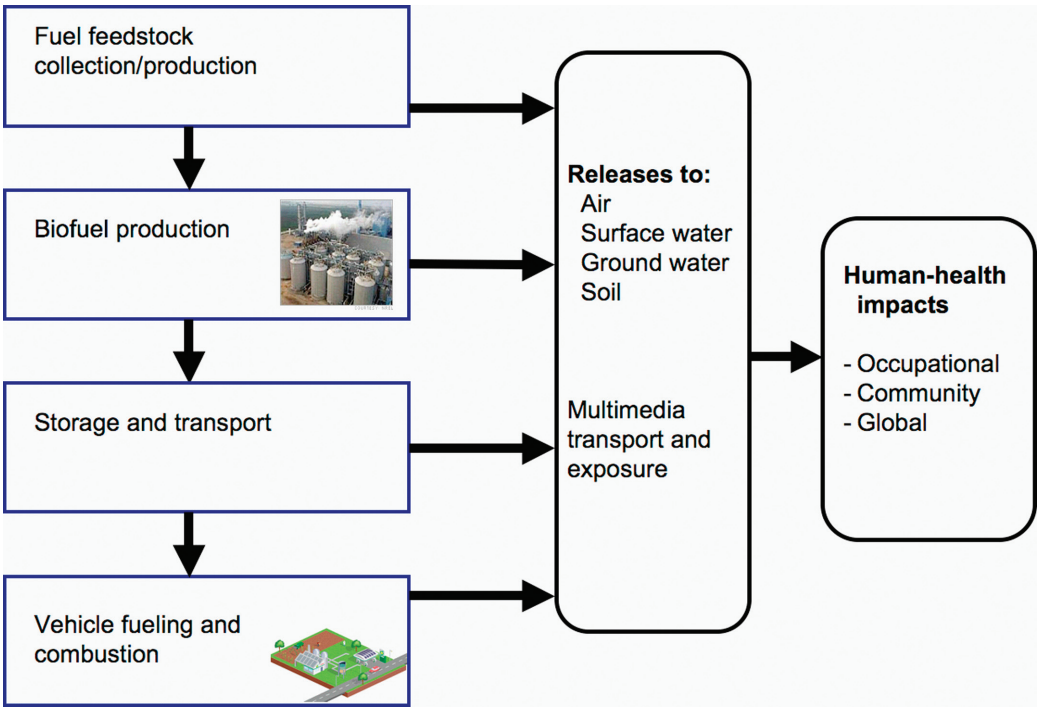

Figure 4.14 | An illustration of the life-cycle approach showing the link of human health impacts to the major life stages of biofuel production and use.

changes on GHG emissions. It has been a major source of discussion since Searchinger et al. (2008) published a paper that explains how increasing demand for corn or farmland causes crop prices to increase, making it profitable for farmers to increase their acreage. If this increased acreage comes from plowing up land that has not been in agricultural production and/or is particularly environmental sensitive (e.g., rainforests in Brazil, pristine ecosystems in the United States), this could actually increase CAP emissions (since burning rainforests would release lots of carbon) and have other detrimental environmental concerns. There is continuing study of this issue. A recent report by the US Environmental Protection Agency considered a range of biomass production scenarios and found significant variability with regard to indirect land use (US EPA, 2009). In some cases, their analysis suggests that significant reduction in CAP emissions relative to gasoline could be largely offset by indirect land use changes. In other cases, the effect is small. These types of results focus attention on a formal treatment of uncertainties in the life-cycle assessment.

4.8.5 Synfuels

Synfuels are considered emerging technologies because most synthetic fuels technologies are either not yet cost-competitive with existing fossil fuels or because they are still in a research and development phase. Synthetic fuels can be made from coal, oil shale, or tar sands. Various fuel gases, such as substitute natural gas and synthesis gas (made from CO and hydrogen) are also included in this category. Synthetic crude oil (often called "syncrude") is a complex mixture of hydrocarbons somewhat similar to petroleum. It is obtained from coal (liquefaction), from synthesis gas (a mixture of carbon monoxide and hydrogen), or from oil shale and tar sands. Gaseous fuels can be produced from sources other than petroleum and natural gas. Syncrude mixtures have a number of key differences in composition relative to petroleum. For example, syncrude from coal usually contains more aromatic hydrocarbons than petroleum. The most important current source of synthetic crude oil is the tar sand deposit that occurs in northeastern Alberta, Canada. Tar sand is a common term for oil-impregnated sediments that can be found in almost every continent. The routes by which synthetic fuels can be prepared from coal involve either gasification or liquefaction.

Atmospheric emissions from synfuel production are generated from mining, processing, retorting, and waste disposal. Large emissions of PM can arise from mining, blasting, conveying, crushing, and on-site retorting operations. The on-site liquefaction/gasification needed to mobilize synfuels also poses the potential for large emissions of oxides of sulfur and nitrogen, mercury and other metals, and carbon monoxide, as well as large numbers of organic compounds, including alkanes, benzene, and polycyclic aromatic hydrocarbons (PAHs) to the local airsheds.

Production of synthetic fuels from geological formations such as oil sands or oil shale also have the potential for impacting human health through significant reductions in water quality. The impacts on water quality are both direct and indirect. Direct impacts arise from the release of contaminants to surface and groundwater from both routine and off-normal operations. Synthetic fuel operations produce large amounts of wastewater that must be stored, treated, and moved through pipelines. Even under ideal conditions, the treatment process can introduce trace amounts of metals and toxic organic compounds to surface and groundwater. Moreover, off-normal events such as leaks in pipes and containment ponds, which can be frequent, will add even more of these substances to both surface and groundwater. Indirect effects are those associated with large demands on limited water supply and impacts from disrupting water-bearing formations. For example, extracting one barrel of oil from an oil sand requires many barrels of water. The demand on surface and/or groundwater for synfuel mining and processing will limit the amount of water available for diluting the pollutants from these processes. Lack of available fresh surface or groundwater can be a disease burden in and of itself. The alteration of geologic formations due to mining operations can limit the storage and transmission of both surface and groundwater, leading to a reduction of freshwater and the health consequences of this privation.

Significant human health impacts are associated with the production and use of synfuels (NRC, 2010). These technologies have documented impacts on occupational health as well as the health of local, regional, and global populations. The life-cycle impacts of synfuels include both upstream processes for extraction, transportation, and reefing the fuel-use stage. The upstream stages have potentially significant local and even regional impacts on air, surface water, and groundwater with resulting impacts on human health. In particular, the need to liquefy or gasify the fuels from the formations that supply them will result in CAP emissions that impose both local and global disease burdens. In the refining and combustion process, the impacts of synfuels are likely to exceed those of an energy-equivalent quantity of gasoline; however, there are currently insufficient data available to accurately make this assessment (NRC, 2010).

4.8.6 Large-Scale Solar and Wind Power Systems

Solar energy has been deployed in both small-scale (mainly rooftop) applications and in large-scale electrical production. A number of large-scale solar power plants are already in operation worldwide, with plans slated for others. Three large-scale technologies transform solar radiation into a form that provides electricity: photovoltaic cells, which generate electricity directly; concentrating solar power thermal systems, which use an absorption medium such as water or oil to transfer absorbed heat to a steam generator that drives a turbine; and solar towers, which are effectively chimneys where rising hot air powers turbine generators.

Wind power or wind energy is the process by which the wind is used to generate mechanical power or electricity and is one of the fastest-growing forms of electricity generation in the world. Archer and Jacobson (2007) produced a global wind-energy resource map that estimated the global potential for wind-generated energy at 72 terawatts, 40 times the worldwide demand in 2000.

Large-scale solar and wind systems are not free of health and environmental impacts. Issues of water demand, land use, maintenance, materials inputs, and energy storage raise concerns for environmental, occupational, and community health impacts. Interest is growing in the large-scale use of nanomaterials in solar applications. Energy storage is an issue currently being addressed with new technologies that may require large quantities of materials whose toxic properties are not well studied. Constructing new transmission lines to areas with the best wind and solar resources also poses significant environmental problems. There is no indication, however, that the overall health burden of these systems will be even close to those from traditional fossil fuel systems. Moreover, the health burdens for large wind power and solar power systems are likely to be lower than even advanced fossil and nuclear power systems. Nevertheless, it is important to anticipate risks in advance in order to head off any unpleasant surprises as new systems come into widespread use.

4.8.7 Geo-engineering Schemes

Concerns about the environmental impacts of GHG emissions and the persistent pollutants from energy technologies have led to a call for large-scale "geo-engineering" projects for mitigating the impacts of global pollutants. Geo-engineering is the deliberate modification of Earth's environment on a large scale to provide for human needs and promote habitability. Keith (2001) emphasizes that it is the deliberateness that distinguishes geo-engineering from other large-scale, human impacts on the global environment, such as those that result from large-scale agriculture, global forestry activities, or fossil fuel combustion. Originally, the term geo-engineering referred to a proposal to collect CO_2 at power plants and inject it into deep ocean waters. The concept of geo-engineering now also includes:

- underground storage of CO_2;
- fertilization of oceans with urea, a nitrogen-rich substance, or with iron, a limiting nutrient, to encourage growth of plankton;
- deflection of sunlight from the Earth through the use of a giant space mirrors;
- injection of sulfur particles into the stratosphere in order to modify the Earth's albedo;

- cloud-seeding by spraying seawater in the atmosphere to increase the reflectiveness of clouds; and
- windscrubbers to filter carbon dioxide from the air.

Each of these concepts carries with it some risk of health and environmental impacts that have not been fully identified or evaluated. In addition, most of these concepts are energy intensive and will thus have an impact that depends on the quantity of energy required and the source of that energy.

4.8.8 Advanced Materials in Energy Systems

Advanced materials such as nanotechnology materials and advanced semiconductor technology play a growing role in both energy supply and energy use. Nanotechnology is increasingly impacting the US and world energy balance, on both the supply and demand sides. On the supply side, nanotechnology is being used to optimize supply from existing energy sources (e.g., crude petroleum) and to exploit new sources, such as heavy oil, liquefied coal, and solar energy (including using solar energy to produce hydrogen). Nanotechnology is also improving and opening new possibilities for the transmission and storage of energy, especially electricity and possibly hydrogen in the future. On the demand side, nanotechnologies have the potential to reduce energy use by making it possible to manufacture lighter and/or more energy-efficient automobiles and appliances. Nanotechnologies can also be used to improve energy efficiency in buildings.

The health and environmental impacts of advanced materials such as nanotechnology materials are not well characterized. There are a number of concerns about both occupation and environmental exposures to the widespread use of these materials and what impact that will have on disease burden (NRC, 2009a).

4.9 Energy Efficiency

4.9.1 Key Messages

- Increases in combustion efficiency have the potential to greatly improve human health, especially in households that use solid fuels for cooking.
- Measures to increase energy efficiency in buildings can improve health by reducing cold-related morbidity and mortality and by increasing psychosocial well-being.
- In homes with relatively low levels of air exchange, energy efficiency measures can have some negative impacts on health by increasing exposure to dust, mold, radon, volatile organic compounds, and indoor tobacco smoke.
- Energy efficiency projects require capital. Fuel taxes or tariffs may be levied to account for these expenditures, while subsidies for poorer consumers may be needed to counteract the effect of increased fuel prices.

4.9.2 Energy Efficiency, Energy Use, and Health

Energy efficiency is often looked upon as the most desirable approach to limiting energy use and as potentially the most cost-effective means of achieving net health benefits. Obtaining the same level of energy service with less primary energy input should entail lower fuel cycle risks, reduce atmospheric emissions of pollutants, limit demands on infrastructure, lower costs, and contribute to economic competitiveness. Although all these factors are generally true, the relationship between energy efficiency and health is more complex.

To a large degree, in fossil fuel combustion, efficiency equates with cleanliness of burning and hence with lower emissions of health-damaging pollutants for a given quantity of fuel and a specified level of energy service. This has most immediate and direct relevance to the indoor combustion of biomass for cooking and heating in low-income households (see Section 4.2), where efficiency of stove technology may appreciably influence exposure to indoor air pollutants, especially for women and children.

Some argue that, at a societal level, increasing efficiency (and hence improving the affordability of energy services) can promote greater overall use of the technology in question than otherwise would occur, resulting in a rise in total per capita energy use, and potentially greater community-level pollutant emissions (Smil, 2005). Among poor populations, an increase in energy services due to greater energy efficiency can have major welfare benefits, including better health. This set of issues is sometimes called the "takeback" or "rebound" effect and is discussed in more detail in Chapter 10.

Increased energy efficiency is a factor in the web of socio-technological influences that contribute to (industrialized) patterns of supply and demand, which have many detrimental (as well as beneficial) consequences for health in rich countries. Among the risks are those associated with increasing dependence on motorized transport (in relation to risk of road injuries and deaths; physical activity with its consequences for obesity, diabetes, cancer risks; and many other health effects; as well as adverse effects on the quality of urban living); overconsumption of energy-dense, processed foods high in salt and saturated fats, derived from intensive agriculture; and diets with a high proportion of meat and dairy products.

Energy efficiency is seen as one means of helping to limit the vulnerability to price volatility in global energy markets and of establishing greater energy security – an argument that applies at national and household levels (see Chapter 5). Though opinion about the imminence

and consequences of peak oil remains divided (Deffeyes, 2001; Frumkin et al., 2007), there is no doubt that the world's low-cost energy reserves are being steadily depleted. Over time, the costs of extraction will rise in financial, environmental, and energy terms, as deposits become less and less accessible. There are justifiable concerns that this trend will be a driver for economic change and restructuring in many countries, with adverse effects on health and life expectancy. Reducing energy dependence through greater efficiency may help to limit these adverse impacts.

Among the various methods by which energy efficiency may be improved is the use of more distributed energy supply systems based on microgeneration and combined heat and power systems. Though broadly desirable, significant uncertainties remain about the adverse impacts that multiple microgeneration facilities may have on air quality in some settings, relative to centralized energy supply and distribution systems. This is due in part to the higher intake fraction (see Box 4.1) of the emissions from such facilities.

Increasingly, energy efficiency interventions – including programs of home insulation and heating system upgrades, as well as building regulation – are being used to tackle GHG emissions. While such interventions are likely to be broadly beneficial for health (e.g., resulting in warmer indoor temperatures in winter, lower fuel use/cost, improved use of space with various psychosocial benefits, etc.), there can be important unintended consequences. One method to increase energy efficiency is to limit the degree of uncontrolled ventilation by improving the air tightness of windows, doors, and other parts of the building fabric. While this may have little effect if the relative reduction in ventilation is small, it may have more critical impact in dwellings that already have fairly modest ventilation rates. The potential adverse health consequences include hazards relating to dampness and mold, indoor air quality (especially increases in radon levels), and in some circumstances, risk of adverse heat-related effects.

There is limited epidemiological evidence about many of these connections, which often are modified by local circumstances. The impacts of energy efficiency therefore cannot be quantified with any precision, despite their importance to a range of energy-related policy decisions.

4.9.3 Household Energy Efficiency

Household energy efficiency merits particular discussion because it is increasingly becoming a target for energy policy in the context of climate change (Stern, 2007; Friedlingstein, 2008) and recent fuel price rises. In developed countries, it is commonly being addressed through a combination of building regulation (e.g., minimum energy efficiency standards for new dwellings) and initiatives aimed at the refurbishment/upgrading of the much larger pool of existing housing stock. The scope and cost-effectiveness of energy efficiency gains is generally greatest for new dwellings, where efficiency measures can be incorporated at the design stage. However, in nearly all settings, new dwellings account for a tiny fraction of the overall housing stock, so that in the short term, the larger potential for changing collective energy efficiency arises in relation to the upgrading and retrofitting of existing dwellings. For such dwellings, the types of upgrades may be limited (older housing stock may not have cavity walls, for example), the basic building fabric may be inherently inefficient from a thermal perspective, and the health benefits and financial returns are correspondingly lower.

The cost and benefits of specific building standards and efficiency upgrades depend on numerous factors, including, crucially, fuel type and price. It is also a function of occupancy levels and occupant behaviors. To date, few systematic attempts have been made to assess the associated costs and benefits to health, though such assessments are now beginning based on risk assessments of a range of housing-related hazards. Energy efficiency upgrades have a number of (mainly unquantified) adverse health costs as well as benefits.

4.9.4 Potential Adverse Health Effects

The main concerns about adverse health effects arise from reduced air exchange, which may increase indoor pollutants. In the most air-tight dwellings, these problems can be alleviated by mechanical ventilation and heat recovery (MVHR) systems, which allow greater ventilation while maintaining energy efficiency by recovering heat from the vented air. However, because MVHR systems require high levels of air tightness for effective operation, it is critical that they are correctly installed and maintained. In dwellings reliant on passive ventilation, pollutants derived from indoor or 'under-house' sources tend to rise as air exchange is reduced.

4.9.4.1 Radon

Radon has received surprisingly little attention despite strong theoretical arguments about its detrimental health effects if ventilation rates are lowered. Radon is a naturally occurring, colorless, odorless radioactive inert gas, with a half-life of 3.8 days, formed from the decay of radium. It is a significant contaminant of indoor air worldwide. Radon results from radioactive decay in rock formations beneath buildings or in certain building materials themselves. As a very heavy gas, it tends to accumulate at floor level.

Exposure to radon increases the risk of lung cancer (NRC, 1999; Darby et al., 2005). A common action level for remediation is 200 becquerels per m^3, a level that corresponds to a 3% lifetime excess risk of lung cancer. In many countries, it is the second most important cause of lung cancer deaths after cigarette smoking, accounting for around 10% of all lung cancer cases in the United Kingdom, for example.

Reduction in air exchange because of energy efficiency may give rise to an appreciable shift in the distribution of indoor concentrations, and hence alter risks of lung cancer. A variety of cost-effective engineering solutions are available to deal with high radon levels. The concern is that dwellings with elevated levels of radon may go unrecognized, or the energy efficiency interventions give rise to a more subtle shift in the population average exposure.

4.9.4.2 Dampness/Mold and House Dust Mite

Dampness and mold are primarily determined by indoor (relative) humidity. With energy efficiency, there is a tradeoff between higher temperatures (which tend to lower humidity, especially in winter months, and thus to decrease mold risk) and lower ventilation, which tends to increase humidity (Oreszczyn et al., 2006).

Although there is insufficient evidence, as yet, of a causal link between the presence of visible mold and the many putative health effects, several epidemiological studies show associations between visible mold (≥ 1 m^2) and respiratory and other symptoms, including asthma, rhinitis, cough, wheeze, nausea, vomiting, and general ill health (Bornehag et al., 2004; Davies et al., 2004). The most vulnerable groups are young children, the elderly, allergy sufferers, and immuno-compromised individuals.

It is difficult to generalize about the patterns of ventilation and mold, which depend on climatic factors, quality of housing stock, and multiple other factors, but mold is a common problem in most settings. At reasonably high levels of air exchange (> one per hour), temperature improvements associated with energy efficiency may tend to lower mold risks. However, concerns arise towards the low end of air exchange in developed countries, i.e., less than 0.5 per hour.

4.9.4.3 Other Indoor Pollutants

Lower ventilation rates may also be important for a range of other pollutants arising from indoor sources (COMEAP, 2004).

- *Volatile Organic Compounds (VOCs)* include over 200 component chemicals typically existing in indoor air, including formaldehyde, benzene, and benzo(a)pyrene (BaP). Potential health effects are complicated: biological effects vary according to the specific chemical components present in the mixture, as well as with environmental factors such as temperature and humidity. Indoor sources are varied and include foam insulation (urea formaldehyde foam insulation), particle board used for construction, furniture, furnishings, and household cleaning agents. Indoor levels in developed countries are generally approximately 10-fold higher than ambient levels. Increased concentrations tend to be associated with newer and/or recently decorated houses. Health effects are poorly characterized but principally relate to allergic responses (Mendell, 2007), comfort and well-being, and some (theoretical) genotoxic/carcinogenic risk.

- *Products associated with combustion, especially nitrogen dioxide (NO_2) and particles* are a significant component of indoor air pollution. The major source of indoor NO_2 is from cooking with gas. On average, concentrations encountered indoors are not high enough to produce serious acute effects but are thought to be sufficient to cause a reduction in lung function and an increase in response to allergens that can cause narrowing of the airways in some sensitive individuals. Other possible health effects of indoor NO_2 include: increased likelihood of respiratory infection, symptoms, or illness in children living in homes using gas for cooking and heating; reduction in lung function in women living in homes using gas for cooking and heating (de Bilderling et al., 2005); impaired respiratory health associated with long-term exposure to NO_2; and a possible effect of NO_2 on the response to allergens in specifically sensitized individuals. Recent work by Chauhan et al. (2003) has shown that exposure to nitrogen dioxide increases the likelihood of viral infections in children and increases the bronchoconstrictor response seen in asthmatic subjects so infected (COMEAP, 2004). This is an important finding, as it is known that such infections play an important role in triggering attacks of wheezing in young children.

- *Carbon monoxide* is an under-recognized risk associated with poorly ventilated or maintained boilers and burners. In relation to energy efficiency, the main impact is more likely to be *reduced* likelihood of exposure (from more modern and efficient combustion devices installed as part of energy efficiency upgrades) than higher levels of exposure from reduced air exchange.

- *Tobacco smoke* poses a significant risk in households where one or more family members are smokers. In dwellings with lower air exchange rates, the known adverse effects of environmental tobacco smoke may be greater for children or other family members.[17]

4.9.4.4 Heat Risks

Greater energy efficiency has the potential to improve protection against heat-related risks by buffering against peak temperatures and smoothing out the diurnal fluctuations in indoor temperatures during heat waves. However, energy efficiency may be detrimental where solar gain is high (e.g., dwellings with large areas of glass facing the sun), as the high level of insulation in the building fabric may then act to maintain and accentuate high indoor temperatures. This may be a particular problem with high energy efficiency, low thermal mass dwellings. Traditional

17 Risks from secondhand tobacco smoke exposures are quantified in the latest CRA. For further information, see Footnote 1.

Table 4.11 | Effects of cold temperature on cardiovascular mortality, and modification by standardized indoor temperature.

Quintile of standardized indoor temperature. Range (mean) in degrees celsius	No. of deaths	% increment (95% CI) in mortality per degree celsius fall in outdoor temperature	
		Unadjusted	Adjusted for region
CARDIO-VASCULAR			
1 <14.8 (13.3)	2648	1.7 (0.5, 2.9)	2.2 (0.6, 3.9)

dwellings in hotter climates typically have high thermal mass, small solar gain (small outward facing windows and doors, inner courtyards), and orientations to promote natural ventilation at night. Although there is reasonable understanding of how dwellings can be adapted to heat, countries that currently do not have hot climates may be optimized for cold rather than the hotter summer conditions that may prevail under climate change.

4.9.5 Health Benefits

Despite the list of potential adverse consequences, improvements in energy efficiency are likely to lead to net benefits through various routes, at least in communities where there are appreciable cold-related impacts and high energy costs.

4.9.5.1 Reduced Cold-Related Morbidity and Mortality

Burdens of cold-related mortality and morbidity are substantial in most temperate climates and are measurable in almost all populations studied to date (see, for example, McMichael et al., 2008). Much uncertainty remains about the degree to which housing quality affects this vulnerability, but evidence from the United Kingdom, which has a comparatively large burden of winter excess death, provides the most relevant quantification (Wilkinson et al., 2001), broadly consistent with other published work (The Eurowinter Group, 1997; WHO, 2007). It shows that the magnitude of cold- and winter-related excess death is greater in people living in dwellings that have low winter indoor temperatures. Specifically, there is evidence to quantify the risk of cold-related mortality in relation to adequacy of home heating, as reflected by the standardized indoor temperature – the indoor temperature measured when the outdoor temperature is 5ºC (Table 4.11). There is less evidence regarding the relationship between housing characteristics and health impacts other than mortality.

4.9.5.2 Psychosocial and Mental Health Benefits of Warmer Indoor Environments

A growing body of evidence indicates that improved household energy efficiency is accompanied by important changes in the use of space, social interaction, and related psychosocial well-being (Gilbertson et al., 2006). What is less clear is the contribution of different effects: sense of control, reduced costs of home heating (for low-income families), or effects that are a direct function of warmer indoor environments.

4.9.5.3 Indirect Effects on Environmental Pollution and Climate Active Pollutant Emissions

Although household energy efficiency is likely to have its greatest impact on health through direct effects on householders, the impact on wider environmental emissions of toxic pollutants and CAPs is also important. However, the evidence is mixed whether energy efficiency gains translate into lower emissions of CAPs. To date, the evidence suggests that much of the benefit of energy efficiency is taken as higher indoor temperatures in winter rather than as energy savings.

4.9.6 Conclusion

The goal of reducing CAP emissions should assume should central importance in the energy policies of many national and local administrations. A range of policy instruments and interventions are could be used to try to limit energy use and drive energy efficiency, as well as to support a modal shift towards renewable energy sources. However, most energy efficiency improvements require appreciable capital investment, and renewable energy sources currently remain more expensive than conventional (fossil) fuels. Carbon taxes or tariffs to support market shifts therefore generally act to increase fuel prices. This may be damaging to poor groups in higher-income countries already unable to pay for their fuel or to those in developing

countries if households are driven down the "energy ladder" to polluting biomass fuels by higher fuel prices. To avoid the adverse health consequences of such policies, it is necessary to provide direct support to low income groups through price subsidies ("winter fuel payments" and the like), though this in part negates the rationale for the carbon tax, or to combine carbon taxation with targeted infrastructure investment to improve energy efficiency for disadvantaged groups.

From a health perspective, however, it is not always clear that such investments represent the most cost-effective gains in public health, as when they are set, for example, against other potential forms of health care expenditure. A consequence of the imperative of tackling the challenges of climate change is that substantial resources will need to be transferred from richer to poorer populations to assist them in attaining and using efficient, low-carbon technology.

4.10 Co-benefits for Climate Change Mitigation and Health Promotion

4.10.1 Key Messages

- For long-term climate protection, CO_2 emissions need to be reduced through energy efficiency and shifts away from fossil fuels, both of which may reduce health-damaging pollutants even if no special emission controls are used.
- Reducing most CAPs, which have substantial direct and indirect health impacts, will lead to substantial health and climate protection over the next decades.
- Other important co-benefits opportunities for health and climate include providing access to reproductive services for women, working to lower meat consumption, and actions to redesign cities and transport systems to reduce physical inactivity.
- Reduction of the CAPs, nitrogen and sulfur emissions, although important for health and ecosystem protection, unfortunately slightly aggravates global warming by reducing the cooling effects of the light-colored particles that are created from current emissions.

There are a number of potential co-benefits opportunities, which ameliorate both health and climate, in the wake of changes in the world's energy system to reduce CAPs.[18] For example, reducing fossil fuel combustion in power production will improve air quality (Markandya et al., 2009), preventing respiratory and cardiovascular disease; and an increase in use of mass transit, cycling, and walking will increase physical activity, reduce obesity, and stimulate social contacts (Woodcock et al., 2009). In high-income countries, where average daily intake of red meat typically exceeds nutritional needs, a reduction in meat production and consumption – especially from ruminant animals, including cattle, sheep, and goats – would confer several health and environmental gains, partly through reduction in energy use from processing, storage, and transport (Friel et al., 2009). Another major set of co-benefits can accrue by promoting reproductive rights for women around the world. Studies show that giving women control over their fertility will lower both maternal and child mortality, which are both important parts of the unfinished health agenda worldwide, as targeted in the MDGs (Smith and Balakrishnan, 2009). Helping countries reach replacement fertility earlier than would otherwise occur will, in turn, reduce energy use and climate impacts (O'Neill et al., 2010). Finally, nearly any improvement in energy efficiency or shift to different sources that reduces carbonaceous fuel combustion will generally have commensurate health advantages, although care must be exercised that other risks are not substituted, for example, from increased indoor air pollution when building insulation is enhanced (Wilkinson et al., 2009).

Although there are a number of examples of important co-benefits to be gained within these classes of interventions, designing acceptable policies to take advantage of them will require consideration of other factors, among which cost is probably most important. It is not straightforward, however, to convert either health or climate protection benefits into economic terms, let alone in a consistent way across both classes of benefits, in order to determine which projects should be undertaken first. There is no space in GEA to provide such analyses across the large range of alternative projects, countries, and impacts, but we have provided some entry into the literature in Boxes 4.2 and 4.6.

Not all CAPs are created equal from either a climate or a health standpoint. Some are substantially more damaging than others and, in the case of climate impacts, some actually have beneficial (cooling) characteristics, although all are damaging to health. This creates a complex landscape for planning interventions that have benefits for both health and climate.

To inform this strategy, in Box 4.2 we provide a brief primer of the climate and health characteristics of the major shorter-lived CAPs emitted from the energy sector, all of which have implications for health.[19] Figure 4.15 summarizes what is understood about them at present (Smith et al., 2009). Figure 4.7, which is taken directly from the IPCC Fourth Assessment (Forster and Ramaswamy, 2007), shows the estimated contributions from these agents of global warming in the year 2005 due to all human emissions since 1750. The CAPs are compared by radiative forcing (RF), which is the metric used for the comparisons of the strength of different human and natural agents in causing climate change (Smith et al., 2009).

18 See the special series on co-benefits in the *Lancet* published November 2009, in particular the summary policy paper (Haines et al., 2009).

19 Not discussed are CAPs such as N_2O, H_2, and NH_3, for which fuel combustion is a minor contributor.

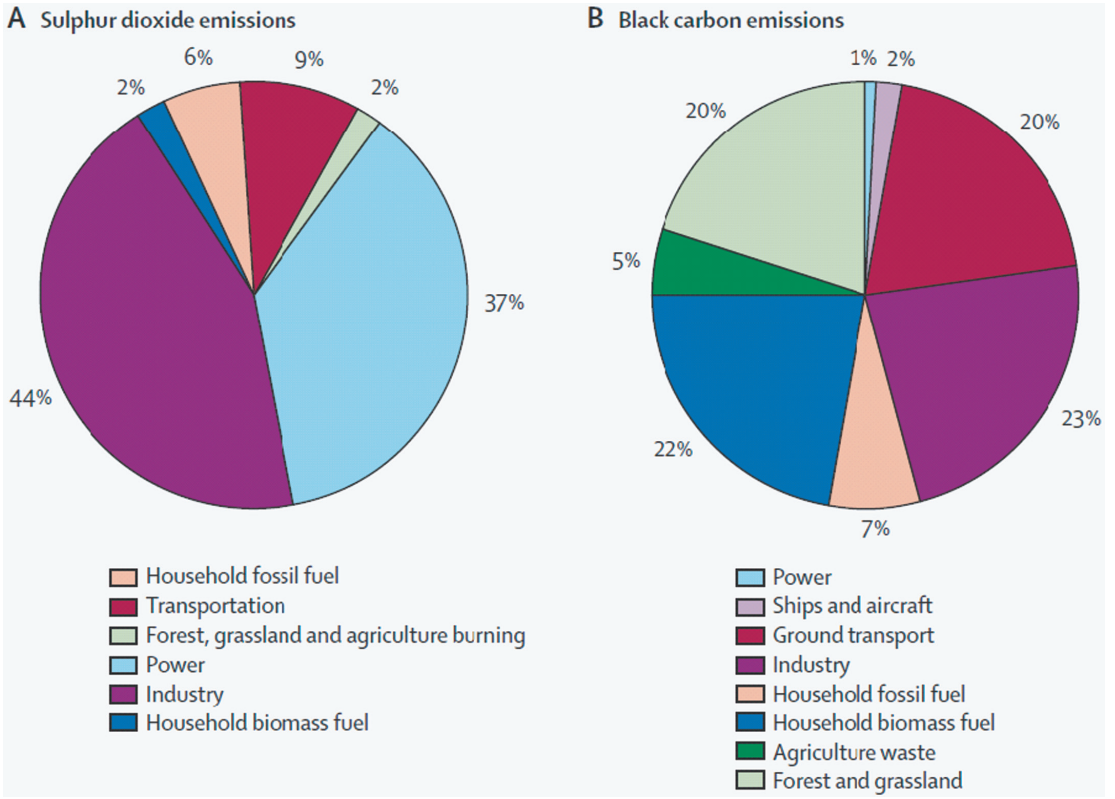

Figure 4.15 | Sulfur dioxide and black carbon emission sources. Source: Smith et al., 2009.

Box 4.6 | Economic evaluations of co-benefits

There is a growing literature attempting to quantify the economic implications of CAP reductions for health and climate protection. Progress has been made in establishing scoping methods (Smith and Haigler, 2008). There are also important and often not well understood atmospheric interactions that require detailed local information and modeling for estimating co-benefits. Nevertheless, studies of growing sophistication, using local data, have been done in Asia and elsewhere to pin down the potentials.[20]

As an illustration of one approach, Figure 4.16 below from Smith and Haigler (2008) compares the cost-effectiveness of a range of interventions in terms of both climate and health protection. For metrics, it uses international US dollars per tonne CO_2-equivalent, which applies a global warming potential to tonnes of methane and nitrous oxides reduced to be able to add them to the tonnes of CO_2 reduced. For health, it uses the approach recommended by the World Health Organization (WHO) for cost-effectiveness, i.e., international US dollars per saved DALY (Murray et al., 2000). WHO recommends that any intervention costing less than three times the local GDP per capita be considered seriously for implementation (WHO, 2003). The price of CO_2-equivalents in early 2012 on the international market was about US$ 9 per tonne CO_2-eq (Carbon Positive, 2012). The projects shown in the figure are only illustrative examples from the literature and are not meant to be best or worst options. Rather, the Figure illustrates one approach for such analysis (see article for details).

20 A good example is the set of studies done in cities around the world as part of the Integrated Environmental Strategies Project of the USA EPA (en.openei.org/wiki/EPA-Integrated_Environmental_Strategies). Many other references are found in Smith and Haigler (2008).

In general, household fuel interventions in poor countries have the highest returns because of the inefficiency by which traditional fuels are currently used, leading to high health-damaging CAP emissions, and the high intake fractions, leading to large health effects.

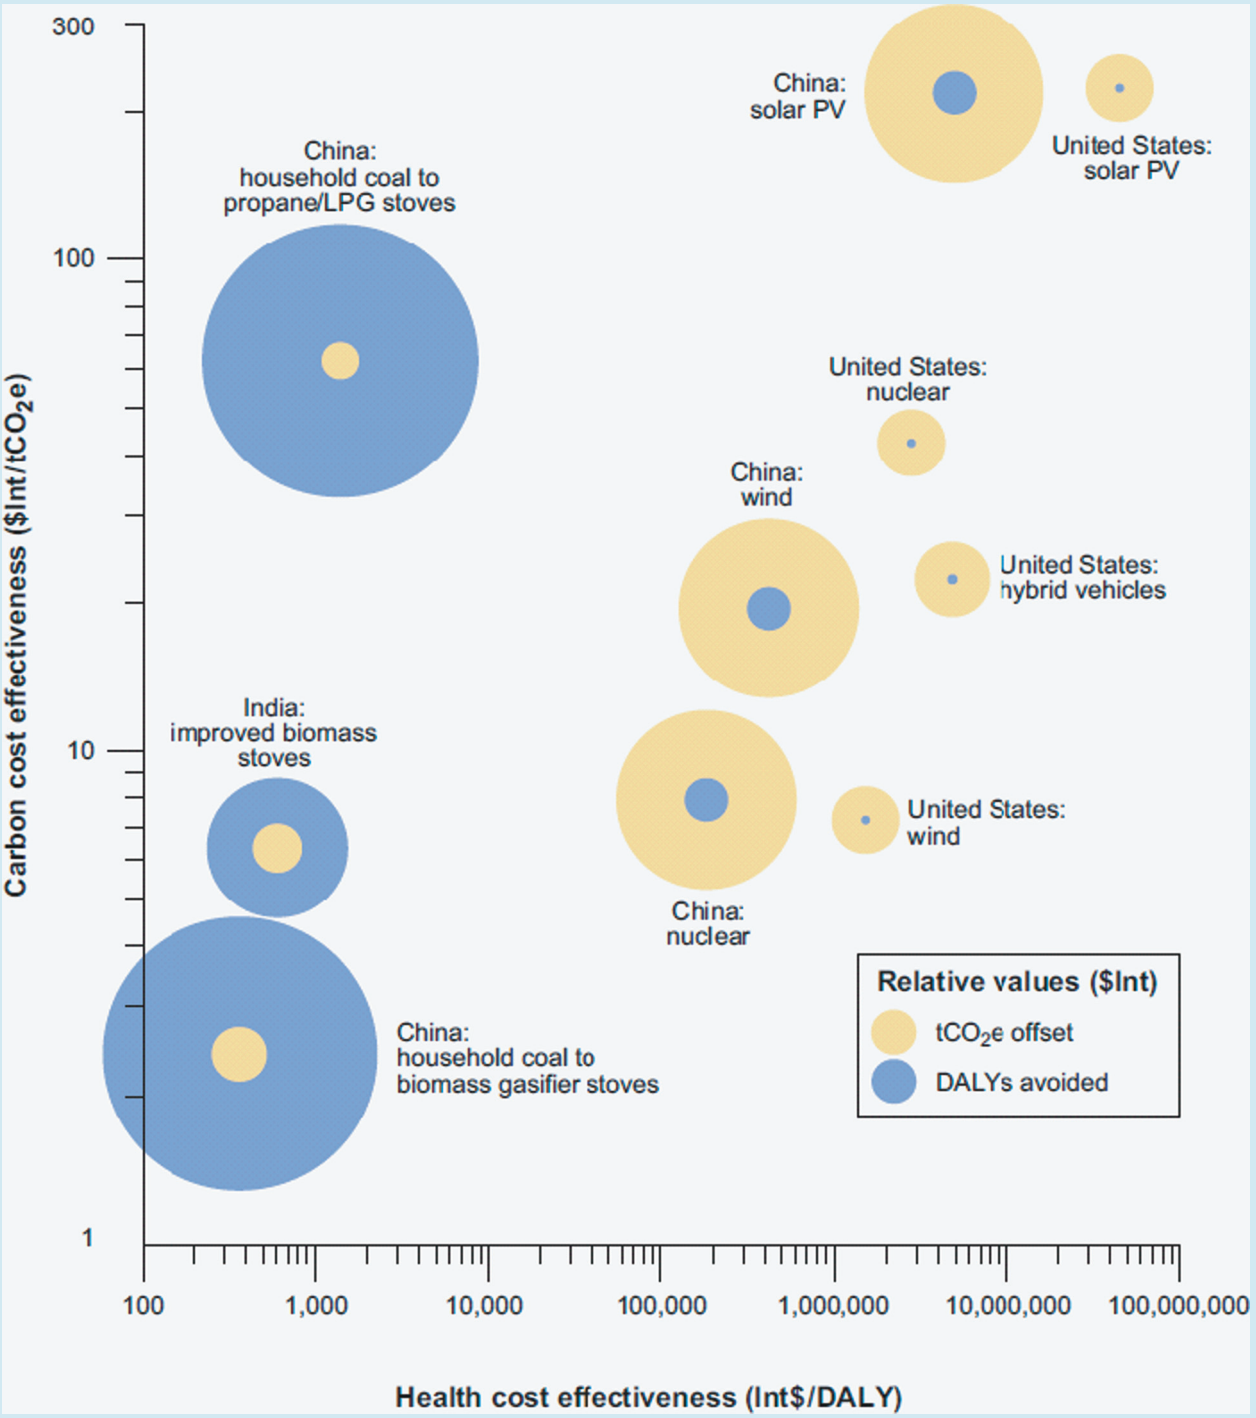

Figure 4.16 | Illustrative examples of co-benefits analysis: comparison of the health and climate cost-effectiveness of household, transport, and power sector interventions. Source: Smith and Haigler, 2008.

Aerosols influence RF directly through the reflection and absorption of solar and infrared radiation (Smith et al., 2009). Some aerosols, such as BC, cause a positive RF (i.e., climate warming) whereas others, such as sulfates, cause a negative RF (i.e., climate cooling) (see Figure 4.7). The direct RF summed over all aerosol types is thought to be negative. Aerosols also indirectly cause a negative RF through the changes they cause in cloud properties, which are not shown in Figure 4.7. It has not been possible to explain the observed global temperature records

for the 20th century with global climate models without a substantial post-World War II cooling term from the burning of sulfur-containing fossil fuels to partially offset the global warming from the CAPs. As nitrogen and sulfur oxides are reduced globally due to health and acid-precipitation concerns, their cooling effect will also be reduced, thus unmasking the climate warming due to other CAPs that they are currently counteracting.

In addition, as it is not possible to control BC emissions without simultaneously controlling the associated OC particle emissions from the same combustion sources, the global climate benefits of carbon-particle control measures, including improved combustion efficiency, depend on the ratio of BC to OC of each source. More recent observations and modeling (Ramanathan and Carmichael, 2008), however, indicate that the estimated warming of BC may be higher than those in the most recent IPCC estimates indicated in Figure 4.7. This would have policy implications because a much broader range of combustion sources would consequently have net climate benefits from combined control of BC and OC (Smith et al., 2009).

It is important to distinguish between direct and indirect RF. Direct RF results when the emitted substance is a greenhouse pollutant itself, such as CO_2. Indirect RF results when the emitted pollutant is not a greenhouse pollutant but takes part in chemical reactions to form a greenhouse pollutant or to change the global distribution of another greenhouse pollutant. SO_2, for example, is transformed in the atmosphere to form aerosol sulfates that act to produce a negative RF. NO_x emissions act to increase the oxidizing capacity of the troposphere, reducing methane (negative RF), but adding to tropospheric ozone (positive RF), while methane, carbon monoxide (CO), and non-methane volatile organic carbons (NMVOCs) contribute to O_3. Athough not emitted directly, nevertheless tropospheric ozone is the third most important human-influenced CAP in the atmosphere, as shown in Figure 4.7 (IPCC, 2007a).

As methane and carbon dioxide are well mixed globally, it is possible to treat emissions in all places and seasons as essentially equal, which led to the deployment of so-called "global warming potentials" by the IPCC, used to gauge the relative importance of emissions of different GHGs in treaties, inventories, and international carbon-offset programs. The complexity, short life, and local dependence of the short-lived CAPs, however, makes it difficult if not impossible to establish official "global" warming potentials for policy making. At present, therefore, they are not included in most international climate policy deliberations, although they are subject to much research and media attention and featured prominently in scientific assessments (Smith et al., 2009).

This gap is increasingly important as the world seeks to reduce global warming risks in ways that are both cost-effective and compatible with other goals, such as protection from outdoor air pollutants. In addition, control of the CAPs will not only have immediate health benefits, but much quicker climate benefits than control of CO_2. Not having a way to systematically look at co-benefits across the CAPs hampers these efforts. In addition, although the aerosols seem to have a net cooling effect, they can still impose regional climate impacts in South and East Asia, for example, and thus should not be considered benign (or beneficial) for the climate in addition to their important health consequences. Some have suggested, therefore, that regional climate disruption potentials might someday be applied to weight the relative importance of emission reductions for these CAPs.

4.11 Conclusions

4.11.1 Key Messages

- Most health impacts of today's energy systems come from the extraction and combustion of solid fuels. Some impacts are among workers collecting and processing coal and biomass. About 40% of the people in the world are exposed to household air pollution from the poor combustion of solid fuels used for heating, cooking, and lighting. This air pollution also contributes substantially to outdoor air pollution.

- Health impacts from most new and renewable energy sources are likely to be much smaller, but vigilance is needed to be sure these energy sources are managed carefully.

- Nuclear power poses low routine health risks to workers and the public if properly regulated. See Chapter 14 for a discussion of accident and proliferation risks.

- For long-term climate protection, CO_2 emissions need to be reduced through energy efficiency measures and a general shift away from fossil fuels. Shifting away from fossil fuel combustion may also proportionally reduce associated health-damaging pollutants, even if no special pollutant emission controls are used.

- Although energy efficiency measures are generally desirable, there are potential health impacts if done poorly, for example as a result of reduced home air exchange.

- Human-engendered climate change, which is largely but not entirely caused by energy use, seems already to be imposing health impacts, particularly among poor populations. Health impacts from climate change can be expected to steadily grow in the next decades unless major mitigation and adaptation efforts are undertaken.

- There are large health benefits from reducing carbon-containing aerosols, but the climate benefits are blunted somewhat because both BC aerosols (which are primarily warming) and OC aerosols (which are primarily cooling) usually decline together.

- There are climate, as well as health, benefits from reducing BC emissions, however, that may land on snow or ice, even if OC emissions are reduced as well.

- Per unit useful energy, the health benefits of emission reduction interventions rise as the combustion is closer to the population, i.e., as the intake fraction rises.

- Per unit useful energy, the health and climate benefits of emission reduction interventions rise with the fraction of incomplete combustion.

- Given the previous two conclusions and the widespread use of solid fuels in households, the largest co-benefit opportunities for health and climate lie in substituting away from solid fuels or increasing the solid fuel combustion efficiency in households. This is illustrated in Box 4.6.

- To capture the potential co-benefits for health and climate of changes in energy systems, society needs to make sure actions do not just shift the hazards from one population to another, e.g., shift the health burden from coal burning to a potentially even higher burden from nuclear proliferation.

- Using a life-cycle approach to evaluate energy sources, especially new and renewable fuels, is important to fully understand the health and climate costs and benefits across production, storage, transport, and end-use processes.

- The rush to find and implement ways to mitigate CAP emissions should not result in significant relaxation of the environmental and safety controls on new or existing energy systems, including those affecting outdoor air pollution, which were developed over the years to protect health.

- ILO and WHO guidelines for the protection of worker and public health should be adopted into law and enforcement practices worldwide.

- Control of primary and secondary aerosols may, in some cases, yield negative effects for either health or climate goals. For this reason, there is a need for multidisciplinary approaches to assessing and establishing aerosol policy goals, such that health and climate co-benefits can be maximized.

Energy systems play important roles in the burden of disease globally. GEA's estimates are that household air pollution from solid fuels was responsible for 2.2 million premature deaths in 2005 and outdoor air pollution was responsible for about 2.7 million premature deaths in the same year. Part of the latter can also be attributed to poor household

Table 4.12 | Rough contribution of energy systems to the global burden of disease, 2000.

Direct Effects [except where noted, 100% assigned to energy]	Total Premature Deaths – million	Percent of all Deaths	Percent of Global Burden in DALYs	Trend
Household solid fuel	1.6	2.9	2.6	Stable
Energy Systems	0.2	0.4	0.5	Uncertain
Occupational*				
Outdoor Air	0.8	1.4	0.8	Stable
Pollution				
Climate Change	0.15	0.3	0.4	Rising
Subtotal	2.8	5.0	4.3	
Indirect Effects				
(100% of each)				
Lead in vehicle fuel	0.19	0.3	0.7	Falling
Road traffic	0.8	1.4	1.4	Rising
Accidents				
Physical inactivity	1.9	3.4	1.3	Rising
Subtotal	2.9	5.1	3.4	
Total	5.7	10.1	7.7	

* One-third of global total assigned to energy systems

Notes: These are not 100% of the totals for each, but represent the difference between what exists now and what might be achieved with feasible policy measures. Thus, for example, they do not assume the infeasible reduction to zero traffic accidents or air pollution levels.

Source: Ezzati 2004.

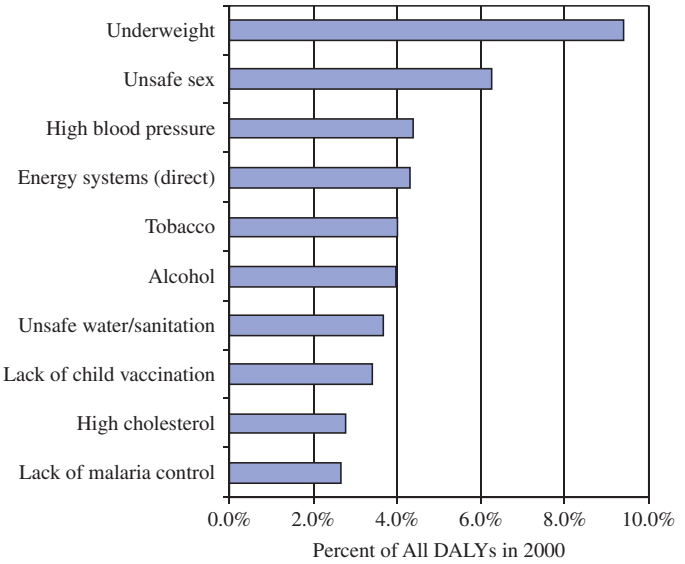

Figure 4.17 | Comparison of global burden of disease from major risk factors, including direct impacts of energy systems around the year 2000. Source: Table 4.12 and WHO Global Burden of Disease database (WHO, 2008).

Note: All expressed as a percentage of the total global burden in lost healthy life years (DALYs).

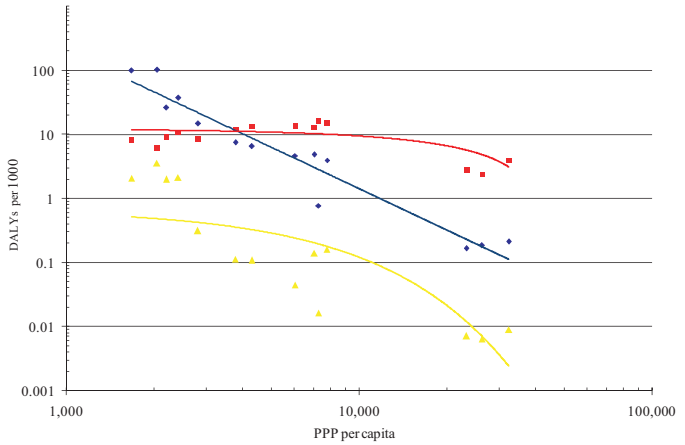

Figure 4.18 | Environmental risk transition: experienced burden of disease from environmental risk factors around 2000. Source: data based on Smith & Ezzati, 2005.

Notes: Household environmental risks (in blue), including pollution from solid fuel use, tend to decline with economic development, while community air pollution and traffic risks from energy use (red) first rise and then fall. Experienced risks from climate change (yellow) also tend to decline with development status. Vertical axis is in lost healthy life years (DALYs) per capita in each of 14 WHO epidemiological world sub-regions distributed by average income per capita. Note log scale on axes.

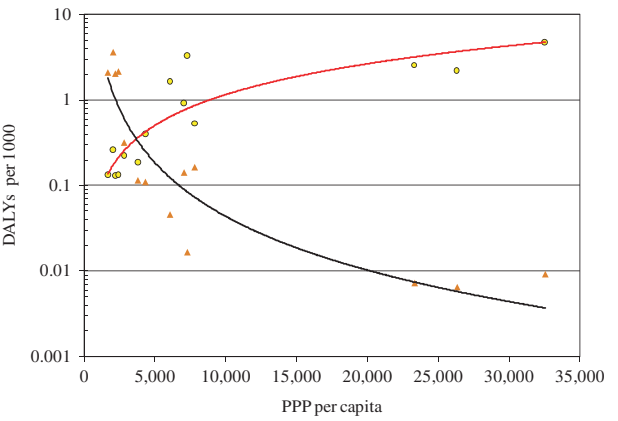

Figure 4.19 | Distribution of health impacts from climate change, experienced versus imposed, 2000. Source: data based on Smith & Ezzati, 2005.

Notes: Based on cumulative CO_2 emissions. Imposed health impacts from climate change (red line) rise with economic development. This is inverse of the pattern for experienced health impacts (black line), resulting in large inequities between rich and poor regions globally. Vertical axis is in lost healthy life years (DALYs) per capita in each of 14 WHO epidemiological world sub-regions distributed by average income per capita.

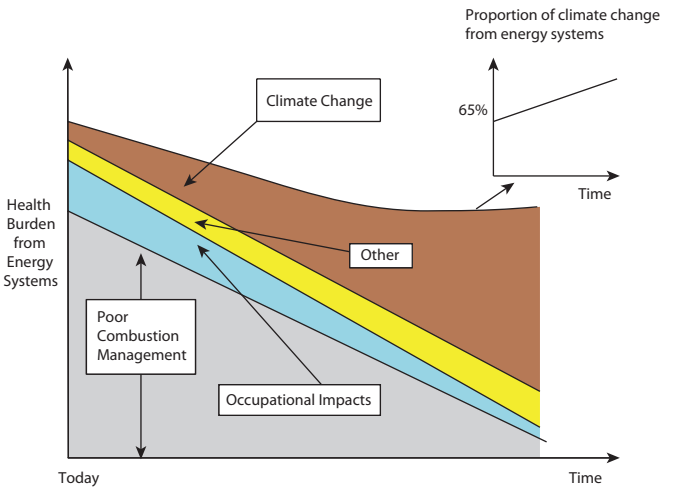

Figure 4.20 | Current trends in health impacts from energy systems.

Note: This represents a pessimistic future projection, in which combustion efficiency improves but effective climate policies do not exist.

fuel combustion. (Details on the calculations used to determine these figures can be found in Chapter 17.) Inclusion of energy's indirect role in lead pollution and occupational risks would probably add another 10–20% to that figure. Although outside the system boundaries of energy supply systems used in GEA, inclusion of road traffic accidents and energy's role in physical inactivity would roughly double these values. Recognizing the uncertainties of such calculations, the direct effects alone put energy systems above the global health impact of all other risk factors except malnutrition and unsafe sex and roughly equal to the global impacts of tobacco, alcohol, and high blood pressure based on WHO estimates for 2000 (see Table 4.12 and Figure 4.17). As noted in this chapter, the vast part of the direct impact comes from the poor management of fuel combustion.

Note these are not 100% of the totals for each, but represent the difference between what exists now and what might be achieved with

feasible policy measures. Thus, for example, they do not assume the infeasible reduction to no traffic accidents or zero pollution levels.

Figure 4.18 shows how these energy system risks vary across the world by income level, illustrating what has been called the "Environmental Risk Transition" (Smith and Ezzati, 2005). Household-level risks tend to fall with economic development because they are so heavily influenced by household solid fuel use. Community (urban) risks, here including occupational impacts, form a more complex pattern by rising first during economic growth and then falling, roughly following what has been called the Environmental Kuznets Curve. Note, however, that there is much variation across the world in this pattern due to earlier or later introduction of policy measures. Experienced global risks due to climate change fall heavily on those living in poverty and thus also decline with development.

Figure 4.19 shows, however, that if global risks are distributed not by who experiences them but rather by who imposes them, the pattern is inverted. Poor countries receive much more impact than they have imposed in terms of their cumulative CO_2 emissions and rich countries impose much more than they experience. This has been called the "largest regressive tax in history."

Most of the health impacts of energy systems today are due to poor management of the combustion of fuels through emissions of incomplete combustion products and contaminants such as sulfur and nitrogen oxides. Second in importance are occupational impacts, particularly in the harvesting and processing of solid fuels. As world energy planning reorients toward reducing greenhouse emissions, there is need to take close account of the potential for doing so in ways that also continue to move society toward other important goals, such as those codified in the MDGs. Energy systems in general, not only have close links to CAP emissions, but in some cases to MDGs as well. In particular, household fuels are the system in which the two are most closely linked, with consequent opportunity to move both climate mitigation and health protection forward together. This is why providing access to clean household fuels and technologies is one of the major goals of the GEA scenarios in Chapter 17.

The health impact of climate change from energy use is relatively minor at present, partly because only about two-thirds of human-caused warming comes from energy systems (see Figure 4.20). The Figure assumes that the goals for the health indicators in the scenarios (Chapter 17) are met, which will mean very much lower health impacts from these two sources within a few decades. The impacts of climate change, however, are more refractory, partly because considerable climate change has already been committed and also because there is no sign at present that world society has found a way to grapple with greenhouse emissions effectively. In addition, as shown in the figure, the fraction of climate change due to energy systems will slowly rise under current trends. Shown in Figure 4.20, therefore, is a pessimistic outcome in which total health impacts from energy systems fall for some period as air pollution and occupational impacts come under control, but then start to rise as the health impacts from climate change begin in earnest. This outcome also depends, however, on the progress of society in dealing with the vulnerability of poor populations, since climate change operates mainly to enhance existing patterns of ill health. Thus, other scenarios than the one shown here are not only desirable but possible, albeit at considerable effort across several sectors.

Executive Summary

Uninterrupted provision of vital energy services (see Chapter 1, Section 1.2.2) – energy security – is a high priority of every nation. Energy security concerns are a key driving force of energy policy. These concerns relate to the robustness (sufficiency of resources, reliability of infrastructure, and stable and affordable prices); sovereignty (protection from potential threats from external agents); and resilience (the ability to withstand diverse disruptions) of energy systems. Our analysis of energy security issues in over 130 countries shows that the absolute majority of them are vulnerable from at least one of these three perspectives. For most industrial countries, energy insecurity means import dependency and aging infrastructure, while many emerging economies have additional vulnerabilities such as insufficient capacity, high energy intensity, and rapid demand growth. In many low-income countries, multiple vulnerabilities overlap, making them especially insecure.

Oil and its products lack easily available substitutes in the transport sector, where they provide at least 90% of energy in almost all countries. Furthermore, the global demand for transport fuels is steadily rising, especially rapidly in Asian emerging economies. Disruptions of oil supplies may thus result in catastrophic effects on such vital functions of modern states as food production, medical care, and internal security. At the same time, the global production capacity of conventional oil is widely perceived as limited. These factors result in rising and volatile prices of oil affecting all economies, especially low-income countries, almost all of which import over 80% of their oil supplies. The costs of energy (primarily oil) imports exceed 20% of the export earnings in 35 countries with 2.5 billion people and exceed 10% of gross domestic product (GDP) in an additional 15 countries with 200 million people.

The remaining conventional oil resources are increasingly geographically concentrated in just a few countries and regions. This means that most countries must import an ever-higher share or even all of their oil. More than three billion people live in 83 countries that import more than 75% of the oil products they consume. This does not include China, where oil import dependency is projected to increase from the current 53% to 84% in 2035. The increasing concentration of conventional oil production and the rapidly shifting global demand patterns make some analysts and politicians fear a "scramble for energy" or even "resource wars."

Import dependency is also common in countries that rely on natural gas to provide heat and generate electricity. Almost 650 million people live in 32 Eurasian countries that import over 75% of their gas. Many of these countries are landlocked and import gas through a limited number of pipelines. The interregional trade in natural gas is projected to significantly increase, with yet more uncertain consequences for energy security. Developments in unconventional gas extraction and liquefied natural gas (LNG) technologies may have a defining influence in this regard.

Vulnerabilities of electricity systems are not limited to power plants relying on imported fossil fuels (which currently provide over 50% of electricity in some 39 countries with 600 million people). Hydroelectric power production, especially from major dams located on internationally shared rivers, is often perceived as insecure, particularly in light of climate change affecting seasonal water availability. Over 700 million people live in 31 countries that derive a significant proportion of their electricity from just one or two major dams and thus are vulnerable to failures of these dams.

Many countries using nuclear power are experiencing an aging of the reactor fleet and workforce, as well as difficulties in accessing capital and technologies to renew, expand, or launch new nuclear programs. Twenty of the 31 countries with nuclear power programs have not started building a new reactor in the last 20 years, and in 19 countries the average age of nuclear power plants is over 25 years. Large-scale enrichment, reactor manufacturing, and reprocessing technologies and capacities are currently concentrated in just a few countries. Transfer of these technologies and capacities to a larger number of countries is constrained by serious concerns over nuclear weapons proliferation, which is one of the main controversies and risks associated with nuclear energy. If nuclear energy can address energy security challenges, it will only happen in a few larger and more prosperous economies.

Various vulnerabilities in electricity supply are often made worse by demand-side pressures. Some 4.2 billion people live in 53 countries that will need to expand the capacity of their electricity systems massively in the near future because they have either less than 60% access to electricity or an average demand growth of over 6% over the last decade. Both fuels and infrastructure for such an expansion will need to be provided without further compromising the sovereignty or resilience of national electricity systems. The reliability of electricity supply is a serious concern, especially in developing countries. In almost three-quarters of low-income countries blackouts are on average for more than 24 hours per month, and in about one-sixth of low-income countries blackouts average over 144 hours (six days) a month. In over one-half of low-income countries blackouts occur at least 10 times a month.

The energy sector also provides vital export revenues for some 15–20 countries. In the majority of these oil- and gas-exporting countries the revenues are not expected to last for more than one generation, and in several cases they may cease in less than a decade. In addition, poor energy-exporting nations are at a high risk of the "resource curse": economic and political instability eventually affecting human development and security.

Almost all countries associate enhanced energy security with higher diversity of energy sources (especially in the transport sector), lower energy intensity of national economies, and reduced import dependency by relying on domestic energy sources. International regimes fostering cooperation between exporters and importers of energy and interacting with global governance arrangements for climate change and energy access are important for achieving these energy security goals. Energy security under sustainable energy transitions will be determined by the dynamics of phasing out fossil fuels and their substitution by new energy sources, as well as by new technologies in the end-use sector. A quantitative analysis of such developments is conducted in Chapter 17.

Table 5.1 | Summary of energy security issues in the world.

Energy sector and its significance	Energy security concerns and the population affected	
	Shorter term	Longer term
Oil (125 countries, 5.9 billion)*	>75% import dependency (**3 billion**) consumption growth >5%/year (**1.8 billion**)	Reserves/Consumption <15 years (**1.7 billion**)
Gas (78 countries, 2 billion)*	>75% import dependency (**650 million**)	Reserves/Consumption <16 years (**780 million**)
Coal (45 countries, 4.5 billion)*	>80% import dependency (**300 million**)	
Nuclear (21 countries, 1.3 billion)**		Average age of nuclear power plants >25 years (**1.9 billion**) Start of last plant construction >20 years (**1.4 billion**)
Hydro (58 countries, 1.5 billion)***	Low diversity (one or two major dams) (**730 million**)	
Electricity (all countries)	>50% dependency on imported fossil fuels (**600 million**) low diversity (one or two fuel sources) (**450 million**)	annual demand growth >6%/year and/or access rate <60% (**4.2 billion**)
Transport	>50% dependency on imported fuels (**4.9 billion**)	annual consumption growth >8% (**1.7 billion**)
Industry (>25% of GDP in 60 countries; 4.5 billion)	>50% dependency on imported fuels (**800 million**)	
Residential and commercial (all countries)	>50% dependency on imported fuels (**500 million**)	Reliance on traditional biofuels for >80% of the residential sector energy (**700 million**)
Cross-sectoral energy supply (all countries)	>50% overall import dependency (**700 million**) low diversity of PES (one or two dominant sources) (**1 billion**) cost of energy imports >20% of export earning (**2.5 billion**); cost of energy imports >10% of GDP (**200 million**)	energy intensity >50% of world average (**400million**) consumption growth >6% (**1.8 billion**) consumption per capita <30 GJ/year (**3 billion**)

Notes: PES – primary energy sources;

Numbers in brackets indicate the number of people who live in countries with the indicated energy security conditions;

* – more than 10% in total energy supply; ** – more than 10% in electricity generation; *** – more than 20% in electricity generation

5.1 Introduction

Energy systems are closely entangled with national and human security. Concerns over the reliability of vital energy services have shaped public opinions and political agendas, eventually affecting broader security issues ranging from risks of armed conflicts, to viability of national economies, and to integrity and stability of political systems. Policies developed in the quest for energy security have been – and are likely to remain – a key driving force in the transformations of energy systems.

Our analysis of energy security in the world is based on a rich tradition of addressing this topic in political, professional, and academic circles. Historically, the notion of energy security emerged in the first half of the 20th century as a concern over the secure supply of fuels (coal and oil) for naval fleets and armies. Political and military leaders sought to ensure security of fuel supplies through diversifying suppliers, substituting foreign imports with domestic production (e.g., synthetic aviation fuel in Germany), restricting non-essential uses of fuels (e.g., rationing of gasoline in the United States) and, finally, seeking military control over energy resources and infrastructure (military campaigns in Indonesia, Caucasus, and other theaters during World War II) (Yergin, 2006).

In the second half of the 20th century, oil became increasingly important not only for the military but also for sustaining such vital functions of industrialized societies as transport, mechanized agriculture, electricity generation, and the heating of buildings. At the same time, the global oil trade dramatically increased as major economies such as the United States became dependent on imported rather than domestic resources. The oil embargoes in the 1970s brought energy security to the forefront of political attention in industrialized countries. Energy security strategies prompted by these embargoes included establishing emergency stocks and joint response mechanisms in Organisation for Economic Co-operation and Development (OECD) countries, substituting oil by other energy sources (natural gas, nuclear, coal, etc.) in heating and electricity generation, investing in oil reserves outside the Organization of the Petroleum Exporting Countries (OPEC) – for example, in Alaska and the North Sea – and promoting energy efficiency to decrease oil intensities of economies.

By the end of the 20th century, many of these strategies bore fruit so that the fear of global oil supply disruptions subsided. At that time, other concerns at the interface of energy systems and national security emerged. One was the security of electricity transmission and generation systems. Vulnerability of nuclear power plants was exposed by the Three Mile Island, Chernobyl, and Fukushima accidents, with Chernobyl virtually halting the construction of new nuclear reactors in the world for two decades. Large-scale blackouts due to failures of generation and transmission exposed the vulnerability of modern societies to even short-term disruptions of electricity supply. At the same time, with the collapse of the Soviet Union, it became clear that the economies of many oil-exporting nations are not viable without steady energy export revenues. This prompted a shift in attention towards "demand security," another aspect of energy security.

Nowadays, the energy security debate is a mixture of many concerns, as "[i]n the background – but not too far back – is the anxiety over whether there will be sufficient resources to meet the world's energy requirements in the decades ahead" (Yergin, 2006). More immediate concerns include high and volatile oil prices, especially painful for lower-income countries; the predicted "plateau" of conventional oil production apparently falling short of the rising demand (see Chapter 7, Figure 7.4); the increasing geographic concentration of conventional oil and gas resources in just a few countries and regions; the shift of oil demand to India and China; and the fear of tensions and conflicts as new and old consumers "scramble" for the remaining, increasingly concentrated resources. The present energy security concerns also include the recent conflicts over deliveries of Russian natural gas to Eastern Europe, and fears over the excessive dependency of some European countries on a very limited number of energy supply options. In light of the September 2001 terrorist attacks and the disruption brought about by Hurricane Katrina, there are also serious worries over the vulnerability of critical energy infrastructure to terrorist attacks or extreme natural events. Moreover, energy security concerns are now closely entangled with other critical energy issues, most notably energy access and climate impacts of energy systems.

Throughout history, energy security has been viewed as protection from disruptions of essential energy systems. The notion of "essential energy systems" evolved from supplies of oil for military purposes to encompass various energy sources, infrastructure, and end-use sectors. The idea of "protection from disruptions" has also evolved from securing military or political control over energy resources to setting up complex policies and measures of strategically managing risks that affect all elements of energy systems.

Though it is possible to discuss energy security at household, community, and other levels, most political concerns and scholarly research are about energy security of individual countries. This is because nation-states have a historic responsibility for security, national energy systems provide appropriate units of analysis of key risks and vulnerabilities, and the majority of policy interventions to maintain energy security occur at the national level. Consequently, the analysis presented in this chapter primarily concentrates on the national level of energy security.

In line with the existing tradition, our analysis defines a nation's energy security as protection from disruptions of energy systems that can jeopardize nationally vital energy services. Numerous definitions of energy security (Box 5.1) are largely elaborations of this broader concept, particularly on the notions of "protection from disruptions" and "vital energy systems."

Box 5.1 | Defining Energy Security

The analysis of energy security in academic literature recognizes that its meaning varies from one country or one context to another. Thus, universal definitions of energy security are less frequently attempted than contextualized discussions of its various aspects or dimensions. One of the most frequently quoted definitions is the "availability of sufficient supplies at affordable prices" suggested by Yergin (2006). It is preceded by the European Commission's (2000) definition of energy security as the "uninterrupted physical availability on the market of energy products at a price which is affordable for all consumers." Energy insecurity is defined by (Bohi and Toman, 1996) as "the loss of economic welfare that may occur as a result of a change in the price or availability of energy."

These definitions contain notions of "availability," "sufficiency," "affordability," "welfare," "energy products" (or "supplies"), and "interruptions," which are open to wide interpretations. For example, Yergin (2006) discusses the different meaning of energy security – within his given definition – for several different countries. This concept of variability of the notion of energy security is also stressed by Müller-Kraenner (2008), Kruyt et al. (2009), and Chester (2010).

In its analysis of energy security, scholarly literature draws different boundaries for energy systems and subsystems. These boundaries differ between how many and which fuels are considered, as well as how far up- and downstream boundaries are drawn within that system. In terms of fuel-related boundaries, studies range from focusing on a specific fuel (generally oil) (Kendell, 1998; Gupta, 2008; Greene, 2010); looking at all fossil fuels (Le Coq and Paltseva, 2009); analyzing the security of an electricity system (Stirling, 1994) or critical energy infrastructure (Farrell et al., 2004) to evaluating the security of the whole primary energy system (Neff, 1997; Jansen et al., 2004; Jansen and Seebregts, 2010). Within each of these divisions, some studies focus only on the supply side, while others integrate supply and demand aspects and indicators.

With respect to the characteristics of energy systems that are associated with their security, various studies propose and discuss different dimensions of energy security. The simplest discussion uses two dimensions of energy security: the "physical" and "economic" dimensions (Kendell, 1998; Gupta, 2008). Another commonly used taxonomy is the 4 A's, or: "availability" (i.e., physical availability of resources), "accessibility" (geopolitical aspects associated with accessing resources), "affordability" (economic costs of energy), and "acceptability" (social and often environmental stewardship aspects of energy) (Kruyt et al., 2009). Other dimensional classifications include "economic, environmental, social, foreign policy, technical and security" (Alhajii, 2007) dimensions, as well as "energy supply, economic, technological, environmental, social-cultural, and military security" dimensions from von Hippel et al. (2009) and others.

Contemporary literature on energy security considers risks linked to natural (e.g., resource scarcity, extreme natural events), technical (e.g., aging of infrastructure, technological accidents), political (e.g., intentional restriction of supplies or technologies, sabotage and terrorism), and economic (e.g., high or volatile prices) factors. Correspondingly, "protection from risks" is defined by various authors as independence, reliability, resilience, availability, accessibility, affordability, or sustainability of energy systems.

This analysis considers three perspectives on energy security linked to distinct policy strategies and rooted in specific scholarly disciplines: robustness, sovereignty, and resilience (Cherp and Jewell, 2011) (see Box 5.2):

- **Robustness** is focused on protection from disruptions originating from predictable and "objective" natural, technical, and economic factors such as resource scarcity, rapid rise of demand, aging of infrastructure, or rising energy prices.
- **Sovereignty** is focused on protection from disruptions originating from intentional actions of various actors (such as unfriendly political powers and overly powerful market agents). Sovereignty implies the ability to control the behavior of energy systems and is often linked to much-discussed "energy independence."
- **Resilience** is focused on protection from disruptions originating from less predictable factors of any nature, such as political instability, game-changing innovations, or extreme weather events.

Box 5.2 | Three Perspectives on Energy Security

For assessing energy security, when it is defined as protection from disruptions of energy systems, it is necessary to understand the nature of such disruptions and adequate protection mechanisms. Energy security policies as well as scholarly literature present three distinct but complementary perspectives on this issue.

Historically, the oldest – "sovereignty" – perspective on energy security focuses on disruptions potentially arising from actions of "external" actors, be it hostile powers or terrorists, "unreliable" exporters, "foreign" energy companies, or overly powerful market agents. Protection from such disruptions is seen in increasing control over energy systems, be it by military, political, economic or technical means. In a broader sense, the sovereignty perspective focuses on interests, intentions, power, and the space for maneuver of various energy actors and institutions. In its most familiar and most simplistic form, a sovereignty strategy is the quest for energy independence.

The "robustness" perspective on energy security focuses on risks that arise from predictable and largely controlled characteristics of energy systems rather than from malevolent actions. Scarcity of energy resources, failures of infrastructure, or inadequate capacity to cope with the rising demand are examples of the issues addressed within this perspective. The main strategies for minimizing the risks of disruptions within this perspective are switching to more abundant and accessible energy sources, investment in infrastructure to minimize the risks of technical failures, and decreasing energy intensity to reduce vulnerability to high prices.

In contrast, the "resilience" perspective emphasizes unpredictable factors affecting energy security. Precisely due to the complexity and unpredictability of energy systems, this perspective focuses on diversity of energy options as the main strategy to cope with the potential threats.

Figure 5.1 shows the three perspectives on energy security in relation to fundamental assumptions about the nature of potential disruptions. The robustness strategies are most prominent when disruptions of energy systems are both controllable and predictable. Sovereignty strategies are focused on disruptions arising from forces outside of our control (these can be more or less predictable). Resilience strategies work in situations of unpredictability, independently of whether or not we have control over energy systems.

Figure 5.1 also shows that many widespread energy security strategies are defined by more than one perspective. For example, increasing diversity of energy suppliers or maintaining competitive energy markets addresses both resilience and sovereignty concerns, since it reduces the power of individual agents to disrupt energy systems and provides a diversity of options which may be useful in the face of unpredictable disruptions. Investing in redundant capacities responds to both robustness and resilience concerns, whereas maintaining emergency stocks and selecting "trusted" partners is an overlap of sovereignty and robustness strategies.

Source: Cherp and Jewell, 2011

"Vital energy systems" that should be protected to ensure energy security were historically interpreted as a supply of oil and subsequently included other fuels, energy infrastructure, and eventually energy services. The literature identified "vital" as linked to "national values and objectives" (Yergin, 1988), "affecting welfare" (Bohi and Toman, 1996), and, in some cases, not associated with unacceptable environmental and social impacts (Sovacool and Brown, 2010) of energy systems.

In this analysis, "vital energy services" mean those that are necessary for the stable functioning of modern societies. Inherent in this definition is the notion that governments and the public perceive the interruption of such services as a national security concern. Such services vary from one country to another but commonly include transportation and energy for buildings. Most countries also depend upon a supply of energy for industrial purposes, and for some countries uninterrupted energy exports provide vital revenues. Security of these vital services is linked to vulnerability of energy sources (such as oil, gas, coal, hydro, and nuclear energy) and infrastructure for energy conversion and transmission (such as power plants, fuel reservoirs, and pipelines). Thus, our analysis is not limited to energy supply but also extends to energy conversion and distribution infrastructure and to the demand aspects within the vital energy sectors. We also analyze the connections between supply, demand, and infrastructure to understand how vulnerabilities propagate within energy systems so that if one element is at risk, other connected elements may also be affected.

Table 5.2 | Summary of the three perspectives on energy security.

Perspective	Sovereignty	Robustness	Resilience
Historic roots	War-time oil supplies and the 1970s oil crises	Large technological accidents, electricity blackouts, concerns about resource scarcity	Liberalization of energy systems.
Key risks for energy systems	Intentional actions by malevolent agents	Predictable natural and technical factors	Diverse and partially unpredictable factors
Primary protection mechanisms	Control over energy systems. Institutional arrangements preventing disruptive actions	Upgrading infrastructure and switching to more abundant resources	Increasing the ability to withstand and recover from various disruptions

Source: Cherp and Jewell, 2011.

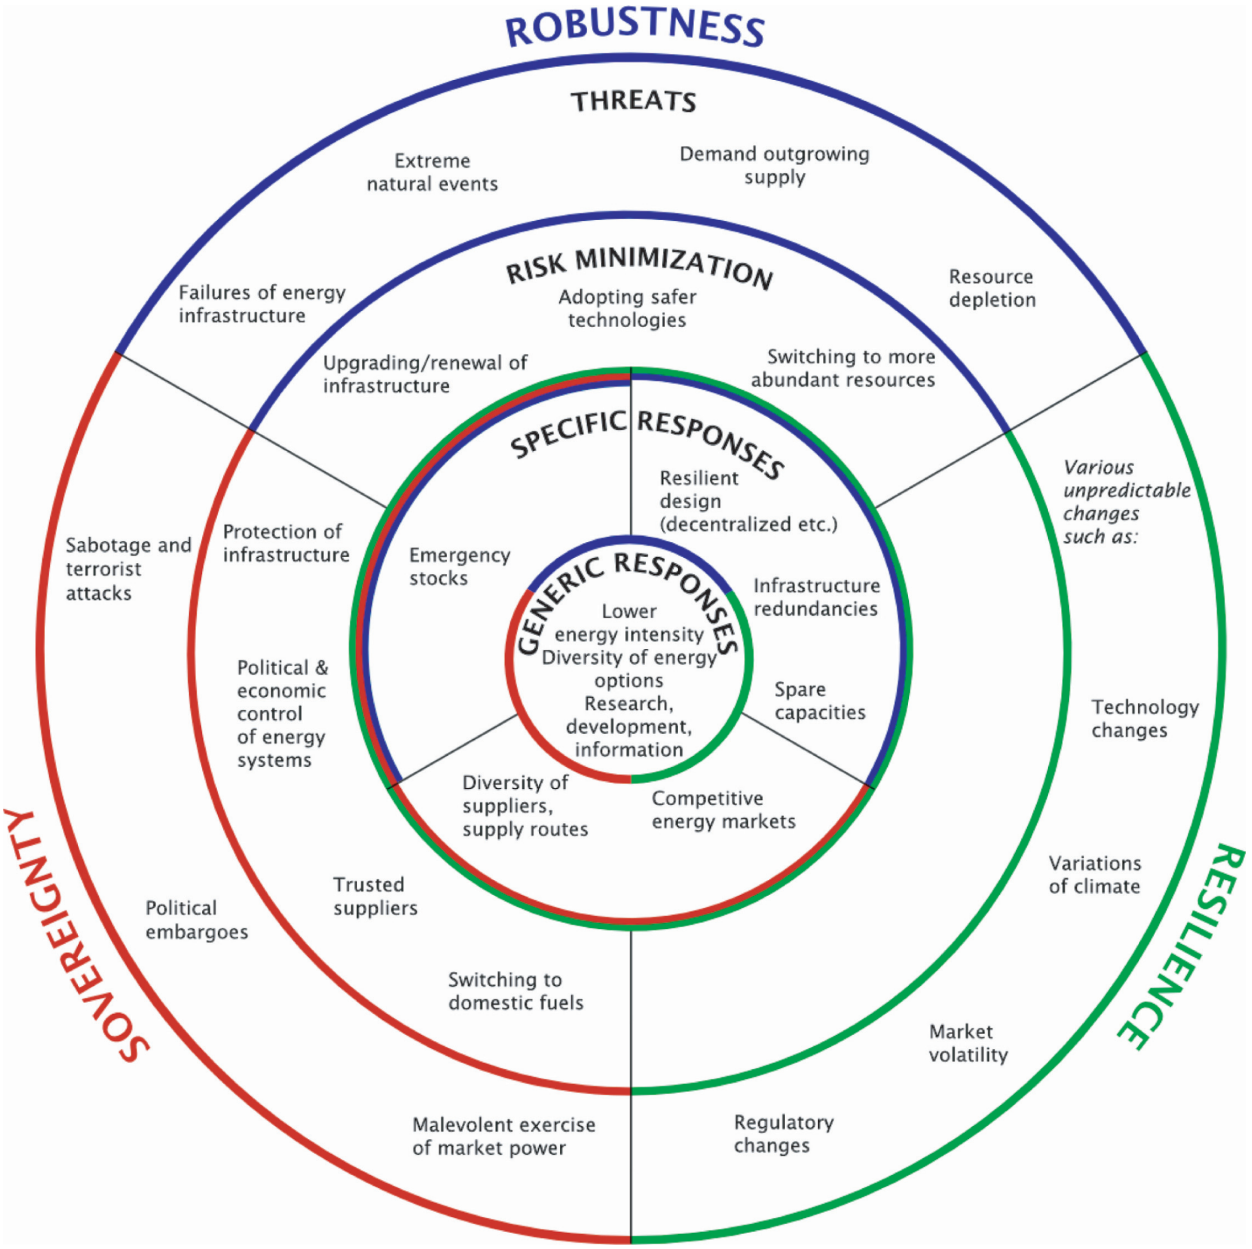

Figure 5.1 | Three perspectives on energy security. With their roots in political studies, natural science, engineering and economics, the three perspectives on energy security focus on different types of threats and risk minimization strategies. Source: Cherp and Jewell, 2011.

This chapter does not consider environmental and social impacts of energy systems as part of energy security, although such consideration is sometimes encountered in academic literature. For example, among 91 scholarly articles on energy security reviewed by Sovacool and Brown (2010), about one-quarter include environmental performance of energy systems in their definition of energy security. Our decision to separate the analysis of environmental and social impacts from the more conventional analysis of energy security is guided by two considerations. First, such impacts are analyzed in other chapters in this publication (Chapters 2, 3, and 4). Second, policies in the majority of countries consider energy security and climate change as distinct, although related, concerns. Thus, an analysis focused on energy security in a more narrow sense may be more policy relevant, as it appeals to a distinct policy community. Nevertheless, we acknowledge strong linkages between energy security and climate change, as explained in Box 5.3 and discussed throughout the chapter.

Box 5.3 | Energy Security and Other Energy-Related Concerns

Energy security concerns overlap with other concerns related to energy systems. This box briefly discusses this overlap with respect to climate and other environmental impacts, energy access and poverty, and energy affordability.

1. **Climate change and energy security.** Limiting the impacts of energy systems on climate change and ensuring energy security are clearly distinct policy concerns, as evidenced by many countries (especially in the developing world) that rigorously pursue energy security agendas without strong climate change agendas. Energy security and climate change concerns are associated with different policy communities, paradigms, and discourses. Yet there are strong links between the two policy areas. First, in some cases changes in climate present energy security risks affecting, for example, availability of water for hydro and thermal power generation or stability of permafrost in areas of oil and gas exploration. In some other cases, climate change results in new energy options such as hydropower from the melting glaciers of Greenland, or additional hydrocarbon resources available for exploration or marine transportation routes opened as a result of a retreat of Arctic sea ice. Second, climate and energy security policies may interact in a synergistic or conflicting manner. For example, reducing reliance on imported fossil fuels and promoting distributed generation from renewable energy sources has both climate change and energy security benefits. On the other hand, switching from imported natural gas to domestic coal advocated on energy security grounds is clearly disadvantageous from the climate change perspective. New technological dependencies, market arrangements, and international regimes associated with climate change governance may also have energy security implications. A similar argument also applies to other environmental impacts of energy systems and energy security.

2. **Energy access and energy security.** Whereas climate change is mostly a global concern, energy security is primarily a national concern, and energy access is often a local concern. Concerns over access to modern energy primarily focus on rural poor people, who are often not a high priority for statesmen dealing with national-level energy security, which concentrates on vital sectors often located in more prosperous urban centers. Likewise, poverty is often tolerated by national policymakers insofar as it does not affect the stability of national political or economic systems. Yet there are several strong links between energy security and energy access. First, enhancing access to modern energy services usually imposes a need to find additional resources and investments, which may exacerbate already existing energy security challenges. Second, lack of access to affordable energy *can* actually catalyze political or economic instability and thus become an energy-related security threat (for example, the uprising that resulted in the change of regime in Kyrgyzstan in April 2010 was allegedly initially triggered by high electricity prices and unreliable supply). Thus, our analysis considers lack of access an indicator of energy insecurity.

3. **Energy security and energy affordability.** Affordability of energy is often quoted as an important aspect of energy security. There is extensive literature analyzing and even defining energy security in purely economic terms. This is understandable, since some disruptions of energy systems are often nothing other than rapid increases in energy prices and can even, in other cases, be translated into economic losses. Yet, there is a clear distinction between "affordability" of energy and energy security. The former is a measure expressing the cost of energy relative to other economic parameters (GDP, income per capita, etc.). Thus energy affordability can be increased or decreased by changes outside energy systems, such as increases in income levels. Affordability also primarily addresses the relative cost of energy in the situation of economic equilibrium. In contrast, energy security deals with price disruptions that are outside economic equilibrium and induced by changes in energy systems (such as supply disruptions) rather than by general economic developments.

This chapter includes three main sections. The next section contains an assessment of energy security in over 130 countries carried out within a framework designed specifically for this purpose. The goal of this assessment is not to compare or rank the nations, but rather to identify common energy security concerns affecting significant parts of the world's population. The following section discusses energy security strategies pursued by individual countries and embodied in various international institutions. The last section provides an outlook for energy security in the future, connecting to Chapter 17 (Energy Pathways for Sustainable Development).

5.2 Energy Security Conditions in the World

This section presents a global overview of energy security in more than 130 countries using a National Energy Security Assessment Framework ("the Framework") specifically developed for this purpose. The Framework is presented in the first subsection and used in subsequent subsections to identify and map vulnerabilities of national energy systems globally.

5.2.1 National Energy Security Assessment Framework

There is extensive scholarly literature on measuring energy security. The methods and indicators used for this purpose vary depending upon the chosen definition of energy security, the intended use of the results of the analysis, the selection of boundaries of energy systems and time-horizons, the assumptions about the nature of potential risks, and the availability of data (Cherp and Jewell, 2010). Table 5.3 summarizes the key choices made in this study as compared to other quantitative evaluations of energy security.

The Framework used in this study proceeds from the definition of energy security as the protection from disruptions of nationally vital energy services. Our analysis aims to identify globally predominant national energy security concerns rather than to compare or rank countries as more or less secure.

This definition and the purpose of assessment leads to certain choices regarding the boundaries of energy systems analyzed within the Framework (see Figure 5.2). At the center of the analysis are national energy systems subdivided into subsystems of primary energy supply (oil, natural gas, hydro, nuclear energy, biomass, and "new renewables"); systems for the generation and transmission of electricity; and energy end-use sectors. This national-level analysis is supplemented by a global analysis of the vulnerabilities of internationally traded fossil fuels (oil, natural gas, and coal) electricity systems, and the nuclear fuel cycle.

The significance of energy end-use sectors analyzed in this chapter varies across countries. The first three of such sectors, discussed in Chapters 8, 9, and 10, are energy for (1) industry, (2) transport, and (3) commercial and residential buildings. The fourth important energy end-use sector is energy exports, which provide vital revenues to certain countries. By analyzing vulnerabilities of export revenues, we address "demand security," a serious concern of energy-exporting countries.

The Framework takes into account the propagation of vulnerabilities from energy sources to electricity systems and to energy end-uses. Electricity generated from less secure primary energy sources is considered more vulnerable. In turn, vulnerability of end-uses depends upon the vulnerabilities of primary energy sources and electricity used in a given sector. With respect to time-horizons we look into short- to medium-term concerns (up to 15–20 years), which are typically predominant in policy agendas.

The second set of choices concerns the nature of potential risks of disruptions of energy systems. The Framework assesses three dimensions of energy security: robustness (protection from disruptions due to predictable natural and technical factors), sovereignty (protection from disruptions originating from external actors), and resilience (the ability to withstand shocks and disruptions of various natures). We have chosen these three dimensions rather than other attributes of energy systems

Table 5.3 | Goals, choices and assumptions for measuring energy security made in this chapter as compared to other studies of energy security.

Choices and assumptions	Existing studies quantifying energy security	Chapter 5 of the Global Energy Assessment
Assessment goals	Rank groups of countries	Identify energy security concerns affecting a large number of countries and people globally
	Identify vulnerabilities of particular countries	
Definition of energy security	See Box 5.1	Low risk of disruptions of nationally vital energy systems
Energy security concerns	See Box 5.1	As reflected in sovereignty, robustness and resilience of energy systems, see Table 5.2. Exclude environmental and social issues
Energy systems and subsystems	Depending on the assessment purpose; often focused on energy supply, especially oil	Global systems for internationally traded fuels and nuclear fuel cycle; national energy systems including subsystems for energy sources, electricity generation and end-use sectors: transport; industry, residential and commercial energy, and energy export revenues
Aggregation of data	Compound or disaggregated energy security indicators	Aggregated for fuel systems, electricity and end-use sectors at the national and, where appropriate, the global level

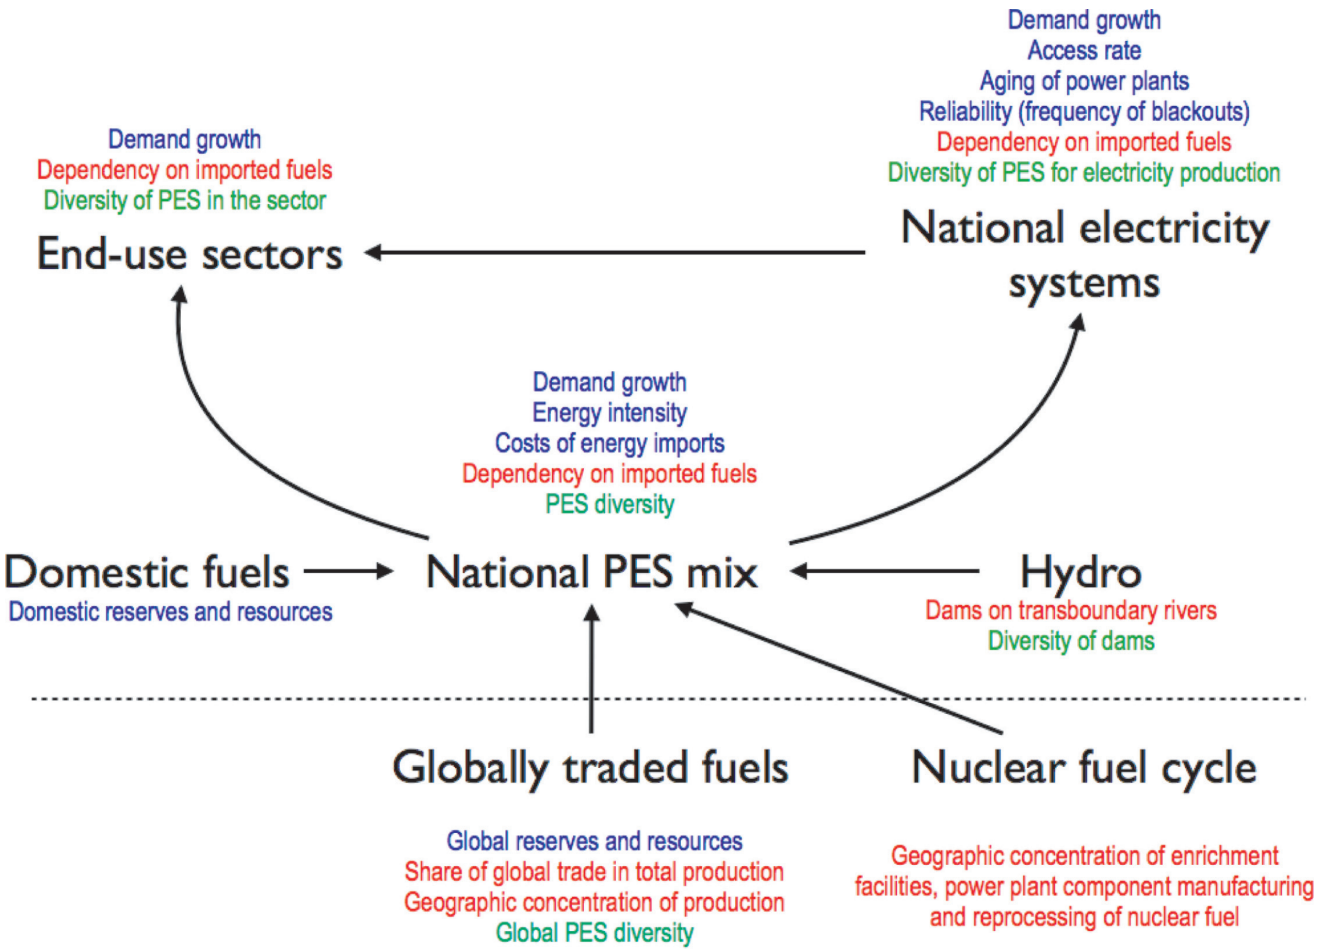

Figure 5.2 | Energy security assessment framework. The framework addresses the security of national energy systems with focus on energy sources, carriers and nationally vital energy services. The figure shows the elements of energy systems and their interconnections accounted for in the framework. The blue, red and green text indicates concerns related to the three perspectives on energy security (see Figure 5.1) – robustness, sovereignty and resilience respectively. The dotted line separates external and domestic factors.

proposed in the literature because they are linked to distinct policy mindsets and strategies, and thus we believe that the analysis along these dimensions will have the most policy relevance, as explained in Figure 5.1 and Box 5.2.

The four types of energy systems and the three dimensions of energy security are combined in a matrix defining key energy security concerns (Table 5.4).

The application of the Framework consists of several elements, as shown in Figure 5.1. This figure and the text below it provide only a brief description of the sample indicators. Further explanation of the choice of indicators and a qualitative analysis are given in the main text of the chapter.

The first element is the analysis of the global vulnerabilities of internationally traded fuels. The main robustness concerns regarding such fuels are available resources and reserves, as well as predicted supply-demand balances. Although these estimates are surrounded by large uncertainties, they nevertheless allow us to compare the major fuels and explain policy concerns about their vulnerabilities. The sovereignty concerns related to globally traded fuels are the share of international trade in total fuel production (which roughly indicates the degree of global dependency on imported fuels) and the geographic concentration of the fuel production (which indicates the market power of individual producing countries). Finally, the resilience concerns of the global primary energy sources system can be measured by the diversity of the global fuel mix.

The nuclear fuel cycle is also first evaluated at the global level, where we look at the concentration of capacities for uranium enrichment, manufacturing of nuclear power plant components, and nuclear fuel reprocessing.

The rest of the analysis is conducted at the national level for each of the 134 countries where the data are available in the IEA database (IEA, 2010b). With respect to the national primary energy supply, the Framework looks into such robustness indicators as domestic reserves and resources of non-renewable fuels, demand growth, and energy intensity. It uses import dependency (by fuel and for primary energy sources as a whole) as indicators of sovereignty concerns. Finally, the overall diversity of primary energy sources at the national level and the diversity of hydroelectric dams are used as an indicator of resilience of energy supply.

Table 5.4 | Energy security concerns analyzed in this chapter.

Energy subsystems	Energy security dimensions		
	Robustness	Sovereignty	Resilience
Global level			
Globally traded fuels: oil, coal, and gas	Availability of resources and reserves	Share of international trade in the overall production	Dominance (share) of a fuel in the total global PES mix
		Geographic concentration of fuel production	
Nuclear fuel cycle		Geographic concentration of uranium enrichment, manufacturing of nuclear power plant components, and reprocessing of nuclear fuel	
National level			
Energy sources			
Fossil fuels: oil, natural gas, and coal	Available domestic reserves (R/C ratio)		
	Demand growth for a particular fuel	Import dependency	Diversity of import routes
Hydro energy	Climate change effects on water availability and variation	Usage of transboundary water resources	Diversity of hydroelectric dams (see also electricity generation)
Electricity generation and transmission	Age of power plant fleet Growth in consumption of electricity Reliability (frequency of blackouts) Access rate	Reliance on imported fuels	Diversity of fuels used for electricity production Diversity of power plants
End-use sectors: industry, transport, residential and commercial, energy exports	Growth (decline*) in energy demand for the sector	Reliance on imported fuels within the sector	Diversity of energy sources used in the sector
National energy systems (cross-sectoral)	Energy intensity Growth in overall energy consumption Energy consumption per capita	Overall import dependency	Overall diversity of PES used in the national energy system

Notes: Concerns quantified by indicators are highlighted in bold. * – for energy exports

With respect to national electricity systems, the robustness indicators are the age of power plants, demand growth, and the reliability (blackout) statistics. The sovereignty indicator is the dependency of electricity systems on imported electricity and fuels. The resilience indicator is the diversity of primary energy sources used in electricity production.

With respect to end-use sectors, the Framework uses the rate of demand growth as the robustness indicator, the share of imported fuels in the sectoral primary energy sources mix as the sovereignty indicator, and the diversity of primary energy sources as the resilience indicator for a particular sector.

The final set of choices in evaluating national energy security concerns the aggregation of indicators and interpretation of results. This chapter recognizes that the nature of energy security risks varies among countries and in time, and thus a unified indicator is not plausible or relevant. The Framework seeks to identify, map, and explain the varying conditions of energy insecurity encountered around the world. It uses simplification and aggregation, necessary for mapping these concerns, rather than producing a single universal energy security index.

The Framework used in this analysis is naturally not capable of evaluating all important energy security concerns. Some of the issues that were intentionally left outside the analysis are discussed in Box 5.4. The method and some of the key indicators used in the Framework are subsequently deployed in analyzing energy security within the GEA Scenario in Chapter 17. The method of such analysis is explained both in Chapter 17 and in the last section of this chapter.

5.2.2 Security of Primary Energy Sources

This section considers the security of key primary energy sources. It starts by analyzing major internationally traded fuels: oil, natural gas, and coal. For each of these fuels, the analysis of their global vulnerabilities is followed by the analysis of national vulnerabilities in individual countries. The second subsection discusses vulnerabilities of nuclear energy: both at the global and the national level. The remaining three subsections discuss vulnerabilities of hydro energy, biomass, and "new renewables." The final subsection contains an analysis of the total primary energy supply of individual countries by aggregating the data on individual sources at the national level. The indicators used for the analysis in this section are summarized in Table 5.5; they cover the robustness, sovereignty, and resilience perspectives on each of the energy sources.

5.2.2.1 Globally Traded Fuels

The three major fuels traded on an international and global scale are oil and its products, natural gas, and coal. Global trade in these fuels means

Box 5.4 | Limitations of Current Analysis

The analysis presented in this chapter does not consider several issues that are occasionally addressed in energy security literature. These issues have been scoped out to maintain the focus of the assessment as well as due to time, space, and data limitations. The limitations relate to the types of energy systems considered in this assessment, time-horizons, and the nature of risks and disruptions analyzed.

First, the assessment is focused on key energy security issues that presently dominate policy concerns in a large number of countries. This means that only major traditional mainstream energy security systems are analyzed. For example, wind, solar, geothermal, and tidal energy at the moment do not make for a large share of energy supply in many countries and thus are not analyzed in detail. Yet, availability of alternative energy sources – to say nothing about technologies and finances – may be key factors in shaping national energy security in certain countries.

For largely the same reason, the analysis in this chapter is focused on short- to medium-term concerns (up to 15–20 years) that typically dominate policy agendas. We believe that energy security in a longer-term future will largely depend on policy choices and may unfold in the context of radical energy transitions. If these policy choices are guided by economic, environmental, and social sustainability goals, energy systems may evolve along pathways described in the GEA Scenario (Chapter 17). Energy security under such pathways is analyzed in Chapter 17 using the assumptions, methods, and indicators developed in this chapter.

Third, energy security is affected by a large number of complex and often intangible factors that are difficult to identify, quantify, or compare on the global scale. Some of these factors are subjective, such as trust between various actors in energy systems, consistency and predictability of policies, or reflexivity of market price-setting. Other factors are related to vulnerabilities of complex technical systems ranging from technological interdependencies (with respect to materials, equipment, expertise, and capacities related to energy systems) to cyber-security of critical energy infrastructure, especially electricity networks. Another critical group of factors relates to financing options, availability and effectiveness of investment, and capacities to develop various energy options. None of these factors could be extensively analyzed in this chapter, which does not make them less important in specific national contexts.

Despite these limitations, we believe that this chapter fulfills its goal of mapping the major energy security concerns of today's world and provides a methodological and factual basis for analyzing the potential evolution of these concerns under sustainable energy transitions.

that their vulnerabilities can be analyzed within the global and national systems using the three perspectives on energy security: robustness, sovereignty, and resilience.

Robustness of globally traded fuels means their physical availability, technological accessibility, and economic affordability (Kruyt et al., 2009). Although each of these characteristics is affected by a number of complex and often uncertain factors, for the purposes of this analysis they can be described by relatively simple proxy indicators such as the global reserves-to-production (R/P) ratio, supply and demand projections, and price dynamics.

At the national level, robustness of a particular fuel source can be characterized by national R/P ratios. Although such ratios are notoriously fluid (because the estimates of "resources" and "reserves" often change in time with economic and technological changes), they still signal important vulnerabilities to policymakers, especially if they are relatively short-term (under 10–20 years). A rapidly growing demand for a particular fuel signals a pressure on resources and infrastructure. Other national-level indicators of robustness of a particular fuel supply are the fuel intensity of a national economy (higher fuel intensity means that it is more difficult to adjust to potential disruptions of supply) and the proportion of national gross domestic product (GDP) or export revenues that is spent on imports of this fuel.

The main sovereignty concern related to internationally traded fuels at the global level is market power of dominant actors, which relates to their potential ability to disrupt prices or even physical supply of that fuel. Proxy indicators of this concern include the share of internationally traded fuel in the total fuel production and the geographic concentration of fuel production in particular countries or regions. These indicators are more informative where there is a single global market for the fuel (as in the case of oil and, partially, coal). In the case of gas, such indicators should be used in each of the separate regional markets.

The main sovereignty concern at the national level is import dependency on a particular fuel. This is probably the most widely used metric of energy security. Import dependency is important for policymakers because it makes their energy supply vulnerable to (a) global price volatility determined by factors beyond their control; (b) market power of major exporters, which may in extreme cases be manifested in direct physical supply disruptions; and (c) exposure to other disruption factors (including in transit countries) along import routes. In addition, many nations are concerned about the security of their energy imports if these originate in countries considered

Table 5.5 | Overview of concerns and indicators of national energy security addressed in this chapter.

Energy sector	Energy security concerns (indicators)*	
	Shorter term >	Longer term
Oil	**Exposure to the global oil market** (import dependency, cost of imports, **Demand-side vulnerabilities** (annual growth in oil consumption, *oil intensity*) **Domestic availability of oil** (R/C) Environmental acceptability of oil production and use	Global conventional oil scarcity ("peak oil")
Gas	**Exposure to the global and international gas markets** (import dependency, cost of imports **Demand-side vulnerabilities** (*gas intensity*)	
	Domestic availability of gas (R/C) Environmental acceptability of gas production and use	
Coal	**Exposure to the global coal market** (import dependency) **Domestic availability of coal** (R/C) Environmental and health acceptability of coal production and use	
Nuclear	Seasonal water availability **Aging infrastructure** (average age of nuclear power plants) **Capacity to replace existing fleet** (start of last plant construction) Access to capital, enrichment, reactor manufacturing, reprocessing Environmental, safety and security acceptability of nuclear power	
Hydro	Reliance on dams which are shared (*transboundary dams* or *dams on transboundary rivers*) Seasonal water availability Aging and silting of dams and other infrastructure **Exposure to risk of dam failure or sabotage** (diversity of dams)	Effects of climate change on water patterns and availability
Electricity	**Exposure to imported fuels** (dependency on imported fuels) **Exposure to a single fuel market** (low diversity of energy sources used for electricity production) **Adequate capacity** (annual demand growth rate, access rate) Underinvestment and aging infrastructure	
Transport	**Exposure to imported fuels** (dependence on imported fuels) **Demand-side vulnerabilities** (annual consumption growth rate)	
Industry	**Exposure to imported fuels** (dependence on imported fuels) **Demand-side vulnerabilities** (industrial energy intensity)	
Residential and commercial	**Exposure to imported fuels** (dependency on imported fuels) **Demand-side vulnerabilities** (annual consumption growth rate) **Adequacy of provision** (reliance on traditional biofuels in the residential sector)	
Energy for export	**Exposure to price fluctuations** (revenue from energy exports as share of GDP) "Security of demand" (diversity of export routes and destinations) "Dutch disease" and "resource curse"	
Cross-sectoral	**Exposure to imported fuels** (overall import dependency, cost of energy imports compared to GDP, cost of energy imports compared to export earnings) **Overall resilience of primary fuels** (diversity of PES) **Exposure to energy price volatility** (overall energy intensity) **Demand-side pressure** (annual growth rate in consumption, consumption per capita)	

Notes: R/C – reserves to consumption ratio; PES – primary energy sources

unfriendly, unstable, unreliable, politically unacceptable, or potentially exercising asymmetrical market power. In other situations, imports come from culturally and politically close and trusted partners and thus lead to few security concerns. In the global context, we do not systematically quantify these idiosyncrasies but comment on them in particularly relevant cases (e.g., in regional energy security discussions).

Finally, the main resilience metric with respect to energy supply is the diversity of primary energy sources, either nationally or globally. Strategic reserves of oil and, to a lesser extent, gas and coal support both resilience and robustness of energy supply, but their presence was not quantitatively analyzed in this chapter due to data limitations.

Global oil supply vulnerabilities

Oil is a non-renewable resource massively traded on the global scale. It is the largest single primary energy source worldwide and dominates the transport sector, where it lacks easily available substitutes. The global demand for oil is steadily rising, particularly as a result of increasing motor

fuel consumption in emerging economies. Given limited new discoveries, the global production of conventional oil is predicted to "peak" or "plateau" in the first half of this century (see Chapter 7 for details) in spite of globally rising demand. This supply-demand imbalance will lead to higher oil prices in the medium to long term, as exploration and production will turn to progressively more demanding, and thus more expensive, sources (such as oil in deep-sea water or the Arctic). The costs are rising even in established production regions. The Kashagan oilfield in the Caspian Sea, one of the biggest discoveries in decades, was due to enter production in 2005. Now the target is 2012, and the costs could exceed US$100 billion.[1] The 2010 disaster at BP's well in the Gulf of Mexico may increase costs further as environmental regulations are tightened.

In addition to this expected medium- to long-term cost increase, global oil prices have been increasingly volatile in the last decade for several reasons. First, the global demand for oil has been growing faster than production capacity, and as a result the spare production capacity (the difference between what is possible to produce in the short term and what is actually produced to meet the demand) has significantly decreased. With the smaller spare capacity, even relatively minor disruptions of supply – whether they are due to natural, economic or political causes – may knock the demand and supply off balance, thus signaling rocketing prices or even a physical scarcity of fuel at least in the short term,[2] or the reverse.

Furthermore, the global oil price has been increasingly affected by highly volatile market expectations through speculation. Future contracts and other derivates have opened the oil market to speculative money, which is blamed as a contributing factor in oil price volatility. Due to the rapid increase in the number of actors and improvements in communication tools, the oil markets have become highly reflexive – i.e., driven by market sentiments and expectations. This reflexivity does not blend well with the decreasing and often uncertain spare capacity. A speculative market combined with low spare capacity and high uncertainty easily results in price bubbles and longer-term volatility.

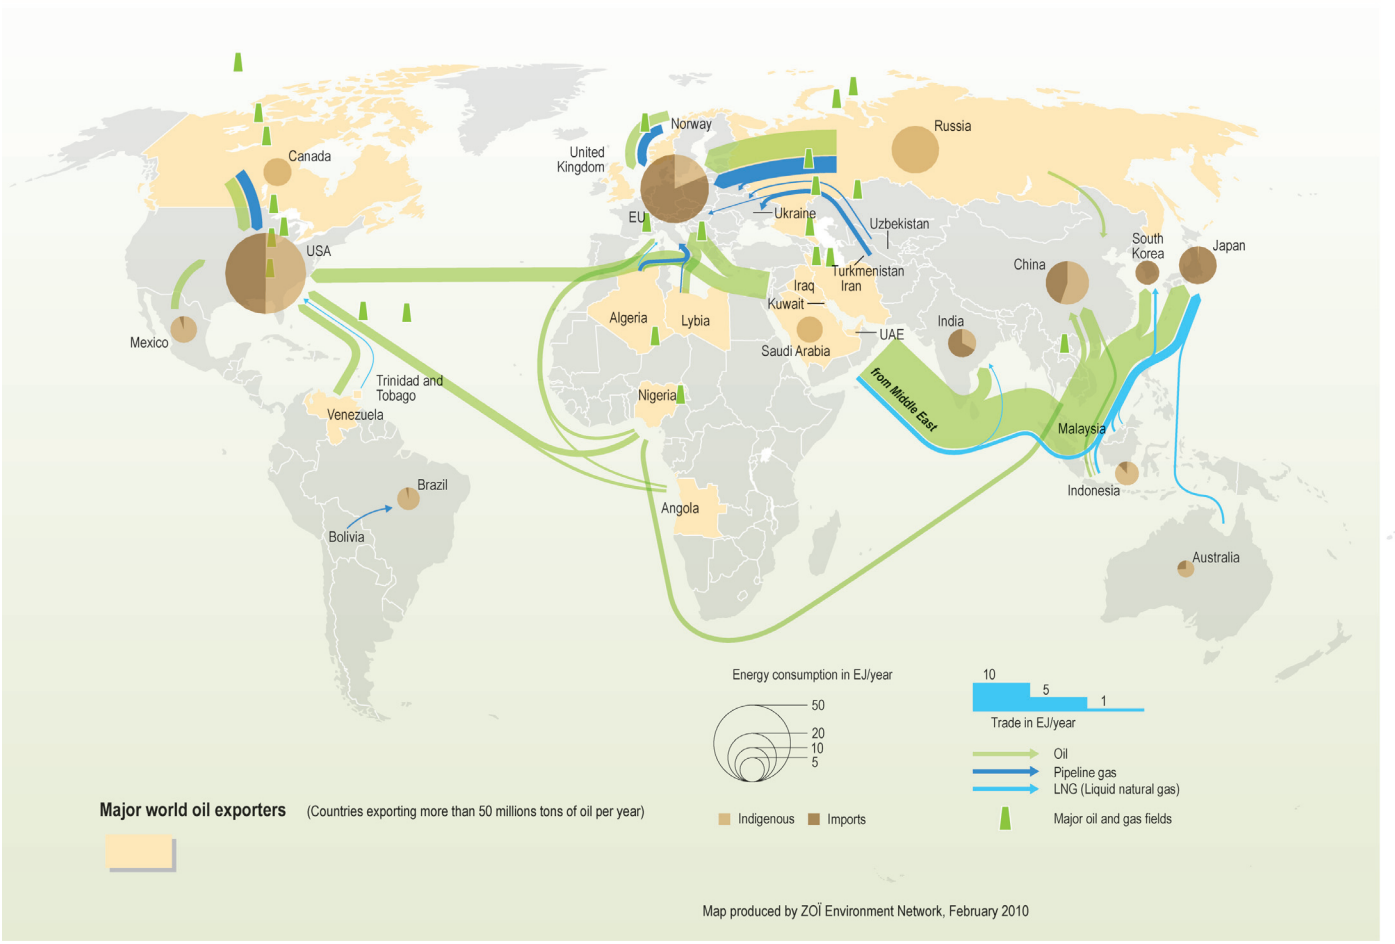

Figure 5.3 | Global oil and gas production and trade. The figure shows the concentration of global oil and gas production in a limited number of regions and large volumes of trade in these fossil fuels. Source: BP, 2009; IEA, 2009a; b.

1 According to the Cambridge Energy Research Associates' (CERA) Upstream Capital Costs Index (UCCI), prices of drilling technology, skilled labor, and equipment have soared. Even in spite of recent economic recession, exploration and development costs in oil and gas have risen by 200% between 2000 and 2011 (IHS, 2011) adding a significant cost to crude supply.

2 When BP had to shut down a single refinery in 2006, world crude prices jumped 2% (Sovacool, 2009).

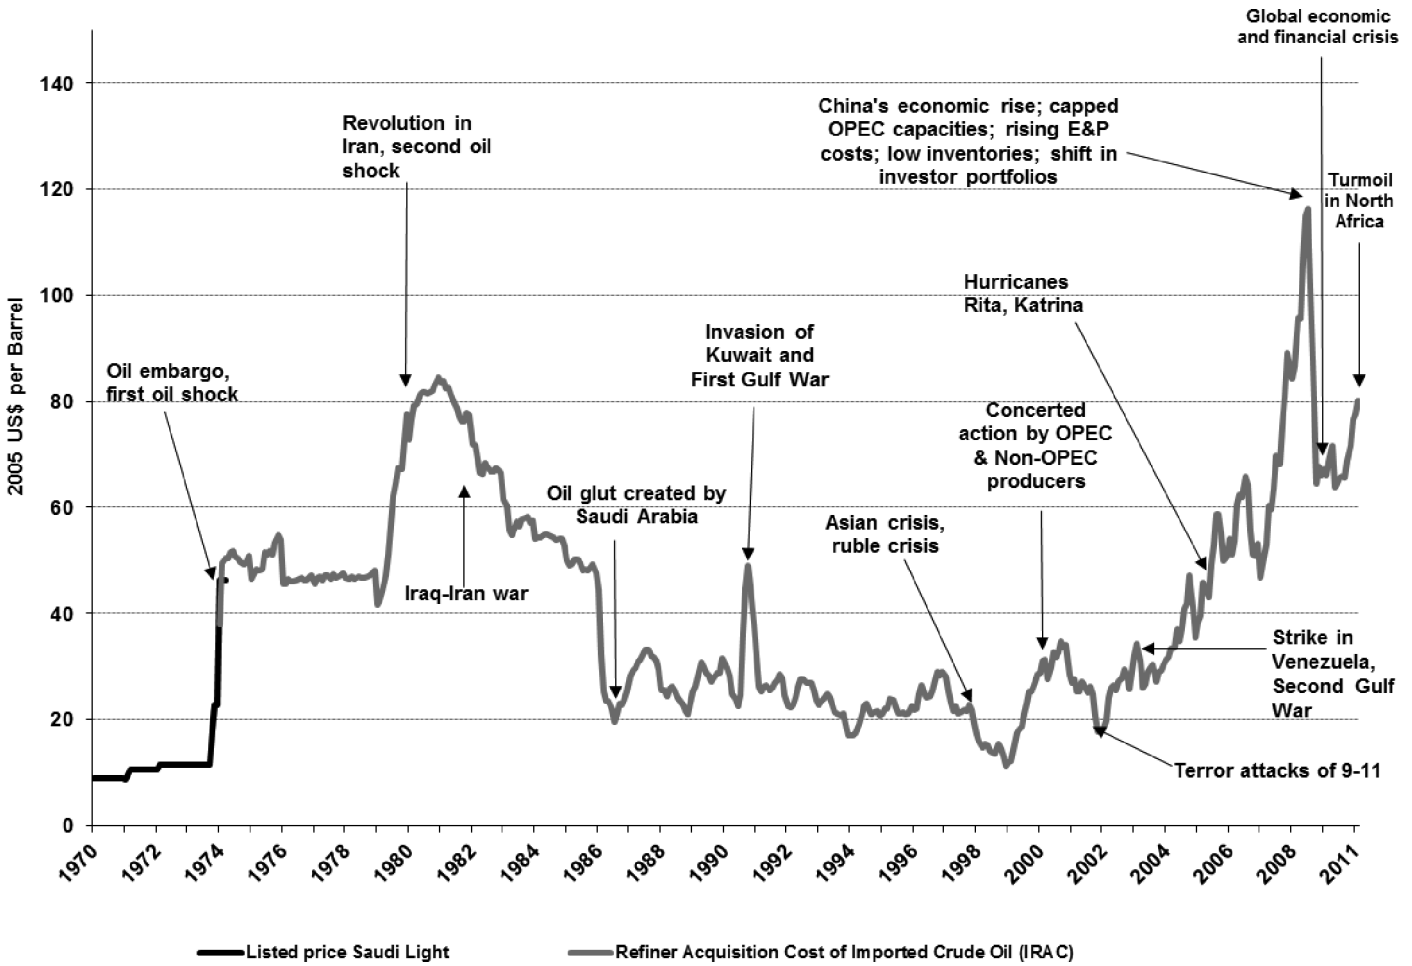

Figure 5.4 | Price of oil (in US_{2005}) and major political events 1970–2011. Source: modified from US EIA, 2011b. Note: Imported Refiner Acquisition Cost (IRAC) is the volume-weighted average price of all crude oil imported to the United States.

Moreover, the volatility of the global oil market is exacerbated by the fact that, whereas oil is traded globally, its production and reserves are heavily concentrated in just a few countries and regions (see Figures 5.3 and 5.4) away from the major consumption centers. In 2006 the Middle East accounted for 62% of the world's identifiable proved liquid reserves and 31% of the output. The world's top 10 producers represent approximately 62% of global output. Eight of the top 10 producers are net oil exporters that collectively supply 34% of global oil demand. On the other hand, seven of the world's 10 largest consuming countries lack sufficient oil production capacity to meet their internal consumption, importing more than 35% of the world's demand (Lehman Brothers, 2008). According to the IEA (2010a), the concentration of oil production and the market power of major producers are expected to increase by 2030, not only in the Reference Scenario but also in the presence of strong climate policies (the "450 scenario"). The interregional trade in oil will increase by over 30% and comprise almost one-half of the total volume of global production by 2035 (IEA, 2010a) in the New Policies Scenario.

This means that global oil supply is becoming increasingly more vulnerable to conditions in oil-producing countries and regions, as well as the demand dynamics and expectations of major consumers. There is an extensive record of political, economic, and natural events, military conflicts, and deliberate acts of sabotage that have either physically disrupted global oil flows or resulted in price hikes. According to (Jones et al., 2004), quoted in (Farrell et al., 2004), 24 oil supply shocks between 1950 and 2003 averaged eight months or 3.7% of the global supply. The 1990 Gulf War, for instance, resulted in production loses of 2.8 million barrels per day (mbd) of Iraqi and 1.4 mbd of Kuwaiti oil – some 7% of global supply (BP, 2007). The strike at Petróleos de Venezuela, SA during 2002/2003 brought to a halt the country's entire oil sector and temporarily reduced global oil supplies by 2.3 mbd, or 3% of total world supply (US Government Accountability Office, 2006). As it coincided with unrest in oil producer Nigeria and the looming US invasion of Iraq, the strike contributed to pushing the nominal price of oil to new highs (Shore and Hackworth, 2003). For an overview linking oil price developments and major political events since the early 1970s, see Figure 5.4.

Thus, countries relying on imported oil are at risk of facing medium- to long-term price increases combined with volatility of oil prices in the short term. Physical supply disruptions similar to the Arab OPEC oil embargo of the early 1970s are less likely nowadays because alternative suppliers can normally be found, given the "liquid" character of the

global oil market, and strategic oil reserves present in most major economies can smooth out such impacts. However, infrastructural limitations (e.g., pipeline capacities or refineries "tuned up" to deal only with a particular kind of crude) can still make physical disruptions very painful for particular countries. For example, several landlocked countries in Central and Eastern Europe receive the majority of their oil supplies from Russia through the Druzhba pipeline and are, therefore, vulnerable to disruptions affecting this particular supplier and the transportation route. Globally, 64% of the global oil supply flows through just 10 supply chain "choke" points, with the top three accounting for 46% of supply (Lehman Brothers, 2008). In addition to the Druzhba pipeline, these include the Straits of Hormuz, Strait of Malacca, Abqaiq processing facility, Suez Canal, Bab el-Mandab, Bosporus/Turkish Straits, Mina al-Ahmadi terminal (Kuwait), Al Basrah oil terminal (Iraq), and LOOP (United States).

In summary, the global oil supply is vulnerable from robustness, sovereignty, and resilience perspectives. The main robustness concerns are the increasing demand in the face of limited conventional production capacities, rising costs of production, and high and volatile prices. The main sovereignty concerns are the increasing concentration of production away from major demand centers and the increasing market power of major producers. The resilience concerns include not only the dominance of oil in the world's energy use and the lack of easily available substitutes for oil in the transport sector (as we will be discussing further later in this chapter), but also the limited diversity of global oil supply routes and the vulnerability of the "choke" points.

National oil supply vulnerabilities

Oil is the only primary energy source that plays an important role in all of the national energy systems except in a few less-developed countries. Virtually every country (125 countries with 5.9 billion people)[3] has at least 10% of its primary energy derived from oil, while over 5.5 billion people live in 112 countries which rely on oil for more than 18% of their total primary energy supply. Moreover, some 370 million people live in 32 countries that use oil for more than half of their primary energy supply.

The majority of countries import most or even all of the oil and petroleum products they need. Over three billion people live in 83 countries that import more than 75% of the oil and petroleum products they consume, and 101 countries with 5.3 billion people import over 25% of the oil they consume.

The number of people living in countries significantly dependent on oil imports is likely to rise in the near future. At the moment there are 3.6 billion people in countries that import more than half of their oil, but a further 1.7 billion people live in countries (including Argentina, China, Indonesia, and the United Kingdom) where the ratio of domestic oil reserves to domestic annual oil consumption is under 15 years.[4] Even though some countries (e.g., Ghana) may become less dependent on imported oil due to new discoveries and developments, this is unlikely to reverse the overall trend of the rapid increase of oil import dependency in the world.

Several of the highly import-dependent countries have additional demand-side vulnerabilities. In 16 such countries (with 1.8 billion people), the demand for petroleum products grew at 5–10% per year on average from 1996–2006. In addition, five of these (including several African countries and Vietnam) have outstanding fuel intensities that make them highly vulnerable to market price disruptions.

China and India – which are together home to about 2.5 billion people – tell a story of their own. Oil consumption in China more than quadrupled between 1980 and 2009. It has grown at the annual rate of over 7% a year in the last 10–15 years. In the WEO (World Energy Outlook)'s New Policies Scenario, it is expected to almost double between 2009 and 2035, increasing on average by 2.4% per year. In this scenario, China accounts for 48% of the global rise in demand for oil. The majority of this increase will likely come from imports, as China already imports over 40% of its oil supply and its domestic reserves/consumption ratio is between seven and eight years. India already imports over 75% of its oil, and its domestic resource/supply ratio is under six years, with consumption growing on average 4.6% per year and projected to grow faster than in China at 3.6% between 2009 and 2035, accounting for a further 30% of the increase in the global demand for oil (IEA, 2010a).

It is worth commenting that all low-income countries (over 600 million people) except Uzbekistan,[5] Myanmar,[6] and Yemen import over 80% of their oil and petroleum products. In sub-Saharan Africa, apart from South Africa, Gabon, Nigeria, Angola, Sudan, Congo, Cameroon, and Côte d'Ivoire, all of the countries are completely dependent on the import of petroleum products!

Global natural gas supply vulnerabilities

Natural gas is the fastest growing fuel of choice for electricity generation in the Western hemisphere and has also gained an increasing importance in emerging economies. In addition, it is extensively used in the residential sector (for heating and cooking) and in many industrial applications. Similarly to oil, gas is a non-renewable resource with reserves and production concentrated in a few countries and regions, and most nations relying on imported supplies. There are, however,

3 According to IEA (2007), oil and its products represented less than 10% of total final energy use in only nine countries: Mozambique, Tanzania, Democratic People's Republic of Korea, Zimbabwe, Nepal, Ethiopia, Democratic Republic of Congo, and Nigeria.

4 The concepts of reserve/production or reserve/consumption ratios are notoriously unreliable when used for projecting the date of "running out of oil." This is because the estimates of reserves are constantly updated and the rates of production/consumption also change. However, the very low (<10–15 years) ratio usually signals serious energy security concerns and the need to develop new reserves, imports, or other energy sources.

5 Uzbekistan has the resource/supply ratio of about 16 years.

6 Currently, Myanmar is a net crude oil exporter, but it imports more than 50% of its petroleum products and has the resource/supply ratio of just 3.75 years.

Table 5.6 | Vulnerabilities of primary energy sources.

Energy security perspectives	Robustness		Sovereignty	Resilience	
Globally traded fuels					
	Global R/P ratio	Projected demand growth 2008–2035*	Share of international trade in global production in 2009	Number of people (billions) in countries with import dependencies over 25/50/75%	Diversity of global producers by region, SWDI
Oil	30 yr.	15%	66%	5.3/3.6/3.1	1.63
Gas	80 yr.	44%	29%	2.2/0.75/0.65	1.84
Coal	150 yr.	19%	14%	1.3/1.1/0.70	1.92
Other energy sources					
Nuclear	Aging of nuclear power plants; sensitivity to political interventions		Concentration of enriched uranium and reactor manufacturing technologies; nuclear fuel cycle controlled for non-proliferation reasons	Generally large facilities; difficult to substitute in case of failure	
Hydro	Sensitivity to water availability; vulnerability to climate change in some regions.		Hydroelectric facilities located on internationally shared rivers	In certain cases extremely large facilities providing majority of electricity of certain countries	
NRES	High initial costs; intermittency of supply		Technological dependencies; potential import dependencies for biofuels	Generally assumed to be higher than in the case of traditional sources due to distributed generation and more diverse energy mix	

Source: see main text; *– New Policies Scenario (IEA, 2010a).

important differences between energy security concerns associated with oil and natural gas as globally traded energy sources.

With respect to globally available resources, the production of conventional gas is likely to peak (or plateau) several decades later than conventional oil in most scenarios. In addition, technological advances have recently added significant quantities of unconventional (primarily shale) gas to global reserve estimates (see Box 5.5). There are, generally speaking, fewer concerns about the risk of rapid increases in gas prices than in the case of oil (Söderbergh et al., 2009; Söderbergh et al., 2010). In other words, "peak gas" may not be as significant a concern as "peak oil."

Yet the global demand for natural gas is projected to increase faster than that for oil (by 44% in the WEO's New Policies Scenario, compared to 18% for oil). A quarter of this rise in global demand is set to come from China, where the consumption of natural gas is projected to increase on average by 6% per year up to 2035 (IEA, 2010a).

On the other hand, similarly to oil, a globally sufficient supply of natural gas depends upon adequate investments in exploration, production, and transportation. Such investment is all but granted, especially in connection with uncertainty over shale gas and other factors affecting gas prices (see Box 5.5). According to the IEA (2007), the total upstream and infrastructure investment needs in natural gas amount to US$4.2 ($US_{2005}$$ 4.0) trillion until 2030.

The difference between oil and natural gas is also in the volumes of international trade. Whereas about two-thirds of the globally produced oil is traded, this share is only about one-third for natural gas (see Table 5.6). However, interregional trade in natural gas is projected to increase very significantly (by 80% between 2008 and 2035 in the WEO's New Policies Scenario (IEA, 2010a) to account for over one-quarter of the total production). China's imports of natural gas are set to grow some 40-fold in this scenario, accounting for some 40% of the total growth in the interregional gas trade over this period (IEA, 2010b).

In contrast to oil, there is no unified global market for natural gas, primarily because the regional price differentials do not exceed the still high costs of interregional transportation (Stevens, 2010). Natural gas is transported via pipelines or between liquefied natural gas (LNG) installations tied with long-term contracts. Natural gas is traded on several largely independent regional markets, most notably the Eurasian, North American, and Asia-Pacific markets. While the North American natural gas market is liquid, regionally integrated, and deregulated, the Eurasian gas market is dominated by long-term bilateral contracts, entailing off-take agreements and destination clauses. Consequently, the Eurasian gas market, though considerably larger in volume than the North American one, is characterized by a comparably lower liquidity and a still marginal, although growing, role of spot markets. The emergence of a global gas market was widely predicted by experts and signaled by considerable investments in LNG infrastructure but delayed by the economic crisis and shale gas developments.

Natural gas is traded in regional markets by pipelines and globally as LNG. This has two major implications for energy security concerns associated with this fuel. On one hand, it prevents the emergence of globally powerful market actors, be it individual producers or cartels (like OPEC in the case of oil). On the other hand, it significantly increases the market power of regionally dominant market actors, such as Russia in Eurasia. Regional markets dominated by long-term contracts may also be more protected from price volatility, especially if the prices of gas are decoupled from those of oil, which has been a long-term trend and expectation (Stern, 2009; Stevens, 2010).

Box 5.5 | Shale Gas Revolution and Energy Security

Over the last several years the production of unconventional shale gas in the United States has dramatically increased (from 1% of total energy supply in 2000 to some 20% in 2009) and its share of total gas reserves increased by 50%. This has been heralded as the "shale gas revolution," with significant implications for energy security not only in the United States but also in the rest of the world, particularly in Western and Central Europe, which may become significantly less dependent on Russian gas imports.

At the same time, many uncertainties have been quoted with respect to shale gas developments. Even in the United States, cost estimates vary widely, and there are concerns over shorter life and low recovery rates of shale gas fields as well as environmental impacts of shale gas exploration. More uncertainties are associated with replication of North American success on other continents. Obstacles to shale gas development in Europe include different geology, lack of tax breaks, lack of technologies and expertise, more sensitive natural and cultural environment, potential opposition of local communities, and different land/natural resource structure than in the United States. Despite the potential shale gas revolution, the IEA New Policies Scenario predicts the overall decline in natural gas production in Western Europe, with the average rate of –1.5% per year up to 2035. Globally, the share of unconventional gas is predicted to increase from the current 12% to 15% in 2030, much of this increase being in North America.

In spite of these potentially positive (although less than certain) effects of the shale gas revolution, there may be some negative effects as well. So far, increasing shale gas production has resulted in decreasing gas prices and cancellation of investment projects in LNG and natural gas infrastructure. If the developments in shale gas do not follow the most optimistic forecasts, there may be a significant lack of capacity to meet the global demand. The shale gas revolution has also slowed down the development of spot trading and the emergence of a global gas market, leading to a temporary "glut" in LNG production and capacity. Investments in renewable energy alternatives to natural gas have also been slowed by this decrease in price.

Another concern associated with shale gas may be technological dependency. Chemicals, drilling technologies, and the expertise required for shale gas production are primarily available in the United States, where they have been developed over decades of trial and error. These will need to be exported, at least in the short term, to enable a similar increase in production in other countries.

Source: Stevens, 2010; IEA, 2010a. See also Chapter 7 for the discussion of technical issues related to shale and other unconventional natural gas.

Thus, sovereignty concerns related to natural gas are highly region-specific. They are most prominently highlighted by the recent gas disputes between Russia and the Ukraine (in 2006 and 2009) which led to interruptions in the supply of gas to members of the European Union (EU). This interruption most severely affected such countries as Slovakia, which is significantly dependent on Russian gas and lacks emergency gas stocks to cope with such short-term disruptions of supply. In another similar case, the Georgian gas supply in 2005/2006 was struck by a sabotaged Russian gas pipeline, causing severe energy shortages during that winter. Subsequently, the EU's energy security debate has become largely framed by the need to diversify the routes and origins of gas imports (as well as to substitute gas by other energy sources). The tense political relations between some Central and Eastern European countries and Russia played an important role in sustaining this debate. Outside Europe such deliberate disruptions of gas pipeline deliveries have been rarer, although not unknown.

Finally, in contrast to oil, which currently lacks readily available substitutes in the transport sector, natural gas can be more easily replaced by other sources such as oil, coal, nuclear power, or imported electricity (not to mention biogas and other renewable sources). Naturally, such a replacement might require substantial infrastructure investment.

In summary, the global vulnerabilities of the natural gas supply are largely similar to those of oil but with several important distinctions. With respect to robustness, it has larger conventional reserves and probably more optimistic expectations concerning non-conventional reserves, although it still remains a limited resource and upstream investment requirements are very high. In the case of natural gas, sovereignty concerns are strongly articulated on the regional level, particularly in Eurasia. With respect to resilience, the substitutability of natural gas is its major advantage, but for many markets the low diversity of origin of imports and supply routes presents a potential vulnerability to natural or political disruptions.

National natural gas supply vulnerabilities

Significantly fewer countries rely on natural gas than on oil. Fifty-seven countries with a population of almost two billion people use gas for 20% or more of their primary energy supply. Among those, 16 countries (with a combined population of over 350 million people) use natural gas for more than half of their energy needs. A further 850 million people in 21 countries rely on natural gas for between 10% and 20% of their energy. Further analysis in this section relates to these 78 countries (which notably exclude India and China, where the consumption of natural gas is still not very high, although it is projected to grow rapidly).

Most of the countries using natural gas have to rely on imports. Almost 650 million people live in 32 countries that import over 75% of all their gas needs. All of these countries are in Eurasia: most are in Europe, Turkey, and the former Soviet Union, but they also include Jordan, Singapore, Korea, and Japan. Remarkably, only seven of these highly import-dependent countries have LNG facilities. Of those, Korea and Japan only import natural gas through LNG facilities, and the remaining countries use pipeline imports as well. The remaining 25 highly import-dependent countries do not have LNG re-gasification terminals and rely exclusively on pipelines for gas imports. Eleven of those countries are landlocked and thus have no prospects of benefiting from LNG trade (Coutsoukis, 2008). At the same time, global LNG markets are rapidly expanding (IGU, 2010).

There are 35 countries, with a combined population of over 750 million people, which import more than 50% of their gas needs, while the number of people living in countries which import over 25% of their gas needs is almost 2.2 billion.

Among the countries that import less than 50% of their natural gas needs, including those relying on domestic reserves (such as the United Kingdom, the United States, Bangladesh, Mexico, Thailand, Brazil, and Argentina), 12 (780 million people) have a domestic reserves/supply ratio under 16 years, which signals the likely increase in import dependency in the near future.

Thus, over 1.5 billion people live in countries that are either seriously dependent on imported natural gas or are likely to experience such dependency soon. In addition, the majority of the 37 countries (with over 2.5 billion people) relying on natural gas for more than 10% of their supply experienced a growth rate of over 6% per year over the last decade, which is likely to put further pressures on their natural gas supply.

Global coal supply vulnerabilities

Coal is the world's fastest growing fossil fuel energy source, currently providing about one-third of the global primary energy supply. Similarly to oil and gas, coal is a non-renewable fuel that is traded on the global market. However, coal is different than oil and gas in several important aspects, which affect the vulnerability of coal supplies.

First of all, the worldwide reserves of coal are larger than those of conventional oil and gas, although they are subject to large uncertainties, as explained in detail in Chapter 7. The global R/P ratio of coal varies between different organizations and years in which estimates are provided but is generally believed to exceed 130 years.[7] Global coal production is expected to increase by some 14%, growing on average at 0.6% per year until 2035 in the WEO's New Policies Scenario. All of this growth is projected to come from non-OECD countries, with over 90% concentrated in China, India, and Indonesia (IEA, 2010a).

Global coal reserves are not as geographically concentrated as those of oil and natural gas. The United States, China, India, and the former Soviet Union together account for some 80% of global hard core reserves. Southern Africa and Australia account for 13% of the remaining 17% of reserves, with the remainder being split among the rest of the world. However, the existing coal reserves and production capacities are largely located in the same countries that consume or are expected to consume the majority of coal. For example, the WEO projects that China will account for half of global coal production in 2035 but will also consume all of this coal, being the largest world consumer and producer at the same time (IEA, 2010a). International trade in coal was only 16% of its total consumption in 2009 (compared to 66% of oil and 29% of natural gas). It may nevertheless increase in both the short and medium term. The main driver of this increase will be consumption and production of coal in China. In 2009, China's imports of coal tripled, but their growth in the future will be determined by the competitiveness of imported coal against the coal domestically produced and transported from China's western provinces. In the WEO's projections the share of globally traded coal will remain at approximately today's 16% of global demand, whereas the absolute volume of trade may grow some 15%. In this scenario the largest exporters will be Australia and Indonesia, and the largest importer, India.

The geographic distribution of coal reserves means that supplies of coal are less likely to be disrupted for such "geopolitical" reasons that are much feared in the cases of oil and gas. However, coal production may be slowed down because of its severe environmental and health costs. (Coal has the highest greenhouse gas emission factor of all fuels and also contributes significantly to local air pollution). Global climate change policies may also affect coal affordability (if carbon capture and storage becomes a requirement). If coal becomes a globally traded commodity, fluctuations of domestic currencies and a host of other factors can also affect its price.

As with other fuels, domestic availability of coal does not automatically mean that it is easily accessible to consumers. A case in point is China, whose reserves are mainly found in its western provinces, while consumption is concentrated on its east coast. Given China's rapidly rising consumption levels, its transport infrastructure faces heavy capacity challenges (see Box 5.6).

7 The BP *Statistical Review of World Energy 2007* gives a coal R/P ratio as 133 years at the end of 2007 (BP, 2007). The *World Energy Outlook 2010* (IEA, 2010a) notes a 1:150 R/P ratio.

Box 5.6 | Coal Use in China

China relies heavily on coal as a primary fuel for industrial use and electricity generation. Coal combustion provided 65% of national electricity in 1985 but ballooned to more than 80% in 2006 (though it shrank to 71% in 2008). From 2002 to 2007, demand for electricity in China grew by about 12%, and more than 70,000 MW of capacity were brought online to meet it. A majority of this capacity was coal-fired, and China is currently constructing the equivalent of two 500 MW coal-fired plants per week, or a capacity comparable to the entire power grid in the United Kingdom every year. During this time, every week to 10 days over the course of five years, a coal-fired power plant opens somewhere in China big enough to serve all of the households in Dallas or San Diego. More than half of China's total coal use is in the non-electricity sector. Coal provides 60% of Chinese chemical feed-stocks, 55% of industrial fuel, and about 45% of China's national railway capacity is devoted to the transport of coal. Coal is, therefore, China's most abundant and widely used fuel, and China is the world's largest coal producer (mining about 2.3 billion tons per year compared to just 1.1 billion tons in the United States). Put another way, coal production and consumption account for more than 65% of China's total energy supply and use. China already uses more coal than the European Union, Japan, and the United States combined.

In 2009, coal imports of China tripled, and for the first time it became a net coal importer. This import dependency may be reversed if coal production capacities of remote western provinces are utilized. For example, the province of Xinjiang holds about 40% of China's total coal resources. According to the expectations of its regional government reported by the IEA (2010a), the planned upgrade of the railway line linking Xinjiang to the east coast may help to increase coal production there by more than 10-fold so that its share of global coal production will be double the share of current oil production of the world's biggest oil field, Ghawar in Saudi Arabia.

Source: IEA, 2010a; Sovacool and Khuong, 2011.

National coal supply vulnerabilities

At present, 4.2 billion people live in 45 countries where coal represents more than 10% of the primary energy supply. About 3.4 billion people live in 28 countries (including China, India, Japan, and the United States) where coal represents more than 20% of the total primary energy supply. About 1.4 billion people live in seven countries (including China) where coal accounts for more than one-half of the total primary energy supply. In Mongolia, South Africa, and the Democratic People's Republic of Korea, more than 70% of the primary energy supply is derived from coal.

Only seven of these 28 countries (approximately 300 million people) import more than 80% of the coal they consume. These include Japan, which imports 100% of its coal. Some of these countries (e.g., Morocco, Slovakia, and the Republic of Korea) may be considered especially vulnerable, as either their coal consumption has been growing at over 5% per year or their economies have very high coal intensities. Despite its rapidly growing coal extraction, India is a net coal importer and is projected to increase its imports of coal more than five-fold between 2008 and 2035 (IEA, 2010a).

Most of the countries that significantly rely on domestic coal (net exporters and those that import less than 50% of their consumption) have a domestic resource/consumption ratio of over 30 years. The only exception is Vietnam, for which this ratio is 8.5 years. This makes the situation for coal very different than that for oil and gas, where import dependency is likely to significantly increase in a large number of countries even if the current levels of consumption do not notably grow.

5.2.2.2 Nuclear Power

Global nuclear energy supply vulnerabilities

Whereas the energy security concerns related to fossil fuels are primarily related to the supply and demand of resources, in case of nuclear power the primary concerns relate to nuclear energy infrastructure and technologies. Unlike fossil fuels, the fuel of nuclear energy (uranium) has a fairly high security of supply, offers protection from fuel price fluctuations, and is possible to stockpile. In comparison to oil and gas, uranium is abundant and more geographically distributed, with a third of proven reserves in OECD countries (NEA, 2008). Recent estimates indicate that even in the face of a large expansion of nuclear energy, proven uranium reserves would last at least a century (Macfarlane and Miller, 2007; NEA, 2008).[8] Furthermore, electricity produced from nuclear energy offers a greater protection from fluctuations in raw commodity prices; while doubling uranium prices leads to a 5–10% increase in generating cost for nuclear power, doubling the cost of coal and gas leads to a 35–45% and 70–80% increase, respectively (IAEA, 2008). Uranium is also a relatively easy fuel to stockpile. The refueling of a nuclear power plant generally provides fuel for two to three years of operation (Nelson and Sprecher, 2008), and it is possible to store up to a 10-year supply of

8 Chapter 7 contains a more extensive discussion of uranium resource availability.

nuclear fuel (IAEA, 2007b). In contrast, oil and gas emergency reserves, where they exist, are measured in days, weeks, or – in exceptional cases – months, not years.

At the same time, there are significant energy security risks associated with technological, economic, and institutional characteristics of nuclear power production. As the most capital-intensive electricity-generation technology, it is economically difficult for nuclear energy to compete in liberalized markets where the investor has to assume the financial risk of investment. As a result, strong government backing is necessary for the development of nuclear power (Finon and Roques, 2008). Such political backing depends on the public support of nuclear power, which has been very uneven. In particular, public opinion is swayed by nuclear accidents such as the ones at Three Mile Island in the United States in 1979, Chernobyl in the USSR in 1986, and Fukushima in Japan in 2011. Each such change of public opinion and the resulting change in the government policy may affect energy security both in the short term (e.g., as a result of shutting down nuclear power plants immediately affected by the accident[9] and those deemed unsafe) and in the longer term (through complicating the investment climate). Unlike other energy sources and electricity-generating technologies, for nuclear energy the risks associated with accidents extend beyond the plant level or national level to the entire nuclear power plant fleet. Thus, nuclear power globally faces the systemic risk of nuclear accidents.

Additionally, in most countries nuclear power plants are aging and often reaching the end of their licenses. The mean age of nuclear power plants worldwide is 26 years (calculated from IAEA, 2010). Since the standard lifespan of nuclear power plants is 30–40 years, many plants are nearing the end of their planned operational period. The IAEA has recently begun efforts to create a dialogue on effective management and safety enhancements to extend the lifespan of many of the world's nuclear power reactors (IAEA, 2007a). The power plants are not the only part of the industry that is old; in many countries the industry faces an aging workforce and a dearth of young workers to replace retiring nuclear engineers and plant operators (Sacchetti, 2008).

Nuclear power and other thermal plants are also subject to heat waves and water shortages. In 2006, France, Spain, and Germany had to shut down or scale back electricity production in several of their nuclear power plants due to low water levels. With growing concerns over water availability due to increasing pressure from uses and climate change, thermal power plants could face problems involving water supply more frequently. In addition to these robustness concerns, there are also sovereignty issues associated with nuclear power since capacities for fuel enrichment and nuclear reactor construction are concentrated in relatively few countries. Only six countries currently possess large-scale enrichment plants, and seven countries possess small-scale enrichment facilities (see Figure 5.5).[10] The fact that several countries (including Australia, Brazil, and South Africa) are considering constructing enrichment facilities indicates that even though countries can relatively easily stockpile nuclear fuel, national governments may feel too vulnerable if they rely solely on foreign suppliers. In addition to the concentration of nuclear fuel enrichment, construction capacity for new nuclear power plants is concentrated in just 12 companies in eight countries (see Figure 5.5). The number of countries holding the ability to forge the bottleneck component of large LWR pressure vessels is currently even more restricted.

National nuclear energy supply vulnerabilities

Currently, 29 countries with a total population of 4.4 billion people operate nuclear reactors. Nuclear power is located in middle- and high-income countries that are almost all relatively stable (see Figure 5.5). Nuclear energy comprises more than 10% of the electricity supply in 21 countries with a population of 1.3 billion people. Of these, only 200 million people live in 13 countries that rely on nuclear energy for at least 30% of their electricity generation, and about 80 million people live in three countries that rely on nuclear energy for more than 50% of their electricity production.

The most pressing energy security concerns for nuclear power in most countries are robustness concerns related to the age and obsolescence of their nuclear power programs combined with a lack of recent investment. Twenty-one out of the 29 countries with nuclear power (with a combined population of 1.3 billion people) have not started constructing a new nuclear power plant in the last 20 years. Without new nuclear power plants, the nuclear industry in these countries lacks the vitality of recent activity. This can, in turn, lead to a lack of dynamic capacity needs of the industry, from both a human resources and a manufacturing perspective.

There is also clear evidence that many of the countries with stagnating nuclear power programs face imminent human resources shortages. A nuclear industry institute in the United States reports that in the next five years as much as 35% of the nuclear workforce may reach retirement (NEI, 2010). The United Kingdom and Germany also face a dearth of young qualified workers: over 75% of nuclear employers in the United Kingdom report that they have trouble filling scientific and engineering positions, and in Germany in many recent years not a single person has graduated in a nuclear discipline (Sacchetti, 2008).

Nineteen of the 29 countries that use nuclear energy (with a combined population of 1.4 billion) have nuclear power plants with an average age greater than 25 years (see Table 5.7). While countries can extend the operating licenses of their existing nuclear power plants, this raises

9 For example, in the immediate aftermath of the March 2011 earthquake in Japan, 10.5 GW of nuclear power capacity was shut down (Nakano, 2011).

10 There are conventional security concerns linked with uranium enrichment due to the link between civilian enrichment capabilities and nuclear weapons. This topic is beyond the scope of this chapter but is discussed in detail in Chapter 14 (Nuclear Energy).

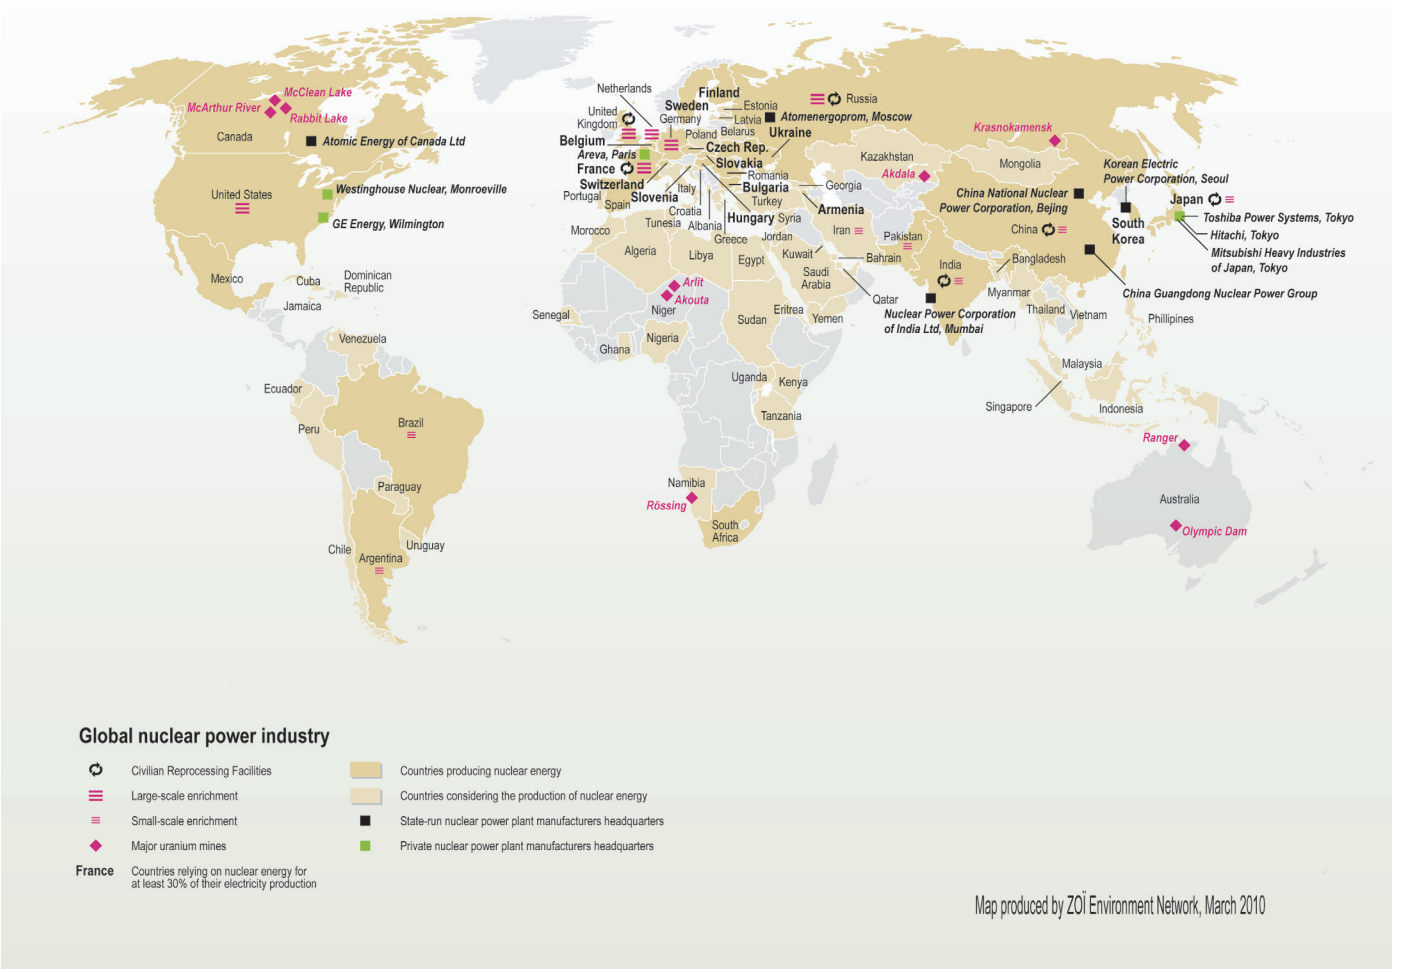

Figure 5.5 | Nuclear power worldwide. The figure shows the concentration of nuclear power and related capacities in a few industrialized countries in the Northern Hemisphere. It also indicates the aspirations of a large number of new countries, predominately in the developing world to deploy nuclear energy. Source: NEA, 2008; IAEA, 2011; Jewell, 2011; World Nuclear Association, 2011a; b; c.

Table 5.7 | The average age of nuclear power plants and the date of the start of the most recent construction.

Start of the most recent construction (years prior to 2010) Average age of NPPs (from the time of completion), years	Less than 22	22 or more
Less than 25	China, Brazil, India, Rep. of Korea	Czech Republic, Bulgaria, Ukraine, Slovakia, Romania, Mexico
More than 25	Russia, Japan, France, Pakistan, Finland	UK, USA, Canada, Germany, Argentina, Sweden, Belgium, Spain, Hungary, South Africa, Slovenia, the Netherlands, Switzerland, Armenia

safety concerns, especially in the wake of the Fukushima nuclear accident, which occurred at an older power plant. In Vermont, in the United States, the state legislature recently voted down extending the license of its nuclear power plant, which currently meets 73% of electricity demand, due to safety concerns over the 28-year-old plant.

Countries with aging plants will face the decision of whether to invest the required resources to jump-start a stale industry or redirect resources to fill the gap that aging nuclear power plants will open up. Such countries as the United States, the United Kingdom, and South Africa have recently expressed interest in restarting their nuclear power programs. However, the ability of these plans to get off the ground remains to be seen. This fact, combined with the lack of recent construction experience in all but eight countries (Table 5.7), indicates that nuclear power faces significant robustness challenges in almost three-quarters of the countries with nuclear power.

Due to safety concerns regarding the obsolescence of the operating technology, Bulgaria, Lithuania, and Slovakia were forced to close their early Soviet-designed plants as a precondition for accession to the EU. Since the Chernobyl-style nuclear power plant in Lithuania, the most recent EU Member State to close its nuclear reactor (at the end of 2009), met about 70% of its electricity demand, the government has had to seriously reconsider its energy strategy. The only

remaining countries that operate Chernobyl-type reactors are Armenia and Russia. Although not an EU candidate country, Armenia has come under significant pressure from both the EU and neighboring Turkey to shut down its nuclear power plant. However, as the nuclear power plant currently meets almost 40% of its electricity generation, there is resistance.

In addition to the 29 countries currently operating nuclear power, an additional 52 countries, often citing growing energy security concerns and electricity demand, have expressed interest in starting a national nuclear power program (Rogner, 2009). While nuclear energy can affect energy security in both types of countries, in so-called "newcomer countries" the energy security risks pertain to the *potential of* and *capacity for* nuclear energy rather than risks to current generating capacity (Jewell, 2011). These newcomer countries will be discussed in Section 5.3.2, which explores the future of energy security.

5.2.2.3 Hydroelectric Power

Global hydropower supply vulnerabilities

Although hydropower is a renewable resource and hydroelectricity is not associated with massive global trade, as in the case of fossil and nuclear fuels, there are still related energy security concerns from the robustness, sovereignty, and resilience perspectives.

With respect to robustness, hydropower is vulnerable to seasonal and annual variability in hydrological regimes, as well as local weather conditions, temperature, and precipitation in the catchment area. These factors affect not only the availability of water for hydropower production, but also the amount of pressure on water resources in a region from competing uses.

The pressures on hydrological resources are likely to be exacerbated by climate change and shifting hydrological patterns. According to the Intergovernmental Panel on Climate Change (IPCC) (Bates et al., 2008), climate change is likely to alter river discharge, and thus water availability, for hydropower generation, although the exact extent of these effects is difficult to forecast. Furthermore, intensified glacial melting, while it initially has a positive impact on hydropower production, will eventually lead to reduced water flows and could seriously affect regions with glacier-fed rivers used for power production.[11] Additionally, an increase in the frequency of extreme weather events (both floods and droughts), which is predicted by the IPCC to accompany climate change (Bates et al., 2008), could alter the temporal availability of hydropower resources and place a greater stress on hydroelectric dam infrastructure.

11 Rain rather than snow in the winter will lead to less snow pack acting as a reservoir for the spring and summer months, leading to summer shortages. Higher temperatures can lead to more evaporation and less generation. Higher summer temperatures lead not only to water scarcity but also to higher electricity demand for air conditioning. This puts an additional pressure on electricity generation.

In addition, changes in the available discharge of a river might have a direct influence on the economic and financial viability of a hydropower project, since hydropower plants have a life of more than 50 years. Even if a significant part of the changes takes place in the distant future, the impacts are inevitable. For instance, in North America, potential reductions in the outflow of the Great Lakes could result in significant economic losses as a result of reduced hydropower generation both at Niagara and on the St. Lawrence River. For a Coupled Global Climate Model (CGCM1) projection with 2°C global warming, Ontario's Niagara and St. Lawrence hydropower generation would decline by 25–35%, resulting in annual losses of C$240–350 million at 2002 prices (Buttle et al., 2004).

Changing hydrology, but also possible extreme events such as floods and droughts (which are expected to increase as a result of climate change), pose sediment risks. More sediment, along with other factors such as a changed composition of water, could raise the probability that a hydropower project suffers greater exposure to turbine erosion. When a major destruction actually occurs, the cost of recovery will be enormous. An unexpected amount of sediment will also lower turbine and generator efficiency, resulting in a decline in energy generated (Iimi, 2007).

In addition to these relatively gradual pressures that hydropower faces, there is the risk of sudden failure either from terrorism, faulty construction, or aging infrastructure. A report by the American Society of Civil Engineers (2009) recently highlighted the risk of dam failure as hydropower dams age.

From the sovereignty perspective, energy security risks associated with hydroelectricity primarily arise in situations where multiple countries share rivers feeding hydropower dams. In such cases, competing uses on different sides of a national border can be exacerbated by the fact that upstream countries can significantly affect the quantity and quality of hydrological resources that a downstream country receives. For example, China's plans to build a series of dams on the Mekong has raised significant concerns downstream in Vietnam, where scientists worry that the planned dams would significantly accelerate the disappearance of the Mekong Delta, thus decimating fisheries and livelihoods of locals in the region. Another example of water scarcity and conflicting uses of water between sectors is manifested in the ongoing tension in Central Asia, where downstream countries (Kazakhstan, Uzbekistan, and Turkmenistan) prefer to use water for irrigation in summer, while upstream countries (Tajikistan and Kyrgyzstan) need it for generating hydroelectricity in winter.

Finally, from the resilience perspective, energy security of hydropower may be considered to be under threat where a nation's electricity is supplied from just one or a few major hydroelectric facilities and thus is vulnerable to failures of these facilities.

National and regional hydropower supply vulnerabilities

Hydropower accounts for at least 20% of electricity generation in 58 countries with a combined population of 1.5 billion people and for at

least 10% of electricity generation in 74 countries with a combined population of 4.6 billion people. About 800 million people live 35 countries that derive over half of their electricity from hydropower. The risks to hydroelectric production are highly contextualized and subject to local factors. This brief assessment considers the regional vulnerability of hydropower to climate change and the diversity of hydropower facilities in a particular country.

The IPCC's projections (Bates et al., 2008) for the impact of climate change on hydropower are available for the following regions:

In Europe, the IPCC's estimates state that the total European hydropower potential is projected to decrease by 7–12% by 2070s. The highest decreases of 20–50% are expected in Portugal, Spain, Ukraine, and Bulgaria. Some countries in Southern Europe are already vulnerable to water shortages. Albania, where 92% of power comes from hydro resources, has experienced severe shortages of power for a few consecutive summers. At the same time, in some parts of Europe, such as Scandinavia and northern Russia, the electricity production potential of hydropower plants is expected to increase by 15–30% by the end of the century.

In Africa, where little of the continent's hydropower potential has been developed, climate change simulations for the Batoka Gorge hydroelectric scheme on the Zambezi River projected a significant reduction in river flows and declining power production (a decrease in mean monthly production from 780 GWh to 613 GWh).

In Asia, changes in runoff could have a significant effect on the power output of hydropower-generating countries such as Tajikistan, which predominately relies on hydropower for its electricity needs and is among the larger hydroelectricity producers in the world. Climate change will also result in an increase in the frequency and duration of extreme climate events, i.e., floods and droughts. For instance, a hydrological model indicates a great risk of substantial increases in (mean) peak discharges in the three major rivers in Bangladesh: the Ganges, Brahmaputra, and Meghna (Iimi, 2007).

In Latin America, where hydropower is one of the main electrical energy sources, expected further glacier retreat is projected to negatively impact the generation of hydroelectricity over the long term in countries such as Colombia, Bolivia, and Peru (Bates et al., 2008). The consequences of droughts and increased energy demand caused a virtual breakdown of hydroelectricity in most of Brazil in 2001, which contributed to a GDP reduction of 1.5% (Kane, 2002). More recently, because of a shift in precipitation patterns due to El Niño, Venezuela experienced a water (and hydroelectricity production) shortage. President Chavez ordered a 20% reduction in electricity consumption in December 2009 (Cancel, 2009).

In 10 countries (with 100 million people), hydropower is derived from one dam; another 11 countries (with 290 million people) rely on one major dam and one to three significantly smaller dams (with a combined capacity less than half the size of the main dam). In another 10 countries, 330 million people rely on two major dams and one to four significantly smaller dams. Ten countries with 560 million people rely on at least three main dams for electricity supply, and 16 countries with 260 million people have four or more dams.

5.2.2.4 Traditional Biomass

There are several difficulties in assessing the vulnerabilities of biomass supply. First, biomass comes in a variety of very different forms ranging from dung, firewood, and charcoal to biodiesel, ethanol, palm oil, and specially grown plant species. Secondly, the flows of "traditional" biomass (which is not commercially produced, processed, and distributed) are often difficult to estimate. The available statistics often do not distinguish between "modern" and "traditional" *solid* biomass, especially when "modern" is used in a decentralized fashion. Yet different types of biomass are associated with different risks and vulnerabilities. We discuss traditional biomass in this subsection and further deal with modern *liquid* biomass (i.e., biofuels) in the next subsection.

Traditional biomass is primarily used for heating and cooking in residential buildings. It is estimated that 2.5 billion people rely on such energy in their daily lives. Over half of these people live in India, China, and Indonesia. In some countries, mainly in sub-Saharan Africa, these sources account for 90% of total household energy use. The main threats to traditional biomass availability are resource scarcity resulting from the growing demand (population growth, migration and other demographics, growth in consumption) and depletion of resources (change of land use, climate change). Though demand for wood-fuel is unlikely to deplete or remove forest cover on a large scale (Arnold et al., 2006), localized wood-fuel scarcities may indeed be projected to occur in parts of Southeast Asia and Africa.

Access to traditional energy resources may be further restricted for political or economic reasons. In many countries large portions of forest areas are controlled by the government, and access and use of firewood might therefore be limited. For example, in India in the mid-1990s about 55% of household needs for firewood were collected for free from common pool resources (CPRs). The share of CPRs has been shrinking at a five-yearly rate of 1.9%; coupled with decreased productivity of what remains, this has seriously restricted the CPRs' ability to meet the growing demand (Chopra and Dasgupta, 2000). Formal and informal privatization of land holdings in Africa have similarly reduced the areas available as CPRs, leading to local scarcity and shortages of firewood (Arnold et al., 2006). Seasonal variability is also an important factor that might undermine the availability of resources: bio-waste is abundant in the time of harvest; without appropriate storage capacity it is difficult to sustain the supply through the year.

Traditional biomass energy systems are typically inefficient, unreliable, and unsafe, with high environmental, social, and health externalities. They often fail to provide the level of services associated with modern energy systems (e.g., adequate heating in winter) and may not be equally available to vulnerable groups (elderly, disabled, landless, etc.). Therefore, residential energy sectors relying on traditional biomass are in most cases considered inadequate and need to be replaced by modern systems. We return to this issue in Section 5.3.3.

5.2.2.5 New Renewable Energy Sources

New renewable energy sources (NRES) include "modern" biomass (in solid, liquid, and gaseous forms), wind, solar photovoltaic, solar thermal, geothermal, tide, waves, and ocean current energy. NRES can provide most of the nationally vital energy services by generating electricity or heat, or providing liquid fuels for transportation. Despite being labeled together as "renewables," these are very different energy sources potentially associated with distinct energy security concerns. At present, these sources significantly contribute to energy supply in only a small number of countries, so there is much less empirical evidence on the nature and scale of their potential disruptions than for traditional energy sources summarized in the previous sections. Therefore, the discussion in this section is limited to general considerations and a brief overview of available quantitative data.

The main robustness concern related to fossil fuels – finite resources – is not applicable to NRES. Instead, the main concerns about the robustness of NRES are costs, intermittency, and sufficient availability in locations where they are needed. With respect to costs, vulnerabilities of NRES are different from vulnerabilities of fossil fuels because the running (fuel) costs account for a much smaller share in the total cost of energy (except solid and liquid biomass). This means that, although NRES are less vulnerable to price fluctuations, they may be more expensive in terms of total lifetime costs per unit of energy. Intermittency of NRES (with the exception of biomass and geothermal) is another concern: it is connected with daily, seasonal, or other variations in natural factors (sun, wind, tides). The impacts of intermittency can be reduced if NRES sources are integrated in larger networks where energy generated in one part of the system can compensate for the shortage of energy in another part. Developing technological solutions concerning electricity and heat storage may be another answer to the challenge of intermittency. More details on these solutions are provided in Chapter 11 (Renewable Energy).

Sovereignty concerns are in general less pronounced in the case of NRES. This is because most NRES are found locally and do not need to be imported as other fuels. The exception is liquid biofuels, which are already traded on a global scale, with Brazil and the United States accounting for over 90% of world production in 2007 (Balat and Balat, 2009). At the same time, most NRES require cutting-edge technologies that are not readily available for the majority of countries. There are signals that dependencies in renewable energy technologies may be perceived as energy security concerns by some countries (Burnett and Dwyer, 2011).

NRES also seem to be associated with better resilience than mainstream energy sources. This is because energy systems based on renewables are typically more diverse with respect to energy sources and more distributed in space. It has been argued (Lovins and Lovins, 1982) that such diversity means better protection from human or natural disruptions. Farrell et al. (2004) partially confirm this conclusion, but indicate that much more research needs to be done concerning the resilience of distributed energy generation.

Thus, NRES are widely perceived as providing better energy security, particularly from the sovereignty and resilience perspectives. That is why promotion of NRES figures prominently in almost all national energy security strategies. Although the number of countries where NRES comprise a significant share in energy supply remains small, some of these (notably the United States, Germany, Spain and China) have witnessed significant growth in NRES in recent years. Detailed information on the growth in the use of renewable energy resources in the world is provided in GEA Chapter 11.

In the residential sector, modern biomass (including waste residues) comprises over 10% of energy use in such high-income countries as Austria, Denmark, Finland, Estonia, France, Croatia, Slovenia, and Greece. Biofuels are used for transport in Brazil (15.4% of the overall transport energy use), Germany (7.2%), Cuba (6.3%), France (3.2%), and the United States (2.3%), as well as in insignificant amounts in smaller countries (IEA, 2010b).

As this discussion shows, energy security concerns associated with NRES are difficult to quantify empirically because the share of NRES in the total energy supply remains limited in the majority of countries. If large shares of renewables were to be used around the world, it might change the energy security landscape considerably and new energy security threats might emerge (e.g., demand for water and arable land). For example, it may turn out that trade in biofuels will acquire many characteristics of the current global oil market, which, as we argued, has many vulnerabilities. Answering these concerns about the security of future energy systems where NRES play a large role is beyond the scope of this chapter. Instead, they are systematically addressed in Chapter 17, which analyses energy security implications of major energy transformations.

5.2.2.6 Overall Energy Supply Security

The sectoral energy security analysis presented in the previous sections makes the most sense for identifying vulnerabilities to relatively minor disruptions unfolding in the short or medium term, when the elements and connections within energy systems remain largely fixed. Under such conditions we can make certain assumptions concerning the

propagation of risks and vulnerabilities. For example, we assume that if the supply of petroleum products is disrupted, the transport system will be affected. However, over a longer term or under much stronger shocks, the energy system may become reconfigured. Liquid fuels may be produced from coal or biomass, or electrically-driven trains may take more cargo and passengers. System-wide, cross-sectoral indicators may reflect the more general vulnerabilities of national energy systems to systemic shocks and long-term threats.

We use both supply and demand indicators of cross-sectoral vulnerabilities of energy systems. On the supply side, we consider the overall import dependency, the diversity of primary energy sources, and the cost of imported fuels as a proportion of GDP or export earnings. On the demand side, we consider the total energy intensity, the overall rate of demand growth, and energy use per capita.

With regard to the supply side, 46 countries (700 million people) have a total energy import dependency higher than 50%. Fifty-eight countries (one billion people) have a low diversity (one or two dominant sources) of primary energy supply. For 15 countries (200 million people), the cost of imported fuels is higher than 10% of GDP, and for 35 countries (2.5 billion people), the cost of energy imports exceeds export earnings by 20% or more. In total, there are 102 countries (3.8 billion people) that are vulnerable in at least one of the abovementioned aspects.

In relation to the demand side, in 24 countries with 400 million people energy use per capita intensity exceeds the world average by more than 50%. In 18 countries (1.8 billion people), including China, the average annual growth in energy use has been higher than 6% over the last decade. There are 55 predominately low- and lower middle-income countries (three billion people) with energy use per capita of 30 GJ/year or lower. Such levels of energy use – at least three times less than even in the least energy-intensive developed countries such as Israel, Italy, or Japan – are likely to signal pressures on energy systems to rapidly and radically increase production to meet the future demand. There are 76 countries (4.7 billion people), primarily low- or lower middle-income, subject to at least one demand-side vulnerability mentioned above.

Cross-sectoral demand- and supply-side vulnerabilities overlap in 63 countries with 2.8 billion people, of which 47 are either low- or lower middle-income countries. Additionally, three billion people live in 52 countries that have either cross-sectoral demand or cross-sectoral supply vulnerabilities. Only 19 countries with 600 million people can be considered free from overall energy supply vulnerabilities.

5.2.3 Security of Electricity Systems

5.2.3.1 General Considerations

Due to the large and growing importance of electricity systems, the risks of their potential disruption are increasingly prominent on energy security agendas. The importance of secure delivery of electricity is growing in every country due to:

- the increasing dependency on electricity (for example, in the information and communications technology [ICT] sectors, and eventually in the transportation sector) of modern economies;
- the expansion in the coverage of electricity grids in developing nations;
- the increasing "electrification" of energy services in emerging economies where the entry into the middle class is often signaled with the arrival of domestic electrical appliances; and
- the advance of "new" energy systems relying on distributed generation, renewable energy sources, and possibly electric propulsion for vehicles.

In contrast to other energy carriers, electricity cannot at present be stored cheaply and easily and should in many critical cases be supplied without any interruption, closely matching the changing demand. This makes electricity systems vulnerable even to short-term disruptions and imposes particularly stringent requirements on electricity generation, conversion, and transmission. The vulnerability of electricity systems can be considered from robustness, sovereignty, and resilience perspectives.

In this analysis we use four indicators to estimate the robustness of electricity systems. Two of them relate to the supply side: the age of electric power plants and the frequency of blackouts. The two others relate to the demand side: the rate of access to electricity and the growth in demand for electricity. Rapid demand growth increases the pressure on existing electricity systems and stimulates countries to seek new sources of energy.[12] Another demand-side vulnerability is the inadequate provision of electricity, reflected in a low rate of access to electricity. The low access rate is untenable for most governments, and therefore results in pressures on the energy system to expand. Thus, all else being equal, a country with low access or higher growth will be less secure, as it will need to expand rather than merely maintain its electricity supply at the present level. Our analysis also considered the third demand-side vulnerability factor: the electricity intensity of the economy. In principle, more electricity-intensive economies should be more sensitive to energy price fluctuations and other disruptions of electricity systems. However, electricity intensity was not found to be a sufficiently discriminating factor in the final analysis.

The sovereignty perspective on the security of electricity systems is reflected in the reliance on imported fossil fuels for electricity generation and on imports of electricity. Finally, a proxy indicator for the resilience

12 Jewell (2011) demonstrates that the rapid growth in electricity demand has correlated with countries launching nuclear energy programs.

of national electricity systems used in this analysis is the diversity of fuels used for electricity generation.

In many industrialized countries, electricity subsystems are undergoing transformations. These include distributed decentralized generation, "smart grids," and possibly an increasing role of international interconnectedness and electricity imports. Energy security factors associated with these new developments will play increasingly important roles in the security of electricity generation, distribution, and transmission in the future. For example, it is often argued that distributed generation of electricity will result in higher reliability and resilience of energy provision (Lovins and Lovins, 1982). At the same time, the empirical evidence that distributed systems are more robust than centralized ones seems to be inconclusive (Farrell et al., 2004). Key technological and institutional developments that may affect the reliability of electricity systems are discussed in Chapter 15.

5.2.3.2 Vulnerability of National Electricity Systems

The primary energy security concerns from the perspective of robustness of electricity systems include the aging of power plants, rapid growth in demand and/or lack of adequate provision of electricity, and the reliability of electricity systems. The aging of power plants is particularly a problem for industrialized countries with established and stagnant fleets. Especially problematic is the aging of nuclear reactors because they typically provide large shares of national electricity and their replacement with other nuclear reactors may be problematic for economic and political reasons (see a more detailed discussion of this point, as well as statistics on the aging of nuclear reactors, in the previous section). Non-nuclear generating facilities are also aging in many countries. For example, in the United Kingdom, the aging of power stations is one of the three major national energy challenges (the other two being decarbonization and an increasing reliance on imported natural gas – see Figure 5.6).

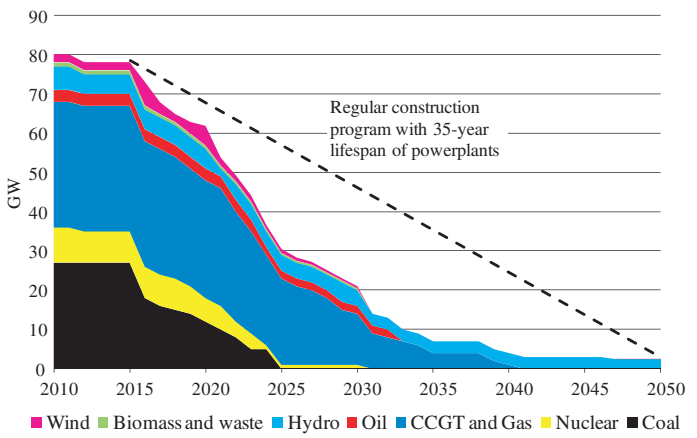

Figure 5.6 | Projected retirement of electricity-generating capacity in the United Kingdom. The figure shows the decline in capacity much faster than if the regular pace of construction was maintained in recent years (as shown by the dotted line). Source: Parsons Brinckerhoff, 2009.

The reliability of electricity infrastructure is addressed in Box 5.7. The scale of the problem is dramatically higher in low- and middle-income countries, although it is high on the political agenda of industrialized nations as well because their economies are increasingly sensitive to even minor disruptions of electricity supply.

There are energy security concerns from the robustness perspective related to the demand side of electricity systems. There are 32 countries with a total population of some 2.4 billion people that have less than 60% access to electricity. In 35 countries with some 2.6 billion people, the electricity demand has been growing at over 6%. The need to increase electricity-generation capacities is especially dramatic in larger low-income countries. For example, Ibitoye and Adenikinju (2007) estimate that under the assumption that Nigeria becomes a middle-income economy and meets its Millennium Development Goals by 2030, it will need to achieve a 25-fold increase in its electricity-generating capacities (from the current 6.5 GW to 164 GW). All in all, 53 countries with some 4.2 billion people experience either one or both of these demand-side vulnerabilities.

The importing of fuels for electricity production or the importing of electricity itself are considered an energy security concern in some countries. Almost 1.3 billion people live in 62 countries that rely on imported energy for more than 25% in their electricity, almost 600 million live in 39 countries importing over 50%, and almost 200 million live in 21 countries that import over 75% of energy for electricity production. Most of this energy is imported in the form of fuels for electricity production rather than directly as electricity imports.[13]

From the resilience perspective, the security of electricity systems may be measured as the diversity of fuels used for electricity generation. The Shannon-Weiner Diversity Index[14] of such fuels is less than 0.2 in 30 countries, which are home to some 360 million people. This means that virtually all of their electricity comes from a single source (often hydropower or natural gas-fired power plants). Even the diversity index of 0.4 (applicable to some 450 million people in 35 countries) can still be considered low.

All in all, some 990 million people live in 62 countries where electricity systems are vulnerable with respect to supply, because they are either significantly (over 40%) based on imported fossil fuels and/or have a low (<0.4) diversity of electricity generation.

13 There are only 12 relatively small countries (six in Europe and six in sub-Saharan Africa) that import more than 25% of the electricity they consume.

14 The Shannon-Wiener Diversity Index (SWDI) is a most common measure of diversity of options or categories. It is based on the idea that the greater the variety and the more even the spread the greater is the diversity. The index is calculated as: $SWDI = -\Sigma_i p_i \ln p_i$, where pi represents the share of each category/option in the energy mix (Stirling, 1998; Jansen et al., 2004).

Box 5.7 | Reliability of Electricity Supply

Challenges for ensuring adequacy and reliability of electricity grids exist for both developed and developing countries. For developing countries, extending electricity networks and increasing generating capacity is the main challenge. Even for households connected to electricity grids, planned outages due to the lack of generating capacity are not uncommon. At the same time, an increasing number of emerging economies and all industrialized countries have sufficient network coverage and generating capacity. However, precisely because these societies rely heavily on permanent access to electricity, any disruptions of the systems are potentially very harmful. The increasing scale, complexity, age, and interconnectedness of modern electricity grids present a serious investment and energy security challenge worldwide.

Advanced electricity distribution systems are spatially distributed and technically complex. The spatial extent of electricity grids means that they face "distributed threats," which are difficult to predict and manage. Moreover, the scale and the degree of interconnectedness of modern grids mean that even a minor failure can have dramatic consequences throughout the system – the so-called "cascading failure." This is especially plausible when the system operates near its critical load. Paradoxically, some measures to control small-scale blackouts may actually increase the probability and severity of large-scale blackouts, since they increase the interconnectedness and thus the size of the system that may fail (Dobson et al., 2007).

There are no comparative international statistics on the number and intensity of disruptions of electricity supply also known as blackouts. However, detailed data that exist on some industrialized countries can be not only interpreted but also compared with analysis of the situation in developing countries.

Several comprehensive studies analyze blackouts in the United States. The analysis of the US data from 1984–2006 by Hines et al. (2008) indicates that the frequency of large blackouts was not decreasing with time despite the introduction of advanced data management, reliability standards, and many other measures. A particularly catastrophic blackout on August 14, 2003 affected approximately 50 million people in the northeastern United States and parts of Canada and resulted in US$3 billion in insurance claims alone. An assessment of major electricity blackouts conducted by the Institute of Electrical and Electronics Engineers estimates that no less than 17 major blackouts have affected more than 195 million residential, commercial, and industrial customers in the United States, with seven of these major blackouts occurring in the past 10 years. Sixty-six smaller blackouts (affecting between 50,000 and 600,000 customers) occurred from 1991 to 1995, and 76 occurred from 1996 to 2000. The costs of these blackouts are monumental: the US Department of Energy (DOE) estimates that power outages and power quality disturbances cost customers as much as US$206 billion annually, or more than the entire nation's electricity bill for 1990 (Hines et al., 2008).

According to Hines et al. (2008), the single most important reason for blackouts in the United States was technical failure (nearly 30% of all events), which together with operator failure, volunteer reduction, and weather conditions accounted for over 85% of all blackouts. Intentional attacks were responsible for some 1.6% of blackouts. Larger blackouts also resulted from earthquakes and hurricanes or tropical storms.

In the report on the reliability of the US electricity system presented to the Assistant Secretary of State for Energy Efficiency and Renewable Energy, Osborn and Kawann (2001) indicate that reserve capacity margins (for both transmission and generation) have been decreasing in most US regions for the past two decades and were projected to decrease until 2020, which may be the single most important factor explaining the lack of a downward trend in the number of blackouts in the United States. The decrease in this margin can be explained by both increasing demand and falling investment in transmission and electricity grid infrastructure. The report connects this fall in investment with institutional and market failures of the electric power system.

The frequency and severity of blackouts are reportedly less in Western Europe than in the United States. Nevertheless, severe blackouts in September 2003 affected some four million people in southern Sweden and eastern Denmark, and the nationwide blackout in Italy was the worst in the history of the nation (Andersson et al., 2005).

Despite concerns that electricity blackouts cause in developed countries, their intensity is dramatically less than in the developing world. The three largest blackouts in world history occurred in developing nations, including the 2005 Java-Bali blackout in Indonesia, which affected 100 millllion people (Donnan, 2005), the 1999 South Brazil blackout, which affected 75 million people (Yu and Pollitt, 2009), and the November 2009 Brazil-Paraguay blackout, which originated in the world's second largest hydroelectric plant and left tens of millions of people in Brazil and the whole of Paraguay without electricity (Reuters, 2009).

World Bank's Enterprise Survey data (World Bank, 2010) clearly show that both the number and severity of electricity blackouts are highest for low-income countries, lower for lower middle-income countries and the lowest for upper middle-income countries in the survey. For most lower-income countries, blackouts are not measured in hours per year (as in the United States and Europe), but rather in hours per *day*. In almost three-quarters of low-income countries, blackouts are on average for more than 24 hours per month, and in about one-sixth of low-income countries blackouts average over 144 hours (six days) a month. There are more than 10 blackouts every month in more than half of the surveyed low-income countries. Companies in Albania, Guinea, Kosovo, Nepal, Pakistan, and Yemen experienced 30 or more blackouts in a month, whereas firms in Bangladesh experienced, on average, 101 blackouts per month. The worst statistics of blackouts were shown in South Asia, followed by sub-Saharan Africa. The results of this analysis should be interpreted with an understanding that companies may, in fact, experience less frequent outages than private customers, as they tend to be located in urban areas with better infrastructure.

In 28 countries with over 500 million people, high supply- and demand-side vulnerabilities overlap. These electricity systems, pressed from both sides, can be considered especially insecure. The majority of the world's population (some 4.3 billion in 65 countries) lives in countries that are vulnerable in at least one of the supply or demand aspects. Finally, some 1.6 billion people live in about 38 countries with relatively secure energy systems, which rely primarily on diverse domestic resources and have high access to electricity and moderate rates of growth in demand.

5.2.4 Vulnerability of End-Use Sectors

A modern state cannot function without several vital services provided by national energy systems. For the purpose of this analysis, we distinguish between four such services. The first three are the "end-uses" discussed in Chapters 8, 9, and 10, i.e., energy in (1) transport, (2) industry, and (3) buildings. The last energy "service" is (4) revenue from energy exports. It is only relevant to a relatively small number of countries whose economies rely significantly on such revenues.

This subsection evaluates the vulnerabilities of each of the vital energy services: transportation, residential and commercial (R&C), industrial, and export-revenue generation. Such vulnerabilities are generally divided into those associated with the energy service itself (demand-side vulnerabilities) and those linked to the properties of the energy system in which a particular service is embedded, particularly the security of relevant energy sources.

5.2.4.1 Energy for Transport

Transportation is vital for almost every aspect of modern societies, ranging from personal mobility to food production and distribution, trade, availability of goods and services, and, not least of all, military security. Transport accounts for over 20% of energy use in virtually all developed countries. It is still under 15% in many developing countries, including China and India (where it is rapidly growing). Only in Least Developed Countries (LDCs) does transport account for under 10% of their total energy use. Modern transport systems rely on motorized vehicles that share fuels with agricultural, construction, and other machinery. Thus, this discussion of energy security for transportation is also applicable for the security of fuels for agricultural production and related sectors.

Among all nationally vital energy services, transport is beyond doubt the most vulnerable. This vulnerability is primarily a result of the reliance on imported oil as transport fuel. The absolute bulk of energy for transport is derived from oil and its products.

Only nine countries (Algeria, Argentina, Belarus, Brazil, Moldova, Russia, Slovakia, Ukraine, and Uzbekistan) rely on oil for less than 85% of their transport energy needs. In all these countries except Brazil, natural gas is the main alternative to oil products in transport. Whereas Algeria, Argentina, Russia, and Uzbekistan have their own natural gas reserves (with the R/S ratio of only 11 years in the case of Argentina), the other countries import most of their natural gas.

This means that the security of energy for transport largely reflects the security of oil supply discussed in Section 5.1.2.1. Around 3.2 billion people live in 85 countries that import[15] 70% or more, and 4.9 billion live in 93 countries (including China)[16] that import one-half or more of their transport fuels. Finally, 101 countries (5.3 billion people) import more than 25% of the fuel used for transport. Two other countries (Argentina and the United Kingdom), which currently import less than 25% of their transport fuels, may face import dependency in the near future, since their oil R/S ratio is under 15 years.

Transport energy systems are also subject to demand-side vulnerabilities. In particular, rapid growth in transport energy use signals a pressure on transport. About 1.7 billion people live in some 17 countries (including China) where transport energy use has grown faster than 8% annually over 1998–2007, and 29 countries with 1.9 billion people

15 Dependency on imported fuels for transport considers all fuels used in transport. In the case of oil, it includes petroleum products and crude oil imports.

16 In 2007, China's dependency on imported fuels for transport was 47.4%. The resource/consumption ratio of domestic oil in China is 7.23 years, and the annual rate of growth of transport energy was 8.8% in 1998–2007.

have experienced a growth rate of over 6%. This is in contrast with some developed countries, notably the United States, where the car fleet shrank by four million vehicles in 2009 and the consumption of gasoline peaked in 2007 (NADA, 2009, quoted in Brown, 2010).

Supply- and demand-side vulnerabilities of transport energy systems overlap in some 15 countries (including China) with 1.7 billion people, which depend on imported fuels for one-half or more of their energy use and at the same time experience over 6% growth in demand. An additional 84 countries with 3.2 billion people experience either supply- or demand-side vulnerabilities. Only about 1.2 billion people live in 31 countries with relatively import-independent and slowly growing transport systems.

5.2.4.2 Energy for Industry

The industrial use of energy – mainly in the form of heat and electricity – varies between countries. Virtually all developed countries use at least 15% of their energy in the industrial sector. In 60 countries with 4.5 billion people, industry accounts for over 25% of their energy use, and in 12 countries with 1.7 billion people (which include Brazil, China, and Ukraine), it accounts for over 40% of their energy use. Many smaller developing and emerging economies are dominated by one or few industries relying on distinct energy systems, which are therefore critical for the energy security of those societies.

The industrial sector is less based on imported fuels than the transport sector. In 23 countries (400 million people) industry relies on fuels that are 75% or more imported, in 46 countries (800 million people) on fuels that are 50% or more imported, and in 77 countries (1.5 billion people) on fuels that are 25% or more imported.

Demand-side vulnerabilities should also be taken into account. Although many economies experience growth in industrial energy use, this cannot be considered as permanent and pressing, as in the case of the transport and residential sectors, because industrial growth may be reversed. Industrial energy intensity, on the other hand, is an important characteristic that can make the industrial sector relatively more or less vulnerable to price volatility and other energy supply disruptions. In 34 countries (including China, the Russian Federation, Brazil, Ukraine, and several other emerging economies) with 2.8 billion people, industrial energy intensity exceeds the world average by 25% or more (159% in Ukraine, 49% in China, 45% in Russia, 35% in Brazil). In the vast majority of these countries industrial products also account for a large portion of GDP (49% in China, 38% in Russia, 37% in Ukraine), which makes them even more vulnerable to industrial energy supply disruptions.

Supply- and demand-side vulnerabilities of industrial energy systems overlap in only two countries: Jordan and Moldova. About 80 countries in the world, with a combined population of some 3.6 billion people, experience either high import dependency of industrial fuels or high industrial energy intensity.

5.2.4.3 Energy in the Residential and Commercial Sector

The R&C sector in all countries vitally depends upon a supply of electricity that is used for lighting, cooking, heating, and other appliances. Other forms of energy are also used in this sector, particularly for heating, which is an important national priority in cold climates. In many countries, prevention of failures to provide adequate heating during cold seasons are rightly considered a matter of national priority.

Another key feature of the R&C sector is that it significantly relies on traditional biomass in many developing countries. Energy statistics typically designate this source as "renewables and combustibles" without making the distinction between "modern" (e.g., pellets, straw boilers, modern heaters) and "traditional" (e.g., firewood or dung used in open cooking stoves) uses of biomass. However, reliance on traditional biomass in the R&C sector represents a national energy security issue because such use is generally considered unacceptable on health, environmental, and developmental grounds. This means that the massive use of traditional biomass in the R&C sector, much like the low rate of access to electricity, is untenable for modern nation-states. When such use is widespread, the energy policy and the energy system are under pressure to find new sources of energy to replace traditional biomass, which can be combined with other pressures to exacerbate a nation's energy vulnerabilities.

The patterns of energy use in the R&C sector differ greatly between developing and industrialized countries. Lower-income countries typically have a higher proportion of R&C energy in the total energy use and a higher share of (mostly "traditional") biomass in R&C energy use.[17] In the following analysis we make a distinction between three groups of countries that differ in the degree to which they rely on traditional biomass in their R&C sector:

- 25 countries (700 million people) rely on combustibles and renewables for over 80% of their R&C energy, most of them low- or lower middle-income countries. These countries are not included in our analysis of import dependency of fuels for the R&C sector.[18]

- 22 countries (3.3 billion people) rely on combustibles and renewables for between 33% and 80% of their R&C energy, of these two-thirds are low- or lower middle-income countries and these rest are

17 All of the 27 countries with R&C energy representing more than 40% of total energy use are either low- or lower middle-income countries. The share of biomass in R&C energy use of those 27 countries is higher than 70%.

18 The rationale for this approach is that the overarching vulnerability for those countries is an excessive reliance on traditional biomass in their R&C sectors rather than import dependency of the relatively insignificant remaining share of their R&C energy.

upper middle-income countries. This group also includes India and China. For these countries we analyze import dependency only for the share of their R&C energy, which does not include combustibles and renewables.[19]

- The remaining 86 countries (2.3 billion people) rely on combustibles and renewables for less than 30% in their R&C energy. About 75% of these countries are high- or higher middle-income. For these countries we analyze vulnerabilities of the R&C sector.

The R&C sector is generally less dependent on imported fuels than transport, but more dependent than the industrial sector. Twenty countries (400 million people) import more than 75% of their energy for R&C. In 39 countries (500 million people), the energy imported for this sector is higher than 50%. Finally, 52 countries (2.3 billion people) rely on more than 25% of imported energy for the R&C sector.

There are also demand-side pressures on R&C energy use. In 28 countries (400 million people), the growth rate of energy use in this sector exceeded 5% per year. In many low-income countries per capita energy use is far below the world average, which probably indicates an inadequate provision of energy services in this area and signals a potential vulnerability. This question will be explored further.

Only three small countries (Portugal, Cyprus, and Albania) have an import dependency on energy for R&C higher than 50% and annual demand growth higher than 6%. Forty-seven countries (1.1 billion people) have either dependency on energy higher than 50% or demand per capita for R&C higher than 6%. These vulnerabilities should be considered in addition to 25 countries (with 700 million people) that primarily rely on traditional biomass in their R&C sector.

5.2.4.4 Energy for Export and Resource Curse

Energy exports are central for several countries where export revenues provide core funding for the public sector and where energy export industries sustain employment and a large part of the economies. To articulate the role of energy exports, these countries sometimes formulate them as "demand security" to contrast with the "supply security" of energy-importing nations. We consider export revenues as another energy sector vital for the stability of economic, political, and social order in exporting countries.

Yet energy exports are as vulnerable to various disruptions as other energy services and can also be considered from the robustness, sovereignty, and resilience perspectives. First of all, energy exports are only possible when sufficient domestic energy resources are available. This presumes both physical availability and accessibility of resources, as well as a reasonably satisfied (or artificially constrained) national demand for such resources. Second, resources can only be exported if there are adequate extraction, conversion, and transportation technologies and infrastructure. Third, any export depends upon safe export routes and destinations. Thus, exports security depends upon the physical safety of export routes (from adverse natural events and deliberate disruptions) as well as upon functioning institutional arrangements (e.g., markets) to match energy supply and demand and ensure sufficient and predictable revenues.

Energy exports can be considered a vital national service for only a few of all energy-exporting countries. There are about 15 countries where energy exports constitute 20% or more of GDP. About half of these countries are LDCs; most of the rest are middle-income countries.

The first insecurity stems from the very fact that a particular national economy extensively relies on oil exports. Worldwide, such dependency is highly correlated with slower long-term rates of economic growth and political problems. The economic and political risks of significantly relying on oil exports are particularly pronounced for poor countries and are extensively analyzed in the literature on the so-called "resource curse" discussed in Box 5.8. Furthermore, domestic oil reserves in some exporting countries are quite limited and will not last longer at current rates of production unless new resources are found or put in production. For example, the R/P ratios for Angola, Cameroon, and Malaysia in 2007–2009 were estimated at 12–20 years and for Argentina at about 10 years (BP, 2007; 2009; US EIA, 2011b).

5.2.5 Energy Security in Selected Regions

The above analysis primarily concerns energy security in individual countries, as well as relevant global considerations. At the same time, energy security issues have a strong regional dimension because countries located in geographic proximity often experience similar conditions with respect to access to energy resources and the structure of energy use, and may be engaged in more intensive mutual trade and transit of energy carriers. This subsection outlines energy security issues from the robustness, sovereignty, and resilience perspectives in the major world sub-regions: Africa, Asia, Europe, and North and South America.

5.2.5.1 Energy Security in Africa[20]

Energy security is an important policy issue in Africa. A number of factors contribute to rising energy security challenges. The rising economic

19 The rationale for this approach is that such countries typically have two distinct residential sectors: one "modern," which can be subject to standard import vulnerability analysis, and the other "traditional," where the vulnerabilities associated with traditional fuels are most prominent.

Box 5.8 | Energy Exports and Resource Curse

Exports of energy resources – primarily oil and gas – have strongly influenced national economies and political systems in different historical periods in many countries. It has arguably supported economic development in such industrialized countries as Norway, the United Kingdom, Canada, and the United States. It has fueled economic development in Malaysia, Indonesia, the United Arab Emirates, and other emerging economies. Yet it has been blamed for slower economic growth, poor governance, political instability, and conflict in several low- and middle-income countries. This latter phenomenon has been termed the "resource curse" or "natural resource trap." There is an extensive body of scholarly literature that attempts to explain the resource curse and find appropriate remedies.

Poor economic performance of energy exporters, observed by many researchers, has been blamed on macroeconomic instability induced by the volatility of energy prices. More often than not, producers that face a season of windfalls spend extravagantly and have difficulty curbing this spending during lower price periods. In addition, some energy exporters tended to unsustainably borrow in times of high oil prices and were saddled with unbearably heavy debts in times of lower prices. Added to this, many low-income energy exporters are faced with money flows that far surpass their absorptive capacity, resulting in overheated economies and rampant inflation.

Another reason for slower economic growth of energy exporters is the so-called "Dutch disease," an economic phenomenon named after the negative impact on the Dutch economy of natural gas-related revenues in the 1970s resulting from over-valuation of the national currency and a set of other factors which inhibit the development of non-energy branches of an economy producing "tradable goods." The result of the Dutch disease is thus a steady decrease in non-oil productive activity and, in the face of the eclipse or lack of a non-oil fiscal base, the growing dependency of state coffers on petroleum rents.

The political consequences of oil wealth have been shown to be equally negative for many countries. Indeed, it is primarily at institutions, the mentalities of decision-makers, and the quality of governance rather than at macroeconomic trends that one must look to account for the predicament of the petro-state. An immediate consequence of oil revenues is the increase in state power and the absolute social, economic, and political centrality it acquires. The boom phase characteristically includes a growth in construction and proliferation of employment in the state sector and the services sector. As the key actor of the domestic economy and main supporter of the lingering private sector through handouts and public contracts, the state is everywhere and in constant expansion. The oil economy is meanwhile managed under a shroud of secrecy. Production levels and financial amounts transacted are matters of speculation; budgets are fictitious; and money flows are the object of unheard-of detours and misappropriations in a context of no public accountability (Ross, 2001). It is, therefore, unsurprising that of the top 15 oil exporters only one (Norway) is a well-functioning democracy and four others (Mexico, Venezuela, Russia, and Iraq) can be considered "imperfect democracies." This lack of accountability extends to the international level. More often than not, oil producers with questionable domestic records are nonetheless courted and protected by oil-consuming states in the industrial world, in a demonstration that oil, on account of its centrality for the functioning of modern economies, is a commodity like no other.

Easy oil money means that the state does not need to expand the domestic fiscal base. In fact, OPEC members' oil revenues represent an average of 42% of total government revenues. In cases where the building of state institutions runs parallel with the availability of oil wealth, no fiscal administrations are created at all. Oftentimes, the state does not seek to pursue this option anyway, for it faces articulate national constituencies that see themselves as legitimate beneficiaries of the national wealth rather than as net contributors to it. This fiscal aloofness strengthens the executive but also cuts its link with society as well as the minimal social contract the link might imply.

These arrangements, however, become unstable at times of low or decreasing oil prices. At such times, a petro-state becomes highly indebted, with a vast unemployed urban working class and a restive youth, a large and intermittently paid civil service, a neglected countryside, and an inequitable pattern of wealth distribution. Recent research shows that, faced with a powder keg of distorted economies and dissatisfied populations, oil states are far more likely than non-oil states to suffer from civil war or separatist bids from resource-rich regions. This political instability and poor governance can feed on each other, creating a vicious circle. In already unstable contexts such as West and Central Africa, for instance, oil is clearly a factor that exacerbates conflict and perpetuates the control of the state by self-seeking elites.

Researchers disagree on the root causes of the resource curse. The term itself tends to underplay two important factors. Regarding the first, it is becoming clear that poor institutions are largely responsible for economic under-performance, and vice versa: poor non-diversified economies are obstacles to improving governance. The second factor is the character of the economy, institutions, and political culture in oil-rich states prior to the arrival of oil rents. OECD oil-producing states had developed the institutions (strong and accountable governments, a free press, a robust political party system, etc.) that proved instrumental in steering oil revenues in a constructive direction decades before oil materialized. In much the same way, many of the problems found in oil-rich-but-poor states were everyday occurrences before oil: fragile economies, despotic rulers, and weak and inefficient institutions. In this context, oil accentuated pathologies that existed already.

More detailed recent analysis shows that endowment with national resources may be a curse or a blessing, depending on many other conditions. The larger the endowment of natural resources, the stronger are the institutions needed to overcome the risk of resource curse. However, under certain conditions – prevalent in many developing countries – the opposite occurs. The presence of natural resources actually weakens the institutions, which in turn are unable to manage the natural resource wealth; this leads to more resource-dependency, further weakening of the institutions, etc. Thus, suffering from resource curse or falling into a natural resource trap is not inevitable. However, it is a matter of very high risk and affects many developing oil-exporting nations. While analysts dispute what is at the root of the disappointing performance of most petroleum exporters – ranging from the single-minded determinism of a resource curse to more nuanced institutional and sociological analyses – there is a near consensus that few states have gone up the developmental ladder by virtue of their oil endowments.

As evidence that the resource curse does not always occur, one recent study looked at oil and gas production in Indonesia, Malaysia, Myanmar, and Thailand from 1987–2007. In each of these countries, including Myanmar, economies have become more diversified, per capita incomes have risen, and life expectancies and living standards have improved along with increased energy supply. Political transparency and accountability have remained constant in Indonesia, Malaysia, and Thailand, and oil and gas have contributed less to government revenues over time in Indonesia and Thailand. The situation in Southeast Asia suggests that extractive resources themselves are neither a curse nor a blessing. Instead, it is how they are used and the particular socio-political environment in which they evolve that determines whether they contribute to peace and prosperity or risk conflict and environmental degradation. The successful practice of managing energy export revenues in Chile included avoiding excessive spending in boom times, allowing deviations from a target surplus only in response to output gaps and long-lasting commodity price increases, as judged by independent panels of experts rather than politicians. Other measures to avoid the resource curse proposed by experts include hedging export proceeds in commodity futures markets, denominating debt in terms of commodity prices, allowing some nominal currency appreciation in response to an increase in world prices of the commodity, but also adding to foreign exchange reserves, especially at the early stages of the boom when it may prove to be transitory.

prosperity of the continent after decades of economic underperformance has led to an increasing demand for modern energy. The rising costs of energy imports constitute a threat to economic resurgence of the continent. Weak investments in energy infrastructure, poor domestic policies that favor poorly targeted subsidies, and limited transportation connectivity across Africa also hamper the extent and pace at which trade in energy can occur between energy-surplus and energy-deficient parts of the continent. Most of the countries in the continent continue to depend on imports from outside the continent to meet the rising domestic demand.

Over the years, energy prices have risen rapidly and become highly volatile. While the upwards trend in global energy prices has led to a massive accumulation of reserves in many energy-rich African countries, net energy importers in the continent have borne the costs in terms of slower economic growth, rising trade deficit, faster depletion of foreign reserves, and rising inflation.

Affordability of and access to modern energy are very poor in Africa though in total, the continent produces more energy than it consumes. In 2009, extraction of crude oil, natural gas, and coal were 3.2, 2.2,

and 1.34 times higher than their respective use, whereas the overall total primary energy supply was more than twice the amount of primary energy used. However, these aggregate figures mask a high degree of intra-African diversity in energy demand and supply, which largely reflects the diverging regional resource endowments.

The TPES in Africa grew by a mean of 4% between 2005 and 2009, mainly as a result of robust growth in crude oil production in North and West Africa. The share of biomass, while still significant in parts of Africa, especially in sub-Saharan Africa, decreased from 62% in 1971 to less than 45% in 2009. However, Africa's use of combustible renewable energy (mainly wood-fuel) still remains significantly higher than the world average. Total primary energy use in the same time period rose by an annual average of 3.7%.

Though the continent exports energy, it is unable to meet the energy needs of its population, especially in sub-Saharan Africa. The systemic energy problem in Africa is especially evident within its power sector. Africa is estimated to require 7000 MW of new power generation capacity each year, but has been installing only 1000 MW annually. Outside South Africa, power consumption averages 124 kWh (4.46 GJ) per person per year. Only one-fifth of the population of sub-Saharan Africa has access to electricity, compared with one-half in South Asia and four-fifths in Latin America. At the same time, the cost of electricity is higher in Africa. Frequent power outages force firms to rely on expensive back-up generators that cost up to US$0.40 per kWh. Many countries rely on inefficient, expensive, small-scale, oil-based power generation. Africa is well endowed with large-scale, cost-effective energy resources, but they tend to be located a long distance from the major demand centers and their development is often too expensive for the countries where they are found.

Energy resource ownership and use vary widely across Africa. For instance, three countries – South Africa, Egypt, and Algeria – account for two-thirds of total primary energy use. Algeria and Egypt account for 73.6% of total natural gas consumption. South Africa and Egypt jointly account for 61% of the continent's hydroelectricity consumption. South Africa alone accounts for 93% of total African coal consumption and 100% of its nuclear energy generation.

Nigeria, Algeria, Angola, and Libya are the major producers of oil, although oil is also produced in Cameroon, Chad, Congo, Côte d'Ivoire, Egypt, Equatorial Guinea, Gabon, Mauritania, Sudan, and Tunisia. Natural gas reserves are located in four major countries: Nigeria, Algeria, Egypt, and Libya.

There is a very limited amount of intra-Africa trade in energy. Only 1.8% of the continent's oil exports go to other African countries. LNG trade from Algeria, Egypt, Equatorial Guinea, Libya, and Nigeria go to countries in North America, Europe, and Asia/Pacific. Three countries – Egypt, Mozambique, and South Africa – are responsible for nearly all the coal exports in Africa. Most of the coal exports go to other African countries – Algeria, Congo Kinshasa, Kenya, Morocco, Mauritius, Namibia, and Senegal. There is also some electricity trading within the continent, especially within the various sub-regions. A good example is the West African Power Pool, designed to interconnect national grids across 5000 km of most West African countries. Another important initiative in West Africa is the West African Gas Pipeline. The US$635 million project was initially developed to utilize some of the gas currently being flared in Nigeria for power generation in Benin, Togo, and Ghana.

The presently low level of energy trade among countries has made it difficult to leverage the huge energy surplus produced in the continent to meet the needs of energy-poorer countries. Hence, significant scope exists for energy cooperation across sub-regions on the continent. Although there are a number of pan-African cooperative energy initiatives, the pace of implementation of these initiatives has been slow.

The diversity of energy resources in Africa is relatively low. Oil is the dominant fuel in most African countries. Four-fifths of the countries derive over 50% of their energy use from oil. Over one-third of the refined petroleum consumed in the region is imported. While the amount may vary, all the countries import some proportion of their product consumption. Over 63% of the countries import more than 90% of the refined products they consume. Paradoxically, Nigeria, the leading producer and exporter of crude oil in Africa, imports 69.8% of its product requirements and accounts for 17.7% of the continent's total imports. Dependency on imported energy is a risk to energy security and makes the country vulnerable to high and volatile world oil prices.

In some African countries, energy sources other than oil dominate consumption. Countries significantly dependent on coal are South Africa (76.4%), Zimbabwe (53.4%), Botswana (41%), and Swaziland (34.7%). Countries with high natural gas dependency are Equatorial Guinea (92.6%), Algeria (64.4%), Tunisia (50.5%), Egypt (49%), Côte d'Ivoire (44.5%), and Nigeria (41.7%). Countries heavily dependent on hydroelectric energy are Mozambique (82.1%), Zambia (75.2%), Congo Kinshasa (68.2%), Malawi (45.3%), and Cameroon (41.6%). Countries that depend almost exclusively on a single primary energy source are Benin, Chad, Djibouti, The Gambia, Seychelles, Sierra Leone, Somalia, and Togo.

The generally low energy diversity in Africa relates to low capacity and a weak technological base in most countries. Poverty and a lack of appropriate technologies have hampered diversification into renewables such as solar, wind, and small hydro.

Several options are open to African countries to address the huge energy gap in the region. These include the use of renewable energy to supplement the non-renewable energy sources that currently dominate the energy mix, the reduction of huge energy losses and wastages and adoption of energy efficiency technologies, increased investment in new technologies and energy supply infrastructure, and an enhanced level of

intra-regional energy cooperation. The latter is required because many African countries are very small and may not be able to finance the huge investment costs needed to develop alternative energy sources. Africa must engage the private sector in addressing its energy supply inadequacies. While energy subsidies may not disappear for a while, such subsidies must be smart and better targeted to meet specific societal objectives.

5.2.5.2 Energy Security in Europe[21]

Europe[22] is among the world's largest energy-consuming regions. Oil, natural gas, and coal constitute the dominant fuels in Europe's energy mix. In 2009, coal accounted for 17% of Europe's total primary energy demand, oil accounted for 35%, and gas for 25%. That year, Europe represented around 18% of the global demand for oil, some 17% of the global demand for natural gas, and 9% for coal. Nuclear made up 14% and renewables 9% of primary energy use in Europe. Overall, Europe, representing 7% of the world's population, accounted for 15% of the world's primary energy demand.

Europe is also a key supplier of energy. In 2009, it produced 2.6% of global oil output, 5.7% of global gas output, 4.6% of global coal output and 11% of global renewable energy. Still, Europe is crucially relying on energy imports to satisfy its needs. In 2009, the EU imported more than half of its energy from non-EU countries. This number has increased in recent years, rising from less than 40% of gross energy use in 1980 to 55% at present. If the present trends continue, European import dependency is likely to steeply increase in the near future, a function of policies aimed at reducing carbon-intensive fuels such as coal with comparably less carbon-heavy fuels such as gas, but also due to declining domestic production, notably in the North Sea.

European energy imports are dominated by a few producers of energy. Some two-thirds of EU-27 imports of natural gas stem from only three countries: Norway, Algeria, and Russia. Russia is also Europe's dominant supplier of crude oil, accounting for some 30% of the bloc's imports in 2008. Even in hard coal, Russia plays an important role, supplying around 24% of European imports. High European import dependency is not a concern for all fuels. The coal market is relatively small in volume, and global reserves are relatively evenly distributed. The oil market is global, liquid, integrated, and therefore unlikely to give a dominant producer much political leverage over the consumer region supplied. Gas markets, however, still remain by and large regional and bilateralized in nature. Given the predominantly pipeline-bound infrastructure in natural gas, alternative suppliers are hard to find in the short to medium term. In light of this, concerns have been expressed over some European countries' heavy reliance on gas imports from Russia, reaching up to 100% of total demand in Central and Eastern Europe, especially the Baltic States. Recent disputes over gas transit between Russia and neighboring Ukraine, and also Belarus, have added to this concern and sparked political initiatives to reduce overall European import dependency on Russia. The degree to which Russian gas actually poses a security problem is, however, disputed. Russia's share of European natural gas imports has in fact declined steadily over the last two decades, from some 75% in 1990 to 31.5% today. Current developments in unconventional gas production (see Box 5.5), coupled with the increasing global capacity in LNG, may possibly also change existing market structures and contribute to a higher integration of regional markets and more gas-to-gas competition in the European market (IGU, 2010). The planned construction of the Nord Stream gas pipeline under the Baltic Sea, connecting Russia directly to Germany and Denmark, is intended to diversify gas trade routes and reduce dependency on transit countries.

Still, policy initiatives center on reducing gas import dependency on Russia by promoting diversification strategies, including pipelines in the "southern corridor" aimed at bringing Caspian gas to European households. A key European initiative in this context is the planned Nabucco pipeline, a 31 bcm per year interconnector for Azeri and possibly Turkmen or even Iraqi gas, via Turkey. Since available gas volumes remain uncertain, the pipeline has so far not left the planning stage. Recent Azeri pledges to commit parts of the gas output generated in the Shah-Deniz II field (planned to come on stream in the next years) may constitute a breakthrough for the project.

In addition to import dependency, European energy security challenges may, however, also be of domestic origin. In particular, they may stem from Europe's commitment to pursue low-carbon energy transition. Policy packages such as the EU's 20–20–20 initiative, aimed at reducing emissions of greenhouse gases by 20% by 2020 and flanked by reaching 20% of renewable energy in total energy use, will put demand-side pressure on European energy generation and systems. Replacing coal in power generation by bridge fuels (notably natural gas) before phasing them out to the benefit of renewables will pose unprecedented challenges with regards to finance, infrastructure, and technology. Adding to this challenge is a rapidly aging infrastructure in European nuclear energy, coupled with stiff public opposition to new nuclear power plants in most European countries.

5.2.5.3 Energy Security in North America

The North American continent has been endowed with immense energy wealth. The United States is among the world's top ten producers of coal, oil, natural gas, and electricity from nuclear and hydroelectricity, while Canada is in the top ten for oil, natural gas, and electricity from nuclear and hydroelectricity production, and Mexico ranks in the top ten for oil production (IEA, 2010a). Despite this, each country has its own set of energy security problems.

21 Sources: BP, 2010; IEA, 2010a; Eurostat, 2011.

22 The term "Europe" is used here to designate European OECD member countries or the European Union Member States.

Probably the most dominant and well known of these problems is that being faced by the United States and its dependence on foreign supplies of crude oil. Every US president, from Nixon to Obama, has set targets, put forward proposals, commissioned reports, and signed legislation in an effort to stem crude oil imports and improve energy security (US DOE, 2010). Today, over 60% of US demand for crude oil is met from imports (US EIA, 2010).

Support for the US transportation system is the driving force behind all energy security legislation put forward in the United States. For example, the 2007 Energy Independence and Security Act (EISA) calls for, amongst other things, reducing vehicular fuel consumption through increased CAFE (Corporate Average Fuel Economy) standards, replacing gasoline with ethanol, and requiring auto manufacturers to develop a new generation of vehicles to operate on electricity (EISA, 2007).

EISA has had unintended consequences. The push for ethanol from cornstarch means that a significant percentage of US farmland is being diverted from food into fuel production; this has had an impact on world corn supplies, indirectly affecting food security in countries such as Mexico (Roig-Franzia, 2007).

The increasing demand for electricity in general, and the inevitable reliance on mains electricity to meet the energy needs of plug-in electric vehicles in particular, will have an impact on (electrical) energy security. At present, about 50% of the electricity in the United States is produced from domestic coal, followed by natural gas and nuclear (about 20% each), hydroelectricity (5%), and a mix of renewables (2.5%) (US EIA, 2011a). Demand pressures are forcing electricity suppliers to plan for new generation capacity and, if climate change is ever addressed seriously by the US Congress, it will be necessary to develop generation facilities that emit little or no carbon. However, the supply mix is only part of the problem – the US electrical grid is showing its age and must be refurbished if it is to meet the expected future reliance on electricity. The costs of new generation facilities (whether or not the United States addresses the issue of climate change) and grid upgrades are estimated in the trillions of dollars – the price of ensuring the availability of the electrical supply.

Until the middle of the last decade, it was assumed that domestic supplies of natural gas in the United States had peaked and, like crude oil before it, would make the United States increasingly reliant on imports of natural gas. To ensure (natural gas) energy security, plans were drawn up for dozens of liquefied natural gas (LNG) facilities around the continental United States (McAleb, 2005). Today, things look considerably different – the use of horizontal drilling fracking is making shale gas available as a replacement for declining stocks of conventional natural gas (Grape, 2006). Shale gas is rich in natural gas liquids (NGLs), meaning it can also improve US energy security by offsetting imports of crude oil (Sandrea, 2010). Optimistic reserve projections have industry analysts suggesting that the United States could soon start exporting LNG (PennEnergy, 2010); this would not appear to be in the long-term energy security interests of the United States. There are also concerns over the environmental impacts associated with the extraction of shale gas (Doggett, 2010); time will tell whether it is considered an acceptable source of natural gas that will improve the energy security of the United States.

Two of the countries on which the United States depends for its energy are its nearest neighbors, Mexico and Canada; both countries are exporters of crude oil and other refined petroleum products to the United States, while Canada also exports natural gas and electricity. The United States' reliance on Mexico and Canada for its energy has politicians and analysts in all three countries talking about North American, or continental, energy security (Angevine, 2010).

North America's energy security is governed by chapter six of NAFTA, the North America Free Trade Agreement, which outlines the rules and regulations regarding the trade of energy and petrochemicals. NAFTA requires a signatory to maintain its energy exports; short of war, any reduction in exports must be met by a proportional reduction in supply within the exporting nation. Mexico is exempt from this provision; Canada is not (NAFTA, 2002).

Mexico is facing energy security challenges of its own. Its most important oil field, Cantarell (in the Gulf of Mexico), is in decline and further exploration is hampered by the Mexican constitution that restricts oil and natural gas development to the state oil company, Pemex.

Canada, unlike Mexico, has few restrictions on international players exploiting its crude oil and natural gas. Despite the availability of these resources, not all Canadians have access to them; for example, although Canada is self-sufficient in crude oil, over 60% of it is exported to the United States, meaning that Canada meets almost 50% of its crude oil needs from imports (Hughes, 2010). Canada is also self-sufficient in natural gas, yet almost 60% is exported to the United States (US EIA, 2011a). Not only is Canada exporting energy that could improve its future energy security, but also it has compounded the problem by failing to develop the pipeline infrastructure to connect parts of eastern Canada with the oil and natural gas fields in western Canada (Hughes, 2010).

Although Canada's production of conventional crude oil and natural gas has peaked, the tar sands (euphemistically referred to as the "oil" sands in the United States) are seen as essential to continental energy security. Canada's current prime minister has gone so far as to call Canada an "energy superpower" with respect to the development of unconventional energy resources such as the tar sands, shale gas, and Arctic oil and natural gas for export to the United States (Hester and Welsh, 2009).

Canada is one of the few countries with the capacity to improve its energy security with its own energy resources. Despite this, Canada's trade and energy policies have evolved to the point where much of the

energy that could be used for its own energy security is, instead, contributing to the improvement of energy security in the United States.

5.2.5.4 Energy Security in Asia[23]

Asia – meant here to encompass the big four energy consumers of China, India, Japan, and South Korea, as well as the developing economies including Southeast Asia and South Asia – faces a series of daunting energy security challenges that crisscross the three themes of robustness, sovereignty, and resilience.

Growth in energy use, both in terms of per capita use and total use in aggregate, is expected to rise dramatically in the next few decades. As a whole, Asia Pacific's per capita electricity demand was only about 1300 kWh in 2005, compared to the world average of more than 2500 kWh. Under a business-as-usual scenario, between 2005 and 2030 energy demand is expected to grow at 2.4%, whereas the world average during the same period will be 1.5%. Net imports of fossil fuels in Asia Pacific are expected to more than double. The region's oil dependency will increase from 57.5% to 66.4%. The region will also need between US$7 trillion and US$9.7 trillion of cumulative investment in the energy sector during this period, of which about two-thirds will be in electricity generation, transmission, and distribution. The 10 countries that comprise the Association of Southeast Asian Nations, for example, will likely experience an annual growth rate in energy demand of 2.5% between 2010 and 2030. If that projection holds true, regional demand for energy will equal the current combined total demand of Japan, Australia, South Korea, and New Zealand. Yet, although Southeast Asia is home to 8.5% of the world population (530 million people), the region possesses about 1% each of the world's oil and coal stocks and less than 4% of total natural gas reserves.

Security of supply has thus become a key economic and political concern. In China, Beijing had to ration its gas supply to shopping malls and supermarkets in January 2010 as a result of extreme winter weather. In 2008, India walked out of the deal to build an Iran-Pakistan-India (IPI) gas pipeline – on which discussions were conducted over 13 years – over security issues and the inability of Pakistan to agree to provide penalties for supply disruptions. Japan buys nearly 90% of its oil from the Middle East, making it vulnerable to disruptions of even a few days on the Strait of Hormuz or through shipping routes from the Middle East.

Threats need not be international or external. Laborers of India's public-sector petroleum company, Oil and Natural Gas Corporation Limited (ONGC), went on a three-day strike in early 2009, shutting down the Hazira plant that processes oil and gas from offshore operations and threatening to create shortages of compressed natural gas used for public transportation in Gujarat. Large parts of China also had to confront energy shortages in 2010 due to a combination of weather and infrastructure factors: the difficulty of transporting coal in the snow, less hydropower output due to freezing temperatures, and reduced coal supplies from Shanxi province due to mine closures. In 2008, shortages of gasoline and diesel occurred in Bali, Indonesia, when oil tankers had trouble accessing the island during a series of storms, and in Kalimantan long lines formed at petrol stations due to a shortfall of 10,000 liters of gasoline. In Jakarta and Java, as well, shortages of premium gasoline and LPG occurred after a refinery had maintenance problems, and disruptions of electricity hit every Indonesian province in both 2007 and 2008.

Trade in energy is another essential challenge. Apart from Indonesia, Malaysia, Vietnam, and Brunei, all other Asian countries are currently net energy importers. This means that the promotion of trade is instrumental to building energy markets so that countries can improve access to multiple sources of energy. Without such access, buyers must negotiate directly with producing nations such as those in the Middle East. Several "energy-poor" nations are relying on trade to overcome their energy shortages. The Bangladesh Power Development Board is currently holding a road show around the world to encourage foreign investors to help them erect about 3500 MW of new power plants and a terminal for LNG. The country suffers from an acute shortage of power, especially during the hot summer months. Pakistan is also facing severe energy shortages, and searching for private foreign investment by offering incentives related to upstream and downstream hydrocarbon development.

Some countries, such as China, India, and Japan, have begun aggressively investing overseas to then export energy fuels back to their mainland. The China National Offshore Oil Corporation (CNOC), after a well-publicized yet unsuccessful takeover bid for Unocal in the United States in 2005, took over Canadian-based PetroKazakhstan in 2006, and since then has won contracts in politically volatile places such as Angola and Nigeria and strengthened ties with Sudan, Cuba, Venezuela, Iran, Sudan, Kazakhstan, and Myanmar. India's government aimed to produce 20 million barrels of equity oil and gas abroad by 2010, and the overseas arm of ONGC has already acquired properties in Vietnam, Russia, and Sudan. Japan, in its quest to produce more "Hinomaru" oil (oil developed and imported through domestic producers), has integrated its key oil companies – Inpex and Teikoku Oil – under a joint holding company, to make them more competitive against foreign oil companies.

5.2.5.5 Energy Security in Latin America and the Caribbean

The Latin America and the Caribbean region (LAC) has considerable energy resources, including oil, natural gas, biomass, and hydro energy, and is a net energy exporter, producing about 8.4% of global energy and consuming about 6.3%. Venezuela and Mexico are among the top global oil exporters, whereas Brazil is the largest ethanol exporter, accounting for half of the world's bio-ethanol exports (US EIA, 2011a). However, these resources are unequally distributed. For example, more

23 Sources: Asian Development Bank, 2009; IEA, 2010a; Bambawale and Sovacool, 2011.

than 90% of proven oil reserves in LAC are concentrated in three countries: Venezuela (which also holds about two-thirds of the region's natural gas reserves), Brazil, and Mexico (BP, 2009).

Moreover, utilization of these resources requires considerable investment and capacities, which can often only be mobilized at the international level. For example, significant investment will be required to develop the giant Lula (Tupi) and other "pre-salt" oil and gas fields recently discovered in Brazil or to implement the ambitious plans for expanding production of hydroelectricity where only 22% of the regional potential is currently used (SESEM-CFT, 2005). The current underinvestment in energy infrastructure is sometimes explained by legal and political uncertainty and insecurity, including changing the rules and nationalization of energy assets in several countries (Iranzo and Carrasco, 2008).

The region is also diverse with respect to capacities of individual countries, some of which are both too small and poor to address their energy challenges. For example, Nicaragua, one of the Heavily Indebted Poor Countries, is dependent on imported oil for almost 40% of its primary energy supply, including electricity generation (IEA, 2010b). Ecuador, another low-income country, relies on oil exports for almost half of its total export earnings and one-third of all tax revenues. Despite its large oil production, Ecuador must still import refined petroleum products due to a lack of sufficient domestic refining capacity. As a result, the country cannot always benefit from high oil prices, which increase its export revenues but also increase its refined product import bill (US EIA, 2009). Almost all of the electricity in Paraguay relies on one hydroelectric plant (Itaipu).

Energy infrastructure in politically unstable LAC countries is often the target of sabotage. Only in 2001, 170 attacks were registered on one of the most important oil pipelines in Colombia, Cano Limón (CEPAL, 2007). The TransAndino pipeline connecting Colombia and Ecuador has also occasionally been the target of rebel forces in Colombia, and an attack in March 2008 shut the system down for several days. Similarly, another oil pipeline in Ecuador, Sistema Oleducto Trans-Ecuatoriano (SOTE), has suffered from natural disasters that severely disrupted Ecuador's oil production. In March 2008, landslides damaged SOTE, shutting operations for several days. In 1987, an earthquake destroyed a large section of SOTE, reducing Ecuador's oil production for that year by over 50% (US EIA, 2009).

In LAC, regional integration is often viewed as a means to both redistribute uneven resources and to pool forces for infrastructure development and needed investment. Several energy integration organizations were created in LAC as long ago as the 1960s and 1970s:

- OLADE (Latin America Energy Organization), formed in 1973 by 26 LAC countries as an umbrella organization promoting the political, institutional, and technical integration of energy systems as well as energy efficiency;
- ARPEL (Latin America and Caribbean Regional Association of Oil and Natural Gas Companies), created in 1976 by 27 public and private companies and organizations that account for 90% of total upstream and downstream operations in the region; and
- CIER (Commission for Regional Electricity Integration), created in 1964 and including all South American countries except Surinam and Guyana.

Energy security has received high-level political attention in the last decade. In the Caracas Declaration (made in 2005), energy ministries of South America agreed to seek energy integration and cooperation. In April 2007, the first Presidential Energy Summit in South America resulted in a common energy strategy known as the "Margarita Declaration" (CEPAL, 2007), which advocates for a stronger role of the state in energy issues and promotion of renewables, especially biofuels. In November 2008, the Energy Ministers of OLADE member countries issued the Buenos Aires Declaration, which stated that energy security (defined as "safe and reliable energy resources availability") is a priority of the region (OLADE, 2007a; 2007b).

Another regional energy integration effort is Venezuela-backed Petroamérica, which provides a framework of cooperation initiatives in the areas of oil and gas supply and infrastructure (PDVSA, 2009). Petroamérica is divided into sub-regional frameworks: Petrocaribe, Petroandina, and Petrosur.

Petrocaribe includes 14 Caribbean countries, as well as Venezuela and Surinam. Within Petrocaribe, Venezuela directly sells oil and products to these countries under favorable financing conditions (CEPAL, 2007; US EIA, 2008; PDVSA, 2009). In 2007, 10 Petrocaribe members signed an energy security agreement that promotes the expansion of refinery capacity, ethanol production, and LNG infrastructure, as well as energy efficiency measures (PDVSA, 2009). Many of the Caribbean countries import oil from Mexico and Venezuela under favorable terms. Under the San Jose Pact, Barbados, the Dominican Republic, Haiti, and Jamaica receive oil and refined products from those two countries.

Petroandia includes Bolivia, Colombia, Ecuador, Peru, and Venezuela. It is an alliance of state oil and energy organizations to promote electric and gas interconnection, mutual energy supply, and joint investments (PDVSA, 2009). As part of Petroandia, Venezuela operates joint ventures in oil exploration, production, and capacity with Bolivia and Ecuador (PDVSA, 2009). Petrosur is made up by Brazil, Argentina, Uruguay, and Venezuela. Activities within Petrosur include the construction of joint Venezuelan-Uruguayan and Venezuelan-Brazilian refineries and the creation of Petrosuramérica, a joint Venezuelan-Argentinean company (Comesaña, 2008).

One area of regional energy integration is jointly constructed infrastructure for transporting natural gas. An agreement on joint construction of "the southern gas pipeline" for transporting natural gas from Venezuela

to Brazil and Argentina was signed in 2005. However, a later discovery of large oil and gas reserves in Brazil decreased that country's interest in the project. The needed investment (around US$25 billion) could not be secured, and the project was shelved in 2009 (Hidrocarburosbolivia.com, 2009). A more recent project, called the "Energy Ring," would connect three gas exporters (Ecuador, Bolivia, and Peru) to four (potential) importers (Brazil, Chile, Argentina, and Uruguay). However, the project was stopped due to the withdrawal of Bolivia and political differences between Chile and Peru. Instead, such countries as Chile have chosen to expand their LNG infrastructure to increase the diversity of gas import energy and routes.

There are also efforts to integrate electricity infrastructure such as a large integration initiative, the "Mesoamerican Integration and Development Project" (Proyecto Mesoamérica, 2009). The Electrical Interconnection System for Central America (SIEPAC), a 1,800 km power line that links six countries (Panama, Costa Rica, Honduras, Nicaragua, El Salvador, and Guatemala), was almost completed at the time of writing and a Regional Electrical Market was being put in place. This infrastructure is complemented by the existing electrical interconnection between Guatemala and Mexico, and a project to interconnect Panama and Colombia (IADB, 2010).

5.2.6 Summary: Energy Security in the World

This section explores energy security conditions in the world with respect to vulnerabilities of primary energy sources at the national and, where appropriate, global level, security of national electricity systems, and vulnerabilities of vital end-use sectors: transport, residential and commercial, industrial, and energy export revenues.

The results of the analysis of energy sources are summarized in Table 5.6. It shows that all primary energy sources have vulnerabilities from the robustness, sovereignty, and resilience perspectives. Globally, oil stands out as the most vulnerable in all three aspects among the internationally traded fuels, although natural gas may develop equally strong vulnerabilities in the near future. Rising demand plays as strong a role as supply limitations. Although the vulnerabilities of nuclear and hydro energy are not directly comparable to those of fossil fuels, they still affect hundreds of millions of people in dozens of countries.

Many countries using nuclear power experience aging of the reactor fleet and workforce as well as difficulties in accessing capital and technologies to renew, expand, or launch new nuclear programs. Of the 31 countries with nuclear power programs, 20 have not started constructing a new reactor in the last 20 years, and 19 countries have nuclear power plants with an average age of over 25 years. Large-scale enrichment, reactor manufacturing, and reprocessing technologies and capacities are currently concentrated in just a few countries. The transfer of these technologies and capacities to a larger number of countries is constrained by serious concerns over nuclear weapons, which is one of the main controversies and risks associated with nuclear energy.

Hydroelectric power production, especially from major dams located on internationally shared rivers, is often perceived as insecure, particularly in light of climate change affecting seasonal water availability. Over 700 million people live in 31 countries that derive a significant proportion of their electricity from just one or two major dams, and are thus vulnerable to failures of these dams.

The analysis also identifies vulnerabilities of national electricity systems. First of all, electricity systems inherit the vulnerabilities of energy sources used for electricity generation described above. For example, power plants relying on imported fossil fuels currently provide over 50% of electricity in some 39 countries with 600 million people. Some 450 million people in 35 countries primarily rely on just one source of energy for generating electricity, which is a concern from the resilience perspective.

In addition, electricity systems in developed countries often bear risks associated with aging power plants (especially pronounced in the case of nuclear reactors, which have not been renewed in most industrialized countries in the last 25 years) and other infrastructure. In developing and emerging economies, electricity systems are under strong demand-side pressures. The majority of the world population – some 4.2 billion people – lives in 53 countries that will need to massively expand the capacity of their electricity systems in the near future because they either have less than 60% access to electricity or demand growth averaging 6% or more over the last decade. Both fuels and infrastructure for such an expansion will need to be provided without further compromising the sovereignty or resilience of national electricity systems.

Finally, reliability of electricity supply is a serious concern, especially in developing countries. In almost three-quarters of low-income countries blackouts are on average for more than 24 hours per month, and in about one-sixth of low-income countries blackouts average over 144 hours (six days) a month. In over one-half of low-income countries blackouts occur at least 10 times a month.

With respect to nationally vital end-use energy services, transport is globally the most vulnerable. The absolute majority of countries rely on oil products for most of their transport energy and, as we have seen, in most of the world this oil has to be imported. Around 4.9 billion people live in 93 countries that import more than one-half of their transport energy requirements. This supply-side vulnerability is made worse by demand-side pressures: in some 17 developing countries with 1.7 billion people, transport energy use was growing faster than 8% annually from 1998 to 2007.

The energy sector also provides vital export revenues to some 15–20 countries. In the majority of these oil- and gas-exporting countries the revenues are not expected to last for more than one generation, and in

several cases they may cease in less than a decade. In addition, poor energy-exporting nations are at a high risk of the resource curse: economic and political instability eventually affects human development and security.

If rapidly growing demand for energy and high risk of resource curse are considered vulnerabilities of energy systems, there will be very few, if any, countries in the world that do not experience significant energy security challenges. The next section considers how national governments and international institutions attempt to deal with such challenges.

5.3 Energy Security Actors and Institutions

The key to understanding energy security is not only in the quantitative analysis of energy systems, but also in examining perspectives and strategies of energy security actors, primarily nation-states. These perspectives and strategies shape energy security risks by posing or dissuading real and perceived threats and by determining responses to likely disruptions. The energy security perspectives and strategies reflect the objective conditions but are also influenced and limited by cognitive and political factors that shape the views of policymakers and by capacities to enact these views. In response to perceived energy security threats, nations initiate energy security strategies, as we describe in this section. We also discuss the interaction of national strategies at the international level through both conflict and cooperation, including within various international institutions.

5.3.1 National Perspectives and Strategies

National energy security strategies exist in an increasing number of countries and focus on minimizing the risks for the energy end-uses (transport, residential and commercial energy, industry or energy export revenues) most vital for a given country. Some strategies are rooted in specific energy security perspectives – robustness, sovereignty, or resilience – whereas other strategies present more generic responses to multiple threats (see Figure 5.1). This section first discusses the historically earlier and more prominent strategies and then reviews robustness and resilience strategies.

5.3.1.1 Sovereignty Strategies

The essence of sovereignty strategies is increasing control over energy systems vis-à-vis "foreign" or "external" agents. Such threats are often perceived as more imminent and more easily catching public attention. They have also historically been at the center of energy security concerns.

In many cases, sovereignty-driven strategies focus on attaining or increasing control over existing energy resources. One example is the so-called "resource nationalism" of energy exporters that has recently attracted significant attention following the re-nationalization of the energy sector in Venezuela in 2003; another example is the transfer of several major oil and gas projects from international oil companies (IOCs) to state companies in Russia in the last decade. Resource nationalism and the resulting dominance of national oil companies (NOCs) (see Table 5.8) is not exactly a new phenomenon (see Box 5.11). It is not uncommon for the states to seek sovereign control over technology and infrastructure, as well as natural resources. For example, there was significant resistance in the UK against Russian Gazprom acquiring Centrica, a gas distribution company, in 2006–2008, while the US blocked the attempt of the China National Offshore Oil Corporation (CNOOC) to buy a US oil company, Unocal, in 2005.

Resource nationalism is not only typical in energy-exporting countries. Most notably the emerging major importers, such as India and China, are supporting their NOCs in acquiring energy assets around the world. Even OECD countries such as Japan and Korea have shown a renewed interest in the idea of securing supply through a state-owned corporation. A plethora of existing bilateral energy deals, long-term contracts, and joint projects reflect the increasing interests of nation-states to enhance their influence over energy resources, if not to full control, then at least to management through a "trusted partner."

As a result of this trend towards state actors in the global energy market, NOCs have come to dominate the scene, as shown in Table 5.8. In fact, only two of the world's top 15 energy companies in terms of reserves are private, while only one is headquartered in an OECD country.

In fact, and contrary to widespread perception, the trend towards a greater role of NOCs in global energy does not fundamentally affect supply, although it increases the market power of certain states. A strong role of NOCs in global energy does not necessarily imply "less market." Producer NOCs supply the same global market as their private counterparts, while major consumer NOCs tend to sell significant volumes of their equity oil on global markets rather than shipping it back home (IEA, 2007).

Similarly to oil, and with the exception of North America, state companies also dominate the supply of natural gas. In Eurasia, these are, among others, Russia's Gazprom, Algeria's Sonatrach, Norway's Statoil and Azerbaijan's State Oil Company of Azerbaijan Republic (SOCAR).[24] State-owned companies also tend to dominate the downstream gas market in Asia (with Malaysia's Petronas, China's China National Petroleum Company [CNPC], and India's GAIL being prominent examples). At the same time, most European downstream markets have been privatized. Due to restricted access of gas producers to attractive European downstream markets, private retail companies – such as Germany's EoN

24 Where IOCs are admitted to exploration and production endeavors (as in the case of the Azerbaijan International Operating Company [AIOC] developing Azeri gas), state companies are at least party to all of the international consortia developing new gas projects.

Table 5.8 | Oil reserves of top 15 companies.

Rank	Company	Type	Proven reserves (bbl)	Percentage of world total (%)
1	Saudi Aramco	NOC	264.3	21.9
2	National Iranian Oil Co.	NOC	137.5	11.4
3	Iraq National Oil Co.	NOC	115.0	9.5
4	Kuwait Petroleum Corp.	NOC	101.5	8.4
5	Abu Dhabi National Oil Co.	NOC	92.2	7.6
6	Petróleos de Venezuala S.A.	NOC	80.0	6.6
7	National Oil Corp of Libya	NOC	41.5	3.4
8	Nigerian National Petroleum Corp.	NOC	36.2	3.0
9	Lukoil (Russian G8 Presidency)	IOC	16.1	1.3
10	Qatar Petroleum	NOC	15.2	1.3
11	Gazprom	NOC	13.8	1.1
12	Pemex (Mexico)	NOC	12.9	1.1
13	Petrobras (Brazil)	NOC	12.2	1.0
14	China National Petroleum Corp.	NOC	11.5	1.0
15	Chevron (USA)	IOC	8.0	0.7
	Total, top 15		957.9	79.3

Source: BP, 2007; Klare, 2008.

Ruhrgas, Spain's Gas Natural, or France's GDF Suez[25] – enjoy a generally powerful position vis-à-vis producers.

Other examples of moves to secure control over resources include an increasing number of deals that involve China, India, Russia, the United States, and other countries to secure access to uranium deposits in Mongolia, Kazakhstan, and other Central Asian countries (Pistilli, 2009).

It should also be noted that asserting full or partial control over fossil fuel resources is not an option for the majority of countries that both lack such resources domestically and do not have economic, political, or military power to project their influence internationally. Their primary sovereignty strategies are to increase their reliance on domestic resources. Among resources available to a majority of countries – and thus playing an increasingly important role in national energy security strategies – are renewables (hydro, wind, solar, and modern biomass) as well as, to a lesser extent, peat and coal. One of the most celebrated examples of increasing energy security by switching to indigenous fuels is the Brazilian ethanol program, which resulted in the replacement of a large share of imported oil as a transport fuel by domestically produced ethanol. Developing renewable energy resources is seen not only as addressing more pressing and immediate concerns with the volatilities and uncertainties of global fossil fuel markets, but also a more systemic and long-term pressure of the perceived scarcity of fossil fuels and in order to reduce climate impacts of energy systems.

25 The French government holds a 37.5% stake in GDF Suez.

Launching or expanding national nuclear energy programs may also be viewed as a sovereignty strategy. Although few states can build and manage a nuclear power plant and the related nuclear fuel cycle on their own, they typically feel that there are fewer uncertainties beyond their control once the facility is up and running. Nuclear power can also be considered a diversification strategy for states relying on fossil fuels. For example, several Gulf States are import-independent but excessively relying on oil and gas for their electricity generation (Jewell, 2010). Another example is Belarus, whose electricity sector almost entirely depends on imported Russian natural gas. Belarus' planned nuclear power plant will be manufactured from Russian parts and most likely use Russian fuel and expertise, thus not reducing the country's dependency on its neighbor. However, it will provide the much-needed diversity in terms of related technologies, markets, and institutions so that disruptions of natural gas supply will not necessarily be devastating for the country's electricity sector.

5.3.1.2 Robustness and Resilience Strategies

Robustness strategies focus on minimizing predictable and manageable risks within energy systems. For example, many industrialized countries have extensive standards concerning the reliability of electricity transmission and generation (European Parliament, 2006; North American Electric Reliability Corporation, 2010). Robustness strategies may also be focused on constraining demand. For example, following the oil crisis of the early 1970s, Japan, the United States, and eight Western European countries (including energy-exporting Norway) reduced their energy intensity by 30–34% (Geller et al., 2006). In its current energy strategy, Russia aims to reduce the energy intensity of its economy by 40% by 2020, as compared to 2007 (Ministry of Energy of the Russian Federation, 2010). However, no single country in modern times has been able to deliberately reduce or even stabilize its overall energy use over a long term, though demand could be reduced temporarily in response to short-term disruptions (Meier, 2005).

Resilience of an energy system is its ability to provide critical energy services in the face of disruptions. The concept of resilience has recently been brought into the public energy security debate, in particular in the United States, where an influential public figure commented in 2008:

> Our aim should not be total independence from foreign sources of petroleum. That is neither practical nor necessary in a world of interdependent economies. Instead, the objective should be developing a sufficient degree of resilience against disruptions in imports. Think of resilience as the ability to absorb a significant disruption, bigger than what could be managed by drawing down the strategic oil reserve (Grove, 2008).

Enhancing the ability to cope with short-term disruptions that do not alter the fundamental character of energy systems is often more prominent in national energy security strategies. For example, emergency fuel stocks, which are currently maintained by all developed and many

developing countries, address the risks of unexpected short-term interruptions of oil supply or price volatility. Some European countries now have emergency storage of natural gas, which serves the same purpose and proved instrumental in dealing with the shutdown of Russian gas deliveries to Europe in 2006 and 2009. Russia is exploring constructing its own gas storage facilities to deal with potential interruptions of delivery, be it for economic, political, or technical reasons.

Another resilience strategy is increasing diversity. Diversity can ensure that an energy system is able to adjust to more systemic disruptions. It is important to distinguish between various types of "diversity" that can relate to individual elements or aspects of energy systems.

Many energy security strategies contain elements of diversification. These range from increasing the number of import/export routes, origins, or destinations, to increasing the number of actors in the energy sector or the number and types of energy facilities and primary energy sources. Some of the diversity strategies only address relatively limited threats. For example, diversification of import and export routes does not address global price volatility or resource scarcity. In order to deal with more systemic and long-term risks to energy security, more profound diversity strategies are needed. For example, many energy-exporting states are aware of their long-term vulnerability to price fluctuations, eventual resource depletion, and the resource curse. Some of them, most notably the Gulf States and Russia, proclaim strategic focus on diversification of their economies away from reliance on energy exports.

Diversity can also be fostered by certain types of institutions. Although the key rationale for introducing energy markets is economic efficiency, markets may also foster diversity. The existence of the global oil market, where the ability of any single actor to significantly disrupt the supply is limited, is an example of enhancing security through diversity. Naturally, markets (and international trade in general) may also have negative effects on resilience and sovereignty, as further discussed below.

5.3.1.3 Limitations of National Strategies

The majority of countries in the world pursues or at least declares energy security strategies that have both resilience and sovereignty dimensions. These strategies, however, have generally not been effective, which is best evidenced by the presentation of the dire situation of energy security in the world. The reasons for this ineffectiveness are manifold. First of all, the strategies may be internally inconsistent or otherwise poorly designed.

It has proven to be very difficult to strategically reconcile various aspects of energy security. Some measures to boost short-term energy security have had negative impacts in the long term. Certain resilience strategies have adversely affected sovereignty, and vice versa. For example, liberalized markets may have increased the diversity of supply options but lead to increased price volatility and reduce the (real or perceived) control of critical resources by the government.

Similarly, some sovereignty strategies negatively affect resilience. Asserting control may increase confidence but also increase the objectively measured risks and vulnerabilities. For example, nationalization of oil and gas sectors has in some cases resulted in decreased government income from energy revenues due to increasing inefficiencies.[26] Squeezing foreign companies out of energy projects has also resulted in underinvestment and thus the deterioration of infrastructure, as national governments have not possesed the necessary capital, technology, and know-how.

The next reason for the mixed record of national sovereignty strategies lies in the fact that energy policies become too entangled with economic interests, foreign policy, and even conventional security imperatives. Foreign bids by Sinopec, PetroChina, and the CNOOC, for instance, tend to be accompanied by Chinese state aid projects; Gazprom's efforts to make the Ukraine pay "market prices" serves both Gazprom's economic and Russian state foreign policy interests. In addition, NOCs do not necessarily rely on financial markets when financing their exploration and production endeavors, and also enjoy a compelling lender of last resort: the state. Such "political" components of the NOCs' operation almost by definition compromise their energy security performance. What is worse, there is a dangerous trend of viewing energy security policies as an extension of conventional security policies, which leads to the discourse of geopolitics considered in more detail in the next section.

The other line of NOCs' evolution is perhaps more promising, even though it goes against the hope of asserting their parent states' control over energy resources. Observers note that maturing NOCs behave more and more like private companies, especially when operating in global or international markets. This is because they are subject to the same market rules and pressures. In particular, and ironically, some NOCs are affected by the same "resource nationalism" of host countries that resulted in their emergence in the first place. The case in point is Petrobras, a Brazilian semi-public NOC, having its assets nationalized in Bolivia. As any globally operating company, NOCs seek a stable and transparent regulatory environment, a level playing field, and well-protected property rights.[27]

The final reason for the lack of success may lie in the fundamental limitations to conceive and implement an energy security strategy by a single nation-state acting alone. It is quite obvious that small economies are rarely, if ever, able to implement energy system transformations on their own, since they simply do not possess the necessary financial,

26 A case in point here is Venezuela's PDVSA, which has experienced a strong downward trend both in output and overall efficiency after Chavez's re-nationalization of the energy sector in 2003.

27 That is why Russian Gazprom is, for example, domestically championing corporate social responsibility and other "good business" causes and the CNOC is reportedly considering joining the Extractive Industries Transparency Initiative (EITI).

technological, and human resources. For example, a study shows that launching a national nuclear power program relying on their own resources may be out of reach for at least 28 of the 52 countries that expressed an interest in nuclear energy based on their energy security imperatives (Jewell, 2011).

Even larger countries face serious limitations in ensuring their own energy security. This is not only due to lack of capacity, but also to the natural reflexivity of energy security. If states start acting alone or in closed groups, other states may perceive their actions as threats to their own energy security. In no time, energy security becomes a "zero-sum game" dominated by "geopolitical" and other discourses drawn from the vocabulary of diplomacy and military security. We turn to such developments in the next section.

5.3.2 Energy, Geopolitics, and Confrontation: the Specter of Energy Wars

A comprehensive understanding of energy security includes perceptions and perspectives of nation-states alongside "objective" indicators. A peculiar aspect of such perceptions is reflexivity: their ability to dynamically influence each other. If the position or actions of a country are perceived as a "threat" to energy security, other countries may start responding in such a way that is also perceived as threatening, causing another round of threatening responses, etc. The situation may escalate into a zero-sum game, with the energy security of certain nations only being achieved at the expense of other nations. Eventually, such developments may result in a lack of much-needed confidence, disrupted cooperation, increased tensions, or even conflicts over energy resources or infrastructure.

The risk of conflicts over energy resources is a significant concern on the global security agenda. The extreme form of such confrontation is a much-feared "resource war" – an inter-state armed conflict aimed to secure access to energy resources. In 1980, the US President Jimmy Carter proclaimed that the United States would use military force in the Persian Gulf region to defend its national interests, specifically "the free movement of Middle Eastern oil" (Carter, 1980). The fear of resource wars has considerably grown in recent years, particularly prompted by the rise of the "new consumers" of globally tradable energy resources (India and China), concerns over inadequate capacity to meet the increasing demand for oil, rising oil prices, and a series of high-profile disputes involving Russian gas supply to Europe. An influential geopolitical school of thought (e.g., Klare, 2008) points to numerous factors increasing the risk of such a confrontation in the near future.

Other researchers (Jaffe et al., 2008) note that there have been very few – if any – resource wars in the recent past[28] (save the Iraq-Kuwait war of 1990) and downplay the risks of such conflicts in the future. The arguments about the future probability of oil conflicts are difficult to resolve. On the one hand, the risk of resource wars significantly depends upon non-energy factors such as the capacity of international and bilateral regimes and institutions; on the other hand, the configuration of global oil production, trade, and use are undoubtedly major factors determining such risks. Moreover, there are several forms of confrontations involving energy resources that are only marginally less worrisome than resource wars.

First, energy resources, particularly oil, have played an important role (sometimes as a weapon) in past inter-state confrontations, including armed conflicts. The "tanker war" linked to the Iran-Iraq conflict, the Arab oil embargo related to the Arab-Israeli war, and other modern examples are listed in Table 5.9. It may be argued that the presence of oil (or many other natural resources, for that matter) have made some armed conflicts more prolonged or destructive.

Second, energy resources and infrastructure have shaped inter-state relations, prompting either collaboration or confrontation or, more commonly, a mixture of both. The most prominent examples include:

- the dispute over borders in the potentially oil- and gas-rich Arctic (but also possible collaboration over the exploration of oil and gas in the Arctic); similar disputes have also been documented in other regions;[29]
- debates over gas and oil pipeline routes in Eurasia (such as the Nord Stream gas pipeline bringing Russian gas to Western Europe and the Baku-Tbilisi-Ceyhan (TBC) pipeline transporting Caspian oil to the Mediterranean); these were closely linked to several heated disputes over gas and oil supplies between Russia and former Soviet states in Eastern Europe (Belarus and Ukraine), as well as in the Caucasus;
- military and development support from major oil importers (notably the United States and China) to some oil-producing and transit countries in Africa (e.g., Sudan and Nigeria), the Gulf Region (e.g., Saudi Arabia), the Caucasus (Georgia and Azerbaijan), and Central Asia (e.g., Kazakhstan); which is often linked to:
- the struggle for influence in the remaining few oil-producing regions among major oil importers (the United States, Western Europe, China, and Japan).

Third, increasingly strained supplies of energy resources justify the growing deployment of military overseas to "protect" oil infrastructure (for example, terminals, tanker routes, etc.) against real and perceived threats and disruptions. The recent creation of the US Navy command

28 On the other hand, historically more wars can be linked to some resource issues. The very devastating Paraguay-Argentinean war (1932–1935) for Gran Chaco was for presumed oil reserves in that area (that never materialized). Many aspects of World War II (e.g., Japanese occupation of the Dutch East Indies or the German-Soviet battle over the Caucasus) also had an oil sub-text.

29 The Spratly Islands are claimed by China, Taiwan, and Vietnam; parts of them are claimed by Malaysia, the Philippines, and Brunei (Klare, 2008). The Falkland Islands (Malvinas) are claimed by the United Kingdom and Argentina (Luft, 2010).

Table 5.9 | Major inter-state conflicts and tensions related to oil and gas systems (since the end of World War II).

Year	Resource/system in question	Security event or measure
1950	US and other oil exports to China	The Western bloc's Coordinating Committee for Multilateral Export Controls placed China under an oil embargo during the Korean War of 1950.
1956	Saudi oil reserves/production	Saudi oil embargo against France and the United Kingdom following the Suez crisis
1967	Middle Eastern oil embargo	Imposed by Arab nations on the USA, the UK or in relation to all oil exports after the beginning of the Six-Day War.
1973–1974	Oil production/reserves of Arab oil exporting countries	OPEC and Arab oil embargo, generating the first "oil price shock"
1979	Oil exports of Iran	Iranian revolution
1980	Crude oil exports of Iran/Iraq	"Tanker War" between Iraq and Iran
1981	Algerian gas supply	"Gas Battle" between Algeria, Italy, the United States and others
1990–1991	Kuwait oil reserves	Iraq invasion of Kuwait eventually repelled by the United States and allies
2003	Russian crude oil delivery/ pipeline infrastructure	Cut-off in Russian oil supplies to Latvia
2003	Iraq and Middle East oil reserves	US invasion of Iraq
2005	Pricing mechanism of Russian gas	Gas dispute/cut-off in Russian gas supplies to Georgia
2006	Pricing mechanism of Russian gas	Cut-off in Russian gas supplies to Ukraine and Moldova
2006	Russian crude oil delivery/ pipeline infrastructure	Cut-off in Russian oil supplies to Lithuania
2007	Pricing mechanism of Russian oil deliveries to Ukraine	Russian interruption of the Druzhba oil pipeline
2009	Pricing mechanism of Russian gas	Cut-off in gas supplies to Western Europe, causing side unclear (Ukraine or Russia)

for Africa (AFRICOM) and Russia's plans to increase its military presence in the Baltic to protect the Nord Stream gas pipeline (as well as the Swedish response of increasing its own forces in the Baltic) are quoted as some examples. US national security and oil imports, as well as the implications of various energy issues for the US Navy, have been the subject of two recent RAND reports (see Box 5.9).

Not only do energy resources (particularly oil and gas) shape inter-state relations, but they may also affect internal security issues, especially in poorer countries that face nation-building challenges. Current inter-ethnic conflicts in Iraq – largely related to oil – are most prominent, but energy resources shape and color internal tensions in many other countries. Civil wars in Angola, Colombia, the Republic of Congo, Indonesia (Aceh), Morocco, and Sudan, as well as a simmering conflict in the Niger Delta in Nigeria (see Box 5.10), have also been linked to oil. Whether the political challenges of allocating revenues from oil and gas production will lead to instability and conflict depends on the quality of governance and institutions as well as key international actors.

Finally, there have been concerns about the connection between energy resources and international terrorism, particularly the argument that oil revenues help to fund terrorist activities. However, very few, if any, facts have been found to support this assertion except circumstantial evidence that certain terrorist organizations and individuals come from the Arab-speaking countries which also happen to have significant oil reserves. On the contrary, many researchers point out that terrorism is a "low-cost activity" that does not depend on oil revenues. Moreover, the emergence of contemporary terrorist networks (such as al-Qaeda) occurred in the mid-1990s when oil revenues were at their lowest. On the other hand, the resource curse – i.e., economic and political problems in many poor oil-exporting countries, described earlier – has contributed to dissatisfaction and disenfranchisement of individuals and social groups that eventually support or engage in terrorist activities.[30]

Box 5.9 | Energy and US Defense Costs

Due to heavy dependency of the United States on imported oil, access to foreign oil remains a top priority driving the country's strategy and defense policy. US military forces have been present in the Persian Gulf since the 1970s to protect access to Middle Eastern oil. US efforts to ensure secure access to foreign oil also include, since the 1990s, deepened ties (economic, political, and military) with oil-producing states in Central Asia, South America, and West Africa.

The presence of US military forces to maintain the security of international oil flows for the global market undoubtedly incurs substantial costs. However, to date, there has been no comprehensive, accurate, publicly available US government study of the costs. Nevertheless, several attempts have been made to quantify them. In general, the analyses addressed the costs incurred by US Central Command (USCENTCOM)[31] in its mission to protect the maritime transit of oil supplies in the Persian Gulf and Indian Ocean, as well as to assist in

30 This hypothesis explains why terrorism often emerges during low rather than high oil prices when the level of popular dissatisfaction may be highest in those economies that primarily rely on oil revenues for their welfare programs.

31 USCENTCOM is a military force created in 1979 to be available for worldwide contingencies. However, its focus quickly tilted heavily toward the Persian Gulf region.

the defense of United States-friendly oil-producing governments. Estimates in these studies have varied from as low as US_{2005}12 billion up to as high as US_{2005}130 billion of military spending per year, representing, respectively, 2.5% and 27% of the defense budget in 2006. This range in estimates reflects the complexity of how US forces are planned and operated and, thus, the difficulty of being very specific in allocating precise costs to this mission.

Recently, two RAND research teams estimated the incremental costs that the US government would likely avoid if it were to entirely drop the mission of ensuring the secure production and transit of oil from the Persian Gulf for the global market. Estimates of potential annual savings amounted to between US$67.5 billion and US$83 billion – respectively, 12% and 15% of the US defense budget. However, these estimates do not claim to be precise. Moreover, RAND's analysis does not argue that a partial reduction of the US dependency on imported oil would automatically lead to a proportional reduction in US spending that is focused on this mission (Crane et al., 2009). Another RAND study predicts that the defense budget is likely to decrease due to future increased social spending for the United States' growing numbers of elderly citizens, which, in turn, will likely affect the incremental amount available for protecting oil supply and transit (Gordon et al., 2008).

Two other academic assessments produce similarly startling figures. Researchers at the Oak Ridge National Laboratory in the United States estimated that from 1970 to 2004 American dependency on foreign supplies of oil has cost the country US$5.6–14.6 trillion in macroeconomic shocks and unnecessary transfers of wealth.[32] When the numbers are adjusted to 2007 dollars, the amount is greater than the costs of all wars fought by the country going back to the Revolutionary War, including both invasions of Iraq. Researchers from the University of California-Davis and University of Alaska-Anchorage calculated that US defense expenditures exclusively to protect oil in the Persian Gulf amount to about US_{2005}28 billion to US_{2005}75 billion per year (Delucchi and Murphy, 2008).

Box 5.10 | Resource Wealth, Civil Conflict and Disruption of Oil Supplied in Nigeria

The complex interplay between resource wealth, political and inter-ethnic conflict, and its impact on production facilities, infrastructure, and output is evident in the case of political conflict in the energy-rich Niger Delta. Nigeria is one of the world's top 10 oil exporters and produced around 3% of the world's total output in 2006 (BP, 2007). Yet traditional tension between different ethnic groups in the Niger Delta, one of the most densely populated areas in the world, turned into violent conflict as oil revenue started to pour into the country. The behavior of large oil corporations and poor capacities of the local government is largely regarded as having contributed to raising the degree of violence and to prolonging conflict. Violence has become a major cause of slowing production and causing interruptions in Nigerian crude deliveries. Attacking installations, kidnapping oil corporations' personnel, and siphoning off crude from pipelines have become common features. In 2006, militant attacks on oil facilities resulted in a shutdown of almost 500,000 barrels per day, or 20% of Nigeria's oil output. In addition, oil tankers have been stolen, with the crude being sold on foreign markets (Vesely, 2004).

5.3.3 Energy Alliances, Institutions, and Markets

Despite the rhetoric of geopolitics, the zero-sum game, and the resource wars, the actual international interaction in the field of energy security has so far been largely dominated not by conflict but by cooperation, albeit imperfect. This section examines the existing cooperation mechanisms as well as their successes and shortcomings.

At the moment there is no overarching global energy institution, but rather a plethora of alliances, multi- and bilateral deals, and arrangements. The most significant international energy alliances unite major exporters and importers of energy (primarily oil). First and foremost, these include OPEC, established in 1960 in Baghdad, with the aim of regulating global oil production. OPEC seeks to influence oil prices by adjusting production levels through the use of a quota system. At present, OPEC member states control around 80% of global oil reserves and almost half of global production. Gas-producing countries established the Gas Exporting Countries Forum (GECF) in 2001, which remains a rather loose gas club that might – depending on the development of the take-or-pay-dominated market – potentially become a future gas cartel similar to OPEC.

32 Source: Greene and Ahmad, 2005. Numbers have been adjusted to US_{2007}.

The International Energy Agency (IEA) is a watchdog for energy-importing members of the OECD. It has developed rules concerning strategic petroleum reserves and a supply shock emergency response mechanism. The IEA can draw on the International Energy Program (IEP, established in 1974) for larger supply interruptions, and on the coordinated emergency response mechanism (CERM), which applies for smaller emergencies.

Another type of energy alliance is formed on the basis of regional proximity. One example is the EU, whose prototype, the European Community for Coal and Steel, was created to govern access to coal resources, the then-dominant energy source. The EU aims to operate a single energy market. For that purpose, it fosters an integrated energy infrastructure (such as in electricity and natural gas) and liberalized cross-border trade of energy services governed by common rules and policy agenda. The EU has also sought to develop a common energy policy towards third parties, encompassing energy security and other energy-related goals as well as environmental and climate-related topics. Vis-à-vis main producers, the EU has initiated steps towards linking up with neighboring regions via energy partnerships within the realm of various agreements, including the Partnership and Cooperation Agreement with Russia, or via efforts targeting the Maghreb/Mashrek region. Project proposals also exist for the large scale import of renewably generated electricity from northern Africa (Komendantova et al., 2009).

Another regional club is the Shanghai Cooperation Organization (SCO) uniting Russia, Central Asian countries (all net energy exporters), and China (an energy importer). Whether the energy role of the SCO will extend beyond declarations is so far not clear. Regional "clubs" with energy agendas also exist in other regions. For example, in West Africa, common arrangements feature the West African Power Pool, West Africa Gas Pipeline projects, and the West Africa Regional Energy Access initiative, all designed to reduce energy insecurity in the region. Similar arrangements are being tried with the East African Power Pool and the Southern Africa Power Pool.

Some energy alliances have also been established based on nations' economic, rather than regional, characteristics. For example, the historically prominent G7, created in the aftermath of the first oil shock in 1973, gathered the largest economies of that time (Germany, Italy, Japan, the United Kingdom, the United States, France, and Canada) to coordinate its members' energy-related and macroeconomic policies. The G7 did not noticeably address energy issues during the almost two-decade-long low-price period on the oil market from the early 1980s to the early 2000s. It was joined by Russia in 2004, becoming the G8, and has recently sought to include other large economies including major consumers and producers of energy (China, India, Brazil, South Africa, and Mexico) to become the G20. However, the G8 and G20's energy activities so far have been limited to declarations rather than to establishing permanent effective institutions.

The relationships between various different alliances are sometimes portrayed as competition or confrontation.[33] In our view, a more accurate description would be that of "non-engagement." As already noted, there are very few global energy rules or institutions extending beyond specific alliances. The International Energy Forum (IEF), an organization that seeks to unite energy exporters and importers, has not yet resulted in any tangible institutions or arrangements. Perhaps the only widely applicable organizing principle is that of a free market for certain energy products, most importantly oil.

Establishing a global oil market was facilitated by the advances in transportation and communication technologies, as well as the end of the Cold War. As a result, many security concerns of the 1970s and the earlier era have subsided. The producer countries are no longer at the mercy of international oil corporations dictating their conditions (see also Box 5.11 on IOCs and NOCs). The consumer countries can seamlessly switch and mix suppliers and not worry about excessive dependency on a single supplier. The global oil trade system can assimilate minor shocks of disruptions in particular countries or regions.

However, the free market has its limitations. For example, it does not function well under conditions of imperfect information or monopoly, which often arise naturally in the case of grid based carriers (compare to Chapter 22). Also the global oil market has increasingly developed some of these features. Information about reserves and production capacities has been severely impeded by an explicit non-reporting policy of OPEC and other exporters. Moreover, due to the increasing geographic concentration of oil reserves and the lack of suitable substitutes, the global supply develops the characteristics of a monopoly. In addition, as discussed above in relation to national energy security, markets tend to under-provide such public goods as sufficient investment in production capacity and infrastructure.

This last feature has been empirically observed in the case of global oil markets. A prime example includes the current global shift from a "strategically planned," vertically integrated approach in the energy industry, practiced even in private companies, towards decision-making based on immediate economic objectives such as return on capital. This shift, partially encouraged by the financial investment community and seen especially in the low oil price environment of the 1990s, led to a decrease in spare capacity in production, storage, and transportation, thus increasing the effects of even small disruptions. Markets in their current shape tend not to reward players for maintaining spare capacity and do not have adequate mechanisms for charging for capacity on a pay-as-you-go basis, which tends to enhance booms and busts. Price hikes effectively allow some of those market players who did invest for extraordinary circumstances to obtain a return on their investments, albeit in a one-off fashion, as opposed to a constant stream of income.

33 For example, the SCO is sometimes considered a "geopolitical bloc" aimed at undermining the US presence in Central Asia. In the eyes of some pundits, such new geopolitical constellations will be increasingly framed by energy issues and will compete with each other (e.g., the SCO competing with the United States and Japan in the Western Pacific). See, among others, Klare, 2008.

To buffer these shortcomings, institutional arrangements need to be strengthened to provide for a greater degree of information, notably data collection and exchange. Here, the IEA's data-generating activities (though notoriously criticized on analytical fronts and short on information on producing countries) and institutions of producer-consumer cooperation such as the IEF in Riyadh become essential. The IEF's Joint Oil Data Initiative (JODI) is a particularly promising step.

Finally, there are vocal concerns that market arrangements might crumble in the face of rapidly unfolding scarcity or another severe energy security crisis. According to Klare (2008):

> Oil will cease to be primarily a trade commodity, to be bought and sold on the international market, becoming instead the preeminent strategic resource on the planet, whose acquisition, production, and distribution will increasingly absorb the time, effort, and focus of senior government and military officials.

While it is difficult to judge the validity of such concerns, history definitely provides many examples of when market arrangements were either heavily modified or entirely replaced by other rules in times of severe crisis. This leads many observers to believe that markets should not be viewed as the only or the most effective mechanism for providing energy security.

To summarize this brief overview of the most notable international institutions, the world governance of energy security has been ineffective for the following two reasons:

First, there has been little success in creating institutions that would serve and include key actors and stakeholders. There is no effective organization that would unite exporters and importers of energy. Some of the largest consumers, China and India, are not part of the "importers club," the IEA. The majority of countries are simply "too small" to qualify for various memberships, although their energy security concerns are no less significant than those of larger countries.

Second, the existing energy security institutions largely focus on oil and partially on naturally gas. This is understandable from the point of view of the present concerns, where these resources are at the front and center of energy security. However, this also shapes the expertise and the frame of reference of the existing institutions and largely predetermines their inability to govern seriously systemic energy transitions involving various supply, infrastructure, and demand elements.

Third, the international arena governing energy security should be more strongly connected to the international arenas governing climate change and supporting the provision of access to modern energy. These three arenas have historically developed in isolation from each other, but it is no longer possible for them to operate independently in the world where energy challenges are increasingly entangled (Cherp et al., 2011).

Potential pathways for the future evolution of global energy security institutions are touched upon in Section 5.3.

Box 5.11 | IOCs, NOCs and the Global Oil Market

The origins of the current global oil market date back to the 1930s. At that point, the industry became dominated by a small number of transnational corporations, controlling most of the sales of oil products. Most oil-rich nations lacked the domestic capacity to develop their reserves and were thus dependent on these large, integrated oil companies, also since the latter controlled the downstream assets in the main Western markets. The notions of the "Seven Sisters" or "Big Oil" still reflect the unprecedented power of the Western-dominated international oil companies (IOCs) in that era.[34] US policies supporting the "one base" or "Gulf plus freight" formula (later revised to the "two base" oil pricing formula) helped maintain a single price for all oil consumers outside the United States and secured enormous rents for this cartel. Until the 1960s, the United States was a major producer and a net exporter of oil. Thereafter, the decline of US mainland production, coinciding with the process of decolonialization and a growth in nationalism in producing countries shifted the balance of (market) power to the countries actually owning the resources. OPEC, initially established to enable producing countries to enhance their share in oil revenues vis-à-vis the dominating Western IOCs, is a result of this process, and profoundly changed the global oil market by introducing production quotas, a tool to influence oil prices. In response to OPEC's cartelization efforts in the 1970s, industrialized countries established the IEA, a consumers' club intended to strengthen the market power of importing nations; in addition, they pushed for energy efficiency improvements and the development of advanced offshore production techniques in the 1970s and the 1980s, leading to the opening up of new hydrocarbon provinces. As a result, the global oil market became more liquid and highly integrated, reducing the power of OPEC to set prices. OPEC defended the high price level established in 1980 by cutting production

34 The "Seven Sisters" consisted of Exxon (or Esso, Humble, Standard of NJ), Royal Dutch Shell, BP (originally British Petroleum, Burmah Oil + Anglo-Iranian), Gulf, Texaco, Mobil (Standard of NY or Socony-Vacuum), and Chevron (Standard of California).

every year until 1986, the long-term trends of world oil demand and non-OPEC supply eventually resulting in longer prices. However, in the new millennium, due to economic globalization and a steep rise in demand from "emerging consumers" (e.g., India and China), the pendulum has again swung back. In addition, financial market actors and mechanisms have entered the global oil market, which is now characterized by a variety of hedging instruments, swap and future contracts.

As this brief historical survey suggests, IOCs – i.e., private players – dominated the oil market for a long time. Historically, many of them (BP and the predecessors of Total, ENI) were fully or majority-owned by Western governments, and even private companies enjoyed a high level of support from their home states. In that respect, their role was somewhat comparable to the national oil companies (NOCs) from emerging importing nations such as India and China: a secure energy supply for their home nations abroad. With a more integrated global oil market, these companies have become fully fledged profit-driven enterprises. IOCs see their core competence in the ability to mobilize the large amounts of capital, equipment, and manpower required to develop and manage large projects; to use their technical expertise and know-how to reach even increasingly difficult reserves; and to live with price and resource market uncertainties and to manage political risks even in "frontier" environments through large investment portfolios. IOCs usually received a share in the upstream (equity oil) of the projects in which they were involved. More recently, and particularly against the backdrop of rising resource nationalism and market pressure to reduce costs, a second set of private players including integrated service providers (ISPs) such as Halliburton and Schlumberger have entered the scene. These companies bring in their specialized expertise and act as contractors to both IOCs and NOCs. In contrast to IOCs, they usually do not engage in exploration and production projects with their own capital.

5.4 The Future of Energy Security

This section considers possible future developments in energy security. It discusses the implications of projected or likely demographic, economic, natural resource, technological, and institutional developments. It also lays the foundation for a quantitative analysis of energy security under sustainable energy transition pathways modeled in GEA. This analysis is presented in Chapter 17.

5.4.1 Technology and Resource Developments

The role of oil on the global energy security scene will likely become even more important in the short- to medium-term future. Oil production will probably become more geographically concentrated, and demand for oil will continue to increase, primarily in Asia. Several present-day exporters (for example, the United Kingdom and Argentina) will likely become importers, and many countries will need to import more in both absolute and relative terms. The *World Energy Outlook 2010* (IEA, 2010a) predicts that both supply and demand of oil will become less responsive to prices, which will likely lead to long-term price increases for this fuel. At one point in the future, perhaps as soon as in one or two decades, the global production of conventional oil will likely "peak" or "plateau."

Many concerns have been expressed in connection with this imminent "peak oil." Some predictions paint a collapse of organized oil markets with catastrophic economic, and possibly political and military, consequences (Korowicz, 2010). It seems more likely that peak oil will have many more localized effects on those countries (mostly in the developing world) that lack the capacity to cope with steep increases in energy prices. Whether the international community will be able to mitigate the shock for these and other countries depends not only on other technological and resource developments but also upon the presence, focus, and effectiveness of global energy governance institutions in the future.

The production of natural gas is also likely to become more concentrated, but it is unlikely to peak in the nearest decades. The main developments affecting the situation with natural gas will most likely be advances in transportation technologies and infrastructure. A much more extended network of gas pipelines is likely to emerge in Eurasia, linking Russian and Central Asian producers not only to Europe but also to China and the rest of Asia. The development of LNG infrastructure will lead to the sharp increase in intercontinental trade. Growing LNG trade, while contributing to the emergence of a truly global natural gas market, may imply similar supply security patterns as the global oil market, including an increasing dependency on less reliable producer countries, transportation choke-points, and global supply-demand balances. Technological developments affecting the accessibility of shale and other unconventional gas may also alter the global gas market landscape, although the exact extent of this much-heralded "shale gas revolution" are difficult to predict.

A likely consequence of the dynamics of global oil and natural gas production will be a shift away from these energy sources, which is already vigorously pursued by many countries. It is unlikely that a new globally dominant source of energy, such as oil, will be found. Instead, there will be a shift to diverse sources, appropriate to national and regional contexts. One such source may be coal, especially if technologically and economically acceptable ways of low-carbon utilization of coal are found.

Nuclear energy will clearly be another alternative to fossil fuels considered by many countries. While the global scale of future nuclear expansion is not clear, it is likely that nuclear energy will be able to address energy security challenges only in a relatively limited number of countries. At the moment, the lion's share of the world's nuclear capacity is concentrated in the United States, whereas almost all short-term growth occurs in China, other Asian economies, France, and Russia. For most of the other countries with existing nuclear energy programs, such programs may become a liability rather than a solution to their energy security challenges.

There are over 50 "newcomer countries" that are interested in launching nuclear energy programs for the first time, by and large, to meet their energy security needs. According to Jewell (2011), safe deployment of nuclear power is likely in only 10 such countries under present conditions. Others will need very significant international help, including possibly forming energy partnerships among themselves, or dramatically altered nuclear energy markets and policies (see Figure 5.7).

Finally, oil, natural gas, coal, and nuclear power may be partially displaced by renewable energy sources. One such source is biomass. If the future biofuels or biomass systems assume production and transportation patterns similar to that of present-day fossil fuels (i.e., concentrated production regions away from consuming regions and large centralized refineries), they may also become subject to similar risks and vulnerabilities. Furthermore, the availability of biomass feedstocks may be disrupted by climate change as well as policies guided by conflicting uses (e.g., food production or ecosystems preservation). Given the emerging state of the present-day biofuels systems, the scale of these risks is difficult to estimate.

Replacing with other renewables (such as wind and solar) will require technological innovation and creation of new infrastructure, including (as penetrations rise significantly) new systems for the storage and distribution of energy and for possible new propulsion systems for vehicles (e.g., electricity or hydrogen). There are possibilities that the storage requirements associated with large-scale electricity system transitions towards distributed renewable resources may be offset by synergies between parallel emerging smart management procedures for distributed energy storage in electric vehicles. Relatively simple co-ordination systems enabling the remote control of certain consumer products also offer an important resource in cost-effective management of intermittency and other electricity security challenges. Specific technologies for carbon capture at centralized fossil fuel plants may also present opportunities for improving capacity to manage intermittency. These developments introduce a potentially significant level of effective aggregate electricity system storage capacity as a side effect. However, the task of

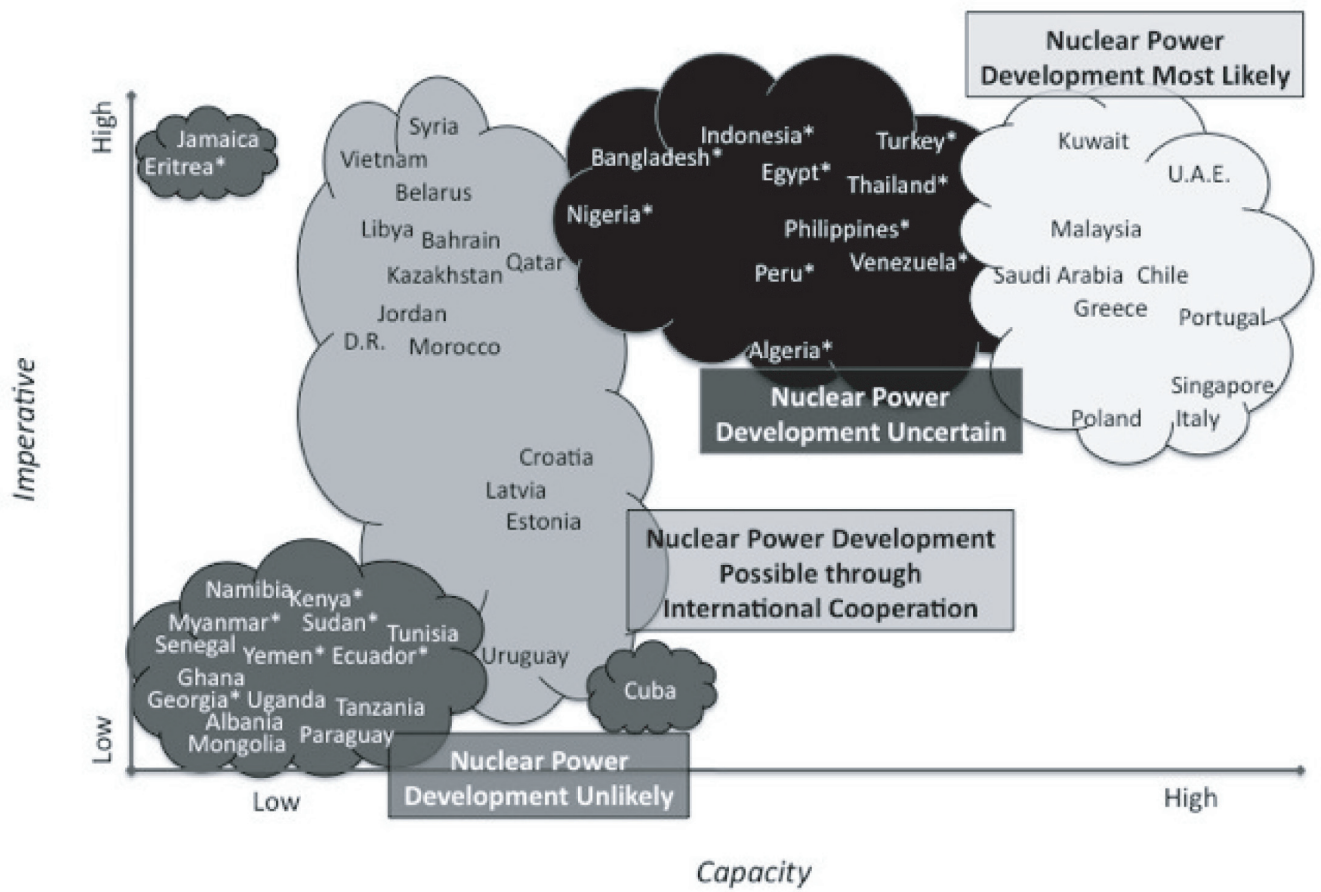

Figure 5.7 | Feasibility and uncertainty of nuclear power adoption by new countries. Source: Jewell, 2011.

Table 5.10 | Factors in future energy scenarios related to national energy security strategies and international institutions.

Focus of national strategies International institutions	Sovereignty	Robustness and Resilience
Less effective	Fragile markets and geopolitics; national state-driven transitions to centralized solutions	Self-organizing markets; decentralized and diverse transitions
More effective	Strong rules and powerful alliances; regulated markets	More uniform transitions at several levels

realizing the positive synergies of these technological innovations raises many challenges for associated infrastructural, organizational, contractual, and regulatory innovation. Wind, solar, and hydro energy are more likely to be produced domestically and thus not invoke traditional sovereignty concerns. However, there are also plans (such as Desertec) to generate solar energy for intercontinental trade.

Another imminent development affecting energy security in the future is the increasing role of electricity in energy systems. Electricity will play a more important role due to the likely advent of plug-in electric propulsion vehicles and the continuing spread of ICTs and other consumer technologies requiring electricity, as well as to the increasing use of electricity by the rising middle class in emerging economies.

An increasing reliance on electricity will mean that reliability of its production and distribution is likely to come to the forefront of energy security concerns in the future. The complexity of future electricity systems is likely to increase to incorporate:

- technologies for storage of electricity;
- "smart grids" including "active load" devices;
- "super grids" for transferring large quantities of electricity over long distances with minimal losses (e.g., through high-voltage direct current lines) when localized distributed systems are not feasible or sufficient; and
- hybrid systems,[35] to increase reliability of power generation and distributed generation such as modular small-scale systems with improved or increased energy storage capacity.

Some of these approaches may reduce the risk of "cascading failures" inherent in modern complex centralized grids. It is possible that other approaches to increasing reliability will evolve as a result of a combination of electric and information technologies. As the role of electricity in energy systems increases, the factors affecting energy security will have increasingly more to do with institutional structures and capacities than with more traditional issues of access to natural resources.

35 For example, hybrid systems using wind or solar photovoltaics to provide emergency back-up to conventionally distributed electricity.

5.4.2 Institutional Uncertainties in Future Energy Security

Energy security perspectives and strategies are both a key driving force of and a central strategic uncertainty in future energy transformations. Security has been a main driver of past technological and political transformations, and it is also a prominent consideration in most, if not all, of the global long-term scenarios. It is not certain which of the perspectives on energy security will prevail in national energy agendas and discourses. Another, separate uncertainty is whether new international energy institutions will emerge and be able to function effectively (see Table 5.10).

If the resilience and robustness perspectives gain more prominence at the national level, countries are likely to promote diverse energy solutions. The focus of national policies may become decentralized and distributed energy generation, improvement of electricity grids, and demand-side measures such as energy efficiency. Regulated but generally liberalized markets may become more common national energy arrangements. Many such measures will also improve sovereignty – i.e., reduce import dependency – although nations driven by these two perspectives may remain open to international trade and investments.

An additional uncertainty in this case may arise at the international level. If effective international energy institutions are created, they will be able to help countries with technology transfer, ensuring investments and well-functioning markets to enhance energy resilience. These global energy institutions may be able to oversee new patterns of intensive international energy trade (e.g., in electricity, hydrogen, or biofuels). This will be a more favorable scenario.

It will be more difficult for most countries to pursue resilience and robustness strategies in the absence of effective international institutions. The pace of transformation to diverse and more robust energy systems may be significantly slowed down, especially in smaller and poorer economies. More disparity in energy security may emerge as a result. In fact, the absence of functioning international institutions may push many countries towards the sovereignty perspective.

If the sovereignty perspective in national energy security policies prevails, countries may view international trade, foreign capital, and even domestic private actors with a degree of suspicion. Energy solutions are likely to be less diverse, more centralized, and relying on state support (e.g., nuclear power, or coal with carbon capture and storage). If international energy institutions continue to be weak, the global energy markets may start failing, especially in the case of increasingly scarce "strategic"

commodities such as oil and natural gas. Geopolitics may become the rule of the day, with stronger and larger countries gaining better "access" to scarce resources. This may, in turn, push national governments towards surprisingly rapid transformations of energy systems. There is naturally no guarantee that such transformations will always be safe or successful.

Finally, one can imagine strong international institutions in the world where most countries pursue sovereignty strategies. The role of such institutions will be more limited than in the resilience scenario, but they will still be able to set the rules of the game (such as market institutions) to prevent geopolitical manipulations from exploding into open confrontation. Regionally or ideologically based "energy clubs" based on "mutual trust" may also become increasingly prominent.

5.4.3 Energy Security under Sustainable Energy Transitions

The GEA argues that energy systems can support such global goals as poverty reduction and the stability of Earth's climate only if they are radically and rapidly transformed. Chapter 17 (Energy Pathways for Sustainable Development) defines multiple pathways for such sustainable energy transitions.

The question is: what are the energy security implications of these pathways? Due to the radical transformations of energy systems, the energy security concerns identified in this chapter cannot be simply projected into the future. While some of these concerns may disappear or become irrelevant, new vulnerabilities may emerge. For example, oil, an energy source that is at the heart and center of most energy security concerns today, may be phased out and replaced by other fuels. But will using these new fuels on the global scale result in similar energy security concerns? Will they be produced in just a few countries and regions that will set terms for the global market? Will they dominate end-use sectors and lack easily available substitutes so that any disruption may be catastrophic? Will poorer countries and regions spend a significant portion of their revenues to procure these new fuels?

This section summarizes generic energy security considerations that form the basis of assessing energy security under sustainable energy transitions. We presume that, although energy security concerns might change in the future, the perspectives on energy security will remain the same. This means that nations will still be concerned about the robustness (i.e., the protection from certain known risks), the sovereignty (i.e., the protection from actions by external actors), and the resilience (i.e., the ability to withstand various disruptions, both known and unknown) of their energy systems.

Applying these three perspectives to energy sources, carriers, end-use services, and regions[36] of the future will answer the following questions:

- With respect to *energy sources*: what will be the energy sources of the future? Will any of them dominate the global energy supply to the same degree that oil, gas, and coal dominate the present-day energy landscape? Will they be based on non-renewable and hence limited resources or utilize renewable energy? Which of these sources will be traded on the global scale? Will their global trade be equally as intensive as it is currently for oil? Will their production be concentrated in only a few regions or be more evenly spread around the world?

- With respect to *energy carriers* and *end-use sectors*: will they be based on diverse energy sources or dominated by one fuel, like the transport sector today? Will they primarily rely on imported or domestic energy sources? Will they experience very rapid and destabilizing growth or decline during any periods of the transition?

- With respect to *countries and regions*: will any of them be significantly dependent on imported energy? Will any of them rely on just a small number of energy sources? Will energy intensity and hence vulnerability to changing energy prices increase or decline?

The above questions are answered in Chapter 17 with the help of a quantitative projection of selected energy security indicators. The overall conclusion of this analysis is that in most pathways of the GEA Scenario, energy systems become more secure from all perspectives and in most of the regions. At the same time, certain vulnerabilities may emerge in particular regions or globally, and these need to be taken into account and mitigated while managing sustainable energy transitions.

5.5 Conclusions

Adequate protection from disruptions of vital energy systems – "energy security" – is one of the most politically prominent energy-related concerns. Disruptions of energy systems may result from both short-term shocks, such as natural events, technical failures, malfunctioning markets, or deliberate sabotage, and slowly unfolding but more permanent threats, such as resource scarcity, aging of infrastructure, and unsustainable demand growth. Such disruptions may affect broader security issues ranging from the viability of national economies and stability of political systems to the danger of armed conflicts. This means that policies developed in the quest for higher energy security have been, and are likely to remain, a key driving force in the transformations of energy systems.

Although energy security concerns differ from one country to another, they typically relate to the robustness, sovereignty, and resilience of energy systems. Robustness means minimizing risks arising from well-defined natural, technical, and economic factors. It is associated with sufficient energy resources, reliable infrastructure, energy efficiency, and managed demand. Sovereignty means the protection from disruptions to energy systems by external agents. Reliance on domestic

36 The GEA model cannot forecast energy developments in individual nations, and the analysis is, therefore, concentrated on the regional level. The caveats of such an analysis of energy security are explained in the relevant section of Chapter 17.

resources and technologies, stable prices, control over infrastructure, and trusted institutions are typically associated with sovereignty. Resilience means the ability of energy systems to withstand diverse and uncertain threats. Resilience is linked to diversity of supply and infrastructure options, redundancies and spare capacities, and institutions capable of adequately adjusting to disruptions, as well as flexibility in demand.

This chapter examines robustness, sovereignty, and resilience concerns with respect to energy sources, electricity systems, and the primary end-uses of energy in over 130 countries. Its main conclusion is that significant energy security concerns from at least one of these perspectives affect the absolute majority of countries and are likely to become more serious in the short- to medium-term if the present trends are allowed to continue. Whereas the primary energy security concern of most industrialized countries is import dependency and aging infrastructure, many emerging economies have additional vulnerabilities such as insufficient capacity, high energy intensity, and rapid demand growth. In many low-income countries supply and demand vulnerabilities overlap, making them especially insecure.

Most globally prominent energy security concerns relate to the oil sector. Oil is a significant source of energy in almost every nation, whereas the majority of countries must import most or even all of the oil and petroleum products they need. Over three billion people live in 83 countries that import more than 75% of the oil and petroleum products they consume. This number does not yet include China, with its 1.3 billion people, where oil consumption has been rising on average by 7% per year over the last decade, and the current oil import dependency of 53% is projected to reach 84% by 2035 (IEA, 2010a). Virtually all of the world's low-income countries import over 80% of their oil supplies. Those that do not have another type of dependency: on oil export revenues to sustain their economies.

Furthermore, the recent rise in the global demand for oil has not been matched by an increase in the supply capacity, which – together with concerns over eventual scarcity – has made markets more volatile. A longer-term issue, the much-discussed "peak oil" – a rapid forced decline in production and consumption – also cannot be dismissed, although it is likely to be initially experienced as painful disruptions of vital energy services in low-income countries rather than as a global energy crisis. Peak oil is covered in more detail in Chapter 7 (Energy Resources and Potentials).

Oil is the main, but not the only, energy source causing widespread energy security concerns. Natural gas accounts for over 10% of primary energy supply in 78 countries with a combined population of some 2.9 billion people. Among those, almost 650 million people live in 32 Eurasian countries that import over 75% of their gas needs. In addition, 12 countries with some 780 million people have a domestic reserves/consumption ratio of natural gas under 16 years and are thus likely to experience significant import dependency in the future.

For many countries, coal is a potential solution to the energy sovereignty problem, since its resources are more abundant and more evenly geographically distributed. Only a small number of countries (12) currently significantly depend on coal imports, and this number is not likely to significantly increase in the near future. However, the use of coal may be subject to environmental and health constraints, as discussed in other parts of this publication.

These vulnerabilities of energy sources affect the security of national electricity systems. For example, almost 600 million people live in 39 countries where over 50% of electricity production is based on imported fossil fuels. In many developing and transition countries these sovereignty concerns are aggravated by low robustness and resilience: inadequate generation capacity, as well as low diversity of electricity generation options. For example, in 35 countries with a population of 450 million people, the absolute majority of electricity production comes from just one or two major power plants. In addition, both developing and industrialized countries suffer from disruptions of electricity systems due to natural and technical failures exacerbated by increasing complexity, poor maintenance, aging infrastructure, and insufficient investment.

In addition to fossil fuels, many countries rely on nuclear power for significant parts of their electricity supply. The sovereignty aspects of nuclear power are access to enrichment, reactor manufacturing, and reprocessing technologies and capacities, which are currently concentrated in just a few countries. For example, large-scale uranium enrichment plants exist in only six countries, and commercial reprocessing facilities in only five. One of the main problems with currently operating nuclear power programs is the aging of reactors and workforce. There are 21 countries with 1.3 billion people with existing nuclear power programs that have not started constructing a new reactor in the last 20 years, and 19 countries (1.4 billion people) have nuclear power plants with an average age of over 25 years. The nuclear power programs in these countries would need to be either "re-launched" or phased out. Access to capital and technology will be critically important for nuclear power expansion and renewal.

An additional 52 countries have expressed their intention to start nuclear power programs for the first time. However, only about one-quarter of them are likely to be able to securely deploy nuclear power with their own resources. In the remaining "newcomers," access to capital and creating necessary institutional arrangements for secure deployment of nuclear power will present serious challenges. For the same reasons, nuclear power will remain beyond the reach of the majority of less-developed countries.

Another significant source of electricity supply in many countries is hydropower. In many regions of the world, notably in Southern Europe, Africa, and South Asia, its long-term security may be affected by shifting patterns of water availability due to climate change. Many existing hydroelectric plants are located on internationally shared rivers, with

divergent water use interests of the riparian states in some cases threatening the secure supply of hydroelectricity. Finally, over 700 million people live in 31 countries that derive a significant proportion of their electricity from just one or two major dams and thus are vulnerable to a variety of natural and technical factors affecting these dams.

Reliability of electricity systems is a source of concern for both industrialized and developing countries. The economies of the former are increasingly sensitive to even minor disruptions of electricity supply, so even relatively short blackouts (typically not exceeding a few hours per year) translate into major economic costs. The scale and frequency of blackouts in most developing countries is at least one to two orders of magnitude higher. Companies in the majority of low-income countries experience 10 or more blackouts averaging 24 hours or more every month, and in some cases the number of blackouts exceeds 100 a month and their total duration approaches 100 hours.

In addition to these supply-side vulnerabilities, electricity systems in developing countries are also under strong demand-side pressures. The majority of the world's population – some 4.2 billion people – live in 53 countries that will need to massively expand the capacity of their electricity systems in the near future because they either have less than 60% access to electricity or average annual demand growth of over 6% over the last decade. Both fuels and infrastructure for such an expansion will need to be provided without further compromising the sovereignty or resilience of national electricity systems.

Insecurities of energy sources and electricity systems affect vulnerabilities of vital energy services: transport, industry, the residential and commercial sector, and providing energy for export.

Insecurities of oil supply affect first and foremost the transport sector, where petroleum products provide at least 90% of energy in the majority of countries. Almost five billion people live in countries that import over 50% of fuels for their transport sector. The situation could get especially serious in 17 countries (with 1.7 billion people) where transport energy use has grown on average more than 8% per year over the last decade.

In the industrial sector, 46 countries with some 800 million people, and in the residential and commercial sector, 39 countries with some 500 million people rely on imported fuels for over 50% of energy use. This does not include 25 countries with some 700 million people that use traditional biomass for over 80% of their residential energy use.

Some 15–20 national economies significantly rely on revenues from energy (primarily oil) exports. In the majority of these oil-exporting countries the revenues are not expected to last for more than one generation, and in several cases they are likely to cease in less than a decade. In addition, poor energy-exporting nations are at a high risk of the resource curse: economic and political instability eventually affecting human development and security.

National energy security strategies throughout the world seek to address those of the above-listed issues that are most prominent in a particular national context. Such strategies generally seek to increase the robustness, sovereignty, or resilience of national energy systems. With respect to robustness, the main strategies are to switch to more abundant and affordable energy sources, stimulate investments in infrastructure, and manage energy demand. With respect to resilience, many states maintain emergency stocks of critical fuels and seek to increase reliability of energy infrastructure by securing necessary investment. Energy exporters seek to achieve resilience by establishing Sovereign Welfare Funds and promoting diversification of their economies. One generic resilience strategy is to increase the diversity of various elements in energy systems: import or export transportation routes, production options and facilities, primary energy sources, or actors on the energy market.

In addition, most nation-states pursue sovereignty strategies that range from switching to domestic energy resources and entering long-term contractual arrangements with trusted partners to nationalizing energy-related assets ("resource nationalism"), establishing nationally controlled energy companies to secure energy resources abroad, and in some cases projecting economic, political, or military power to secure access to energy resources. Domestically, sovereignty strategies may mean increasing state control over the supply and use of energy.

Many nation-states lack the capacity to implement coherent and effective energy security strategies. One reason is that they often focus on shorter-term issues and solutions such as potential disruptions of supply, especially by "hostile" actions of "foreign" actors. Thus, politically it is often challenging to strike the right balance between short-term sovereignty and longer-term resilience strategies. Moreover, energy security strategies need to be reconciled with broader foreign policy and economic strategies that do not necessarily favor the most secure energy solutions. Finally, many countries simply lack financial and other resources to implement the required energy security measures.

Resource nationalism and some other sovereignty strategies may be beneficial when they mobilize additional resources and capacities to energy systems but may turn self-defeating in the international context, where the pursuit of energy security may become a zero-sum game, where states seek to achieve their own energy security at the expense of each other. Thus, in some situations concerns over energy security – especially in relation to oil and to a lesser extent natural gas – translate into broader geopolitical concerns. Although all-out "resource wars" are highly unlikely in the foreseeable future, the "energy security factor" already plays a significant role in US defense outlooks and may increase the tensions between states and make existing confrontations more protracted.

However, the present international interaction in the field of energy is largely dominated by cooperation rather than conflict. Unfortunately,

the plethora of existing energy institutions and alliances have not always been successful in reducing national energy security concerns. This may be largely due to their narrow focus (on a particular energy sector, region, or a group of countries) not reflecting the systemic nature of the energy security risks and their connection with other energy issues such as access and climate change.

The future of energy security will be affected by a variety of technological, economic, and natural factors. It is likely that the production of conventional oil will reach its maximum in the next few decades, whereas the resources of both oil and natural gas may become more geographically concentrated as the center of consumption will shift towards Asia, especially China and India. New nuclear energy programs – despite their large costs – may be able to alleviate energy security concerns in some of the larger and more prosperous economies. At the same time, the inevitable phasing-out of some of the existing nuclear programs will result in new energy security issues. Many countries are likely to expand energy supply from domestic resources such as coal and renewables (including biofuels). The prominence of energy security concerns related to electricity will undoubtedly increase. Whereas the overall demand for energy, and especially for electricity, will grow dramatically, especially in developing countries, there may also be significant gains in energy efficiency, reducing this demand to more manageable levels.

The energy security landscape of the future will depend critically on both the direction of national strategies and the nature of international energy institutions. In the scenario where national strategies focus on sovereignty concerns and international institutions are weak, one can expect centralized but not internationally integrated energy infrastructure and fragile markets subordinated by resource nationalism and geopolitics. In the opposite scenario, when the national strategies focus on resilience under strong international institutions, it may be possible to support transitions to more secure energy systems even in those countries that lack the capacity to do it on their own.

Under sustainable energy transitions modeled in the GEA Scenario in Chapter 17, the energy security landscape will change so significantly that many of the current energy security threats may disappear and new ones may emerge. To assess energy security in the future, it is important to know how diverse and geographically concentrated the future global energy supply will be, what the diversity of fuels used in key end-use sectors will be, and whether some regions will continue to be seriously dependent on imported energy sources.

Executive Summary

The three most basic drivers of energy demand are economic activity, population, and technology. Longer-term trends in economic growth for a particular economy depend on underlying demographic and productivity trends, which in turn reflect population growth, labor force participation rate, productivity growth, national savings rate, and capital accumulation (USEIA, 2011).

Several historic shifts are likely to fundamentally alter global demographics over the coming decades. First, as developing nations move from poverty to relative affluence, there is a fundamental shift from agriculture to more energy-intensive but much more productive commercial enterprises. Second, labor forces in the developed countries are aging considerably, which has implications on many fronts, including energy use and employment structures. Third, for the first time the majority of the world's population has become urbanized, with the largest urban centers emerging in developing regions where energy access is a serious constraint. All of these will have immense impacts on the level and quality of energy demand and on concerns about energy security.

Global energy security and sustainability in the twenty-first century will depend less on the total global population than on incomes and their distribution. This in turn will depend to a large extent on how effectively the lack of energy services, which now limit economic opportunities in the less developed regions, is addressed. In addition, energy security will depend on the ability of countries to maintain reliable sources of energy to meet their needs.

As economies develop, countries' energy needs and priorities change. The evolution of demand at different stages of economic development changes. As economies develop, as happened with industrialized countries, the tendency is to adopt more efficient technologies for the provision of energy services, and the composition of economic activities change with energy intensity tending to decline over time.

Prices play several essential roles in economic production and demand. Most importantly prices send signals to buyers and sellers. Yet it is important to distinguish between prices and costs. There are four types of costs: monetary costs, opportunity costs, environmental (and health) costs, and sociopolitical costs. Most consumers are predominantly exposed to monetary costs and less to the other ones, although these are also important.

Renewable energy technologies, energy efficiency, advanced energy technologies and their associated products and services have been among the most rapidly growing sectors for investment in recent years, with major developing countries becoming investment leaders rather than simply technology transfer followers. In spite of this progress, the total public and private funding of energy-related research, development, and deployment remains much less than the amount needed for the transition to a sustainable, climate-constrained world.

Due to their importance as major contributors to job creation and economic growth, small and medium enterprises are potential leaders in business model transformation in many parts of the world.

6.1 Introduction

The primary role of Chapter 6 is to define the nature and magnitude of the demands on local and global energy systems arising from economic activity. Energy is not an end in itself but rather the means for providing energy services. The energy system is driven by the demand for energy services – a demand that in turn is driven by population and demographic trends, by the level of economic activity and income, and by technological and structural changes. In essence, providing energy services involves investment, operating costs and, if applicable, fuel costs.

Energy fuels the economy, which provides for the establishment of necessary energy infrastructures – from resource and material extraction to the technologies producing electricity as well as other energy carriers and end-use equipment to deliver the desired energy services. The economy is also the financier of energy systems and of its components and energy flows. A central question is: how much energy do economies need to function smoothly and thus being able to augment social development and well-being.

At the same time, economic and demographic developments play a fundamental role along with other drivers (e.g. technology) and GEA sustainability goals (e.g., access, security, and environmental and climate protection) in determining the energy needs and structure of energy systems. Chapter 6 focuses on these two drivers central to GEA. Both were assumed exogenously so as to be in the middle of the range in the literature (see Chapter 17). However, the convergence of per capita gross domestic product (GDP) was assumed to be stronger than in other median economic projections. In order not to subtract from the energy focus of GEA, single, median GDP and population projections were chosen.

An important reason is that economic and demographic developments like other GEA goals are in themselves necessary dimensions of sustainability. The relative GDP convergence enhances the achievement of other GEA goals and enables the transformation of energy systems and achievement of sustainable development. For example, economic development furthers technological change through higher investments and more rapid capital turnover.

Given the long time frames under consideration, serious attention to incorporating highly energy efficient end-use technologies has the decisive potential to address the major energy related challenges addressed in GEA (Goldemberg et al., 1985).

Infrastructures such as power plants, roads, railways, buildings, and so on are inherently long-lived, with service times counted in decades to half-centuries and more. Longevity means stability and inertia at the cost of short-term flexibility. Still, energy systems are constantly in flux – at rates often difficult to detect in the short run at the level of supply. Rates can be much faster on the energy demand side, as energy-using appliances, plants, and equipment have much shorter lifetimes than supply-side infrastructures. The shorter lifetimes are directly related to the growth and changing mix of goods and services provided by the economy.

The evolving energy system epitomizes technology change and innovation. Technology is the crucial tether between the energy system and the economy, especially the modern economy[1]. Energy and economy evolve in tandem, and technology defines which energy carriers and services the system can provide and which the economy can demand. The industrial revolution was powered by coal, which provided industries and households with a much more concentrated fuel. This enabled a higher productivity with respect to wood fuels and which boosted economic progress and urbanization. In the nineteenth century, abundant access to coal increased productivity and stimulated economic development.

Today access to modern forms of energy or rather secure, clean, affordable energy carriers fundamentally defines the modern economy. Electricity is key in this regard, as it is most compatible with the needs of the modern economy. It is more than just an energy carrier in the strict physical sense. Electricity enables all kinds of transactions – from information exchange to transportation. Its productivity in economic production and consumption as well as cleanliness at the point of use is second to none. The factors contributing to income disparities within and between countries can be traced to many reasons that vary across countries and regions. A lack of access to modern energy carriers and services is one of these contributing factors (Modi et al., 2005).

The world is now in the midst of an unparalleled period of dramatic growth in multiple parameters, also known as "the great acceleration" (see also Chapter 3). Major populous developing countries are actively and successfully pursuing industrialization and socioeconomic development with concomitant growth in demand for energy-intensive goods and services. As a consequence, energy demand is rising rapidly compounded by population trends. If current trends continue, human beings will use more energy over the next half-century than in all of recorded history. Energy demand on this scale will put increasing pressure on global energy resources and distribution networks. This is unsustainable without a fundamental transformation of the energy system. The unsustainability, however, has many other elements than resource availability, including energy services for economies and poverty alleviation, as well as addressing various social and environmental and health dimensions, security and peace (see also Chapters 2–5).

The dominant fossil energy resources today, especially oil, are concentrated in only a few regions. Energy security – that is, the potential disruption of supply – is viewed by many countries as a potential threat to their economic well-being (see also Chapter 5).

1 Technology is more than just hardware and includes a range of factors from cultural aspects to education and training (Arthur, 2009).

Providing access to energy services involves the conversion of primary energy resources as well as the manufacturing (and construction) of required technologies and distribution networks. These activities take material from the environment and inevitably split them into desirable products and wastes of various forms. The latter are returned to the environment, increasingly at levels beyond the carrying capacities of ecosystems, and threatens to have environmental damages undermining economic gains.

Achieving the partly conflicting objectives of environmental protection and economic gains will require substantial input from the economy in the form of finance as well as research, development, and deployment (RD&D). The *2009 World Energy Outlook* of the International Energy Agency (IEA, 2009a) estimated that US$20 trillion will be required over the next 25 years just to meet the projected increase in global energy demand by 2030. Similarly, the GEA pathways from Chapter 17 show that the transformation of the energy system would require dedicated efforts to increase global energy-related investments to between US$1.7 trillion and US$2.2 trillion annually, compared with about US$1.3 trillion in annual investments today (see also Chapter 24). Out of this total, about US$300 to US$550 billion of efficiency-related investments are required on the demand-side of the pathways. This includes only the efficiency-increasing part of the investment to improve energy intensity beyond historical improvement rates. The full demand-side investments into all energy components of appliances might thus be significantly higher. Total investments into energy supply and efficiency-related investments at the demand-side correspond in sum to a small fraction (about 2%) of global GDP. Future transitions with a focus on energy efficiency achieve the targets at more modest cost and thus represent the lower bound of the investment range (see Chapter 17 for further details).

Current modest levels of investment in clean energy facilities and energy efficiency measures contrast starkly with these immense investment requirements. Furthermore, significantly strengthened innovation will also be essential to support the continued development of new solutions to these critical energy challenges, as governments and industry struggle to expand new energy resources and new ways to use existing resources in a sustainable manner.

The demands of a changing energy paradigm have wider institutional implications. The institutions created over the past several decades are struggling to remain relevant in the face of profound geopolitical and economic changes (outside the domain of their membership). New institutional frameworks more suited to the needs of today are urgently needed. These institutions would need to support the delivery on the goals of access to affordable modern energy carriers and end-use conversion, enhanced energy security, climate change mitigation, and health and environment.

In the twenty-first century, a global energy system for sustainable societies must reflect multiple objectives that include energy availability, affordability, security, and consistency with climate change goals (see also Chapters 2–5). These have been further complicated by the usual market implementation issues that have been aggravated by the current global economic crisis.

The required energy system transformation will be difficult to accomplish without some transformation of the world economy – a process that will be complex and characterized by marked clashes of interest. This transformation will therefore require a long-term vision and sustained cooperation among a large array of diverse stakeholders at both the national and international level, coupled with strong public policy support and private-sector engagement.

6.2 Basic Drivers of Energy Demand

The three most basic drivers of energy demand are population, economic activity per capita, and technology performance. Based on these fundamentals, this century is likely to see major shifts in energy demand and development. According to a recent UN report (UNFPA, 2011), global population by 2050 is projected at 9.3 billion, a revision upwards from previous reports (UNDESA, 2004). Virtually all this projected population growth will occur in the developing world. By comparison, the present world population is 7 billion, and was only 2 billion as recently as 1930.

This unprecedented massive global population growth over little more than a century is arguably one of the most defining events of our era. The past century also represents a period of intense technological expansion, which has fundamentally increased humanity's ability to harness energy. This has contributed to changing the historic equilibrium between human fertility and mortality. As a result, average life expectancy worldwide more than doubled over the last century from 32 to 67 years, and it continues to increase steadily.

6.2.1 Demographic and Income Changes

Extending population projections beyond 2050 depends on uncertain fertility, mortality, and migration assumptions. Researchers at the International Institute for Applied Systems Analysis (IIASA) have addressed this uncertainty constraint by developing probabilistic population projections that reflect a realistic range of uncertainty (Lutz and Samir, 2010). Table 6.1 outlines these projections through 2100 for 13 major world regions. The results suggest that the world population will most probably peak by 2050 at slightly less than 9 billion[2] and remain above 8 billion through at least the remainder of this century. Yet the probabilistic shifts in population distribution among the continents

2 A more recent study by the UNFPA (2011) has adjusted this figure slightly upward to 9.3 billion as mentioned above.

Table 6.1 | Population projections.

	Total Population (millions)		
	2010	2050	2100
North Africa	208	307 *(+48%)*	324–346 *(+56%–+66%)*
Sub-Saharan Africa	799	1,617 *(+102%)*	2,074–2,247 *(+160%–+180%)*
North America	339	427 *(+26%)*	421–468 *(+24%–+38%)*
Latin America	595	834 *(+40%)*	909–977 *(+53%–+64%)*
Central Asia	65	96 *(+48%)*	101–108 *(+55%–+66%)*
Middle East	215	359 *(+67%)*	392–417 *(+82%–+94%)*
South Asia	1,625	2,289 *(+41%)*	2,016–2,140 *(+24%–+32%)*
China & CPA	1,468	1,342 *(–9%)*	829–881 *(–56%—40%)*
Pacific Asia	542	699 *(+29%)*	649–689 *(+20%–+27%)*
Pacific OECD	152	137 *(–10%)*	85–103 *(–44%—32%)*
Western Europe	462	449 *(–3%)*	320–364 *(–31%—21%)*
Eastern Europe	120	94 *(–22%)*	54–60 *(–55%—50%)*
Former Soviet Union	228	169 *(–26%)*	103–111 *(–55%—51%)*
WORLD	6,816	8,816 *(+29%)*	8,280–8,920 *(+21%–+31%)*

Source: Lutz et al., 2008.

during this time are dramatic. Europe and China are projected to have population reductions on the order of 40–50% by the end of the century, while Africa and the Middle East are likely to double their populations and Latin America and Central Asia are expected to have population increases on the order of 50%.

Four historic shifts, revealed in the most recent United Nations population data, are likely to fundamentally alter global demographics over the next several decades (UNFPA, 2011). First, the relative demographic weight of the world's industrialized nations is forecast to decline by at least 25%, with a corresponding shift of economic power to developing nations. As these nations move from poverty to relative affluence, there is a fundamental shift from agriculture to more energy-intensive commercial enterprises. Second, the labor forces in the industrialized countries will age considerably. Third, most of the world's expected population growth will be concentrated in today's poorest countries, which typically lack employment, capital, and educational opportunities. Finally, the majority of the world's population is becoming urbanized, with the largest urban centers found in the world's poorer regions, where energy access typically remains a serious economic constraint. All of these shifts point to substantial growth of demand in developing countries where energy systems are notoriously underdeveloped and therefore open early and sizable prospects for an effective energy system transformation. Expanding systems simply offer more opportunities for market penetration of new technologies than stagnating or shrinking systems. Being a multiplier of demand for goods and services including energy, however, population remains a major driver of, especially adverse, impacts (Campbell et al., 2007). Given the absolute limits of the planet, as illustrated by the need to limit concentrations of climate-altering pollutants, reductions in population growth trends can give valuable additional decades to resolve energy and other problems before these planetary limits are reached. There is no coercion implied here, as studies show that there are hundreds of millions of women wishing to control their family size who do not have access to modern

contraceptive technologies (Cleland et al., 2006). Analyses show, for example, that doing so could lower CO_2 emissions from energy use by 30% in 2100 over what is projected otherwise (O'Neill et al., 2010). Providing reproductive health services to these women is also an equity issue as all women, not just those in rich countries, ought to have access to such services (Prata, 2009). It is also an important health issue as spacing births, which, along with reducing growth rates, gives men and-women access to contraception, which has major benefits for both child and maternal health (Smith and Balakrishnan, 2009).

In light of these enormous demographic challenges, the global economy is significantly underperforming mainly in industrialized countries, while developing economies performances are not sufficient to provide for everybody. Given the annual addition to the world of about 40 million workers and the average levels of GDP per worker, the world economy has to generate at least $500 billion in additional output each year just to employ new workers (Martin, 2005). At current growth rates, tens of millions of workers will remain unemployed. Unfortunately, the issue of how to achieve sustainable world economic growth is still not being effectively addressed. Education is the key. As Lutz et al. (2008) point out, "education is a long-term investment associated with near-term costs, but in the long term it is one of the best investments societies can make in their future."

Nearly 80% of the people in the world continue to have inadequate purchasing power parity (PPP) to afford basic needs and thus live in poverty (Chen and Ravallion, 2008). Lack of access to modern forms of energy is a constraint on the economic and social progress for a large fraction of this population. Indeed, due to extreme poverty[3], huge rural and urban populations are being largely excluded from the social and economic development processes in which markets are a part. Unless this growing demand for energy is met by cleaner, safer, and more efficient energy technologies, the negative impacts on global health and environmental will continue to grow.

The economic prosperity of the world's population is, however, rapidly increasing. Barring a cataclysmic crisis, global economic output is projected to increase at the rate of 3–4% over the next several decades (IEA, 2011; USEIA, 2011). As a result, and as was the case in the last century, global income will most likely increase far faster than population. Indeed, stabilization of the world's population has been shown to be a direct result of increased prosperity. In 2000, the poorest half of the world's population owned only about 1% of total global wealth (Davies et al., 2008). This extreme poverty is decreasing as nations develop and their standards of living steadily improve.

The rise in world affluence holds promise for improved well-being but also comes with significant ecosystem risks if prevailing patterns of energy demand, supply, and waste persist. Since the Industrial Revolution, economic development and expansion have been tied to increased energy use, and this link remains strong today. Without the grand transformation in the global energy system as explored in GEA, fossil fuels will remain the dominant energy source through at least the middle of the century under any achievable circumstances – a definite challenge for achieving greenhouse gas (GHG) stabilization at 450 ppm. Fossil fuels with carbon capture and storage (CCS) or moving beyond fossil fuels to cleaner, renewable and other non-carbon energy sources will require a much larger and sustained commitment as well as accelerated upfront investments. In 2009, non-fossil fuel energy resources provided approximately 22% of the world's primary energy supply (see Chapter 11). Providing adequate energy supplies at minimum GHG emissions begins with the large-scale adoption of currently best available technologies (BAT) and practices (Pacala and Socolow, 2004; IPCC, 2007) but eventually will require a major upscaling of this BAT. In either case this only occurs when people have the incentives to adopt innovative technologies and are willing to forego excessive current consumption for future benefit. Investing in BAT and technological progress is a major concern, as the demands for short-term returns on investment constrain the strategic development opportunities on which those returns ultimately depend.

The challenges facing rural regions over the next 50 years are significant. Fertility rates are much higher than in urban areas, where health care and education are relatively advanced and available. Not only will these rural regions be the source of a large portion of the world's population growth, but they must be able to help feed the world. Only about 13% of global land area is arable, and the average population density in the developing world is expected to increase from about 60 people/km^2 to around 96 people/km^2 by 2050. This compares to an industrial-world stable population density of about 25 people/km^2 and poses unprecedented problems of land use and preservation in the developing world (UNDESA, 2004).

Countries' energy priorities and services demand change dramatically as their economies develop. Thus global energy security and sustainability in the 21st century will depend less on the total global population than on population incomes and how that income is distributed. Nations are very different with respect to their incomes. For example, member countries of the Organisation for Economic Co-operation and Development (OECD) currently account for approximately 18% of the world's population but for almost three quarters of GDP. By comparison, China and India represent some 37% (20% and 17%, respectively) of the world's population and about 11% of global GDP in terms of market exchange rates (MER) (World Bank, 2011ba). Even if expressed in units of Purchasing Power Parity (PPP), their share of global GDP was below 25% in 2010 (GEA scenario database, see www.globalenergyassessment.org).

Figure 6.1 depicts the disparity of income measured in terms of GDP per capita across 11 world regions in 2005. The level of primary energy use appears to mirror the level of affluence in a region, and there is a

3 Currently defined as per capita income of less than US_{2005} 1.25 per day (Chen and Ravallion, 2008).

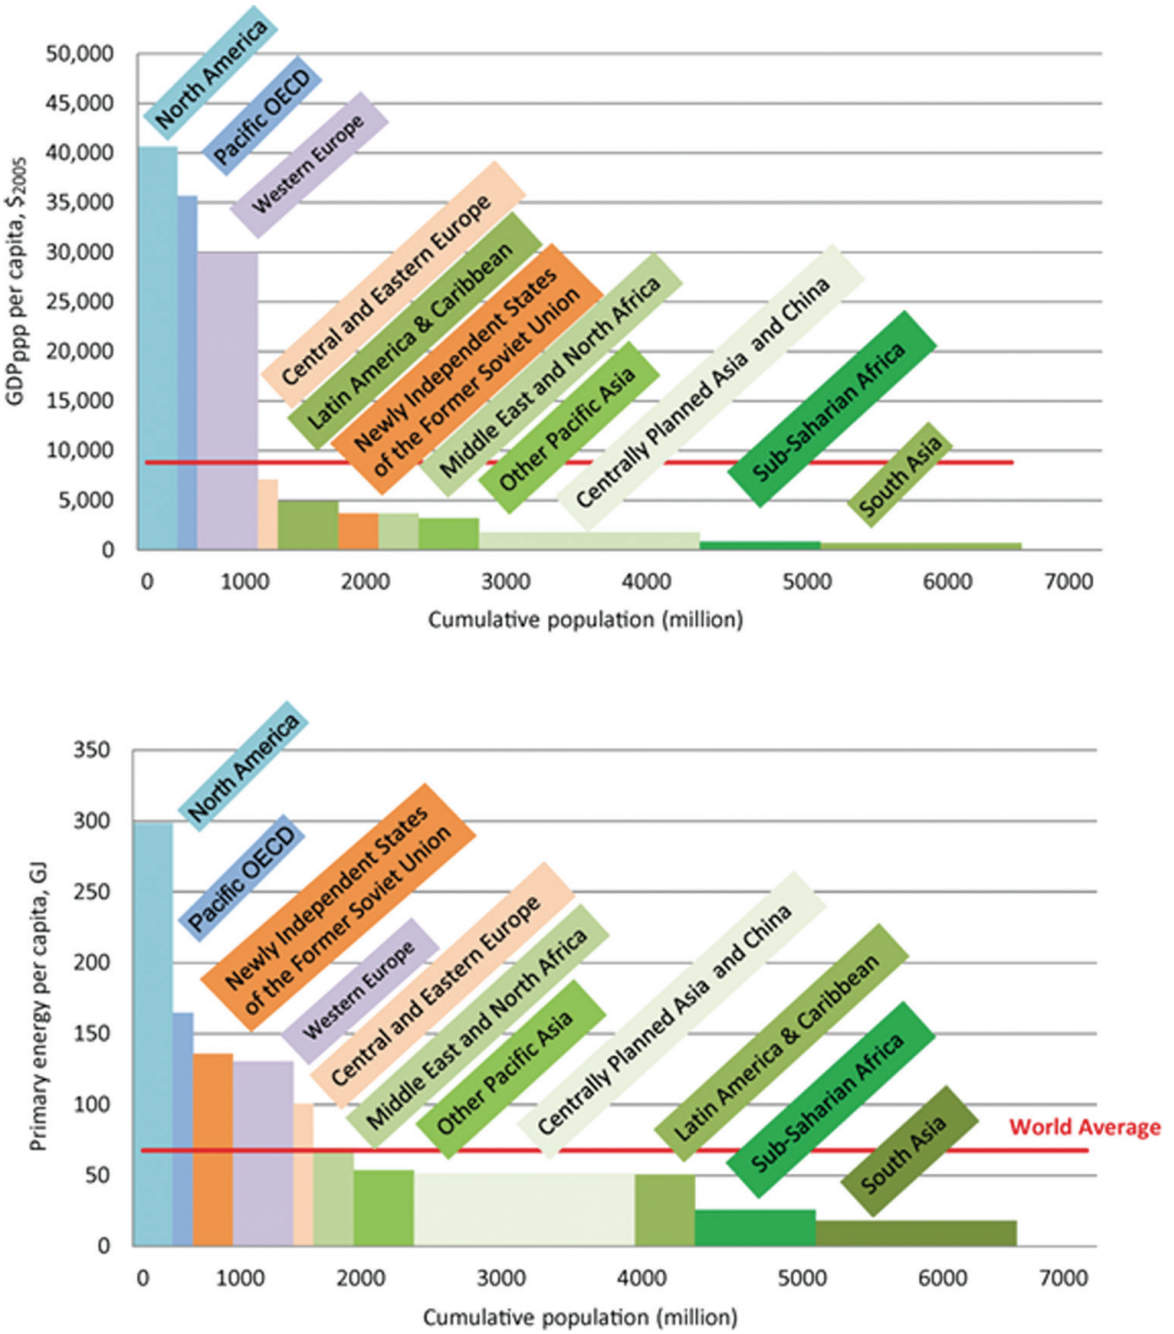

Figure 6.1 | Regional disparities in income and energy use per capita in 2005.[4]

common understanding that the access to clean and affordable energy is critical for achieving the Millennium Development Goals (MDGs)s and enabling sustainable economic development. The UN Advisory Group on Energy and Climate Change (AGECC) defines energy access[5] as "access to clean, reliable and affordable energy services for cooking and heating, lighting, communications and productive uses" (AGECC, 2010).

6.2.2 The Move to Modern Energy Carriers—Advances in Electricity

Electricity provides the essential key to energy access and enables technical innovation and productivity growth – the lifeblood of a modern

4 Figure 6.1 depicts the large income and energy use disparities between major regions and countries. However, it is important to note that access disparities within nations are typically greater than between nations.

5 For definitions of energy access, see Chapters 2 and 19.

society. Electricity's central role in achieving economic and environmental progress is broadly accepted throughout the world, depending on how the electricity is produced (see Chapters 3 and 4). The determining factor is whether nations will find the leadership and make the commitment necessary to harness and expand electricity's unique capabilities. Ironically, the electronic technological revolution that electricity has enabled over the past decades has largely been ignored by the electricity supply industry itself (Galvin and Yeager, 2009).

The pacing factor is the necessary investment for the innovative technologies that are needed to replace today's generally centralized and aging electricity infrastructure and establish a truly intelligent global electricity infrastructure spanning from generation to end use. The accelerated growth of intermittent renewable technologies combined with the introduction of smart grids may make it possible to transform them into useful and valuable fuels. Of equal importance is that electricity provides a continuous efficiency improvement opportunity, i.e., the inherent intelligence that comes from the incorporation of modern digital electronic monitoring and control technology throughout the electricity delivery and utilization networks.

While renewable technologies are desirable for providing clean energy carriers to the unconnected, especially in rural areas, one must not ignore the ongoing urbanization trend and industrialization aspirations of developing countries. Cities have a much higher energy demand density per hectare than rural settlements. Energy-intensive industries represent large-scale off-take nodes. While supply densities of renewables or distributed electricity generation are consistent with the demand densities and offer opportunities in cities as well, metropolitan areas will continue to require a certain share of baseload electricity from large central conversion facilities such as large scale hydro, nuclear, or fossil fuels with CCS.

Today, global electrification is distributed very unevenly (see Chapters 2 and 19). The highest proportion of people without electricity is concentrated in rural sub-Saharan Africa and South Asia – regions that are also projected to have very high population growth this century. A realistic and universally achievable goal over the next decades is therefore to eliminate the electrification gaps for the 1.4 billion people without access today and to even more by 2030 under business-as-usual conditions (see also Chapters 17, 19, and 23). This goal is not just a matter of equity but an essential prerequisite for eliminating extreme poverty and stabilizing population in fast-growing developing regions. In order to keep pace with the world's growing population and to provide the foundation for the corresponding economic development, electricity must reach at least an additional 100 million people per year for at least the next 30 years. This is more than twice the current rate.

6.2.3 Economic Production Processes

In the context of the economic production process, the output of which is measured in terms of GDP, energy is but one production factor. It is a necessary but not sufficient input[6] to the production process.[7] Other essential production factors are capital, labor, land, and materials. A simple production function then would take on the following form: GDP = f(capital, labor, energy, land, materials and know-how).[8] The contribution of each factor (or input quantity) to output depends on the state of development of an economy, physical conditions and location (e.g., climate, geography, land), relative factor prices, and factor productivity as well as social and cultural conditions. Within certain limits production factors can substitute each other.

The ease of substitution is a matter of relative production factor prices, availability of factors, vintage of technologies, and lock-in in existing infrastructures, timelines, etc. For example, as an agriculture-based economy advances, higher incomes make labor more expensive (or more productive elsewhere in the economy), and rural workers are progressively replaced by machines (capital), energy (fuel for the machines), and materials. In the case of rising energy prices, substitution of capital and materials for energy can lower the physical energy input to the economy (although the economic value of the input may not change due to the higher prices of fuel and technology). Efficiency improvements are largely a substitution of capital and know-how for energy. Using the production function approach, the optimal energy input and thus energy demand can be determined by a first-order derivation of the production function where the marginal productivity equals the factor price.

Figure 6.2 presents three capital-energy combinations – all of which produce identical outputs (isoquant) both in terms of quantity and quality (labor and materials remain constant). Option A is an energy-intensive process but uses little in terms of capital (investment). Option B is much more energy-efficient but requires a more capital-intensive production structure. The most economically efficient option then is determined by the combined effect of the respective factor costs – that is, the price of fuel p_E, capital p_k (interest and depreciation), labor p_L (wages), and materials p_M. If factor costs, say for energy, were to include externalities (which generally is not yet the case), this would make energy more expensive, hence change the slope of the optimal factor combination (dashed line in Figure 6.2), i.e., from point C to B (lower energy – higher capital input). Therefore policies enforcing the internalization of externalities would encourage capital for energy substitution (for identical energy services) or change the nature of energy services demanded. Similarly energy subsidies reduce the incentive to deploy capital and energy efficiency measures resulting in higher energy use than otherwise.

6 According to the laws of thermodynamics nothing can be changed without energy input (or rather exergy consumption).

7 While long recognized for its many limitations, economic output is predominantly measured as GDP, either at market exchange rates or purchasing power parities even though alternative measures have been proposed.

8 Production functions found in the economic literature are way more complex than the illustrative example presented here. A more detailed discussion of production functions is beyond the scope of this chapter.

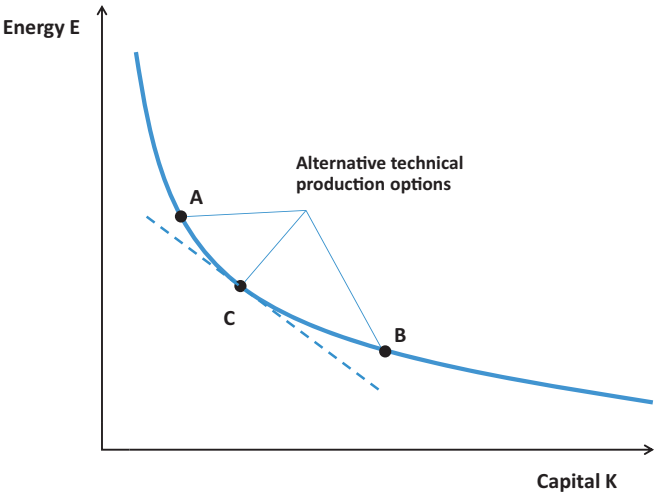

Figure 6.2 | Capital-energy substitution frontier.

Production costs $C = p_k K + p_E E + p_L L + p_M M$

The optimal factor combination results when

$dC = 0 = p_k dK + p_E dE$ (as dL and dM are zero by assumption) or

$$\frac{dE}{dK} = -\frac{p_K}{p_E}$$

which at constant factor costs leads to the dashed straight line with the slope $-p_K/p_E$ shown in Figure 6.2. The cost optimal factor combination results where the line touches the output isoquant – that is, Option C.

Generally it takes longer for substitution processes to materialize for a variety of reasons, ranging from system inertia and lock-in to the availability of capital and finance costs. The vintage structure of the capital stock and thus the natural rate of capital replacement due to wear and tear are ideal dates for the introduction of more-efficient plant and equipment or building stock. In the short run, a recently opened new factory or apartment building is unlikely to modify its heating and cooling equipment in response to, say, higher natural gas prices. If prices remain at elevated levels for extended periods of time, displacement of natural gas by inter-fuel substitution or efficiency improvements become economically attractive. Refurbishment of an aging building stock, the early retirement of boilers in a factory, or relocation of energy-intensive manufacturing process to a lower energy cost area are routine economic decision processes based on cost functions and relative factor prices.

6.3 Challenges of Projecting Energy Demand

In generating projections of future energy requirements, a key difficulty arises because the demand for energy derives from the demand for various services required by the industrial production of goods and services as well as buildings and energy-using appliances, such as refrigerators or cars. Energy demand therefore depends on evolving personal preferences and behavior, including how the demand for energy services evolves at different stages of economic development (Haas et al., 2008). A variety of approaches have been used to estimate energy demand on the basis of the use of different types of energy-dependent services. They include:

- "bottom-up" approaches that evaluate the mix of economic activities and the energy intensity of these activities for each sector of the economy (Schipper and Meyers, 1992);
- approaches that consider the relationship between the demand for energy services and efficiency improvements in service provision (Ayers and Warr, 2009); and
- detailed studies of the price of energy services (such as lighting), economic development, and the consumption of energy services (Nordhaus, 1997; Fouquet and Pearson, 2006; Fouquet, 2008).

Since the early 1970s, a large number of empirical studies of energy demand have also sought to identify the effect of real incomes on energy demand (Griffin, 1993; Espey, 1998; Hunt and Ninomiya, 2003; Espey and Espey, 2004). In general, the estimates from these statistical analyses show that the income elasticity of the demand for energy is positive (i.e., rising incomes will lead to increased energy use). However, the magnitude of these elasticities[9] differs by stage of development. In industrialized countries, the estimated income elasticities tended to be less than one (e.g., a 10% increase in income would result in an increase in energy use of less than 10%). Judson et al. (1999) analyzed data from OECD and non-OECD countries and concluded that income elasticities are lower at low levels of economic development, rise substantially at medium levels, and fall at higher levels. Hence the state of economic development and the standard of living of populations in a given region strongly influence the link between economic growth and energy demand (USEIA, 2011).

Based on empirical evidence, the evolution of demand at different stages of economic development can be described as follows (Fouquet, 2008). The demand for energy rises rapidly at early stages of economic development as an economy evolves from an agrarian economy and industrializes, with an associated increase in mining and manufacturing activities. Industrialization is also associated with a rapid rise in demand for heating and for freight transport. As the industrialized economy matures, the demand for energy by the industrial sector continues to grow in absolute terms but declines relative to the household and service sectors, in part because energy-intensive imports are substituted for domestic production. Household demand for energy continues to grow in absolute terms and rises with disposable incomes because of increased demand for space,heating and cooling, and individual transportation.

9 Income elasticity of energy demand is the ratio of percentage change of energy demand to the percentage change of income.

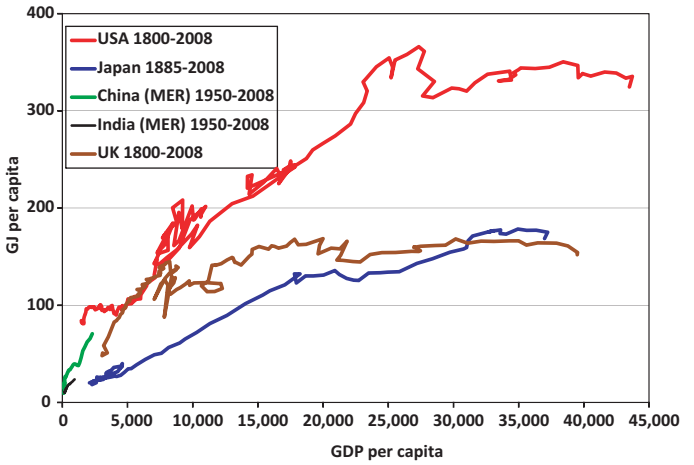

Figure 6.3 | Primary Energy Use per capita (GJ) versus GDP (at market exchange rates in US_{2005}) per capita. Data sources: US, Japan: updated from Grubler, 1998, UK: Fouquet, 2008, India and China: IEA, 2010b and World Bank, 2010. Note: Data are for the United States (1800–2008), United Kingdom (primary and final energy, 1800–2008), Japan (1922–2008), China (1950–2008), and India (1950–2008). For China and India, also GDP at purchasing power parities (PPP, in $International_{2005}$) are shown.

While it might be expected that the demand for energy will reach a saturation point at high levels of development, the evidence available to date suggests that if new, more-efficient technologies reduce the amount of energy required to operate appliances and equipment, the implied cost reduction often serves, everything else being equal, to stimulate additional energy-dependent activities. This is referred to as the rebound effect and arises because improvements in energy efficiency effectively decrease the cost of energy services, leading to additional disposable income and so potentially increases demand (see Chapter 22). Consumers and businesses change their behavior – they may raise thermostat levels in the winter, cool their buildings more in the summer, buy more appliances and operate them more frequently, or drive their vehicles more (IEA, 2005). However, as the price of energy services is what matters, higher fuel prices may well outweigh the benefits of more-efficient appliances, plants, equipment, and infrastructures. Data for the United States and Japan suggest that once annual per capita income levels exceed US$30,000, per capita energy use no longer increases with GDP (see Figure 6.3) and that total energy demand is largely a function of population and prices. However, it can be argued that per capita energy use in the United States is higher than shown in Figure 6.3 as it excludes embedded energy, i.e., the energy content of imported goods and services as energy-intensive materials, mining, processing and manufacturing occur abroad. Likewise, accounting for embedded energy would reduce per-capita energy use of export-driven Japan.

A simple approach to present the energy – economy link is by way of demand functions such as the aggregate top-down relation:

$$E = POP \times \frac{GDP}{POP} \times \frac{E}{GDP}$$

where energy demand (E) is the product of population (POP), per capita income (GDP/POP), and the energy intensity of the economy (E/GDP), usually measured in megajoules per unit of economic output or GDP.

For all countries, population growth is a modest to strong driver of energy demand. The income effect in terms of GDP and GDP per capita is positive and generally larger in developing countries, where small improvements in per capita income translate into an over-proportional use of energy services. Energy intensities vary from region to region depending on the stage of economic development, geographic and climate conditions, and energy prices, but intensities have been declining in most countries and regions and thus are chiefly responsible for keeping energy demand growth in check globally. Figure 6.4 shows the average growth rates of primary energy, population, primary energy per capita, primary energy and electricity intensities of GDP for four consecutive 10-year periods in the World, OECD, Reforming Economies, Middle East and Africa, Asia, Latin America and Caribbean.

As described above, the relationship between energy availability and economic growth has been the subject of many studies, but no clear causality has emerged. Instead, the research suggests that the direction of causality differs as energy efficiency becomes a higher priority among countries, especially between industrialized and developing countries. In industrialized countries, the link now appears to be relatively weak, with energy use decoupled from economic growth. In developing countries, energy demand and economic growth have been more closely correlated in the past, with demand tracking or exceeding the rate of economic expansion (USEIA, 2011). These countries are still in the process of building their human and physical capital, which is inherently more energy-intensive than the operation of well-developed infrastructures.

6.4 Relationship Between Economic Growth and Energy Demand

As noted earlier, economic growth and energy demand are linked, but the strength of that link varies among regions and their stages of economic development. The state of economic development and the standard of living of individuals in a given region strongly influence the link between economic growth and energy demand. Advanced economies with high living standards have a relatively high level of energy use per capita, but they also tend to be economies where per capita energy use is stable or changes very slowly. In industrialized countries, there is a high penetration rate of modern appliances and motorized personal transportation equipment. To the extent that spending is directed to energy-using goods, it often involves purchases of new equipment to replace old capital stock. The new stock is often more efficient than the equipment it replaces, resulting in a weaker link between income and energy demand (USEIA, 2011).

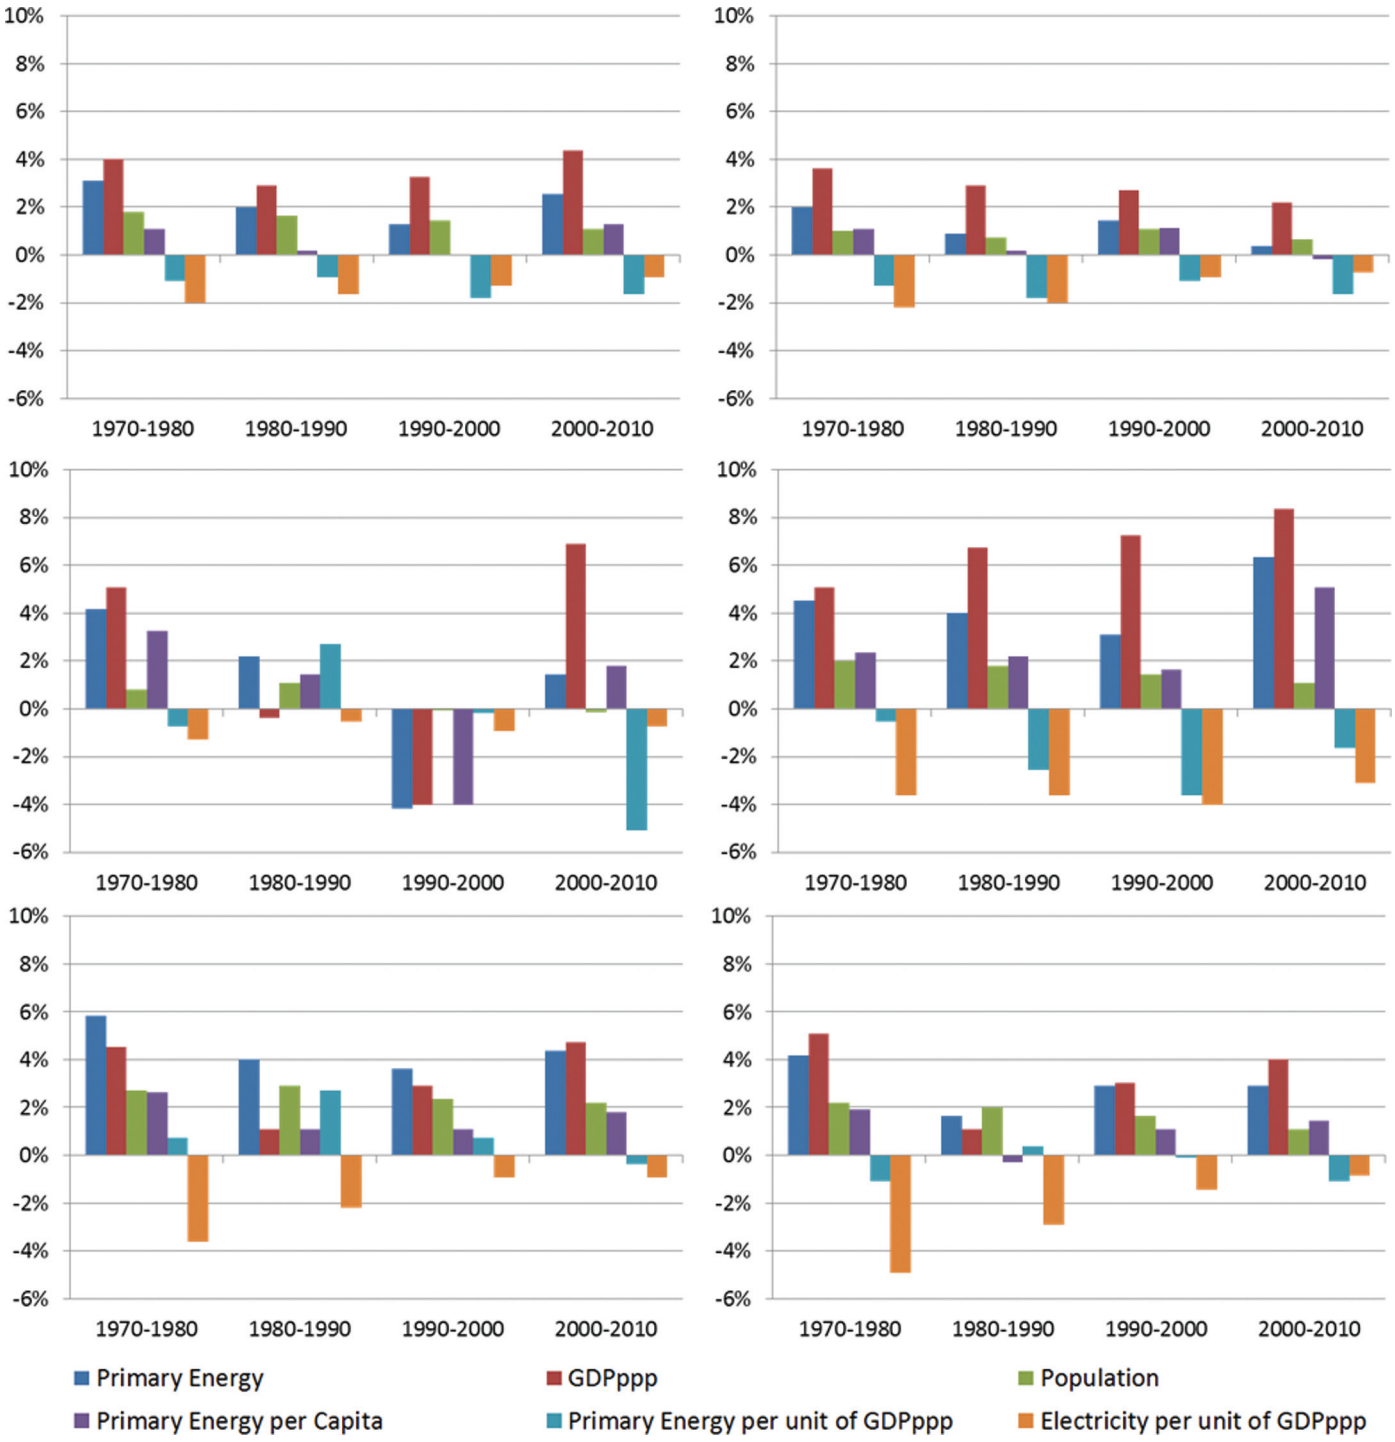

Figure 6.4 | Annual growth rates of indicators for primary energy demand, GDP, population changes and selected indicators for four ten-year time-periods and different regions (World, OECD, REF: reforming economies, ASEA, MAF: Middle East and Africa, LAC: Latin America and Caribbean). Source: data from GEA database.

6.4.1 Industrialized Countries

Historically, and beginning with the industrial revolution, increased energy use has fueled economic development in advanced industrialized societies (Fouquet, 2008). The first industrial revolution, which began in the eighteenth century, merged into the second industrial revolution around 1850, when technological and economic progress gained momentum with the development of steam-powered ships, railways, and, later in the nineteenth century, the internal combustion engine and electrical power generation. Although a number of social and non-energy factors were responsible for the productivity increases of that era, there is agreement that the transition to the use of available energy sources such as coal coupled with technology innovations accounted for the impressive growth results achieved during this era (Landes, 1969; Ayers and Warr, 2009).

A commonly observed characteristic of this development is that advanced industrialized countries use less energy per unit of economic output and more energy per capita than poorer societies do (Toman and Jemelkova, 2003). Figure 6.5 show the energy intensity of various regional economies in 2005. In contrast to energy use per capita, OECD countries have generally lower energy intensities than developing and transition countries. The latter are less efficient in their economic production, which indicates a large potential for efficiency improvements as these regions industrialize and adopt the best available technologies.

The stylized trend in energy intensity is for a rapid increase of industrialization, reaching a high plateau, and then a decline, especially when services begin to dominate the economic production. Changes in the demand for energy services associated with structural shifts in the economy are especially important in explaining the upward trend in energy intensity with industrialization. This rise is often exaggerated, however, by the lack of estimates of non-commercial energy sources. When wood fuel is included in statistical studies, and even human and animal power, there appears to be a more gradual rise in energy intensity (Schurr et al., 1960; Nilsson, 1993; Fouquet, 2008).

A more reliable observation is that as industrialized countries adopt more-efficient technologies for energy supply and use and as the composition of economic activities changes, energy intensity tends to decline over time (Nakićenović, 1996). In the last 30 years, the dominant driver for the declining trends in energy intensity have been technical improvements (Liu and Ang, 2007). Also, despite variability across countries, energy intensities tend to converge (Markandya et al., 2006; Liu and Ang, 2007). Even then, total energy use and energy use per capita continue to rise in most industrialized countries.

One of the first major studies of the relationship between energy use and economic growth in industrialized economies was undertaken in the United States for the period from 1947 to 1974. Although that study found that economic growth had a causal effect on energy demand (Kraft and Kraft, 1978), subsequent studies (Yu and Choi, 1985; Erol and Yu, 1987; Abosedra and Baghestani, 1989; Hwang and Gum, 1991; Cheng, 1995) alternately confirmed or rejected these conclusions (Soytas and Sari, 2003).

More recent studies suggest that the direction of any causality is country-specific. Soytas and Sari (2003) re-examined the relationship between economic growth and energy supply in the top 10 emerging economies and G7 countries and found that growth of GDP raised energy demand in the United States and in Italy, but that energy use raised GDP growth in Turkey, France, Germany, and Japan. The authors' conclusion was that in the long run, restriction on energy use, which reduces productivity, may harm economic growth, and that this may in fact have occurred in Turkey, France, Germany, and Japan. Another recent study of about 100 countries tested for causality between energy and GDP and found that causality from energy to GDP is more prevalent in OECD countries than in developing countries (Chontanawat et al., 2008).

At the aggregate level, the OECD region has seen steadily declining population growth rates over 40 years, caused by and large by an aging population and low fertility rates (see Figure 6.4). GDP per capita growth rate also declined steadily from 2.5% during the 1970s to less than 1.5% between 2000 and 2010 (GEA Database). Everything else being equal, population and per capita income together would have caused total primary energy demand to expand on average by 2.7% annually between 1970 and 2010. In reality, primary energy demand

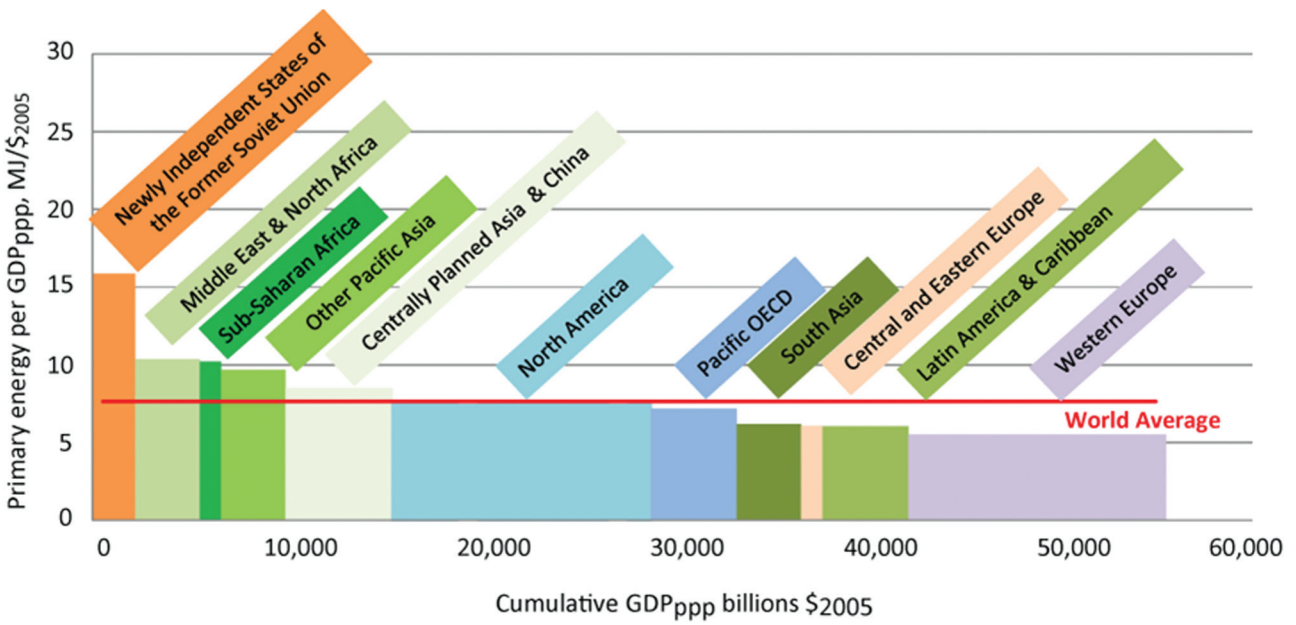

Figure 6.5 | Primary energy intensities across regions in 2005. Source: data from GEA Scenario Database.[10]

10 See www.globalenergyassessment.org

grew only by little more than 1.1% per year as a result of energy innovation, efficiency improvements, and structural economic change but also due to policy and energy price responses, all of which reduce the average energy input required for the production of one unit of GDP. The OECD graph clearly depicts how during the 1990s low energy prices slowed down energy intensity improvements with energy demand growth rebounding (see Figure 6.4). The first decade of the this century is marked by a very modest growth in primary energy due to higher prices, policy incentives stimulating efficiency improvements, and consequent lower energy intensities leading to negative growth rates of per capita energy and electricity demand.

6.4.2 Developing Countries

Despite fluctuations in global economic growth, some countries are consistent regional economic growth leaders[11]. The dynamics and influence of these countries, particularly China, India, Brazil, and South Africa, will be critical in terms of shaping not only the developing world but global energy, economic, and climate change mitigation trends. The enormous investment needs in energy infrastructure by these countries in the coming decades will provide a unique window of opportunity for sustainable, low-carbon energy development. At the same time, they will continue to face the challenges of sustaining economic growth and eliminating poverty.

A proper understanding of the type and direction of causality between energy use and economic growth in developing countries would help illuminate the role of energy in the future evolution of these counties' economies. Soytas and Sari (2003) concluded that there is bi-directional causality in Argentina and causality running from GDP to energy use in Korea. An earlier paper tested for co-integration between total energy use and real income of six Asian nations: India, Pakistan, Malaysia, Singapore, Indonesia, and the Philippines. Masih and Masih (1996) concluded the existence of unidirectional causality from energy to income for India, unidirectional causality from income to energy for Indonesia, and mutual causality for Pakistan. The pertinent inferences that were drawn by the authors from these conclusions were that improving living conditions and providing goods and services will require more energy services, and therefore an energy carrier is necessary. How much of this energy carrier is needed will depend on the energy end-use efficiency achieved in converting the energy carrier to energy services.

Another paper, based on data sets from 18 developing countries, refuted the neutrality hypothesis and concluded that energy use generally causes GDP growth and not vice versa (Lee, 2005). A recent paper focusing on China used a co-integration analysis and an error-correction model to examine the long-term equilibrium relationship between GDP and energy supply and use in 1980–2005 (Wang et al., 2008). It concluded that the two variables are co-integrated but specifically that the growth of GDP forcefully drives the growth of energy supply to increase while energy has a little effect on GDP. Based on this analysis, they concluded that if scientific actions were taken regarding development in the energy sector by: keeping a reasonable economic growth rate; optimizing industrial structures; exploring the use of high-efficiency energy utilization, and developing energy technology, then reducing the country's energy intensity by 20% in five years is achievable.

Despite not many publications being available on the causality between energy and economic development in Africa, Wolde-Rufael (2009) provided a good introduction to this issue and examined the relationship between energy use and economic growth for 17 African countries in a multivariate framework that included labor and capital as additional variables. He found the existence of causality between energy use and economic growth in 15 of the 17 countries. In Kenya and Zambia, energy relative to labor and capital was the most important determinant of economic growth, but causality running from energy use to economic growth was marginally rejected. In 11 countries, energy was not even the second most important factor when compared with capital and labor. Even though energy's contribution relative to output was not so high as that of capital or labor, its contribution to output growth was still relatively high in Algeria (29%), Cameroon (41%), South Africa (23%), and Tunisia (44%). Energy made the least contribution to economic growth in Côte d'Ivoire, Gabon, Senegal, Sudan, and Zimbabwe (Wolde-Rufael, 2009).

An important observation is that for most African countries energy appears to be a smaller factor in economic growth and not as important as labor and capital. In contrast, for many industrialized and developing Asian economies energy is a relatively important contributing factor (Soytas and Sari, 2003; Soytas and Sari, 2006). This conclusion is consistent with the economic growth, energy supply, and use realities of most African countries. Many of these nations are characterized by low economic development, which is reflected in their limited energy development and consumption. In many cases energy supplies are unreliable and the infrastructure needed to meet the needs and demands are lacking.

There is also the issue of consumers lacking access to commercial energy markets. All these characteristics of the energy sector tend to decouple energy supplies and use as drivers for economic growth and development. What is clear is that African countries must endeavor to find ways to direct investments into energy infrastructure development as well as to reduce inefficiencies in energy supplies and use in order to stimulate and promote sustainable economic development. In recent years, a number of African nations have become oil producers, boosting GDP and offering a source of funding for the development of energy infrastructure. Nevertheless, the proximity of oil production does not imply that more energy will get to African households and smaller businesses. Instead, coherent policies will be needed to ensure that the infrastructure and supply reach them.

11 Defined as large emerging economies with global impacts on demand and supply balances.

Despite the many studies which estimate the effect of energy on economic development in developing economies, the research is fraught with difficulty. First, many low-income economies are predominantly agrarian. Much of their energy services are provided through muscular effort of human and animal power, which is not included in energy statistics. Similarly, a great deal of the heating, either for cooking or warming space and water, is fueled using biomass, which is also omitted from most estimates of energy use. Few econometric studies of the causality of energy on GDP (or for that matter, of GDP on energy) incorporate these traditional fuels. Also, time series studies in developing countries are based on few data points, and cross-sectional analysis suffers from a great deal of economic, political, institutional, social, and cultural factors that are hard to include as variables. Thus, conclusions about the smaller influence of energy on GDP in developing economies compared with post-industrial ones must be taken with some caution (Chontanawat et al., 2008).

6.4.3 Small and Medium Enterprises

In both developing and developed countries, small and medium enterprises (SMEs) are major contributors to job creation and economic growth (UNCTAD, 2001). The figure and facts below show the important role of SMEs and the need to take them into account when examining the energy and economy nexus in any economy.

SMEs account for over 90% of the number of businesses in the world and for 50–60% of worldwide employment (USAID, 2009). Their contribution to GDP and employment share increases when national economies mature and branch out. In an evolutionary view to the economic structure, they are crucial in providing diversity ("mutations") in goods and services offered, from which the evolving preference structure of consumers choose. They are the backbone of innovative and dynamic technology development, often crucial in bridging the "valley of death" between lab and the marketplace. In emerging economies and liberalized markets they can also be important vehicles of social mobility. Evidence shows that SMEs have played a major role in the growth and development of all the leading economies in Asia (UNCTAD, 2001).

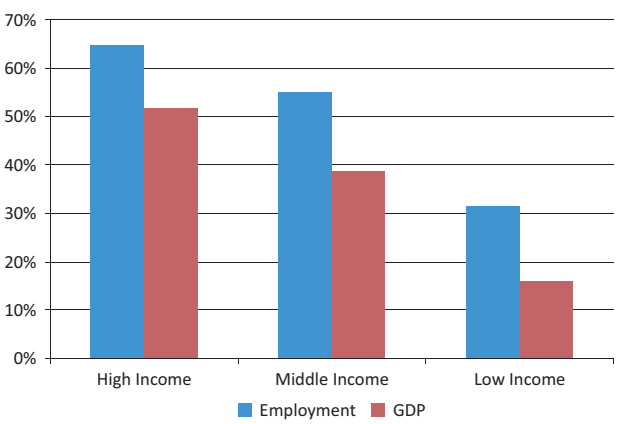

Figure 6.6 | SME contribution to employment and GDP. Source: Yago, 2007.

Access to reliable, affordable, high-quality modern forms of energy is vital for SMEs to operate efficiently and profitably. Large enterprises can afford back-up generators and often benefit from preferential tariff structure and supply security from the utilities. SMEs in contrast pay the highest electricity and modern fuel prices (USAID, 2009), and energy expenses of SMEs in developing countries commonly range from ten to more than 65 percent of the total costs of production. The estimated costs of intermittent electricity provision in several African economies ranges in the order of magnitude of 5–10% of GDP (World Bank, 2011a); the dominant share of this is due to effects on SMEs

Even within the energy sector, SMEs can provide important technology initiatives. The commercialization of formerly unconventional tight and shale gas deposits in the US was largely led by small and medium size energy companies, and significantly changed the supply security of the US gas market. Also in Europe (particularly in Denmark and Germany) small and medium sized enterprises contributed to technology development and reshuffling of the energy markets. A condition was the effective liberalization (and unbundling of supplier and network operator for grid based energy carriers) and democratization of access to energy markets, e.g., through feed-in-tariff structures.

6.5 The Prices and Costs of Energy

6.5.1 Prices as Market Signals

Prices play several essential roles in the economic production and consumption process. Most important, prices send signals to buyers and sellers. When market prices change, they provide incentives to consumers and producers, and demand and supply of goods and services adjust accordingly. Higher prices may signal scarcity and provide incentives for buyers to purchase less of that good or service or look for alternatives. Higher prices can also adversely affect the affordability of basic services and thus extend poverty. For producers, higher prices stimulate additional supplies and increase sales. In short, prices regulate the quantities of goods and services supplied and consumed. If prices increase because of demand exceeding available supplies, they also are a way to let producers know what consumers demand.

Prices also determine income and profit. For producers, price times the quantity sold results in the total revenues, which – when corrected for production costs and taxes – become income. For consumers prices determine affordability, and price time the quantity purchased governs the disposable income left for other activities.

It is important to distinguish between prices and costs. While the price of a commodity or service represents indeed costs to the buyer (the cash outlay at the time of purchase), from the perspective of the consumer

there are other economically relevant "cost" factors – ranging from inconvenience and individual preference to regulation and externalities. For example, in terms of direct costs, heating a home with coal would still be the cheapest way in many jurisdictions. When affordable, however, most home owners prefer fuels such as natural gas. It is simply more convenient (no shuffling of coal, easy temperature control, no extra space for coal storage), cleaner, and more benign for the environment. Moreover, coal combustion in residential areas is banned in many communities. In essence, the price includes a component of willingness-to-pay for the avoidance of inconvenience. In the absence of monopolistic supply situations, price in a competitive market is to a large part a matter of opportunity costs.

Producers or sellers determine the price of providing the fuel, with production cost usually lower than the sales price and with the difference being profit. Sellers test the market and explore what prices consumers are willing to bear and adjust supply in response to demand.

6.5.2 Costs Associated with Energy Supply and Use

The economic literature often distinguishes four types of costs: monetary costs, opportunity costs, environmental and health costs, and sociopolitical costs (Schipper and Meyers, 1992). Most consumers are predominantly exposed to monetary costs – that is, the money they pay for the goods and services they consume, such as the monthly electricity bill or the price at the pump when filling up the car. Enterprises purchasing raw materials, compensating workers (paying wages), servicing debt and dividends, or paying property taxes are also paying monetary costs.

Opportunity costs represent the value of alternative uses of investments, labor, materials, and so on if used for other economic purposes instead of for the supply or use of energy. For example, what is the cost of sequestering carbon by growing trees on a tract of fallow public land? In particular, what is the value of the land, which could well be zero "cost" because the land currently does not earn any rent? In terms of opportunity costs, the cost of the land is to be measured as the value of the output that could be received from that land if used for other activities, such as a shopping mall or soccer pitch.

Health and environmental costs include the premature deaths, injuries, and illnesses suffered by workers in energy supply industries as well as the public at large as a result of effluents and accidents associated with energy supply; damages to buildings, infrastructures, agriculture, and forestry productivity, tourism, and so on; climate change, overloading the carrying capacities of ecosystems, and loss of biodiversity; and nuisance from noise and odor, congestion, or visual blight (Schipper and Meyers, 1992).

Sociopolitical costs include adverse impacts on energy security, geopolitical relations, income distribution, or land use patterns resulting from energy supply and use. Also included are undesired impacts on cultural, community, and family values.

While the monetary costs associated with energy supply and use are fully paid by the producer or user, this is only partially the case for the opportunity, health and environmental, and sociopolitical costs. Insofar as these are not incorporated into the monetary costs, they are called "externalities."

6.5.3 Externality Costs

Externalities arise when an economic agent enjoys benefits or imposes costs without having to make a payment for doing so. As such, externalities can be positive or negative. For example, the adverse health and environmental damages (hidden costs) caused by fossil-sourced electricity generation that are not compensated by the producer are negative externalities. At the same time, the cheaper electricity (without externalities) enjoyed by consumers and that contribute to overall welfare generation represent positive externalities. Factoring external costs into the market price of energy ("internalization") would raise prices. It would send correct pricing signals to the marketplace and thus change the merit order of investment and operating decisions as well as reduce demand and emissions, with subsequent lower externalities.

Negative externalities are often associated with using public goods provided by the environment for free (e.g., air, soil, water, landscape, ecosystem services). To reduce these, a utility needs to take countermeasures, such as installing pollution abatement equipment or making compensation payments for the damages caused. Identifying, measuring, and monetizing externalities are particularly important steps for the quantification of hidden costs and assessment of the effectiveness of policy instruments aimed at internalizing external costs. Since private enterprise normally does not incorporate external costs in investment decision-making, government intervention is necessary to "internalize externalities" resulting from energy supply and use. According to the International Energy Agency, "governments are best positioned to assess, on a broad scale, the social and environmental costs and benefits associated with power generation, as well as the energy security aspects of, for example, a high dependence on natural gas imports destined to the power sector" (IEA/NEA, 2010).

With the exception perhaps of climate change, the internalization of externalities has been inextricably linked with socioeconomic development. As incomes and welfare grow, parts of the health and environmental impact costs have been increasingly internalized through regulation, such as mandatory emission abatement, caps on effluents or waste charges, higher wages compensating for occupational risks, employer-paid insurance schemes, and user fees. As regards climate change, cap-and-trade arrangements such as the European Emission Trading System, carbon taxes, mandatory performance standards, etc. are tools for internalizing the costs of using the atmosphere as a carbon

dioxide waste repository. Their individual effectiveness depends on several factors ranging from levels of caps, tax rates and assessed penalties to rigor to implementation (enforcement) and possibilities of leakage.

The evaluation or monetization of externalities is highly controversial. While the evidence that externalities are real is generally unquestioned, their quantification has been fraught with uncertainties arising from issues of boundaries (what to include) to the valuation of loss of life. Externalities attributed to emissions from energy supply and use have been assessed using the impact pathway approach – that is, the pathway from emissions through dispersion, exposure, physical impact, and damage to the monetization of the damage costs to individuals or society at large (Rabl and Spadaro, 1999; Ricci, 2010). Controversy usually emerges in the last steps of this chain.

Other methodologies include the willingness to pay (WTP) and willingness to accept (WTA) approaches (Markandya and Boyd, 2002). Both WTP and WTA are closely related to the valuation of opportunity costs. WTP/WTA can be interpreted as the willingness to pay for the avoidance of a damage cost or the financial compensation for any damage inflicted that is deemed acceptable. Paying tolls for the use of a highway to avoid congestion and reduce commuting time is an example for WTP. (Note: the congestion charge presents a positive externality for motorists who stay on the regular roads that now are less congested.) Accepting a higher wage for a risky construction job is an example for WTA.

Several studies have attempted to quantify externalities, most of which focus on electricity generation (EU, 2003; Ricci, 2010). The latest systematic analysis of external costs of various electricity supply technologies and their associated chains is available from the European Commission's CASES project (Markandya et al., 2010). Figure 6.7 provides the summary results for the 27 countries of the European Union (EU), estimated for the period 2005–2010.

Human health impacts due to classic air pollutant emissions and the adverse consequences of GHG emissions dominate the external costs across all technologies. On a life-cycle basis, renewables and nuclear power emit only a few grams of GHGs per kWh. The full technology chain for nuclear energy includes the front end of the fuel cycle, power plant construction and operation, the back end of the fuel cycle (including reprocessing), the construction of interim and final repositories, and plant decommissioning. The main contributors to GHG emissions are plant construction (emissions from cement and material production and component manufacturing) and, in the case of nuclear power, enrichment of uranium (depending on enrichment technology and fuel mix used for the electricity input) (Rogner, 2010).

Due to the higher amount of GHG emissions and air pollutants along their respective energy chains from resource extraction, conversion, transmission and distribution to end-use, fossil-based electricity generation followed by biomass-sourced technologies have considerably

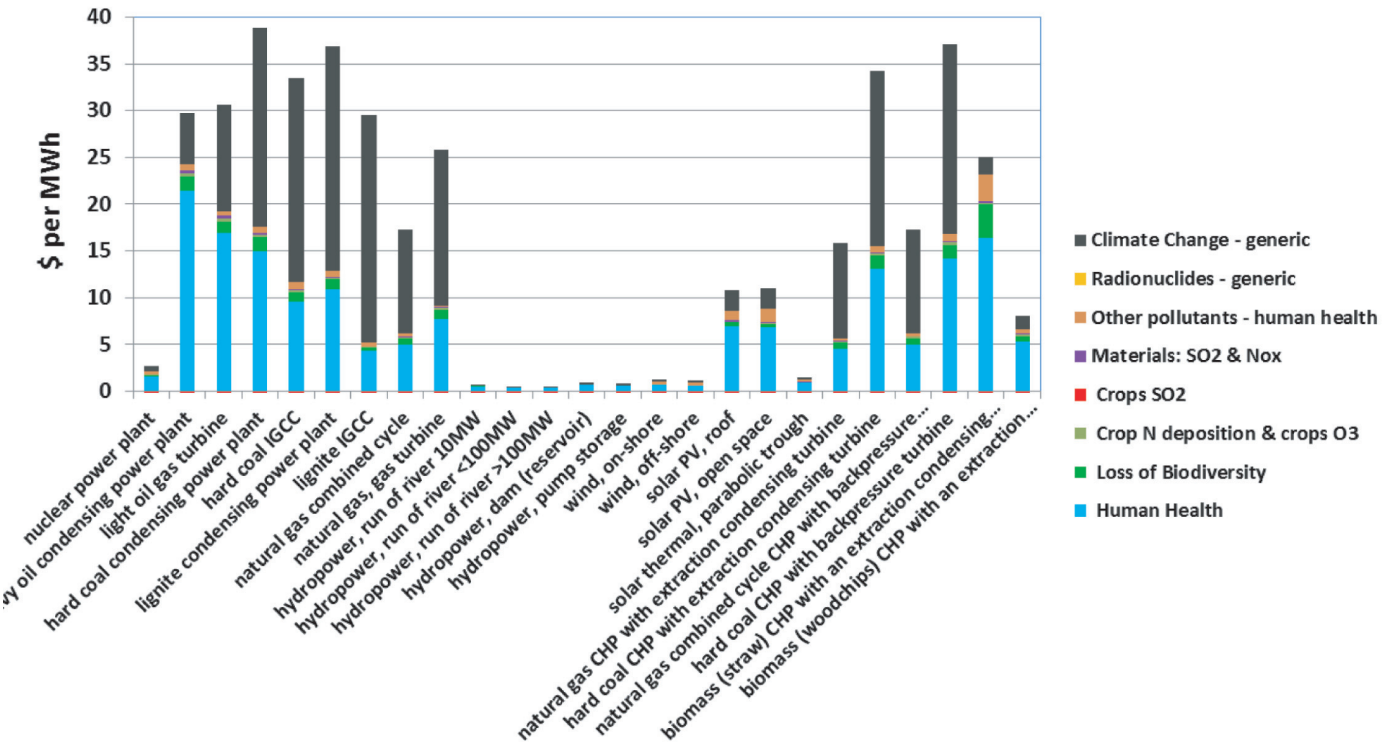

Figure 6.7 | Average external costs for the European Union. Source: Markandya et al., 2010.

higher external costs than renewables and nuclear power, generally ranging between 8.1 and 39.0 US$/MWh which is more than nuclear power and most non-biomass renewables technologies. Externalities are also location dependent as well as how wide the boundaries of the analysis are drawn, i.e., what is included in the analysis and what is not, especially with respect to indirect factors.

Finally, a few words of caution: In addition to the uncertainties associated with quantifying externalities, the external cost data discussed here are dynamic over time and highly nonlinear. Technology change affects the overall economic and environmental performance of energy conversion technologies (higher efficiency, better abatement equipment, etc.). Effluent reductions often result from capital turnover of retired plant and equipment by new technology. Next, the costs are highly nonlinear because of either saturation or threshold effects, which have different implications:

- An example of a saturation effect is found in certain disease risks from air pollution in which an increase in pollution causes a much larger increase in health burden for populations living in relatively clean environments than the same pollution increase causes in populations already living with high pollution levels.

- An example of a threshold effect is found in the impact of acid precipitation on some ecosystems in which the environment is able to absorb extra acid up to a point without much damage but above that level (sometimes called a "tipping point"), the damage increases dramatically.

Moreover, external costs vary considerably from location to location, depending on population density, geography, land use patterns, wind speeds and direction, regulations, and so on.

6.5.4 Resource Depletion as an Externality

Resource economics finds its roots in the perception that natural nonrenewable resources are being extracted too quickly and sold too cheaply for the good of future generations – that is, their excessive cheapness has given rise to wasteful use and inefficiency. As Harold Hotelling noted in 1931, "contemplation of the world's disappearing supplies of minerals, forests and other exhaustible assets has led to demands for regulation of their exploitation" (Hotelling, 1931).

A dynamically efficient allocation occurs when the present value of marginal profit or marginal scarcity rent for the last unit produced is equal across various time periods. Therefore, for resource markets to be in equilibrium, the marginal profit from resource sales must rise at the rate of interest (see Figure 6.8). Then owners of resource stocks are indifferent between extracting the marginal unit of the resource and leaving it in the ground, since the return on holding the resource stock as an asset is equal to the return on alternative interest-bearing assets (SAUNER, 2000). It also implies that if there is no substitute for a resource that is essential to society, there is no maximum resource price. The efficient extraction path may then be identified by noting that the resource stock must reach zero in infinite time.

The rationale behind what is known as Hotelling's Rule is that as a finite resource is produced, less will be available in the future – causing scarcity rent, and thus the resource price, to rise. Increasing prices reduce the quantities demanded by the market and preserve the resource for future use.

In the presence of an alternative technology or a substitute for the resource (usually referred to as backstop technology), the resource price rise is capped at the level when the backstop becomes economically viable (backstop price). In Figure 6.8, the backstop price is the flat part of the price path (P_b), which, once reached, causes discontinuation of production. At this point (T), the resource is said to be "economically exhausted" even though there is plenty of the resource remaining in the ground (Q_T).

However, Hotelling's approach to efficient resource extraction trajectories ignored production costs, technical progress in exploration and

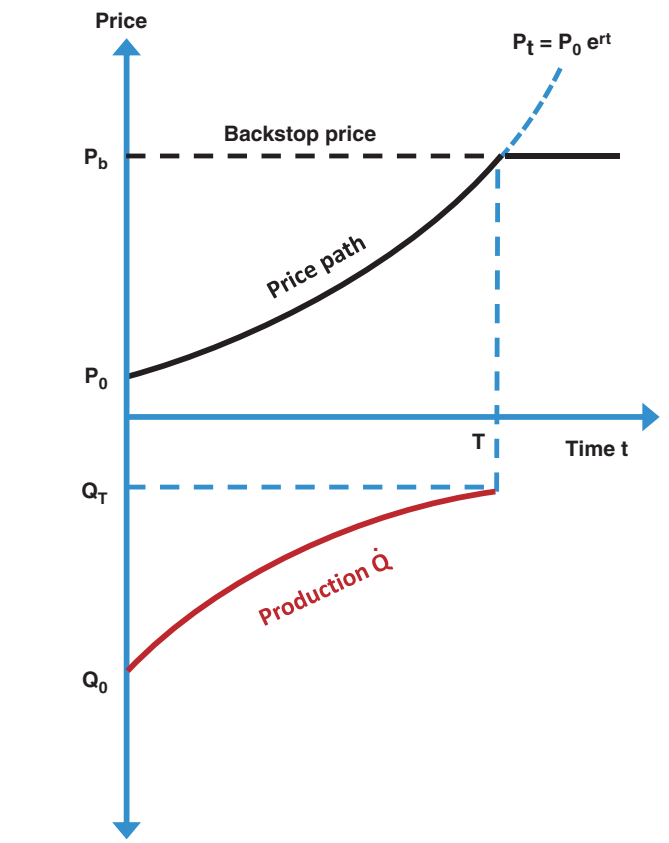

Figure 6.8 | The role of backstop technologies in capping resource prices.

production technologies, and new discoveries. Over the years, several authors have extended the analysis and included these essential real-life aspects in the analysis (e.g., Hartwick and Hageman, 1993; Krautkraemer, 1998, for extraction costs; Dasgupta and Heal, 1979, for exploration and new discoveries).

The questions of interest are whether the historically observed resource prices bear any relation to the Hotelling rule and, more important in relation to the "peak oil" debate, to what extent the observed price paths are an indication of resource growing scarcity over time.

Barnett and Morse (1963) analyzed mineral resource prices between 1870 and 1957, finding that prices fell. They attributed this to new discoveries, to technological progress in resource extraction and processing, and to substitution of alternative materials. Periods of increasing prices have been noted, such as oil prices during the 1970s, but they were attributed to geopolitical tension and Organization of Oil Exploiting Countries supply restrictions (Barnett and Morse, 1963). Lack of investment in exploration and production capacity by producer countries and an unforeseen strong demand growth have been blamed for the oil price hikes during the first decade of this century (IEA, 2008b).

Berck and Roberts (1996) offer three possible explanations for stagnant or decreasing resource prices: technological progress in resource exploration, extraction, and processing; high natural abundance (so scarcity is not yet an economic problem); and environmental or policy constraints limiting production or use where the physical occurrence of the resource is not the limiting factor and the resource is not therefore economically scarce (SAUNER, 2000). Norgaard (1988) attributes the failure of resource prices to rise to the shortsightedness of markets. Increased scarcity is not a sufficient indicator as long as markets are not capable of reflecting it. Markets are simply not farsighted enough for the intertemporal arbitrage function required for price paths to be determined by resource scarcity.

The expectation that innovation and technical progress may reduce the cost of the backstop technology below the scarcity rent trajectory well before existing stocks approach depletion is another explanation for prices staying below scarcity rents. The threat of a cheap backstop encourages depletion of reserves more quickly rather than restricting production and causing prices to rise.

Regarding projections of future energy resource price paths that usually reflect Hotelling's rising scarcity rents (Manne and Schrattenholzer, 1986). Berck and Roberts (1996) found that the probability of rising rents depends on the econometric model used and the assumption about the size of resource stocks.

A final issue on trends in resource prices is the divergence between long run prices of energy and of energy services. Nordhaus (1997) and Fouquet (2011) showed that over decades or more these price trends tend to diverge. This implies that studying long run trends in energy prices, and the apparent resource scarcity, indicates only partially the prices and incentives facing consumers, who benefit from technological development. Indeed, resource scarcity and higher energy prices tend to encourage the adoption of energy efficiency measures that after accounting for all implementation and transaction costs involved, lower energy service prices. So, despite some threats of resource scarcity, the long run trends in energy service prices have been downwards since the Industrial Revolution (Fouquet, 2011). Thus, although there may be short- and even medium-term scarcity related to individual fuels, it is questionable whether consumers are likely to face rising long run trends in energy service prices (Nordhaus, 1997; Fouquet, 2011).

6.5.5 Discounting and Discount Rates

Generally, the discount rate accounts for the time value of money. It reflects the general attitude that money available today is worth more than the same amount in the future. It is expected that deferred consumption, say by investing in bonds issued by a utility, should earn interest. The discount rate then determines the present value of future interest payments received by the investor. The discount rate also reflects the risk and uncertainties associated with an investment – that is, higher risk projects command higher returns, hence higher discount rates. In short, discounting is a critical step in determining whether a project or investment is desirable and is used as a tool to make costs and benefits with different time paths or different risks to the investor comparable. Arguments for why costs and benefits with different time profiles are not comparable typically make several points (Dasgupta and Pearce, 1972; Arrow et al., 1996). The first is that individuals expect their level of consumption to increase in the future, so that the marginal utility of consumption can be expected to diminish. Alternatively, individuals can have a positive pure time preference either because they are generally impatient or myopic or because they perceive a risk associated with not being alive in the future. A second argument for discounting future costs and benefits takes the perspective that capital is productive and that resources acquired for a particular project can be invested elsewhere, generate returns, and so have an opportunity cost.

Discount rates are key elements in most energy investment decisions, especially when the choice is between high upfront investments but low operating costs versus low upfront and higher operating costs (essentially all technologies potentially involved in large scale energy system transformation share the common characteristic of higher upfront investment costs and lower operating costs than traditional forms of energy service supplies). Public policy considerations affect the choice of the social discount rate and opportunity costs more than private sector entities where competitive returns on investment commensurate with vthe (perceived) risks determine discount rates.

Choosing the appropriate social discount rate has long been contentious. Setting the social discount rate too high could preclude many socially desirable projects or investments from being undertaken, while

setting it too low risks encouraging a lot of economically inefficient investments. Further, a relatively high social discount rate, by attaching less weight to benefit and cost streams that occur in the distant future, favors projects with benefits occurring at earlier dates, while a relatively low social discount rate favors projects with benefits occurring at later dates. The choice of the social discount rate affects not only the ex-ante decision of whether a specific project deserves funding but also the ex post evaluation of its performance (Zhuang et al., 2007).

At an individual level, the discount rate affects inter-temporal consumption decisions. Insofar as the choice of energy requires the purchase of energy-using capital equipment, the amount of investments consumers choose to make will depend on the perceived financial profitability. There is evidence that consumers use high implicit discount rates, hindering the adoption of energy-efficient technologies. Specific causes of high implicit discount rates include a lack of information about the cost and benefits of efficiency improvements, a lack of knowledge on how to use available information, uncertainties about the technical performance of investments, a lack of sufficient capital to purchase efficient products (or capital market imperfections), a low income level, high transaction costs for obtaining reliable information, and risks associated with investments (Train, 1985; Lutzenhiser, 1993; Jaffe and Stavins, 1994b; Jaffe and Stavins, 1994a; Howarth and Sanstad, 1995).

In the case of low-income populations, capital scarcity, liquidity constraints, and high transactions costs associated with borrowing can result in households having particularly high implicit discount rates. Hausman (1979) and Train (1985) also argue that implicit discount rates vary inversely with income. Evidence from India suggests that these high implicit discount rates among poor consumers can hinder the adoption of cleaner-combusting, more efficient and convenient fuels and technologies (Reddy and Reddy, 1994; Ekholm et al., 2010). Due to the fact that the use of high implicit discount rates may be a function of asymmetric information, bounded rationality, low incomes, and/or transaction costs, it is argued that policy instruments may affect the implicit discount rate used by consumers by targeting those market imperfections (Howarth and Sanstad, 1995). In the study by Ekholm et al. (2010), the availability of easy and cheap microfinance, for instance, influenced consumer choices regarding cooking fuels and technologies by lowering the costs of borrowing and making upfront capital stove purchases more affordable. In many richer industrialized countries as well, studies have shown that financial incentives that lower the upfront cost of investments can influence individuals' technology adoption and investment decisions (WEC, 2008).

6.5.6 The Impact of Long-term and Short-term Energy Demand

The price of energy is but one element in determining the price of an energy service. It is the price of the service – the combination of the prices of service technology (building, heating system, vehicle, or light bulb) and the fuel (and convenience) – rather than the price of the fuel alone that matters to consumers.

Demand for a particular fuel then derives from the demand for energy services provided by that fuel, the price of the fuel, and the techno-economic performance of the conversion technology and related infrastructure. For heating services this would include the building envelope, the boiler, the heat distribution system (in short, labeled "service technology"), and possibly any environmental compliance plus, of course, climatic conditions and the preferred indoor temperature.

Here the time horizon plays an essential role. In the short term the service technology is "fixed" and represents a "sunk" cost, which explains the focus on day-to-day oil price movements or the adjusted structure of electricity rates. In the longer run, services technologies as well as infrastructure are replaced ("capital turn-over") as they reach the end of their service times (see Chapter 1). This opens the opportunity of replacing the aged and underperforming equipment with more-efficient and cleaner models and designs. How quickly the energy-related capital stock can be replaced and to what degree best-available technologies will be adopted depends, however, on several constraints, ranging from access to finance, individual preferences to information, policy incentives, and market transparency (IEA, 2010b). Moreover, consumers attempt to optimize their utility of using energy for meeting the desired energy services over time. Especially, the market penetration of service technologies with high upfront investment costs is largely determined by the underlying individual discount rate described earlier.

Figure 6.9 depicts the interplay between short-term and long-term demand responses to a generic one-time energy price rise. The point of

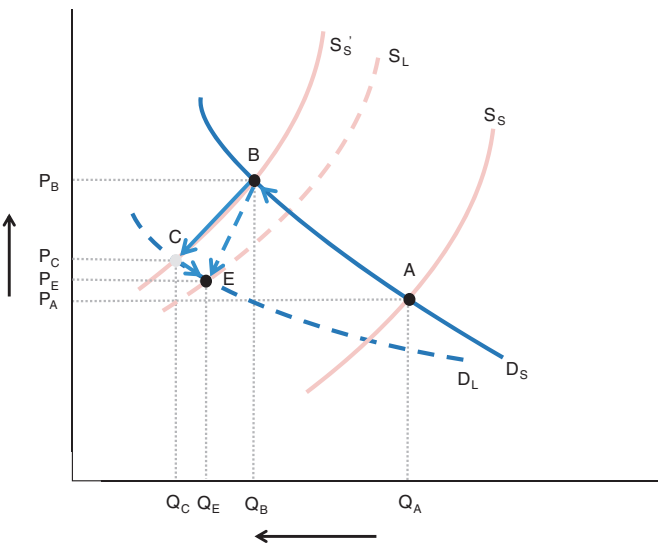

Figure 6.9 | Short and long-term demand/supply responses to a price increase due to a loss of supply capacity. Source: adapted from Samuelson et al., 1988.

departure is a market equilibrium situation at point A (that is, demand and supply functions intersect for demand Q at the market clearing price P_A). A price increase to P_B caused by a loss of supply capacity due to a geopolitical conflict induces short-term demand responses. A steep rise in gasoline prices leaves most consumers with little choice in the short run: pay the high price at the pump, drive less, or shift to other modes of transportation (behavioral adaptation). All this results in a movement from point a along the short term demand curve to point b. The option of purchasing a more efficient car usually arises when the current vehicle approaches the end of its economic service life. In the graph, demand moves along the short-run demand curve D_S, characterized by the fixity of existing capital infrastructure. The loss of supply capacity shifts the supply curve S_S to S_S'.

Although demand is reduced to point Q_B, consumers pay an overall higher energy bill than before despite the cutback in use. In the longer run, when more-efficient appliances, vehicles, and capital in general penetrate the marketplace or when buildings are progressively better insulated, demand declines further to Q_C-, now determined by the new long-term demand curve D_L, which represents the efficiency, technology, and infrastructure adjustments undertaken in response to the price increases. The shift of the demand curve and lower demand reduce supply requirements, and prices drop to P_C. In the interim, higher prices also simulate energy supply- side measures, (e.g. additional exploration, additional mining capacity, etc.) which effectively easing the pressure on prices. The combination of demand and supply-side responses leads to the new equilibrium E. Market clearing now occurs at demand Q_E (lower than Q_B but higher than without the supply side response Q_C) and at a market price P_E.

The production function represents the energy supply to economy link needed for providing key services, including information exchange, transportation, heating and cooling. In contrast, the demand function represents the economic income effect on the demand for energy services influenced by economic growth and development. Regardless of the methodology applied, the influence of economic activity on energy demand is unquestioned. Equally unquestioned is the importance of energy input for economic production, process, and economic development, but the relationship between energy and economic growth is not unidirectional. A major source of uncertainty, however, concerns the dominance over time of relationships between the economy and energy requirements to fuel the economy, on the one hand, and energy as the driver of economic (GDP) growth, on the other. As such, energy plays a vital role in economic development and growth, and it underpins countries' ability to provide employment for their populations. Increased production requires more energy inputs, while greater disposable income increases the demand for heating, cooling and mobility. More generally, the demand for energy is likely to vary at different stages of economic development, with the availability of resources and technologies, according to economic, social, and institutional structures and policies, and across cultures.

6.5.7 Energy Markets and Energy Price Subsidies

While markets are playing a growing role in funding energy investment, significant impediments continue to fundamentally constrain progress in moving toward an energy system and supply patterns for a more sustainable society. Key issues include energy prices that are not cost-reflective, and energy subsidies which distort markets. Energy subsidies and cross-subsidies have profound effects on countries' ability to lift incomes and economic growth by making energy affordable. Feed-in tariffs for low-carbon electricity generation are policy tools for guiding action and channeling investment into socio-politically desirable directions, assisting technology learning (cost buy-down) and reducing investor risks. In essence, subsidies absorb risks and costs private sector entities are not willing to bear for reasons of competitiveness and profitability. However, if not time-bound and performance based, subsidies in the longer run do not create incentives for energy suppliers to recover their costs and invest in a timely manner, discourage new entrants and private-sector investment, and undermine the pursuit of energy efficiency objectives.

Many hundreds of statistical studies have been undertaken to assess the responsiveness of the demand for different forms of energy – including electricity, natural gas, oil and oil products, coal, or total demand for all forms of energy – to changes in prices. Irrespective of the form of energy considered, the demand for energy is typically price-elastic, so that energy use declines as the price of energy increases (and vice versa). A recent study of energy use expenditure in the United States between 1970 and 2006, for instance, found that use of all forms of energy declines in response to energy price increases (Kilian, 2008), although there are important differences across different forms of energy. The study identified a short-run (over one year) price elasticity of gasoline of –0.48 (so that a 10% price increase in gasoline will reduce consumption by 4.8%), and a price elasticity of electricity of –0.15 (so that a 10% electricity price increase will reduce consumption by 1.5%). Elasticities of energy demand with respect to price are typically higher over the longer term, as users have time to adjust, either by switching to alternative fuels or by conserving energy.

In the normal course of events, rising energy prices associated with a scarcity of energy resources would therefore tend to discourage use, but at a minimum it would ensure that energy is not "wasted" and that GHG emissions are not created needlessly. The prevalence of energy price subsidies, in particular subsidies of fossil fuels, however, fundamentally undermines this objective. In some countries (mostly industrialized market economies) energy markets have been deregulated so that prices for energy carriers and services provided to consumers are broadly cost-reflective. Many countries, however, including many developing nations, have administered energy pricing regimes that are not cost-reflective and that entail significant cross-subsidies from one sector (for instance, industry) to others, such as the residential or agricultural sectors. Thus a recent extensive survey found that 37 countries account

for over 95% of global subsidized fossil fuel consumption, leading to higher levels of consumption than would occur without price distortions IEA, 2010a; World Bank, 2010). Overall subsidies amounted in 2008 to US$557 billion (an increase of US$215 billion from 2007).

Phasing out these subsidies would provide a clear incentive to use energy in a more efficient manner and would facilitate the switch from fossil fuels to less GHG-intensive energy sources. Modeling undertaken by the IEA (2010b) indicates that phasing out energy subsidies between 2011 and 2020 would:

- cut global energy demand by 5.8% by 2020;
- cut global oil demand by 6.5 million barrels per day in 2020, predominately oil used in the transport sector; and
- reduce carbon dioxide emissions by 6.9% by 2020, the equivalent of 2.4 Gt of carbon dioxide.

Subsidized energy prices that do not reflect the costs of producing and supplying that energy (including the cost of the very significant infrastructure required to do so) encourage wasteful consumption, but they will also not provide sufficient compensation to producers. Timely investments to meet growing demand are therefore not undertaken by existing utilities; the incentives for new investors to enter the market are similarly removed. While low energy prices may promote access to modern energy carriers in the short term, in the longer term such policies discourage investment in the energy sector, thereby constraining supplies and economic development.

Policies to phase out subsidies for kerosene, liquefied petroleum gas (LPG), and electricity must be carefully designed not to restrict access to essential energy services, as these fuels often are used to meet the basic needs of the poor people. IEA (2010b) analysis indicates that today 1.4 billion people around the world are still without access to electricity and around 2.7 billion people rely on traditional biomass as their primary source of energy (see Chapter 2). However, subsidies to kerosene, LPG, and electricity in countries with low levels of modern energy access (that is, with electrification rates below 95% or access to modern fuels below 85%), represented just 11% of the US$557 billion in consumption subsidies in 2008.

Furthermore, while fuel subsidies are often justified on the grounds that they help address income inequality and provide assistance to low-income groups, in practice such subsidies represent inadequately targeted transfers, with most of the benefit accruing to the largest consumers of oil products, who are typically not the poorest members in the society (World Bank, 2010). A reduction in subsidies combined with a more effective system of taxation would enable government revenues to be better targeted at income transfers, with the broader aim of supporting investments in education, health, and physical infrastructure to assist in economic development (Barnes et al., 2008).

6.6 Investments in Energy

6.6.1 Investment Characteristics and Trends

The transition to modern energy systems is characterized by increasing investment levels in technology and infrastructure. Investments are necessary for energy resource extraction, energy conversion to usable fuels, transmission and distribution systems, and end-use infrastructures. In principle, there are two major categories of investments that are intimately interrelated: investment in the expansion of (and replacement of retired) technologies and infrastructures under competitive or regulated market conditions and investment in innovation, development, and commercialization, including market formation. While the first category is important for supporting energy system growth – from mobilizing upstream exploration and resource extraction to energy conversion and supporting access to energy services, especially in the short-run for balancing demand and supply – it is the second category that enables energy system evolution and transformation, and hence progress in terms of socioeconomic development and environmental protection. The second category is also dependent on policy support, especially market formation.

Market-formation investments include public and private investments in the early stages of technological diffusion and are sometimes also referred to as "niche market" investments. In the energy domain, these investments include policies with respect to certain technologies (such as feed-in tariffs or production tax credits) and public procurement. They also include private investments that may take advantage of markets created by government policies, such as renewable performance standards or price instruments like carbon taxes (UNDESA, 2011).

Market-formation investments in the energy sector as a whole are difficult to track, because many transactions are unreported, the ways of measuring market-formation investments are not yet harmonized internationally, and efforts to track such investments are only relatively recent.

Investment in infrastructure growth and innovation are interlinked, as investment in innovation is a prerequisite for the development of improved and better-performing technologies and processes. Investment in growth and replacement of plant and equipment creates market opportunities for the diffusion of innovative technologies, whereas growth generally offers larger penetration opportunities than mere replacement in an otherwise stagnant market. Using the natural rate of capital turnover for the introduction of innovative technologies has lower transaction costs.

Investment is deferred consumption, and all the features of risk, discount rates commensurate with the risk, present value considerations, opportunity costs, and of course demand discussed earlier apply equally here as well. Energy sector investment time horizons are long-term: investments are made over periods of up to 15 years before the first

revenues are received, and capacities are built to last for 15–60 years and more. The long lifetime of energy sector capital means a slow turnover of its capital stock – a limiting factor to speedy energy system transformation. The recent financial economic crises and the uncertainty in financial markets about the indebtedness of key industrialized countries have made energy infrastructure a highly risky proposition, resulting in underinvestment in key energy sector areas (exploration, production capacity, transmission, and distribution grids). Nationalistic policy solutions focusing on the short run without a global vision (such as of energy system transformation or a global international environmental agreement) further aggravate uncertainty for private-sector investors and result in lock-in effects for the little investment that takes place. The risk premium on such investment and the widening demand-supply gap lead to higher energy prices until additional investment is forthcoming. However, absent solid and predictable energy policy objectives and long-term policy targets which are hugely important ingredients for investor confidence, such investment is unlikely forthcoming.

Since 1980, global total annual investments have fluctuated between 21 and 24% of gross world product with at times a significantly higher share in developing countries and a slightly lower share in the industrialized world (UNCTAD, 2007; IMF, 2011). The share of capital formation allocated to the energy sector is estimated at about 4–8% of total investment, or 1.0–1.8% of GDP. These figures exclude energy-related investments at the end use of the energy system (buildings, heating systems, cars, refrigerators, etc.) that are delivering the energy services that consumers demand.

At the country level, especially for small but energy-exporting countries, the share of energy supply–related investments of GDP can be much higher than the global share and at times can amount to 5–10% of GDP or more.

6.6.2 Energy Supply Investments

Data on energy supply investments are extremely limited, so the literature typically relies on limited surveys or on model estimates (multiplying statistical data and/or estimates on capacity expansion with average technology-specific investment costs to derive total energy supply investments). Energy supply modeling studies have been available since the mid-1990s in academia (e.g., Nakicenovic and Rogner, 1996; Nakicenovic et al., 1998; Riahi et al., 2007) as well as from the work of the IEA, particularly the *World Energy Investment Outlook* (IEA, 2003); the *Energy Technology Perspectives* (IEA, 2006b; IEA, 2008a); and the recurrent projections of the *World Energy Outlook* (WEO) (e.g., IEA, 2006a; IEA, 2007; IEA, 2008b; IEA, 2009a; IEA, 2010a; IEA, 2011), which also contain unique survey data on energy supply investments, particularly in the oil and gas industry.

A common feature (and drawback) of all modeling studies is that energy sector investments are not reported for their corresponding base year values but instead as cumulative totals of the projection period of typically 30 years. The absence of published base year input data for energy sector investment projections not only reduces the credibility of the studies, it also makes an assessment of current investment levels and structure and a comparison among the different studies almost impossible.

The assessment in this section summarizes available information by drawing on the only modeling study that has disclosed its underlying base year energy investment numbers (Riahi et al., 2007) and the surveys reported in IEA's WEO (IEA, 2006a; IEA, 2007; IEA, 2008b; IEA, 2009a; IEA, 2010a; IEA, 2011). Because of the significant price escalation observed for energy sector investments (particularly for oil and gas since 2004), the Riahi et al. (2007) estimate (which refers to year 2000 investments and price levels) can be considered a lower bound, assuming recent price escalations will not remain permanent. Conversely, the IEA numbers can be considered as an upper-bound estimate of investments in energy supply. Comparing and making sense of investment estimates or quotes from different sources is fraught with uncertainty as boundaries of what is included in a particular estimate and what is not, which price basis and exchange rate has been applied, etc. are rarely clearly specified and documented.

Despite differences and uncertainties in estimated supply-side investments per supply category, the available data suggest a range of energy supply-side investment during the mid 2010s of US$700 billion a year to some US$840 billion a year (in 2005 dollars). Investments are dominated by electricity generation and by transport and distribution (T&D), at some US$500 billion. Fossil fuel supply, particularly the "upstream" component (exploration and production), accounts for US$250–400 billion annually, mostly for oil and gas.

Renewables are still relatively minor players under current energy market conditions despite substantial subsidy support for market formation. Liquid and gaseous biofuels account for US$20 billion, including US$8 billion for Brazilian ethanol (UNEP/SEFI/NEF, 2009). Large-scale hydropower (approximately US2005$40 billion for annual capacity additions of between 25 and 30 gigawatts) accounts for some 17% of current supply-side investments. Nevertheless, it should be noted that investments in renewable investments are increasing significantly in recent years. According to REN21 Global Status Report (2011), investments in renewables amounted to 211 billion in 2010 up from 160 billion from the previous year and five times the size of similar investments in 2004.

Exploration and resource extraction are the prime components of upstream investment in fossil fuel supply, although detailed data are difficult to come by due to proprietary issues and clear separation from extraction investment. Major differences also exist for electricity transport and distribution infrastructure investments, for which only modeling study data are available, and estimates differ by about a factor of three. The IEA WEO (2008b) projection of average annual electricity T&D infrastructure investments of US$230 billion over the period 2007–2015 appears high, possibly due to large replacement investments in OECD countries, and is comparable to corresponding electricity generation capacity expansion investments.

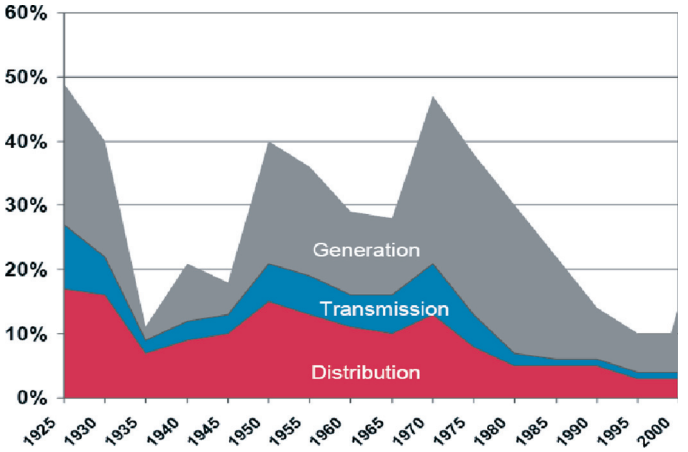

Figure 6.10 | Declining investments (as share of revenues) in the US electricity sector, 1925–2000. Source: Modified from EPRI, 2003.[12]

Given the scarce data available on time trends of supply-side energy investments, an intriguing empirical finding from the United States, however, shows a significant decline in energy supply-side investments for electricity generation in the second half of the twentieth century (see Figure 6.10.) The declining investments (as a share of revenues) in the US electricity sector suggest a substantial thinning of resources available for capital turnover and diffusion of new technologies as a twin result of slowing demand growth and energy sector deregulation and liberalization. At present, it remains unclear if this trend is a specific phenomenon of OECD countries or of US electricity supply (an increasingly deregulated sector), but the example supports the conclusion that better current and longitudinal data on energy sector investments are needed for both in-depth analysis and improved decision-making.

6.6.3 Energy End-use Investments

Investment in energy efficiency, appliances, heating systems, and related infrastructure (buildings, factories) throughout the economy is a necessary prerequisite for the energy system transformations needed.

The decentralized nature of these investments by private households (and their corresponding classification as consumer expenditures rather than investments) and by firms (whose energy-specific investments go unrecorded) explains the absence of energy end-use investment numbers in the literature. The small-scale nature and formidable definitional challenges of these numbers also contribute to their absence.[13] This lack of data, or even of model estimates, introduces a serious challenge in both energy modeling and policy, because the potentially largest opportunity for energy demand (and emissions) reduction is either entirely ignored or assumed to cost nothing.[14] Customary energy and climate policy models deal with energy end-use costs by either "assuming away" missing data by exogenous (and policy-independent) autonomous energy efficiency trends or by considering investment costs for the incremental component of energy end-use investments related to improved energy efficiency, which in itself provides a formidable definitional and data challenge.

GEA addressed the gap and presents the first global, bottom-up estimate of total investment costs in energy end-use technologies (see Chapter 24). Volume data (production, delivery, sales, and installations) and cost estimates to approximate total investment costs in 2005 are estimated for both end-use technologies and their specific energy-using components.[15] Low and high sensitivities around central estimates are included, taking into account uncertainties in both volume and cost assumptions. The intention is to provide a first-order, educated guess benchmark for comparison with supply-side investments. Supporting data and a discussion text are posted on the GEA Chapter 24 website to document the assumptions underlying the estimates here, to solicit feedback and comments, and to invite further research in this critical area.[16]

To ensure comparability between supply-side and demand-side investments, a clear definition unit of analysis and boundaries is needed. Supply-side investments are quantified at the level of the power plant, refinery, or liquefied natural gas terminal. These are complex, integrated technological systems with energy conversion technologies at their core. These energy-conversion components are configured within their corresponding technological system to provide a useful service to intermediate users (e.g., utilities, fuel distributors, pipeline, or shipping companies).

The demand-side analogues are the aircraft, vehicle, refrigerator, or home heating systems. Although generally less complex, each of these technological systems similarly has an energy conversion technology at its core (e.g., the jet engine, internal combustion engine, compressor, boiler, or refrigerator). In addition, each is configured to provide a useful service to final users.

12 More recent data indicates that the trend persists to today. According to the Edison Electric Institute (EEI), for example, which publishes annual utility revenue and investment reports, there has not been any significant change in the percentage of revenues being invested in infrastructure over the past 10 years.

13 For instance, it is far from trivial to discern the energy component in the total investments of a new building. Depending on where the systems boundary is drawn, one could look at the heating and air conditioning system, including that part of the building structure that determines its energy use (insulation, windows). Indeed, the entire building structure may be considered.

14 Some studies include incremental energy end-use technology investments associated with additional energy efficiency gains above a typical "business as usual" scenario (e.g., IEA, 2009b). Apart from introducing additional definitional ambiguities (i.e., what constitutes incremental investments?), the modeling is usually only done for a few technologies (e.g., transport), which limits its usefulness for informed policymaking.

15 Available data do not allow a further disaggregation into those subcomponents of investments on energy efficiency improvements, which remain an important future research task.

16 See chapter 24 at www.globalenergyassessment.org

With demand-side technologies, however, this definition of the unit of analysis is problematic. Investments in (and performance of) end-use technologies are dependent on investments in associated infrastructure, such as airports, roads, and buildings. Is it meaningful to quantify the investment cost of a home heating system without quantifying the investment cost of the home and the insulation level that determine the dimensioning of the home heating system in the first place? Is the end-use technology to consider the furnace or the building?

Although the same issue exists on the supply side, it is largely addressed by additionally quantifying investment costs in associated T&D infrastructures in policy models, as comprehensive statistics are also lacking on the supply side. The problem on the demand side is that the same approach would result in a sum of the total investment costs in all building structures, roads, railways, ports, airports, industrial machinery, equipment, and appliances. Such an exercise would amount to a *reductio ad absurdum.*

A pragmatic pathway out of this system boundary ambiguity is to provide a range of estimates for a range of system boundaries of energy end-use technologies. An initial broader definition and data set describe end-use technologies as the smallest (or cheapest) discrete units that can be purchased by final consumers. This implies boilers and air conditioning units, not houses, and dishwashers and ovens, not kitchens. A second, narrower definition and data set describe the specific energy-using components of these end-use technologies. This implies engines in cars and light bulbs in lighting systems. Table 24.12 (see Chapter 24) summarizes these distinctions for the technologies analyzed. In some cases (e.g., industrial motors, mobile heating appliances), a distinct energy-using component was not identified.

The investments in 2005 in end-use technologies are estimated at US$1–3.5 trillion; the estimate in 2005 in the energy-using components of these end-use technologies is on the order of US$100–700 billion.

Given these definitional problems, the appropriate point of comparison for estimates of supply-side investment costs is a range spanning the narrow category of "energy-using components" at the lower end to the broader category of "end-use technologies" at the upper end. Taking also into account the extent of end-use technologies missing from this analysis, the range of demand-side investment costs is conservatively on the order of US$300 billion–4 trillion. This compares with the range of supply-side investment costs on the order of US$950 billion a year.

The upper bound of demand-side investment outlays is five times higher than the supply-side equivalent whereas the latter is likely a (potentially substantial) underestimate. It is noteworthy that the GEA findings align well with the IEA estimation that demand-side investment needs exceed supply-side investment needs by a factor of 4.5 in climate policy scenarios (IEA, 2008b).

6.7 Financing

6.7.1 The Constraints

The need for a shift in emphasis to higher efficiency and low emissions technologies implies the need for accelerated and up-front energy-related investments over the next several decades. However, even existing low-cost clean technologies in energy supply as well as at end use, particularly when they entail long-lived capital assets and infrastructures, will take decades to fully penetrate the energy sector. Given the long lead times for new technology development, deploying advanced technologies on a large scale after 2025 requires a strong policy response and creation of market incentives today, especially in order to facilitate innovation in such technologies. For example, market incentives to move from obsolete electromechanical to real time electronic, internet-based control of energy delivery and end-use devices would have a major positive impact on energy efficiency.

6.7.2 Energy efficiency investment constraints

Achieving even cost effective improvements in energy efficiency is commonly hindered by a range of market and non-market barriers and failures and many of them can be described as principal-agent problems. The extraordinary large number of actors involved, fragmented institutional framework and often comparatively small size of individual investment needs for energy efficiency improvements and long payback time make this market little attractive for individual investors. Regional energy agencies and energy service companies (ESCOs), together with developing banks, gathered experience with energy efficiency contracting. Almost always, both financiers and end users require some degree of independent assessment. For example, where a trusted ESCO might be able to fully meet the needs of both parties, usually the financier or the end user still wish to have some level of independent technical assessment. Choices then need to be made concerning the degree of outsourcing. Among end users, major industrial enterprises often may conduct technical assessments largely in-house, with perhaps only some very specialized expertise acquired from outside. Building owners, on the other hand, usually outsource nearly all of the project development and assessment effort. The situation among financiers also varies: some development finance institutions may have quite sophisticated in-house technical assessment capacity, whereas many commercial banks will contract out such work to trusted partners. In all cases, energy efficiency investment financing mechanisms must include efficient and cost-effective organizational and institutional arrangements for delivering marketing and technical assessment requirements in which incentives of all the parties are properly aligned. In each respective economic environment, this is likely to include differing combinations of in-house expertise and outsourcing arrangements.

Box 6.1 | Barriers to Energy Efficiency Improvements

Barriers to achieving cost saving investments in energy efficiency include:

Low or underpriced energy. Low energy prices undermine incentives to save energy.

Regulatory failures. Consumers who receive unmetered heat lack the incentive to adjust temperatures, and utility rate-setting can reward inefficiency.

A lack of institutional champion and weak institutional capacity. Energy-efficiency measures are fragmented. Without an institutional champion to coordinate and promote energy efficiency, it becomes nobody's priority. Moreover, there are few energy-efficiency service providers, and their capacity will not be established overnight.

Absent or misplaced incentives. Utilities make a profit by generating and selling more electricity, not by saving energy. For most consumers, the cost of energy is small relative to other expenditures. Because tenants typically pay energy bills, landlords have little or no incentive to spend on efficient appliances or insulation.

Consumer preferences. Consumer decisions to purchase vehicles are usually based on size, speed, and appearance rather than on efficiency.

Higher up-front costs. Many efficient products have higher up-front costs. Individual consumers usually demand very short payback times and are unwilling to pay higher up-front costs. Preferences aside, low-income customers may not be able to afford efficient products.

Financing barriers and high transaction costs. Many energy-efficiency projects have difficulty obtaining financing. Financial institutions usually are not familiar with or interested in energy efficiency, because of the small size of the deal, high transaction costs, and high perceived risks. Many energy service companies lack collateral.

Products unavailable. Some efficient equipment is readily available in high-and middle-income countries but not in low-income countries, where high import tariffs reduce affordability.

Limited awareness and information. Consumers have limited information on energy-efficiency costs, benefits, and technologies. Firms are unwilling to pay for energy audits that would inform them of potential savings.

Lack of capacity in terms of trained people and regulatory frameworks in the energy using sectors (Chapters 8–10 and Chapter 25).

6.7.3 Financing Energy Efficiency

Success in capturing a bigger share of the large numbers of financially attractive energy efficiency retrofit projects has proven stubbornly difficult, primarily because the intrinsic nature of the projects and their broader setting make it hard for effective markets to develop naturally. In some countries, price distortions may undermine incentives, but in most sectors in Brazil, China, and India, and many other countries, this is not the case, as project financial returns are high in most instances. Flow of information about energy efficiency opportunities is far from perfect, but it has improved. In some countries, the required technical or managerial expertise is lacking, but in the case of Brazil, China, and India the issue is more how to bring existing strong expertise to bear. For energy efficiency investments to be made, energy efficiency concepts must be marketed to enterprises, and specific projects must be identified, designed, and appraised. This requires marketing, project development, and technical assessment skill, typically provided by local energy efficiency experts. Human and organizational capacity is needed to define target markets and market outreach strategies, identify project opportunities, design appropriate project packages at end-user facilities, assess financial returns and the risks influencing delivery of the project cost savings cash flow, and understand the incentives to participate by each of the designated parties. For countries such as Brazil, China, and India, the main issue is how to most efficiently access existing project development capacity (Taylor et al., 2008).

Keeping transaction costs reasonable is often a major challenge, especially given the relatively small size of energy efficiency loans. Design of programs to achieve this requires creativity and innovation. For example, for their general and energy efficiency lending to SMEs, Indian banks have relied on new geographical and industry-specific clustering approaches. For investment delivery mechanisms integrating project development and financing to be successful in increasing energy efficiency project investment, they should build upon the following principles: Delivery mechanisms need to be customized, based on a careful diagnostic review of the local institutional environment, including the financial sector, local capacities for technical assessment, the energy efficiency market, and the role of government. Such diagnostic review critically requires local expertise.

End users need to face commercial terms for the financing and technical services being provided as the best foundation for the creation of an energy efficiency market. End-user subsidies tend to ultimately undermine sustainable market development, because they are usually short-lived and can create market distortions and unrealistic expectations. However, concessional financing has often proven valuable to help buy down the high costs and risks of starting up new commercially oriented programs, build necessary new capacity, and assume risks with new approaches. Appropriate incentives must be included for the various actors in each mechanism to participate. Particularly important are incentives to generate deal flow. Combined with the last point, this implies a focus on organizational and institutional arrangements ("deal structuring") that deliver positive incentives for all actors without relying upon long-term market-distorting subsidies (Taylor et al., 2008).

6.7.4 Financial Sources and Instruments

Following are some of the main financial instruments used to support energy efficiency policies:

A. State or Municipal Bonds: Given the magnitude of needs, the high degree of public ownership in the energy sector of the project countries and the limited funds available from external sources, this is one of the most important financial sources.

B. Grants: Many bilateral and multilateral partners provide grants under different programs for financing energy efficiency. Some of the most important international organizations include the United Nations Development Program, the United Nations Environment Program, the World Bank and the Global Environment Facility (GEF) – the financial mechanism of the United Nations Framework Convention on Climate Change (UNFCCC). In the Global Environment Facility, climate change activities are currently divided into four areas: (a) removing barriers to energy efficiency and energy conservation; (b) promoting the adoption of renewable energy by removing barriers and reducing implementation costs; (c) reducing the cost of low greenhouse gas emitting technologies and (d) supporting the development of sustainable transport.

C. Loans: These are mostly provided by many actors including banks – both private and public development banks, international financial institutions, and private investors. International Financial Institutions (IFIs) have increased their role in this important category of financial instrument. Their involvement can provide political motivation to pursue energy sector reform and promote investment. IFIs can play a particularly important role in low income developing countries by building up a standardized risk data base and enhancing the quality of governance. This would both facilitate the use of appropriate investment instruments and help the international investment community achieve the confidence needed to invest in low income countries. This underscores the catalytic role that IFIs can play in promoting policies that stimulate and stabilize internal cash generation, and attract substantially higher levels of commercial and private investment.

D. Equity financing: Under these arrangements, investors take a whole or fractional share of ownership, and thus sharing both risks and benefits from that investment. The types of investors under this category are very diverse including institutional, government, and private investors.

E. Leasing: Under a leasing contract, a lessor conveys to a lessee the right to use a piece of property for an agreed period of time against payment or a series of payments. It is sometimes chosen to be the mechanism, which provides the project owner with necessary equipment under performance contracting.

F. Tax and customs tariffs incentives: Another option for countries to promote measures in energy efficiency is through stimulating utilities or the market for technology distribution and providers of energy efficiency services. This may also be called a form of indirect financing. Yet another is to diminish or abolish customs tariffs on imported energy efficiency equipment.

G. Revolving fund: This is a financial scheme aimed at establishing sustainable financing for a row of investment projects. The fund may include loans or grants and aims at becoming self-sustainable after its first capitalization. The objective is to invest in profitable projects with short payback time, be repaid, and use the same fund to finance new projects. It can be established as a bank account of the owner or as a separate legal entity. There are several parties in a revolving fund: The owners can be either public or private companies, organizations, institutions or authorities. The operator of the fund can be either its owner or an authority appointed by him. External donors and financiers provide contributions to the fund in the form of grants, subsidies, loans or other types of repayable contributions. The borrowers can be either the project owners or contractors. According to the conditions of the revolving fund, savings or earnings gained from projects should be paid back to the fund within a fixed period of time, at certain time intervals. The revolving fund, as financial instruments has its advantages and drawbacks.

H. Venture Capital: Venture capital is particularly important for investments in new technology. By providing early up-front investment finance

to companies that have high potential but also high risk, venture capital plays an important role in innovation. It could also play an important role in the setting of new businesses with little or not operating history or that are too small to raise their own funding. The trust placed by venture capital to launch many of these could be essential.

I. Energy Service Companies: Although not a financial instrument *per se*, ESCOs constitute an indirect way to attract capital to investments or third party financing. The ESCOs may fulfill the functions of project identification, planning, implementation and financing. Financing is obtained through contractual relations between the ESCO and the project owner; the investment is carried out by the ESCO and is financed from the costs savings achieved. There are two types of contracts. The first is a guaranteed savings contract, in which payments from the project owner are made according to savings achieved. The second might not include the ESCO in the contract but it makes the project owner liable to cover the capital outlays; payments to the ESCO from the project are not related to the actual savings achieved.

Box 6.2 | Financing Mechanisms

Very large investments will be required to develop new energy technologies and also to increase their uptake throughout the world. Almost all growth in energy demand over the coming four decades will occur in non-OECD countries, where financing capacity is weakest with the exception of the large emerging economies like China and Brazil. The availability of finance and transfer of clean energy technologies into these markets is often considered essential. IFIs and Multilateral Development Banks are expected to play a central role in the process of technology transfer. According to a recent study, multilateral development banks are increasing their role in energy finance in developing countries significantly (BNEF, 2010). From 2008 to 2009, loans to developing countries increased three-fold to some $21.1 billion. Some national development banks, both in OECD countries which invest in developing countries, as well as some in developing countries such as the BNDES, Brazilian Development Bank, have also become major actors and suppliers of energy finance. Over the past five years, KfW of Germany has had financial cooperation commitments for energy projects in developing countries amounting to €3.8 billion KfW, 2011.

The overall contribution of the World Bank Group to energy investments over the past 20 years had been varying considerably, with a lowest point at about US$1 billion in 2004, but had been increasing since then to about US$ 7 billion in 2009 and over US$10 billion in 2010, of which $4.9 billion went to renewables. Compared to the overall portfolio of World Bank investments, the energy sector contributed about 15% of World Bank lending in that time period. Compared with the global investment in the energy sector of many hundred billion and exceeding several trillion if end use-investments are included, these contributions are just a small share of the total investment capital needed (World Bank, 2011a).

The GEF – an operating entity of the financial mechanism of the UNFCCC – has been a key contributor to helping countries eliminate market barriers to the introduction of new technologies and catalyzing energy investments in developing countries. Up to 2009, the GEF has allocated some US$ 2.7 billion to support climate change mitigation projects in developing countries and economies in transition. It has also leveraged an additional $17.2 billion in project co-financing, most of which are energy-related projects. This has resulted in more than 1 billion tons of greenhouse gas emission being avoided between 1991 and 2009, thanks to the support of the GEF. The portfolio of GEF projects is diverse. The energy efficiency portfolio ranges widely from district-heating to efficient lighting, industrial energy efficiency and pioneering guarantees for energy efficiency investments. Through its life-time, the GEF has provided support to over 40 different technologies, many of which were new to the countries into which they were introduced.

The Climate Investment Fund is another more recent and specialized financing mechanism of various development banks set up to provide climate change funding pending the setting up of the Green Climate Fund being established under the UN Framework Convention on Climate Change. It contains two funds of direct relevance to the funding of energy. The Clean Technology Fund which provides concessional finance at as significant scale to help developing countries formulate projects that can be included in the National Appropriate Mitigation Actions emerging from the climate change negotiations and a second one for scaling up renewable energy in low-income countries.

Lastly, it is also important to mention that as a result of the recent financial and economic crisis, many countries such as the Republic of Korea, China, and many others have set up stimulus packages with a significant focus on green investments and the promotion of investments in low carbon technologies. Many of these middle income countries are also playing an increasingly important role in trilateral arrangements as well as south-south cooperation for technology transfer and finance.

6.8 Technology Innovation and Diffusion

In its sixteenth meeting of the Conference of the Parties of the UN Framework Convention on Climate Change, and more specifically in its Cancun Agreements (UNFCCC, 2010), the Parties recognized that "deep cuts in global greenhouse emissions are required…with a view to reducing greenhouse gas emissions so as to hold the increase in global temperature below 2 degrees above pre-industrial levels…". The Intergovernmental Panel on Climate Change have also called for reductions of 50% or greater in global GHG emissions to keep the concentration of these gases below 450 ppm (IPCC, 2007). According to the IEA, achieving this objective would require "major improvements in efficiency and rapid switching to renewables and other low carbon technologies, such as carbon capture and storage (CCS)" and "deployment and development of technologies still under development, whose progress and ultimate success are hard to predict" (IEA, 2008a). Such a shift, "if achievable, would certainly be unprecedented in scale and speed of deployment" IEA, 2008a). The World Bank similarly states that addressing climate change "requires … widespread diffusion of renewable energy technologies… and breakthroughs in technologies from batteries to carbon capture and storage" (World Bank, 2010).

While there is a general recognition that new technologies will need to be developed for a transition to a less energy-intensive and emissions-intensive world, neither public nor private funding of energy-related research, development, and deployment is remotely close to what is required (World Bank, 2010). (See Box 6.3.)

In absolute terms, public energy-related RD&D expenditures in the OECD have declined since 1980 and fell by almost half from then to 2000, to around US$10 billion, before rebounding to US$15 billion in 2008. The expenditures reported for 2009 reach an unprecedented high of US$23 billion (in 2009 prices and exchange rates), with fossil fuels and technologies absorbing the lion's share (US$3.8 billion) of the increase of US$8 billion from 2008 (IEA, 2011).

Private energy RD&D, estimated at US$40–60 billion a year, far exceeds public spending (Chapter 24). At 0.5% of revenue, private expenditures on energy RD&D remain small, however, for instance, compared with 8% of revenues invested in RD&D in the electronics industry and 15% of revenues in the pharmaceuticals sector (World Bank, 2010). (Note: the latter are largely non-energy-related.) Taken overall, the energy-related figures pale in comparison to estimates of required RD&D expenditures in the order of US$100–700 billion a year (World Bank, 2010).

Within the OECD, Japan spends 0.08% of GDP on research and development (R&D), compared with the 0.03% of GDP average for the high- and upper-middle-income members of the OECD (World Bank, 2010). By contrast, in the United States the share of public and private R&D fell from 10% to 2% between 1980 and 2006 (Weiss and Bonvillian, 2009). Total energy R&D now accounts for less than 1% of the annual revenues of the US energy sector. Weiss and Bonvillian offer several explanations for this decline:

- deregulation of energy markets, which has increased competition and led to cutbacks in discretionary expenditures, including R&D;
- an extended period of relatively low energy prices; and
- a mature and cost-competitive sector, which has generally tended to deter new entrants and potential competitors.

Box 6.3 | The Role of Entrepreneurial Innovators

The path to global sustainability will require nearly US$2 trillion annually of primarily private sector investment, plus making hundreds of thousands of sites available for often locally controversial energy facilities and training hundreds of thousands of energy workers at all levels each year. Governmental institutions that support innovation are generally unprepared for this challenge. The energy sector is also dominated by large, risk-averse corporations with strong interests in preserving their comfortable status quo and with a resulting history of underinvestment in innovation.

The role of entrepreneurial innovators will thus be crucial. However, the energy sector has not been very encouraging to entrepreneurial innovators for several decades.[17] Also the priority of avoiding risk at all costs of most governmental organizations has deterred investors in entrepreneurial firms from entering energy markets. This is particularly true for governmental regulatory agencies that have typically put protecting the incumbent industries they regulate ahead of innovation goals. This has inhibited the reallocation of economic resources from the established to the new entrepreneurial organizations that necessarily lead transformative innovation (see also Chapters 24 and 25).

17 Entrepreneurs in wind and solar PV have been successful in some countries, including: Germany, Spain, Denmark and Bangladesh.

The process of technology deployment and adoption is widely seen as being about much more than the technical aspects or performance of some piece of equipment. This is particularly true in developing countries, where many factors influence technology adoption and where capacity building will be crucial to enable developing countries to adopt new technologies (Tomlinson et al., 2008). Technology "diffusion" then covers the process of understanding, using, and replicating technologies, as well as adapting them to local conditions and integrating them with other technologies (IPCC, 2000).

The increasing importance of investment flows to promote technology is the focus of current research to promote climate-friendly development. The majority of global investment and technology diffusion occurs via the private sector in the form of corporate R&D, venture capital or asset financing arrangements, or funds raised in public markets (UNEP/SEFI/NEF, 2009). Studies assessing technology transfer and diffusion in developing countries have accordingly noted that openness to trade is a necessary prerequisite for successful transfer.

A second key factor for facilitating technology transfer (see also Chapter 25), which relates directly to the incentives for private firms to undertake R&D, is intellectual property rights (IPRs). Predictable and clearly defined IPRs can stimulate technology transfer from abroad, while weak IPR enforcement discourages foreign firms from investing in R&D activities, licensing new technologies, and investing in domestic enterprises abroad (World Bank, 2010). For example, foreign subsidiaries of global wind equipment producers have registered very few patents in Brazil, China, India, or Turkey, all of which have weak IPR regimes.

At the same time, there are trade-offs. IPRs may hamper innovation if a patent blocks other useful inventions by being too broad in scope, or they can hamper technology transfer if firms refuse to license their technology. To date, overly restrictive IPRs have not been identified as a material barrier to transferring renewable energy production capacity to middle- income countries (ICHRP, 2011), but this situation may change if patenting activity accelerates in photovoltaics and biofuels and if equipment supplier consolidation continues in the wind sector (World Bank, 2010). The World Bank (2010) therefore highlights a role for high-income countries in ensuring that:

- excessive industry consolidation in the renewable energy sectors does not reduce incentives to license technology to developing countries;
- national policies do not prevent foreign firms from licensing publicly funded research for clean technologies of global importance; and
- concerns over IPRs and the transfer and innovation of clean technologies are considered in international treaties such as those of the World Trade Organization.

The importance of the RD&D effort for developing new low-emissions technologies and the observed shortfall in activity suggests that there is an ongoing role for government in this area. The role of governments is threefold and extends beyond energy RD&D: first, in general support for knowledge creation (education, support for international science and technology cooperation, and information exchange); second, in supporting basic and applied energy technology R&D via direct public R&D expenditures as well as by creating and maintaining appropriate incentives for private sector R&D; and third, creating favorable market deployment incentives as well as removing existing barriers for the adoption of more-efficient and cleaner energy technologies.

Broadly speaking, government has a role in RD&D where there are specific "market failures" that will inherently limit private RD&D, but it also needs to put in place a framework in which research activities and innovation are facilitated (IPCC, 2007). There are many market failures that can prevent technology development and deployment. A fundamental failure occurs when prices do not reflect the full costs of the service rendered. Subsidized consumer prices are one example.

Another prominent example, as described earlier, is the failure to internalize the health and environmental damage costs from fossil fuel combustion, especially the costs caused by climate change. Failing to charge the full costs sends the wrong signal to the marketplace and results in overuse of services and underinvestment in more-efficient and cleaner technologies and processes. The net result is reduced demand for climate-friendly technologies and private-sector incentives stimulating innovation. Failures of this type can be addressed by establishing a corresponding market mechanism, for instance in the form of a carbon price, or by removing subsidies.

Additional market failures include monopolistic market structures, different incentives between short-run first-cost minimization (e.g., apartment buildings) by contractors and operating costs over the longer term, access to finance for technologies with higher up-front investment and transaction costs, lack of institutional support, and limited awareness and information.

More generally, new technologies usually face a range of technical and market hurdles and associated uncertainties about entering into widespread commercial use, including innovation uncertainty, technology performance, cost, financial risks, lengthy timescale for deployment, and very large sunk costs. Here governments have a role to play by putting in place the enabling "infrastructure" required to support RD&D and innovation, including the rule of law, open markets, the protection of intellectual property, and the movement of goods, capital, and people.

Several promising efficient and environmentally benign technologies are in their infancy and thus require public RD&D support, while others are more mature and need primarily market incentives for deployment

and diffusion. Providing effective deployment incentives is therefore another area for public-sector involvement. These include corrections of the market failures just mentioned, financial incentives (tax credits, carbon prices, fuel taxes, technology rebates, time-limited subsidies), a reliable and predictable regulatory framework, institutional arrangements (e.g., energy service companies), public procurement, promotion, and education.

6.9 Institutional Change

In the face of the profound demographic changes occurring throughout the world, the institutions that were created over the past three decades to help ensure energy security are struggling to remain relevant. The rapid changes of the last few decades point to the need for a more nimble mechanism or system that could help address the complexity of security, global environmental and social and economic concerns, and so on. In order to be effective, this mechanism or system would need to balance the interests of governments, importers, and exporters while aligning with the needs of the private and state-owned firms that provide most of the energy infrastructure investment.

A broad-based cooperative leadership coalition for positive change is the indispensable but missing ingredient needed to transform the energy systems that sustainable societies would require. There is no shortage of governance institutions in today's energy markets. What is missing is a practical strategy for setting effective norms for governing the global energy economy. The basic problem lies in the massive economic and political risks inherent in new projects, particularly those that supply energy across national borders and thus face a multitude of uncertainties. Longtime antagonists must work together to create a shared vision of, and an implementation commitment to achieving, a new, sustainable global energy strategy. This means setting clear goals to address the pivotal challenges of energy access, security, poverty, health, climate change and environment and crafting the necessary policies and practices to achieve these goals. The key challenges can be overcome through a blend of carefully targeted policy initiatives that build on the power of the market, plus public-private partnerships for financing and technology development

Support for new "green" or low-carbon technologies is a second area where a governance vacuum has made progress difficult. Firms are not likely to invest the trillions of dollars needed to develop energy infrastructure in the coming decades without credible signals that governments are serious about establishing and maintaining policies that enable the private sector to confidently cash in on their investments. Based on experience, a sharper focus on energy investments is likely to be much more successful than the more typical broader multilateral governmental agreements on foreign investments.

6.10 Conclusion

Following are the main conclusions and key messages of the chapter:

- Energy is not an end in itself but a prerequisite for economic development (including for the achievement of the Millennium Development Goals), and for the achievement of growth.
- Energy is crucial for the necessary transition to a more equitable and sustainable world and one where all have access to the energy services required for comfort and for a secure and healthy livelihood.
- Energy service demand is a function of population and income, as well as technology. While more affluence may lead to a demand for more energy intensive services it could also lead to a demand for cleaner energy carriers.
- The immense global population increase of the past century has been matched by a period of intense technological expansion that has increased the capacity to harness energy more efficiently and effectively. The reality is that while technology has expanded dramatically, for the most part it is not yet being commercially implemented to meet the 21st Century needs.
- Electricity provides the essential key to energy access, and is the energy prime mover enabling technical innovation and productivity growth. Filling the global electrification gaps to an ever-growing 1.4 billion people today is an essential requirement for eliminating extreme poverty and global security threats.
- A healthy economy is needed to ensure that the energy demands are met, that investments and infrastructure work is carried out and that resources for Research and Development flow to meet the needs and requirements for a sustainable future.
- Most clean technologies are capital-intensive however; they also lower energy demand and fuel consumption. Proper incentives and financial schemes to promote their development are essential.
- Prices play an essential role in the production and consumption process by sending important signals to sellers and buyers. But it is important to distinguish between prices and costs.
- Ideally, the life-cycle cost is what matters when assessing the costs of energy carriers (rather than the cost of fuels or capital costs being accounted for separately as is often the case).
- While monetary costs associated with energy supply and use are fully paid by the producer and/or user, this is only partially the case for other costs associated with "externalities."

- Energy, capital, labor and materials are, within limits, substitutes of each other and the optimal mix is a matter of their relative factor prices.
- Demand responds to price changes – slowly in the short-run because lock-in effect leaves little room for immediate fuel switching and efficiency improvements but in the longer run, it does respond more profoundly through capital replacement (e.g., buildings, refurbishment, new technologies, process adaptation, etc.) and market penetration effects.
- As incomes rise energy demand grows but eventually the tendency is for this growth to take place slower than GDP.
- Investment in R&D drives innovation and is the key for technology improvements, for new technologies to emerge and for a lower energy intensive production of GDP.
- Required investments in clean energy systems are staggering and require investors with a long-term vision – usually with the support of governments which would ideally come in to provide the strategic policy certainty and level playing field for private sector involvement.
- The shift to higher efficiency and more sustainable forms of energy require accelerated and up-front energy-related investments over the next several decades that will need to be sustained and supported by coherent and coordinated policy and regulatory frameworks to mitigate the many existing constraints.
- Although investments in clean energy systems in recent years have been impressive and continue growing, much more is required for the energy transitions that GEA necessitates, including to avoid lock-in effects associated with obsolete energy infrastructures with little short-term flexibility.
- Subsidies change the relative merit order based on private cost only, and can, if well designed, reflect the externalities in market conditions. Subsidies are required for transitions to energy systems supporting a sustainable future.
- Overall energy system performance (intensities, cleanliness, affordability) is more dependent on investments in end-use infrastructures and technologies than on traditional energy sector investment although the latter are also important.
- Energy transitions do not happen in isolation. They require a robust public policy framework and an adequate institutional infrastructure to help make things happen. The evidence shows that major policy and institutional reforms are necessary to lead us into the energy transitions that the GEA necessitates.

Executive Summary

An energy resource is the first step in the chain that supplies energy services (for a definition of energy services, see Chapter 1). Energy services are largely ignorant of the particular resource that supplies them; however, often the infrastructures, technologies, and fuels along the delivery chain are highly dependent on a particular type of resource. The availability and costs of bringing energy resources to the market place are key determinants to affordable and accessible energy services.

Energy resources pose no inherent limitation to meeting the rapidly growing global energy demand as long as adequate upstream investment is forthcoming – for exhaustible resources in exploration, production technology, and capacity (mining and field development) and, by analogy, for renewables in conversion technologies.

Hydrocarbons and Nuclear

Occurrences of hydrocarbons and fissile materials in the Earth's crust are plentiful – yet they are finite. The extent of the ultimately recoverable oil, natural gas, coal, or uranium is the subject of numerous reviews, yet still the range of values in the literature is large (Table 7.1). For example, the range for conventional oil is between 4900 exajoules (EJ) for reserves to 13,700 EJ (reserves plus resources) – a range that sustains continued debate and controversy. The large range is the result of varying boundaries of what is included in the analysis of a finite stock of an exhaustible resource, e.g., conventional oil only or conventional oil plus unconventional occurrences, such as oil shale, tar sands, and extra-heavy oils. Likewise, uranium resources are a function of the level of uranium ore concentrations in the source rocks that are considered technically and economically extractable over the long run.

- Oil production from areas that are difficult to access or from unconventional resources is not only more energy intensive, but also technologically and environmentally more challenging. The production of oil from tar sands, shale oil, natural gas from shale gas or the deep-sea production of conventional oil and gas raises further environmental risks, ranging from oil spillages, groundwater contamination, greenhouse gas (GHG) emissions, and water contamination to the release of toxic materials and radioactivity. A significant fraction of the energy gained needs to be reinvested in the extraction of the next unit, thus further exacerbating already higher exploration and production costs.

- Historically, technology change and knowledge accumulation have largely counterbalanced otherwise dwindling resource availabilities or steadily rising production costs (in real terms). They extended the exploration and production frontiers, which to date have allowed the production of all finite energy resources to grow. The question now is whether technology advances will be able to sustain growing levels of finite resource production and what will be the necessary stimulating market conditions?

- Resources need first to be identified and delineated before the technical and economic feasibility of their extraction can be determined. However, having identified resources in the ground does not guarantee its prerequisite technical producibility or its economic viability in the market place. The viability is determined by:

  - the demand for a resource (by the energy service-to-resource chain);
  - the price it can obtain; and
  - the technology capability, economic performance and environmental limitations. The last is becoming increasingly difficult to accomplish (see Sections 7.2.6 and 7.3.9).

- Thus, timely above-ground investment in exploration and production capacities is essential to unlocking below-ground resources. Private sector investment is governed by the expected future market and price developments, while public sector investment competes with other development objectives. The time lag between investment in new production capacities and the actual start of deliveries can be up to 10 years and more, especially for the development of unconventional resources. Until new large-scale capacities come online, uncertainty and price volatility will prevail.

Table 7.1 | Fossil and uranium reserves, resources, and occurrences.[a]

	Historical production through 2005	Production 2005	Reserves	Resources	Additional occurrences
	[EJ]	[EJ]	[EJ]	[EJ]	[EJ]
Conventional oil	6069	147.9	4900–7610	4170–6150	
Unconventional oil	513	20.2	3750–5600	11,280–14,800	> 40,000
Conventional gas	3087	89.8	5000–7100	7200–8900	
Unconventional gas	113	9.6	20,100–67,100	40,200–121,900	> 1,000,000
Coal	6712	123.8	17,300–21,000	291,000–435,000	
Conventional uranium[b]	1218	24.7	2400	7400	
Unconventional uranium	34	n.a.		7100	> 2,600,000

[a] The data reflect the ranges found in the literature; the distinction between reserves and resources is based on current (exploration and production) technology and market conditions. Resource data are not cumulative and do not include reserves.

[b] Reserves, resources, and occurrences of uranium are based on a once-through fuel cycle operation. Closed fuel cycles and breeding technology would increase the uranium resource dimension 50–60 fold. Thorium-based fuel cycles would enlarge the fissile-resource base further.

- There appears to be general consensus that the occurrence of fossil and fissile energy resources is large enough to fuel global energy needs for many centuries. There is much less consensus as to their actual future availability in the market place. While the 'barrels' of exhaustible resources may well be humongous, the sizes of their taps that enable the flow from the barrels to the market are subject to a variety of components, including:

  - smaller and smaller deposits in harsher and harsher environments;
  - rising exploration, production, and marketing costs;
  - excessive environmental impacts;
  - diminishing energy ratios;
  - rate of technology change; and
  - environmental policy.

These factors inherently reduce accessible stocks (size of the barrel) and flow rates, while demand, high prices (plus associated investments), innovation, and technology change tend to increase stock sizes and flow rates. The question arises, which of these opposing forces is going to prevail in the mid-to-long term? It suffices to say that because of these constraints only a fraction of these resources is likely to be produced.

Renewables

Renewable energy resources represent the annual energy flows available through sustainable harvesting on an indefinite basis. While their annual flows far exceed global energy needs, the challenge lies in developing adequate technologies to manage the often low or varying energy densities and supply intermittencies, and to convert them into usable fuels.

Annual renewable energy flows[1] are abundant and exceed even the highest future demand speculations by orders of magnitude (Table 7.2). The influx of solar radiation[2] that reaches the Earth's surface amounts to 3.9 million EJ/yr. Accounting for cloud coverage and empirical irradiance data, the availability of solar energy reduces to 630,000 EJ/yr. The energy carried by wind flows is estimated at about 110,000 EJ/yr and the energy in the water cycle amounts to

1 The numbers presented here are different than in other reports; please see Table 11.3 for an explanation.

2 A good graphical summary of renewable energy flows can be found in Sorensen (1979).

Table 7.2 | Renewable energy flows, potential, and utilization in EJ of energy inputs provided by nature.[a]

	Utilization 2005	Technical potential	Annual flows
	[EJ]	[EJ/a]	[EJ/a]
Biomass, MSW, etc.	46.3	160–270	2200
Geothermal	2.3	810–1545	1500
Hydro	11.7	50–60	200
Solar	0.5	62,000–280,000	3,900,000
Wind	1.3	1250–2250	110,000
Ocean	–	3240–10,500	1,000,000

[a] The data are energy-input data, not output. Considering technology-specific conversion factors greatly reduces the output potentials. For example, the technical 3150 EJ/yr of ocean energy in ocean thermal energy conversion (OTEC) would result in an electricity output of about 100 EJ/yr.

more than 500,000 EJ/yr, of which 200 EJ/yr theoretically could be harnessed for hydro electricity. Net primary biomass production is approximately 2200 EJ/yr, which, after deducting the needs for food and feed, leaves in theory some 1100 EJ/yr for energy purposes. The global geothermal energy stored in the Earth's crust up to a depth of 5000 m is estimated at 140,000 EJ/yr. The annual rate of heat flow to the Earth's surface is about 1500 EJ/yr. Oceans are the largest solar energy collectors on Earth absorbing on average some 1 million EJ/yr. These gigantic annual energy flows are of theoretical value and the amounts that can be utilized technically and economically are significantly lower. Renewables, except for biomass, convert resource flows directly into electricity or heat. Their technical potentials are thus a direct function of the performance characteristics of their respective conversion technologies as well as of factors such as geographic location and orientation, terrain, supply density, distance to markets or availability of land and water, while the economic potentials of renewables depend on their competitiveness within a specific local market setting.

7.1 Introduction

This chapter reviews the world's endowment of exhaustible and renewable energy occurrences. It foremost attempts to clarify what nature has to offer, what it may cost to make its resource stocks and flows accessible to the market place, and what the social and environmental implications of their extraction are. It does not *per se* speculate whether, how, or how much of these resources will be utilized – this is the subject of Chapter 17 (Scenarios) and Chapters 8–16, which cover energy-conversion technologies throughout the energy system to the supply of energy services (for a definition of energy services, see Chapter 1).

This is not to say that demand is irrelevant. On the contrary, without a demand dimension any resource assessment is a futile undertaking. Indeed, nature's offerings become relevant resources only in the presence of demand and the existence of an appropriate technology for mining and harvesting at affordable costs. Therefore, in the presence of demand, technology and technology change (innovation) are fundamental in bringing energy resources to the market place. This chapter restricts its assessment to technologies necessary for mining and mobilizing hydrocarbon or fissile materials, for improving land productivity, or for damming up water. Here, advances in geosciences, exploration techniques, mining methods, or biotechnology are examples that will shape our knowledge about resource dimensions, producibility, costs, and potential adverse consequences.

This approach works for finite resources, but not for most renewables – the degree of their future use is rather a question of the anticipated technological and economic performance of technologies that feed on these natural flows and not the magnitude of the flows themselves, as these are undeniably enormous.

The natural question arises of how to reconcile the apparent contradiction between the approach adopted here and the above statement that resources are determined by demand, technology, and costs (relative to alternatives). To begin, the assessment takes stock of the material volumes contained in the Earth's crust, the magnitudes of renewable flows, and the land available for energy-crop production. Next, the quantified stocks and flows are divided into separate resource categories or classes to reflect the different degrees of quality or technological challenge of extraction and/or harvesting, whenever possible by way of cost tags. For example, aggregate supply cost curves are developed for oil and coal, while wind energy resources are presented in categories of specific wind speed, general geographical condition, etc.

Finally, supply cost curves and resource categories serve as an input to the scenario and technology chapters. These chapters determine the overall call on resource utilization (the demand) depending on the relative merit order of the various conversion technologies (technology and costs) and associated energy inputs (resource categories). Finally, feedback from the technology and scenario chapters helps to refine the resource categories and supply cost curves of this chapter.

7.1.1 Definitions and Classifications

There is no consensus on the exact meanings of the terms reserves, resources, and occurrences. Many countries and institutions have developed their own expressions and definitions, and different authors and institutions have different meanings for the same terms. This lack of consistent definitions is one cause of confusion. Another cause is rooted in the fact that most reserves quantities, estimated as deposits, are often located several kilometers below the surface. The estimates are based on inherently limited information and the geological data derived from exploration activities are subject to interpretation and judgment. "Reserves estimation is a bit like a blindfolded person trying to judge what the whole elephant looks like from touching it in just a few places. It is not like counting cars in a parking lot, where all the cars are in full view" (Hirsch, 2005).

Principally, this chapter adopts the concept of the McKelvey box (Figure 7.1), which presents resource categories in a matrix that shows increasing degrees of geological assurance and economic feasibility. This scheme, developed by the US Bureau of Mines and the US Geological Survey (USGS), is reflected in the international classification system used by the United Nations (USGS, 1980; UNESC, 1997; ECE, 2010).

In this classification system, 'resources' are defined as "concentrations of naturally occurring solid, liquid, or gaseous material in or on the Earth's crust in such form that economic extraction is potentially feasible." The geological dimension is divided into 'identified' and 'undiscovered' resources.

'Identified' resources are deposits that have a known location, grade, quality, and quantity – or that can be estimated from geological evidence. Identified resources are further subdivided into 'demonstrated' and 'inferred' resources, to reflect varying degrees of geological assurance, or lack thereof. 'Undiscovered' resources are quantities expected or postulated to exist based on materials found in analogous geological

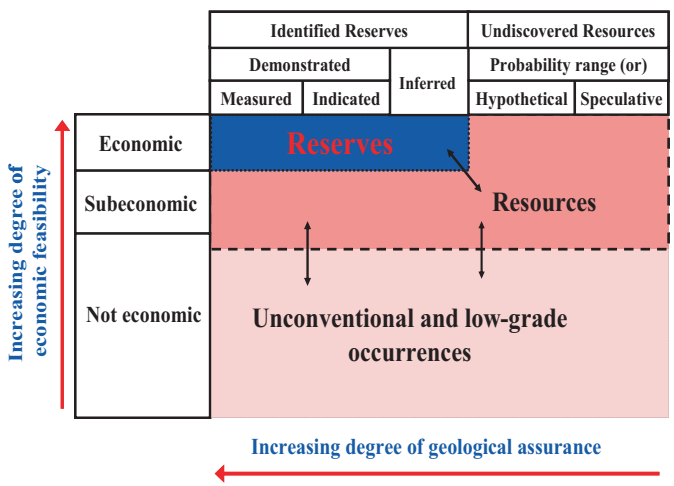

Figure 7.1 | Principles of resource classification. Source: McKelvey, 1967.

conditions. 'Other occurrences' are materials that are too low grade or for other reasons not considered technically or economically extractable. For the most part, unconventional resources are included in this category.

The boundary between 'reserves' and 'resources' is the current or expected profitability of exploitation, governed by the ratio of future market prices to the long-run cost of production. Price increases and production cost reductions expand reserves by moving resources into the reserve category and vice versa. Production costs of reserves are usually supported by actual production experience and feasibility analyses, while cost estimates for resources are often inferred from current production experience, adjusted for specific geological and geographical conditions.

Reserve outlooks reported by the media are usually framed within a short-term market perspective, which focuses on prices, who is producing from which fields, where might spare capacity exist to meet short-term demand peaks, the politics of oil, and how this all balances with demand.

In contrast, long-term supply, given sufficient demand, is a question of the replenishment of known reserves with new ones presently either unknown, not delineated, or from known deposits currently not producible or accessible for technoeconomic reasons (Rogner, 1997; Rogner et al., 2000). Here the development and application of advanced exploration and production technologies are essential prerequisites for the long-term resource availability. Technologies are continuously shifting resources into the reserve category by advancing knowledge and lowering extraction costs. The outer boundary of resources and the interface to other occurrences is less clearly defined and often subject to a much wider margin of interpretation and judgment. Other occurrences are not considered to have economic potential at the time of classification. Production inevitably depletes reserves and eventually exhausts deposits, yet over the very long term, technological progress may upgrade significant portions of occurrences to resources and later to reserves. In essence, sufficient long-term supply is a function of investment in research and development (R&D) of exploration and new production methods and in extraction capacity, with demand prospects and competitive markets as the principal drivers.

More precisely, this assessment uses the following definitions in decreasing order of certainty and economic producibility:

- 'Occurrences' are hydrocarbon or fissile materials contained in the Earth's crust in some sort of recognizable form (WEC, 1998).
- 'Resources' are detected quantities that cannot be profitably recovered with current technology, but might be recoverable in the future, as well as those quantities that are geologically possible, but yet to be found. Undiscovered resources are what remain and, by definition, one can only speculate on their existence.
- 'Reserves' are generally those quantities that geological and engineering information indicate with reasonable certainty that can be recovered in the future from known reservoirs under existing economic and operating conditions (BP, 2010).[3]

Another major factor in estimating future availabilities of oil, gas, coal, and uranium is the difference between 'conventional' and 'unconventional' occurrences (e.g., oil shale, tar sands, coal-bed methane [CBM], methane clathrates, and uranium in black shale or dissolved in sea water). Again, terms that lack a standard definition are often used, which adds greatly to misunderstandings, especially in the debates on peak oil, gas, or coal. As the name suggests, unconventional resources generally cannot be extracted with technology and processes used for conventional oil, gas, or uranium. They require different logistics and cost profiles, and pose different environmental challenges. Their future accessibility is, therefore, a question of technology development, i.e., the rate at which unconventional resources can be converted into conventional reserves (notwithstanding demand and relative costs). In short, the boundary between conventional and unconventional resources is in permanent flux.

This chapter is based on a comprehensive literature review which revealed a wide range of resource quantifications with particularly high variability for unconventional oil and gas over short time intervals at the national or regional levels. Here the responsible author(s) used their expert judgment on which data to report in this assessment.

For renewable energy sources, the concepts of reserves, resources, and occurrences need to be modified as renewables represent, at least in principle, annual energy flows that, if their flows are harvested without disturbing nature's equilibria, are available indefinitely. In this context, the total natural flows of solar, wind, hydro, and geothermal energy, and of grown biomass are referred to as theoretical potentials and are analogous to 'occurrences.' 'Resources' of renewable energy are captured by using the concept of 'technical potential' – the degree of use that is possible within thermodynamic, geographical, or technological limitations without a full consideration of economic feasibility.

'Reserves' of renewable energy would then correspond to the portion of the technical potential that could be utilized cost-effectively with current technology. Future innovations and technology will change and expand the technoeconomic frontier further, so 'reserves' will move dynamically in response to market conditions, demand, and advances in conversion technologies. For example, the economic potential of solar is largely a matter of the cost of photovoltaic or concentrated solar

3 The industry associates proved reserves (so-called 1P reserves) with quantities recoverable with at least 90% probability (P90) under existing economic and political conditions and using existing technology. Reserves based on median estimates and at least a 50% probability (P50) of being produced are referred to by industry as probable or 2P (proved plus probable) reserves. 3P (proved plus probable plus possible) reserves characterize occurrences with at least a 10% probability of being produced. 2P and 3P reserves reflect the inherent uncertainties of the estimation process caused by varying interpretations of geology, future market conditions, and future recovery methods (SPE, 2005).

conversion systems, electricity system integration, and local market conditions, and not of the overall amount of solar radiation.

Conversion technologies are outside the scope of this chapter, but are extensively dealt with in Chapters 8–16. Chapter 17 (Energy Pathways for Sustainable Development) integrates demand, resources, and all technologies throughout the energy system and balances supply and demand. However, some basic assumptions regarding the current and future performance of conversion technologies to harvest renewable energy flows as well as system aspects, distances to demand centers, etc., are necessary to quantify 'resources.' Therefore, the term 'practical potential' is used in this assessment as proxy for renewable resources.

The reserve, resource, and potential estimates of this chapter serve as inputs to the later chapters that present different energy future pathways and technology reviews. At the same time, feedback from the technology and scenario chapters has helped refine the resource categories and supply cost curves in this chapter. In this context, it is important that there is one fundamental difference between this resource chapter and the technology and scenario chapters. The latter report potentials or utilization in terms of output (e.g., kilowatt-hours [kWh] or megajoules [MJ]), while this chapter presents resources and potential in terms of inputs (e.g., the kinetic energy of the wind hitting the turbine blades of a wind power plant).

7.1.2 The 'Peak Debate'

How much oil, gas, coal, or uranium does the Earth's crust hold? This question has preoccupied resource analysts since the dawn of the 20th century and the answers provided reflect a deep divide between representatives of different disciplines, i.e., between geologists and economists. Over time, the divide appears to have widened rather than narrowed, resulting in what is now termed the 'peak debate.' Traditionally, its focus has been on the availability of conventional oil (e.g., Aleklett et al., 2010), but more recently the notions of peak coal (Heinberg and Fridley, 2010), peak gas (Laherrère, 2004), and peak uranium (EWG, 2006) also entered the debate. The arguments brought forward in support or rejection of an imminent peak are largely the same for each resource. Therefore, the following paragraphs summarizing the peak-oil debate are representative for all resources.

An increasing number of analysts expect the production of oil to peak in the near future, i.e., over the next 10 to 20 years. Some even argue that 'peak oil is now' (EWG, 2007). They base their projections on the fact that large oil discoveries ('super giants') ended in the mid-1960s, followed by a substantial decline in the discoveries of new reserves (Figure 7.2). Between 1980 and 2009, slightly more than 65% of global oil production was reported to be offset by new additions of oil reserves (Figure 7.3) (BP, 2010). However, it has been argued that the increased levels of reported oil since 1980 are merely the result of belated corrections to previous oil-field estimates. Backdating the revisions to the years in which the fields were discovered reveals that

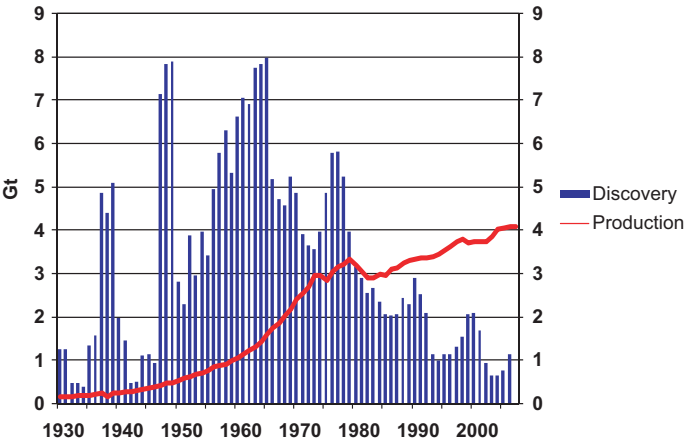

Figure 7.2 | Oil discoveries and oil production. Source: adapted from Earth Policy Institute, 2007.

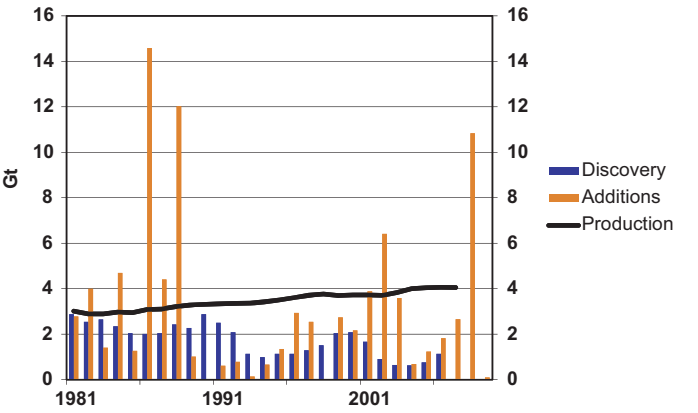

Figure 7.3 | Oil production, oil reserve discoveries, and oil reserve additions. Source: adapted from Earth Policy Institute, 2007; BP, 2010.

reserves have been falling because of a steady decline in truly new-found oil deposits. On this account, for each barrel of oil newly listed as discovered some 4–6 barrels are removed from the ground (Campbell and Laherrère, 1998; Hirsch, 2005). For example, the reserve additions in 2008, reported by BP, are "primarily due to an upward revision in Venezuela of 73 billion barrels (10 Gt)" (Rühl, 2010).

Continuously removing more oil than is offset by new reserve additions will eventually result in reaching a level of "peak oil" at approximately the time when half of the oil reserves have been used. After peak oil, the global availability of oil will decline year after year at a rate depending on the rate of production. The assumed ultimate global oil reserve endowment is therefore a critical parameter in determining both the level of peak production and the point in time when it will occur.

'Estimated ultimate recoverable oil'[4] (EUR) refers to estimates of the total amount of the world's conventional oil – that which has already

4 EUR includes past production.

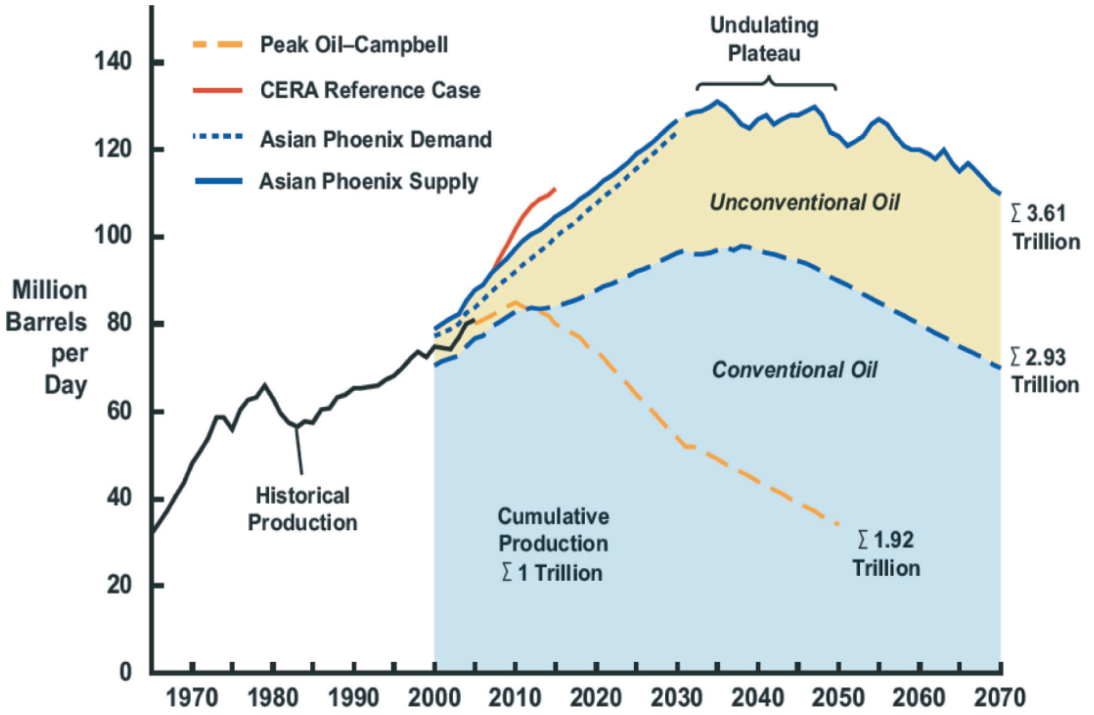

Figure 7.4 | Undulating plateau versus peak oil. Source: Witze, 2007.

been taken out of the ground and that which remains. Since the 1950s, approximately 100 different estimates have been made. The majority lie in the range 12.6–16.7 ZJ (300–400 Gt[5]). By the end of 2008, cumulative oil production amounted to some 6.5 ZJ (156 Gt). For the lower estimates, this means the half-way production mark (the peak) has almost been reached. Using the higher estimates would shift the peak only by a decade or so.

The term 'recoverable' in 'estimated ultimate recoverable oil' means that it is not a measurement of the total amount of oil in place, but refers only to the portion that is recoverable, taking into account geological complexities and economic limitations. Estimates, therefore, include certain (usually tacit) assumptions about costs, markets, and technology. It is this interplay between technology (innovation and knowledge) and prices, but also with demand, that prompts some analysts, especially with an economics background, to be more sanguine about EUR estimates. Not that the economists ignore the ultimate finiteness of exhaustible resources or that peak oil production will eventually take place – this is not the issue. In their view, human ingenuity has kept ahead of reserve depletion and there is no obvious reason why this should change (Bentley and Smith, 2004) as technological innovation will continue to unlock additional reserves currently not identified or understood, or not economically extractable with existing technology and market conditions.

In terms of economic factors, higher prices not only push the frontier of marketable resources (exploitation of smaller fields, higher recovery rates, ability to operate in more challenging environments, etc.), but also stimulate upstream technology R&D for expanding exploration and production activities. At the same time higher prices generally suppress demand, lowering pressure on supply. Claims that recent skyrocketing oil prices reflect that the peak has arrived ignore these market fundamentals. As was observed in the second half of 2008, a slight reduction in global oil demand started a precipitous drop in prices along the entire oil chain.

'Unconventional' oil resources are not included in EUR estimates until they become economically and technically producible. The inclusion of unconventional oil resources in the standard future production profiles of the 'peak oil' analysts would radically change the shape of the global oil production profile (Odell, 2004; McKenzie-Brown, 2008). In fact, the notion of 'peak oil' is misleading. When total (conventional and unconventional) oil production approaches a maximum level, production is likely to be characterized by an 'undulating plateau' (see Figure 7.4) rather than by a peak followed by a sharp drop-off in output (IHS-CERA, 2006; Witze, 2007). However, the 'peak oil' proponents would counter that even if the resource base of non-conventional oil is tapped, production would be constrained by high specific investment and production costs as well as environmental regulations. As rising costs continue to push prices, consumers

5 1 t = 42 MJ = 7.33 barrels of oil (bbl).

would eventually turn to cheaper non-oil alternatives leaving plenty of untapped oil in the ground.

Both sides do agree that conventional oil production is going to peak in the foreseeable future, e.g., sometime between now and 2040, with a peak production volume between 4.1–4.5 Gt/yr (82–95 Mbbl/day). Differences in EUR estimates and the role of technology and price explain the variations in time and volume.

Both sides see a role for unconventional oil in future oil supply. There is agreement that the overall 'barrel' of conventional and unconventional oil resources is large indeed, but there is disagreement about the size of the tap, i.e., the rate at which the barrel's (finite) contents be developed, and on the related economic and environmental costs. Potential financial, environmental, and sociopolitical constraints that could limit exploitation of unconventional oil include:

- the high capital intensity of bringing unconventional oil to the market;
- the extraction of unconventional oil is more energy intensive than conventional oil (up to 30% of net output, with corresponding increases in GHG emissions); and
- enormous local environmental burdens (severe soil and water contamination by chlorinated hydrocarbons and heavy metals) from processing unconventional oil into marketable oil.

Large-scale exploitation of unconventional oil necessitates conditions of low financial, environmental, and geopolitical risk averseness, which the 'peak oil' school simply does not see forthcoming. Indeed, most of the unconventional oil in place may never reach the market place. However, this is less a resource-existence issue, but more a result of sociopolitical choice. Then again, leaving aside such constraints, unconventional oil may well postpone the overall decline of oil into the second half of the 21st century.

7.1.3 Units of Measurement

This chapter uses the International System of Units (SI) and reports on energy resources in exajoules (1 EJ = 10^{18} joules). Other units are used intermittently for reasons of comparison with the units commonly used by the different trades.

Tonnes are metric tonnes (1 t = 10^6 g). The energy resource-related industry and energy-related statistics or resource surveys report oil occurrences in gigatonnes (1 Gt = 10^9 tonnes) or gigabarrels using the energy equivalent of 42 GJ/tonne of oil equivalent (GJ/toe) and 5.7 GJ/bbl, respectively (see Table 7.3).

Gas resources are usually reported in teracubic meters (1 Tm^3 = 10^{12} cubic meters) and are converted to EJ using 37 GJ/1000 m^3.

Table 7.3 | Energy conversion factors and prefixes of the metric system used in Chapter 7.

	Tonnes of oil (toe)	Barrel (bbl or boe)	Cubic feet of gas (CFG)	Cubic meter of gas (m^3)	Tonnes of coal equivalent (tce)	Megajoule [MJ]	Brtish Thermal Unit (BTU)
Tonnes of oil (toe)	1	7.33	40,000	1124	1.429	41,868	40×10^6
Barrel (bbl or boe)	0.136	1	5414	153.3	0.195	5712	5.414×10^6
Cubic feet of gas (CFGc)	0.25×10^{-6}	0.185×10^{-3}	1	0.028	35.997×10^{-6}	1.055	1000
Cubic meter of gas (m^3)	0.890×10^{-3}	6.523×10^{-3}	35.31	1	1.271×10^{-6}	37	31.35×10^3
Tonnes of coal equivalent (tce)	0.7	5.131	$27.78 * 10^3$	786.634	1	29,000	27.78×10^6
Megajoule (MJ)	24×10^{-6}	0.175×10^{-3}	0.948	0.0268	34.121×10^{-6}	1	947.867
British Thermal Unit (BTU)	25×10^{-9}	0.185×10^{-6}	0.001	28.32×10^{-6}	35.997×10^{-9}	1.055×10^{-3}	1

Milli (m)	10^{-3}
Centi (c)	10^{-2}
Kilo (k)	10^3
Mega (M)	10^6
Giga (G)	10^9
Tera (T)	10^{12}
Peta (P)	10^{15}
Exa (E)	10^{18}
Zeta (Z)	10^{21}

Coal resources are usually accounted for in natural units, although the energy content of coal may vary considerably within and between different coal categories. The Bundesanstalt für Geowissenschaften und Rohstoffe (BGR; German Federal Institute for Geosciences and Natural Resources) in Hannover (Germany) is the only institution that converts regional coal occurrences into tonnes of coal equivalent (1 tce = 29.3 GJ). Thus coal resource data comes from the BGR.

Uranium and other nuclear materials are usually reported in tonnes of metal. The thermal energy equivalent of 1 tonne of uranium in average once-through fuel cycles is about 589 terajoules (IPCC, 1996).

7.2 Oil

7.2.1 Overview

Oil is one of the most important sources of global energy because of its high energy density, high abundance and easy transportability at standard temperatures and pressures. In 2009, oil was responsible for over one-third (34.8%) of the world's total primary energy supply. Almost 70% of global oil production is used for transportation and petrochemistry (IEA, 2010a).

Analysts fear resource depletion of oil will produce significant supply scarcities in the near future. Currently, annual oil production exceeds added new oil reserves. Resource estimation is by no means an exact science and is dynamic by nature (see Section 7.1.1). As a result of advances in exploration and production technologies, the borders that distinguish reserves from resources and resources from occurrences are increasingly blurred. To a large extent, this explains the variability of reserve and resource estimates over time, as well as those of different authors. For example, the USGS estimates of oil resources have nearly doubled since the early 1980s. Figure 7.5 shows the evolution of oil resource estimates since 1940. However, it is important that new additions of resources or reserves, especially in recent years, may not be the result of new discoveries, but of improved extraction technologies or processes, deposit reevaluations, changing economic conditions, or underreporting in the first place.

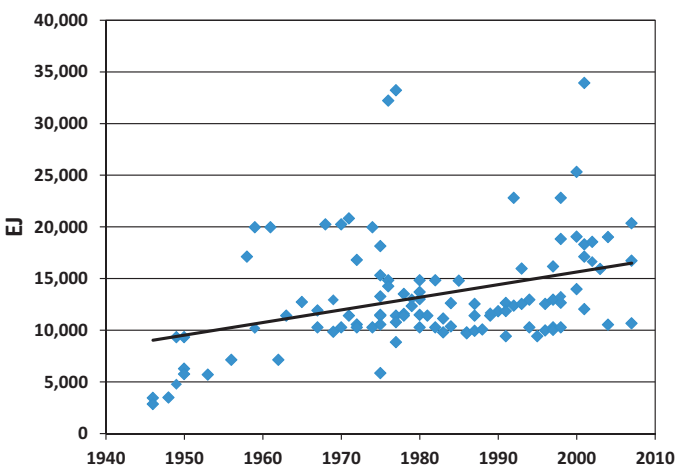

Figure 7.5 | World oil resource (reserves and resources) estimates, 1940–2007. Sources: adapted from Ahlbrandt and Klett, 2005; NPC, 2007; IEA, 2008; BGR, 2009.

7.2.1.1 Classifying Conventional and Unconventional Oil

Oil occurrences can be divided into many different subclasses and categories, depending on the physical properties of the oils. Some oils are classified as heavy or extra heavy, which implies that they have high viscosities and do not flow easily. Other oils are sour, which signifies that they contain a certain amount of sulfur. Other oils are considered unconventional, which implies that they are not recoverable using the standard technologies used to extract conventional low-viscosity oils from subsurface reservoirs.

The term crude oil typically refers to conventional oils, but many countries or organizations have their own criteria to define the boundary between conventional and unconventional oils.

The BGR defines conventional oil as oil having a specific gravity of less than 1.0 g/cm^3. This is equivalent to the American Petroleum Institute (API) definition, which specifies API gravity greater than 10°.[6] However, the USGS defines conventional oil as oil having API gravity greater than 15°. 'Conventional oil' generally also includes gas condensates and natural gas liquids.

Unconventional oil includes oils of high viscosity, as well as the oils extracted from kerogen-rich shale (oil shale). The term 'viscous oil' is used generically for all oil with viscosities greater than 100 mPa·s. Kerogen is semisolid organic matter that can be directly converted into oil through pyrolysis. While other definitions exist (e.g., Head et al., 2003; Meyer and Detzman, 1979), the definitions used in this report for the various subclasses of oils are given in Table 7.4.

Many also consider unconventional oil to include products such as biomass oil, synthetic oil from conversion of natural gas, and coal liquefaction (Farrell, 2008; IEA, 2008a). While these are, indeed, potential sources of liquid hydrocarbon fuels, they are not considered unconventional oil in this assessment. Natural gas, coal and biomass are covered in Sections 7.3, 7.4, and 7.7, respectively.

The distinction between conventional and unconventional oil is further distorted when regarding deep offshore or Arctic oil. Despite having API gravity greater than 10°, some assessments consider these as 'unconventional' because of the novelty of deep-sea drilling or Arctic production. It is also important that some unconventional oils are cheaper to recover than some high-end conventional oils, e.g., oil sands versus arctic oil.

6 10° = 1.0 g/cm^3

Table 7.4 | Definitions of oil terms.

	Term	Definition	Physical properties
Oil type	Conventional oil	Oil that is mobile in situ and can be produced economically using conventional methods	μ < 100 mPa·s[a] Low S content
	Viscous oil	Inclusive term for the next three categories below	μ > 100 mPa·s
	Heavy oil	Oil that is only slightly mobile in situ, usually requiring stimulation techniques to improve mobility	μ 100–10,000 mPa·s S content <1%
	Extra-heavy oil	Oil of exceptionally high gravity (ρ >1.0) that has some mobility because of high in situ temperatures (particularly used to refer to Orinoco, Venezuela oils)	μ <10,000 mPa·s, ρ >1.0 S content >1%
	Bitumen	Oil that is immobile in situ so that large viscosity reductions or mining methods are needed	μ >10,000 mPa·s ρ >1.0[b] S content >1%
Rock strata	Oil sands	Sand strata > 25% porosity, containing extra-heavy oil or bitumen, more viscous than heavy oil	*k* >0.5 Darcy, usually μ > 1000 mPa·s
	Heavy-oil NFCRs	Naturally fractured carbonate reservoirs (NFCRs) containing viscous oil	μ >100 mPa·s Porosity 10–20%
	Oil shale	Kerogenous shales and marls that produce more than 50 l/t of product during Fischer Assay tests	Porosity >15–20%

[a] μ = measure of viscosity in mPa·s = cP = 0.01 g/cm·s.

[b] ρ = specific gravity in g/cm^3.

The boundary is further blurred with respect to currently mined deposits. Using standard conventional extraction technologies, only around 20–40% of oil in place is recoverable by natural depletion of the reservoir. To extract further quantities, improved oil-recovery technologies, which can extract 30–60% of the oil in place, need to be applied (DOE, 2010). The goal of enhanced oil recovery is to alter the original properties of the oil, to restore formation pressure, or to improve oil-displacement efficiency or fluid-flow patterns in the reservoir. There are three major types: chemical flooding (e.g., alkaline flooding or polymer injection), miscible displacement (e.g., carbon dioxide [CO_2] or solvent injection), and thermal processes (e.g., steam flooding or in situ combustion). The application of each technology depends on reservoir temperature, pressure, depth, permeability, net pay, residual oil and water saturation, porosity, and fluid viscosities (Schlumberger, 2010).

7.2.2 Estimates of Conventional Oil

Estimates of the amount of oil are derived from only a limited number of sources. While both production and reserves data are collected by government agencies at several levels, reserves data are less commonly published than production statistics. Several private companies (e.g., IHS Energy Inc., Wood Mackenzie, BP p.l.c., and others), industry journals (e.g., *Oil and Gas Journal*), and government agencies (e.g., International Energy Agency [IEA], US Energy Information Administration [US EIA]) compile and publish these data.

Reserve estimates are burdened with uncertainty as some countries hold such data as confidential. Estimates published in databases and in the literature are often made by the authors themselves. Growth potentials for undiscovered resources and reserves understandably suffer from greater uncertainties than those of proven reserves. Most reports provide estimates for yet-to-be-discovered resources, but only a few give estimates for reserves-growth potential. Some reports give aggregate estimates for the world as a whole, others for individual countries or regions, but few sources cover the entire world in detail, which adds a further difficulty to a general synthesis of reserves estimations. The USGS and BGR provide the most comprehensive set of estimates.

Table 7.5 compares recent estimates of conventional oil reserves. The estimates vary between 116.3 Gt (EWG, 2008) and 181.7 Gt (BP, 2010). Importantly, some estimates include reserves of oil sands, which are, by definition, unconventional oils.

The low estimate of the Energy Watch Group stems from their suspicion that the reserve data reported by the governments of the Middle East are politically motivated and hence unrealistically high. The USGS estimate, which dates back to the year 2000, appears low as well. However, the USGS reports much higher oil resources than the recent BGR (2009) assessment (see Table 7.6), which suggests that some resources of 2000 became reserves in 2009.

As previously mentioned, terms like 'resources' and 'reserves' are used with varying definitions by different authors. Further confusion arises when resource statistics are interpreted to be more comprehensive than in actuality. While reserves reporting in the United States require a 90% (1P) probability of recovery under existing economic, technological, and political conditions, other reporting bodies typically declare reserves at a median, 50% (2P), probability. Despite this, reserve estimates given at 1P have tended to increase over time. While some growth may be legitimate because of better extraction or surveying technology, this cannot explain all the reserves growth experienced. Some reports claim that reserves have been deliberately underreported so that estimates could be revised upwards over time to give a comforting yet misleading image of steady growth (WEC, 2007).

Considering oil reserves in a narrow sense, largely conventional oil, cumulative production to date is roughly equal to the remaining proven reserves – for the proponents of 'peak oil' a clear indication of the imminent peak.
