Section 18.3 analyzes current global, regional, and city-specific urban energy use, and comprises new 'top down' estimates of urban energy from a global perspective, complemented by 'bottom up' urban-scale energy-use data collected through the GEA Chapter 18 City Energy Data Base.

Urban energy use and systems as a whole are accompanied and shaped by multiple challenges, discussed in detail in Section 18.4. These include

2 With a paucity of 'official' urban scale economic data reporting, this assessment also relies heavily on estimates rather than statistics, with data derived either from 'grey literature' expert estimates (e.g., Hawksworth et al., 2007) or spatially explicit 'downscaling' exercises (e.g., Grubler et al., 2007).

issues of energy access, energy demand densities, and associated key environmental externalities, as well as energy supply constraints, which include reliability and security.

Section 18.5 outlines opportunities and response options to the urban energy challenges. Key drivers of urban energy use, policy players and main policy leverages, and some of the key infrastructure issues linked to specifics of urban systems, such as urban transport, urban energy infrastructure planning, design and implementation, and urban air-quality management are discussed. Section 18.5 also includes novel model simulations to illustrate the respective impacts of policy interventions along three main opportunity areas: urban form and density (and their influence on transport energy demand), buildings efficiency, and urban energy systems integration and optimization.

Section 18.6 summarizes the key messages and conclusions. The research, data, and information needs identified are summarized at the end of the each section rather than in a separate section at the end of the chapter.

18.2 An Overview of Urbanization

18.2.1 Overview of Urbanization, Past and Scenario Trends

18.2.1.1 The Multiple Dimensions of Urbanization

The process of urbanization involves multiple dimensions, characterized by different theories, methodologies, and literatures that follow four distinct disciplinary perspectives: demography, geography, economics, and sociology.

The resulting effects of the scale and concentration of human activity in urbanized areas are the focus of research in various disciplines. Economists often emphasize the benefits of scale of larger labor markets in cities and agglomeration effects of clustering of various industrial and service activities (Krugman, 1991; Fujita et al., 1999; UNIDO, 2009; World Bank, 2009). Climatologists discuss the consequence of urbanization on albedo changes, radiation balances, and weather patterns (Kalnay and Cai, 2003; IAUC and WMO, 2006; Souch and Grimmond, 2006). Transport planners are concerned with avoiding negative externalities of urban density, such as traffic congestion. Environmental researchers study typical patterns of the generation and distribution of pollutants in urban centers and the exposure of target populations to such hazards (McGranahan et al., 2001; McGranahan and Marcotullio, 2007). Social scientists are investigating particular urban social structures and challenges, and urban cultural modes of creativity and innovation that result from the immediate proximity of many million people that can exchange, cooperate and profit from high degrees of specialization. Understanding the consequences of urbanization on energy use in general, however, is an area of research that has attained surprisingly little attention in empirical studies, given the relevance of urban areas for overall energy demand (IEA, 2008), their particular vulnerability to energy supply disruption, and their potential for energy savings and climate-change mitigation.

The economic, geographic, and sociological perspectives of urbanization are discussed in greater detail as driving forces of urban energy demand (see Section 18.5.2). Following these different disciplinary perspectives, four complementary concepts describe the process of urbanization:

- The demographer's approach emphasizes population. To a demographer, urbanization is the process by which a rural population becomes urban. That is, the *population* is becoming urbanized by an increase in the proportion of the population classified as urban.

- In the geographer's approach, a defined geographic area gradually loses the characteristics associated with rural areas (e.g., dominance of agricultural land uses) and gains characteristics associated with urban areas (e.g., built-up land, and high density of buildings and technological infrastructures) – the *region* is becoming urbanized).

- The economist's approach is the process of economic structural change away from primary economic activities (agriculture, forestry, mining, etc.) toward manufacturing and services (secondary and tertiary economic activities). This usually involves spatial concentration and co-location of economic actors[3] that profit from agglomeration externalities: the *economy* is becoming urbanized.

- In the sociologist's approach, individuals move from rural to urban areas and take on urban characteristics: individuals and their aggregate (i.e., *society*) are becoming urbanized.

The demographic study of urbanization is among the oldest research traditions and also the most quantitative, including scenario projections into the future. Along with economics it is also the dimension with the closest direct causal link to urban energy use. This being the reason why in the subsequent discussion the demographic perspective of urbanization is highlighted. The economic, geographical, and sociological perspectives of urbanization in turn are discussed in greater detail as driving forces of urban energy demand (see Section 18.5.2 below).

Table 18.1 illustrates these multiple dimensions of urbanization at the global level for the year 2000, the latest common year for which the various indicator data sets available. With the exception of remotely sensed urban land areas (that turn out to display the largest uncertainty range of a factor of ten) and population for which data are available directly at

3 In economics this is referred to as agglomeration externalities that arise from economies of scale and economies of scope effects. See Chapter 24 for a more detailed discussion and exposition of these concepts.

the urban scale, all other indicators represent derived estimates, combining spatially explicit data sets of urban extents consistent with UN urban population statistics with other spatially explicit data of human activity.

18.2.1.2 Urbanization in a Historical and Demographic Context

People have lived in cities for millennia. Cities and their associated urban agglomerations have and continue to play key roles as centers of government, production, and trade, as well as knowledge, innovation, and productivity growth (UN, 2008). Yet during most of the past, the number of city dwellers remained exceedingly small – the majority of the population continued to live in rural areas and worked in agriculture.

Before 1800, large cities (by contemporary standards) being exceedingly rare, with Chang'an and Baghdad being likely the first examples of cities that approached one million inhabitants (Chandler and Fox, 1974; Chandler, 1987). This started to change dramatically with the (rapid) improvement of agricultural productivity, which freed people for new industrial jobs and migration into cities (the Industrial Revolution). Many cities grew to much larger sizes; rural settlements were transformed into cities, and new cities were founded. The rate of urban population growth (the twin result of natural growth in urban populations plus net in-migration into cities) exceeded significantly that of the overall population and resulted in a secular trend toward *urbanization* (i.e., an increase in the rate or percentage of a population living in urban areas). Estimates suggest that by 1900–1920, between 12 and 14% of the global population could be classified as urban. Because of their lead in industrialization and agricultural productivity growth, the more developed countries had an urbanization rate of some 30% by the 1920s, and developing countries of only some 6% (UN DESA, 1973). Urbanization trends have accelerated ever since.

The UN reconstruction of global population trends from 1950 onwards (UN, 2008) documents a historically unprecedented global population growth in the second half of the 20th century, peaking at about 2% annually between 1965 and 1970. Global population growth rates have declined since, and current projections indicate a leveling off of global population growth toward the third quarter of the 21st century.

In 55 years, the world's population grew by about 4 billion people to approximately 6.5 billion in 2005. A defining feature of this growth is its diversity across regions, especially between more- and less-developed ones. Having entered the demographic transition earlier, OECD90 countries and countries undergoing economic reform (Eastern Europe and the former USSR) increased their population between 1950 and 2005 by a comparatively modest 62% and 51%, respectively. All other GEA regions, by contrast, more than doubled their populations. The fastest population growth occurred in the Middle Eastern and African regions, where the population more than quadrupled between 1950 and 2005. The population in Latin America and the Caribbean more than tripled, and in Asia, already the most populous region of the world, in 2005 the population was 2.7 times larger than that in 1950.

18.2.1.3 Past Urbanization Trends

The inevitable uncertainty in urban population and urbanization levels does not affect an assessment of the dynamics of the urbanization process, provided the system of national definitional criteria does not change too often over time (occasional definitional changes of individual countries do not markedly affect global or regional trends).

While populations in all regions grew over the past half century, urban populations grew even faster (Table 18.2). Between 1950 and 2005, the UN DESA (2010) estimate suggests that the Middle Eastern and African urban population multiplied more than ten-fold, increasing from 44 million to 478 million. Asia registered in 2005 an urban population almost six-times higher than it had in 1950 (175 million versus 1.3 billion), and the urban population of Latin America and the Caribbean increased more than five times, from 68 million to about 429 million people (UN DESA, 2010). By 2005 about half of the global population (3.2 out of 6.5 billion) was urban. By the time of the publication of the GEA report (2012), more than half of global population will be urban.

Table 18.2 | Urban population (millions) and as a percentage of world total urban population, and total population (in millions) for the five GEA regions and the world since 1950. Countries undergoing economic reform = Eastern Europe and former USSR.

	Urban Population				Total Population

18.2.1.4 Urbanization Levels

As the urban population grew, its relative weight also increased. In 1950, just about 30% of the world's population of 2.5 billion people lived in urban areas, while the vast majority still lived in rural areas. Even for the more advanced OECD90 region, in 1950, 57% of its population lived in urban areas, while a substantial proportion of its population (43%) lived in rural areas. All other major regions were predominantly rural. Latin America and the Caribbean, and the countries of Eastern Europe and the former USSR currently undergoing economic (transition) reform already had high urbanization levels (41% and 38%, respectively) in 1950. Populations in the Asian and the Middle Eastern and African regions were still predominately rural, with just about 14% and 16% of their populations living in urban areas, respectively.

By 2005, the world had become almost 50% urban, but with significant differences across the regions. In the OECD90 and Latin America and the Caribbean countries, three out of four people lived in urban settlements; and in the Asian and the Middle Eastern and African regions about two out of five people were urban dwellers.

18.2.1.5 An Urban Future

Trends in population aging and urbanization are inevitably important to the immediate and medium-term demographic future. Population growth is still a persistent element of demographic trends in developing countries. For some developed countries, however, population growth has not only tapered off, but may be reversed with population decline as a defining feature.

Significant negative population growth is currently expected to persist for countries undergoing economic reform (i.e., the countries of the former Soviet Union/USSR and of Eastern Europe), with their population projected to shrink by about 39 million people: from 404 million in 2005 to 365 million in 2050. All other GEA regions are projected to increase their populations between 2005 and 2050 (UN DESA, 2010). There is, however, great diversity not only between GEA regions, but also, and more significantly, within the regions and between countries. There are also different causes for the continued population growth within most GEA regions. Populations in the OECD region, which have experienced low or even very low fertility during recent decades, are expected to increase slightly, mainly because of net gains from international migration. For example, Western Europe is projected to lose about 1.4 million people between 2005 and 2050, when net migration gains are included. In the absence of that gain, in 2050 Western Europe would have about 15 million less inhabitants than in 2005 (UN DESA, 2010).

Population growth in the other GEA regions is caused by very different factors: momentum that stems from young populations and above-replacement fertility. The latter is increasingly less important because of a continued fertility decline. Combined, these factors generate the addition of 1.1 billion people to Asia, 1.2 billion to the Middle Eastern and African region, and 173 million to Latin America and the Caribbean to 2050.

Against this background, the growth of the global urban population is estimated to range from some additional 2.7 to 3.2 billion people, depending on the projected urbanization rate of growth (see Box 18.1). The generally larger growth of the projected urban population not only means that urban settlements will absorb all of the population growth between 2005 and 2050, but also that there will be a sizable redistribution of rural populations to urban areas. In addition, urban growth will be predominantly a phenomenon of the less-developed regions.

Figure 18.1 summarizes the GEA scenario results on the global level, and Figure 18.2 summarizes the five GEA world regions in terms of urban and rural populations. The continued growth of the world's urban population is set against a different growth path of the rural population.

Globally, rural population growth is projected to come to a halt around 2020, when it will reach a peak at about 3.5 billion people. This figure

Box 18.1 | Urbanization Projections Methodology

I. The UN World Urbanization Prospects

The UN World Urbanization Prospects (WUP) provides biannual estimates and projections of core demographic indicators of urbanization for all 229 countries or areas of the world and for the most populous urban settlements. The data include time series of total populations by urban and rural residence for the period 1950 to 2050, and of populations in 590 large urban settlements with 750,000 and more inhabitants for the period 1950 to 2025. In total, the entire WUP database contains estimates and projections for 4501 urban locations, covering two-thirds of the global urban population.

The WUP use a projection method that is described and discussed extensively (UN DESA, 1971; 1974; Ledent, 1980; UN DESA, 1980; Ledent, 1982; Rogers, 1982; Ledent, 1986; O'Neill et al., 2001; National Research Council, 2003; Bocquier, 2005; O'Neill and Scherbov, 2006). Such long-term projections include many uncertainties, reflected in the three urbanization scenarios discussed here. The method uses the growth difference between urban and rural populations or between city populations and total urban populations to model the dynamics of the urbanization process, an approach that is equivalent to a logistic curve fit (UN DESA, 1974). Starting with the most recent observed growth rates, future trends are calculated by taking into account the empirical observations that the pace of urbanization slows down as the proportion of the urban population increases (a characteristic feature of logistic growth processes beyond the 50% level of its asymptote). Consequently, the observed growth differentials are adjusted such that they approach a hypothetical norm obtained from past empirical observations (UN DESA, 1980). A distinguishing characteristic of the WUP is that only one central projection is performed in which the ultimate upper level of the urbanization process is not constrained; that is, all countries could ultimately converge to an urbanization rate of up to 100%.

II. Other Urbanization Projections

There are no real independent urbanization projections to the UN Urbanization Prospects as alternative scenarios invariably use the UN historical and current data as model inputs and also deploy a comparable methodological framework. The literature, however, reports scenario variants on the UN projection by either extending the time horizon beyond 2050 (the end-year reported by the UN projections) and/or alternatively relaxing the convergence assumption toward a 100% urbanization rate. For an OECD study on the climate vulnerability of port cities, Nicholls et al. (2008) extend the UN projections to 2100 and then apply a constant growth fraction to port cities at the national level to determine future port-city populations exposed to climate-change risk. In an integrated scenario exercise that explores future uncertainty in GHG emissions, Grubler et al. (2007) also extend the UN urbanization projection to 2100 and develop two additional scenario variants in which the asymptotic urbanization level is varied to explore the implications of lower urbanization. These three urbanization-rate scenarios were then combined with three alternative total population-growth scenarios (low, medium, and high) to determine the uncertainty range of future urban populations. This alternative scenario method estimated the uncertainty in the level of world urban population to range from 4.7 to 10.5 billion people by 2100, and from 5.6 to 7 billion compared to the 6.3 billion projected by the latest UN Urbanization Prospects projection for 2050 (UN DESA, 2010).

III. GEA Urbanization Scenarios

Methods and qualitative and quantitative assumptions that underlie the GEA transition pathways are described in detail in Chapter 17. In collaboration, this chapter and Chapter 17 also explore the issue of urbanization scenarios. In this context, two main features of the GEA scenario approach stand out: (1) their focus on energy issues and (2) their normative nature; that is, their objective to describe alternative, but successful, pathways toward an energy sustainability transition. As a result, the scenarios are based on a single central demographic-economic development scenario (e.g., based on the most recent UN medium population projection). The scenarios also describe pathways in which current widespread economic and energy disadvantages of poor rural populations are addressed successfully, for example with universal energy access achieved by ca. 2030. As a result, the qualitative scenario storylines describe developments in which, arguably, the pressure for rural to urban migration is significantly relieved, which suggests their reflection in the GEA urbanization scenarios. Therefore, three urbanization scenario variants based on a single medium population projection were developed. One scenario (GEA-supply) uses the UN Urbanization Prospects projection directly as input, whereas the other (lower) scenarios (GEA-mix and GEA-efficiency) adopt the methodology outlined in Grubler et al. (2007) using a model recalibrated to the most recent (2010) UN urbanization data. The resulting scenario differences in projected rural and urban populations bracket the potential impact of successful rural development policies that relieve urban migration pressures (GEA-efficiency) compared to largely unaltered patterns in rural and/or urban locational advantages (GEA-supply) and illustrate to policymakers the potential effects of altered policies that change the locational advantage of rural versus urban places.

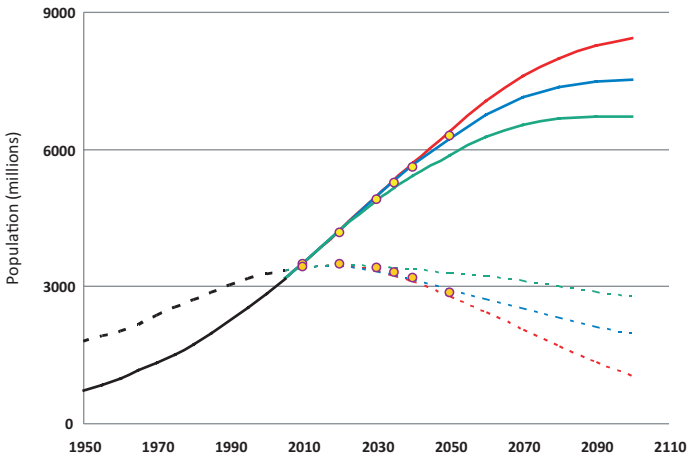

Figure 18.1 | Global urban (solid lines) and rural (dashed lines) population (in million). Historical trends 1950–2005 and scenarios to 2100 combining a medium population growth scenario (see also Chapter 17) with three alternative scenarios of urbanization rate growth (red, green, and blue, based on Grubler et al., 2007) and comparison to the most recent UN Urbanization Prospects projection (yellow and orange circles). Source: adapted from UN DESA, 2010.

is unaffected by the uncertainty of the urbanization scenarios and is a major, robust conclusion emerging from this assessment. The finding also adds urgency to corresponding efforts to improve energy access for the rural poor because if energy does not reach them soon, they will have an additional incentive to seek access in urban areas. After entering a path of negative growth, the rural population is projected to range from 2.8 to 3.3 billion by 2050 and to decline even further thereafter. However, the global picture masks stark regional differences: the Middle Eastern and African region will likely experience rural population growth until 2050 (or at the latest to 2080 in the GEA-efficiency scenario), while for all other regions the beginning of the decline the scenatio in rural populations is imminent or is already occurring (in the OECD90 region and in countries undergoing economic reform).

In 2050, the world is projected to be 70% urban with a comparatively narrow scenario uncertainty range of 64–70%. Latin America and the Caribbean, as well as the OECD90 countries, are expected to approach 90% urban, about the level of urbanization of the United Kingdom or Australia today.[4] By 2100, world urbanization levels could range from 71% to 89% with a corresponding urban population from 6.7 to 8.4 billion people. Thus, even in the lowest scenario, the world urban population in 2050 will be larger than the entire global population today.

18.2.1.6 Heterogeneity in Urban Growth

Patterns of urbanization are heterogeneous, including settlements of rapid growth, slower growth, and even cases of declining cities (Box 18.2). Urbanization is often equated with the growth of megacities. These vast, often crowded and complex, metropolitan areas with populations of 10 million or more are highly visible, and epitomize the challenges and problems of a rapidly urbanizing world, with pervasive poverty, slums, stressed infrastructures, etc. However, the reality of urbanization, both in terms of current settlement sizes (Table 18.3) and as historical and projected growth trends, is dominated by cities of smaller size (Figure 18.3). By 2005, just 19 cities worldwide met the megacity criteria (>10 million inhabitants) and their 284 million residents accounted for only about 9% of the global urban population. Conversely, some two billion people lived in cities with less than one million inhabitants, which corresponded to 63% of the world's urban population. Some one billion people or 37% of the urban population lived in smaller cities, less than 100,000 inhabitants,[5] in the year 2005.

The virtual absence of smaller cities and towns in statistical reporting, data collation, and modelling poses a serious problem and adds substantial uncertainty to any statement on urbanization trends. However, this should not lead to the erroneous conclusion not to focus analytical and policy attention on those cities that dominate the global urbanization phenomenon, most with <100,000 inhabitants. These numerous smaller cities pose a triple challenge for policymaking: data are largely absent, local resources to tackle problems with urban growth are limited, and governance and institutional capacities to implement policies for more sustainable urban growth are thin.

18.2.2 Urbanization Dynamics

18.2.2.1 Introduction

Modern towns and cities are generally recognized in the urban studies' literature as complex, largely self-organizing systems (Allen, 1997; Amaral and Ottino, 2004; Batty, 2005) that exhibit important agglomeration effects (National Research Council, 2003; World Bank, 2009). Cities are complex in the formal sense that recording their detailed behavior has vast information requirements. They are self-organizing in that interactions between partially informed citizens and between citizens and the city's 'hardware' form self-reinforcing patterns of land use and allocation of time. What was 'town planning' in the early 20th century is now seen more realistically as the facilitation of spatial patterns trying to emerge naturally (Hall, 2002).

Urban settlements show extraordinary resilience. Long-standing settlements reinvent their *raison d'être* many, many times. Large cities usually

4 Projected urban populations by 2050 at the country level (UN DESA, 2010) suggest that the two countries with by far the largest urban populations by 2050 will be China and India with some 1 and 0.9 billion, respectively. Ten countries are projected to have urban populations above 100 million by 2050 and, with the exception of the US (370 million), all of these are currently developing countries (projections by 2050 in millions: China, 1040 million; India, 875; Nigeria, 220; Brazil, 200; Pakistan, 200; Indonesia, 190; Bangladesh, 125; Mexico, 110; Philippines, 100).

5 Calculated mainly as a residual to the estimates of total urban population.

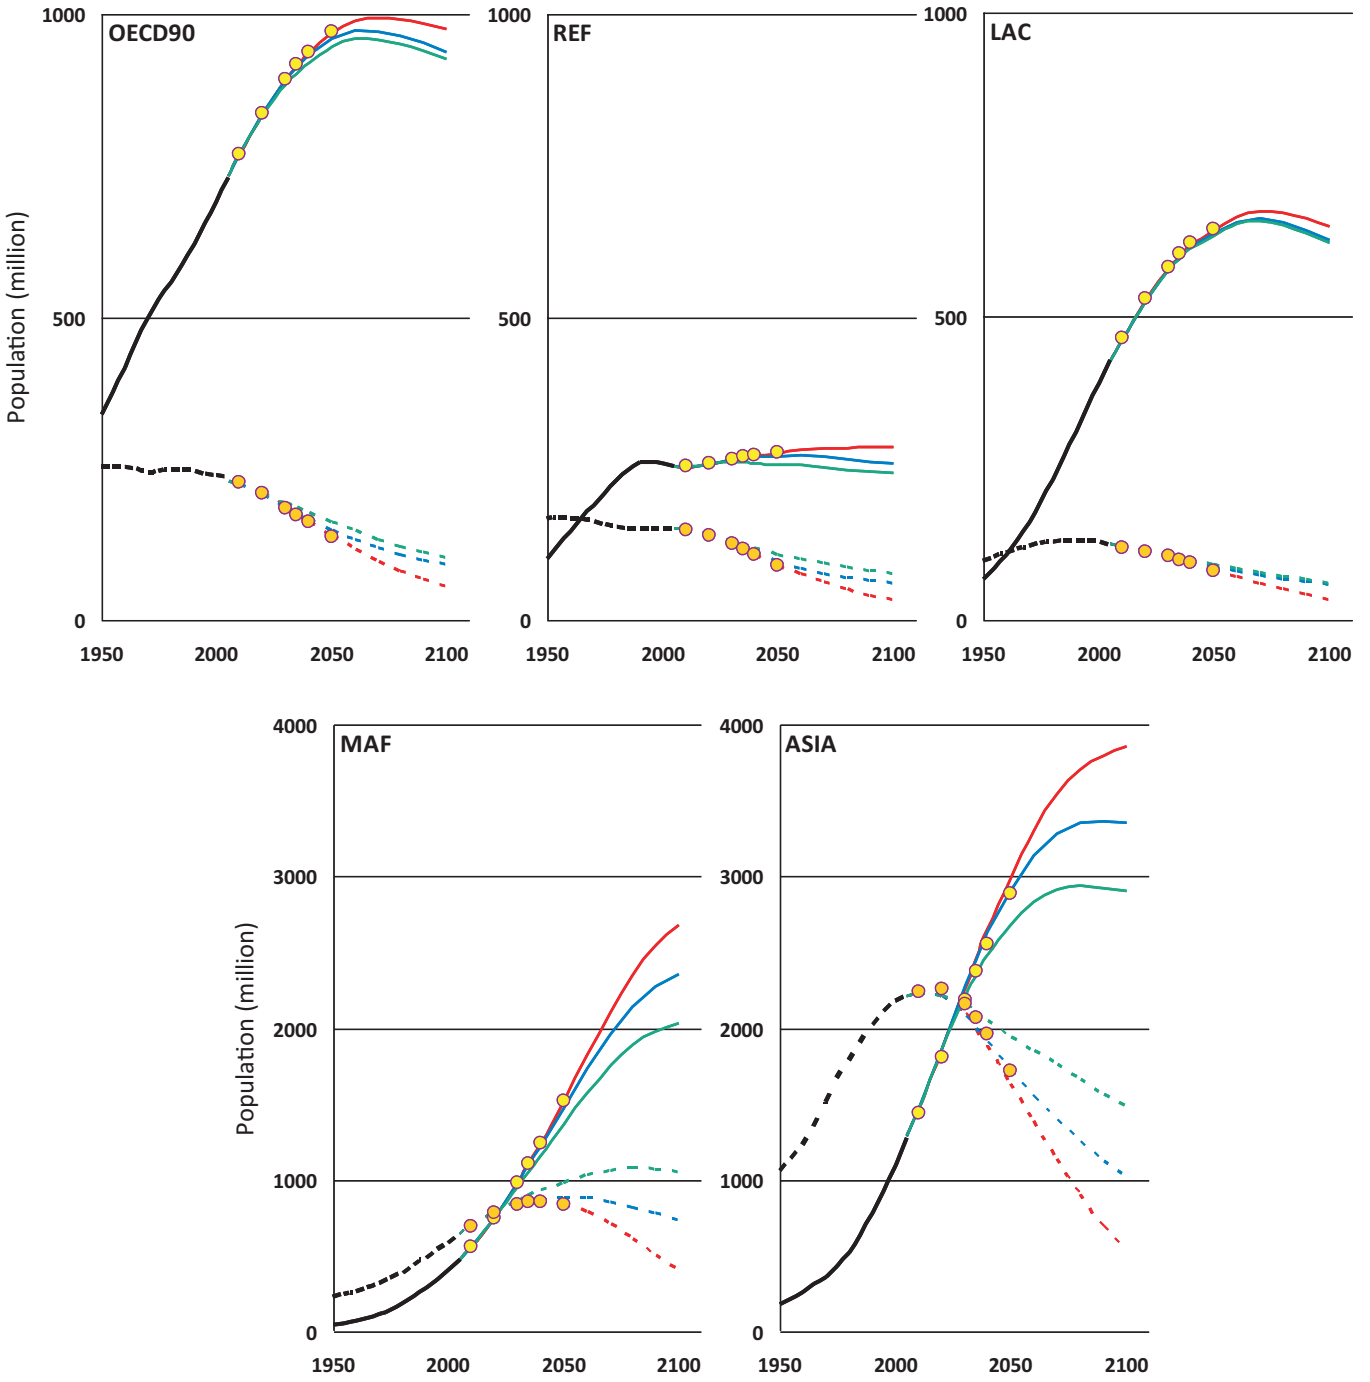

Figure 18.2 | Regional scenarios of urban and rural population (millions) for a medium population growth scenario (see also Chapter 17). Historical trends 1950–2005 and scenarios to 2100 for the five GEA regions (in millions). Regions: OECD90, OECD countries as per 1990 membership; REF: Countries undergoing economic reform, i.e., the reforming economies of Eastern Europe and the ex-USSR; LAC: Latin America and the Caribbean; MAF: Middle East and Africa; ASIA: developing economies of Asia. Urban population, solid lines; rural population, dashed lines. UN Projections (yellow and orange circles) and three alternative scenarios (red: GEA-supply, blue: GEA-mix, and green: GEA-efficiency).

confront constraints to existing paradigms first and have to develop innovative solutions (like freshwater-supply networks, and the use of clean secondary fuels) that are then taken up by innovation diffusion to smaller settlements. Energy *demand* considerations often serve as a shaping factor in settlements. Urban settlements, at least in times of peace, are more easily served by transport when in a valley, on a river, or on the seacoast. Differentiation of rental value takes place downwind of the pollution of energy-intensive industries. Prevalent solar and wind conditions often account for orientation patterns of streets and squares. In contrast, energy *supply* considerations have taken a secondary role in determining urban *form*. Indeed, the reverse has been true – urban form selects the energy mix. Large 19th century settlements needed coal because of the

Box 18.2 | Shrinking Cities

Urban growth is not a law of nature, as cities have stagnated in size over long periods of time, or even shrunk, and may well do so in the future. In addition, as national and international production and trade patterns change, some cities may lose their economic or strategic advantage and so shrink or even be abandoned entirely, for which history also provides ample examples. In the United States and Europe, many of the great 19th and early 20th century steel, textile, and mining centers and ports have lost economic importance and population (Cunningham-Sabot and Fol, 2009; Wiechmann, 2009); so too have some of the major manufacturing cities – for instance Detroit as a center of motor vehicle production. Also, in various high-income nations, from the 1970s there appeared to be a reversal of long-established urbanization trends nationally or within some regions with a net migration from large to small urban centers or from urban to rural areas. This was labeled counterurbanization, although much of it is more accurately described as demetropolitanization because it was population shifts from large metropolitan centers or central cities to smaller urban centers or suburbs or commuter communities.

Few systematic analyses have been performed on contemporary shrinking cities (UN HABITAT, 2008). Based on the latest assessment by the UN (UN DESA, 2010), of the 3552 cities with 100,000 and more inhabitants in 2005, 392 experienced a combined population loss of 10.4 million people between 1990 and 2005. While this seems a rather modest figure given the 3.2 billion urban dwellers in 2005, but for some cities population decline was substantial: a few hundred thousand inhabitants. The decline in urban population can, in some cases, be far from gradual but very fast, as in the eastern German city of Hoyerswerda (Pearce, 2010).

In the 80s, it had a population of 75,000 and the highest birth rate in East Germany. Today, the town's population has halved. It has gone from being Germany's fastest-growing town to its fastest-shrinking one. The biggest age groups are in their 60s and 70s, and the town's former birth clinic is an old people's home. Its population pyramid is upturned – more like a mushroom cloud.

Fearing decay, vandalism, and costs, high-rise apartment buildings are now being torn down. Cities also shrink as a reaction to an often painful economic restructuring process, as observed in countries of Eastern Europe and the former USSR undergoing economic reform. Most OECD90 countries have had persistently low fertility, well below replacement levels, for extended periods of time. If low fertility rates continue, overall population decline will become a reality. Shrinking cities amidst a growing or stable national population could then be replaced by a regime of national and city populations shrinking simultaneously. How this will affect urbanization remains one of the biggest challenges for understanding long-term urbanization trends.

The energy implications also remain an important area to be explored. Shrinking urban populations yield reductions in urban energy use. Such trends are, however, likely to be counterbalanced by the effects of potentially larger residential floor space available for the remaining population as well as increases in transport energy use associated with lower population density. The economic viability of urban transport and energy infrastructures in shrinking cities may also be challenged, but on this aspect no data or studies are available currently.

transportation problems associated with taking wood into the dense center. Later, they needed the coal processed into town gas to provide better quality services, like lighting. Urban settlements developed in inhospitable environments once they could depend on the provision of high-grade energy to run mechanical and electrical building services (Banham, 1969). Over the long perspective of future energy-infrastructure planning and population growth, the self-organizing properties of urban space need to be taken seriously. An historical novelty would be a reconfiguration of the urban form to reflect constraints on energy supply.

18.2.2.2 Inter-Urban Complexity

Some of the most compelling evidence that complexity theory is at work is that settlements within the range of a mobile population as ranked by population size approximately conform to Zipf's rule – size is inversely proportional to rank (Zipf, 1949; see Figure 18.4). This is true at least to within the indeterminacy of the definition of an urban population. Each urban center is then in a dynamic equilibrium with the larger urban system and, although urban settlements may present themselves as 'self-contained,' they are far from it. The implication is that at the margin, urban settlements show no total economies or diseconomies of scale. If they did, they would simply disperse to a uniform size or accumulate in a single megatropolis. This conclusion may not apply to any specific economic activity (e.g., the location of energy-intensive industries or finance centers). Large cities and small towns do different things, but large and small appear to show no special advantages in the economy as a whole. The implications of the urban rank-size rule for this assessment suggest that any undue overemphasis on the top end of the distribution curve (i.e., an exclusive focus on 'megacities') is certainly not

Table 18.3 | Population in urban locations by city size class in 2005.

Size class	Total City population	Proportion of total urban population
	2005	
	Millions	*%*
Total urban population	3,167	100
<100,000	1069	34
100,000–1,000,000	932	29
1,000,000–5,000,000	673	21
5,000,000–10,000,000	209	7
>10,000,000	284	9

warranted, as smaller cities constitute the majority of the continuum of the rank-size distribution curve.

At present, few data or studies are available that explore the implications of the rank-size rule for urban energy use. Bettencourt et al. (2007) identified economies of scale effects for urban energy infrastructures for gasoline distribution and electricity distribution grids (cables); i.e., large cities (in terms of population size) have proportionately smaller energy infrastructures than smaller cities, at least in Germany and the United States. In terms of energy use, the sparse available evidence is mixed: transport energy use (gasoline sales) seems to be somewhat lower in larger cities in the United States, which appears plausible in view of the impacts of higher population density on lower automobile dependency. Conversely, electricity use appears to grow somewhat overproportionally with city size (United States, Germany, and China). However, it is unclear whether this is a genuine urban scale effect or simply reflects fuel substitution effects where larger and denser cities exhibit higher preferences for clean, grid-dependent energy carriers (more electricity and/or gas and less oil and/or coal) compared to smaller cities. This remains an important area for future urban energy research.

It now seems likely that the power-law size distribution results from many co-existing stochastic processes (Sornette and Cont, 1997) with a similar statistical effect to that of a long tail power law. The only constraint on candidate processes is that the stochastic growth retains a long tail power-law distribution on average as the national population grows. In fact, very simple growth processes can generate power laws. For example, Ijiri and Simon (1975) obtained a power-law tail by assuming that annual population growth is randomly distributed across settlements in proportion to their size. The key to maintaining a power-law distribution over time is not the modeling of the largest settlement, but the model mechanisms for creating and retiring the smallest.

The robustness of the Zipf law means mechanisms that populate the large number of smaller settlements play a more important role in urbanization dynamics in most countries than the growth of the few largest cities, as amply confirmed by urbanization statistics (see Section 18.2.1.6), which adds to the conclusion herein on the urgent need to study smaller sized cities in terms of their energy and environmental implications.

18.2.2.3 Intra-Urban Complexity

While the smallest settlement is, to some extent, a matter of statistical definition, at its most basic level there is an economic and physical limit to the size of settlement that can manage its own water, sewage, power, and administration collectively, at a few thousand people. This reasoning about the dynamics of growth replicates within the urban settlement itself (Batty, 2008). Quanta of growth similar in size to the minimum urban settlement appear in the history of large cities, marked out by physically distinct districts. There is a subtle interplay between the technical quanta defined by the constraints of urban engineering and the economic and social aspirations of citizens. It is possible to think of a district as a cellular automaton that can be flipped in status according to rules that relate the status of adjoining districts. This dynamic suggests that up to some rate-of-event threshold the city remains heterogeneous, with districts changing their designation from time to time. Above some co-existence threshold, groups of districts start to cluster together in one class and the designations segregate (Schelling, 1969), which can act as a precursor to the formation of slums and ghettos as development capital is diverted elsewhere. This phase change can be seeded by an infrastructure change (an investment in public space or a waste incinerator). Cellular automata models can reproduce many of the key social spatial statistics of urban settlements (Batty, 2005).

The attachment of new zones and transformation of others reflect urban-area attempts to gain the advantages of agglomeration while

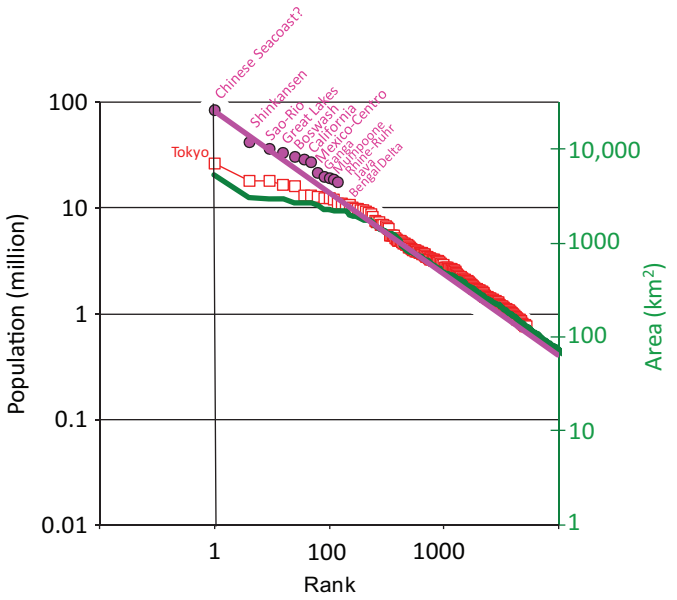

Figure 18.4 | Rank-size distribution of global cities by population. Note the irregularity in the distribution at the largest cities when defined by their administrative boundaries. Conversely, by aggregating individual cities to 'urban clusters' or 'corridors' the regularity of the global city rank-size distribution is maintained. The designation of an emerging urban cluster along the Chinese seacoast is entirely speculative. The currently largest urban cluster is found in Japan along the Shinkansen corridor, with some 70 million inhabitants. The rank-size distribution of global cities not only extends to their populations (red for cities and magenta for urban agglomerations), but also to their area (land cover; green). Source: Grubler et al., 2007, based on Marchetti, 1994; city area distribution from Yamagata, 2010, based on Kinoshita et al., 2008.

internally separating discordant functions (Fujita et al., 1999). Zoning, whether imposed or emergent, is then a natural property of an urban settlement. The dynamics of these processes have long been recognized as complex (Forrester, 1969). Indeed, modern urban planning frequently uses techniques from statistical mechanics to find the most likely aggregate properties from the nearly random effect of the thousands of citizen choices (Wilson, 2000). Administrative boundaries do not always follow the expansion of an urban area and care needs to be taken, for example, as to whether an urban settlement's quoted energy statistics refer to the current political or to the practical spatial reality.

Urban expansion can be seen as a process with land as an input, in effect making the town or city a 'space machine' reorganizing land use and connections (Hillier, 1999). Indeed, only a limited number of stable connectivity patterns seem to emerge for expanding urban spaces. This may, in part, reflect that the existing connection patterns have a very strong influence on the optimal connections within a new zone or district. Such an assumption underlies much of the modeling with cellular automata applied to understanding urban growth. Preferred joining rules are a common property in large complex systems that grow while remaining unconditionally stable (Fisk and Kerhervéa, 2006).

One constraint on the network is that expansion needs to occur such that the urban settlement remains socially and economically viable at all stages of growth. It may, in part, explain why urban areas adopt one of only a few configurations. The 'idealized' European city physically expands by absorbing smaller satellite centers and creating annular transport networks, to form a scale-free connectivity that enables access on foot to public transport. Low-income, low-rent areas cluster around those areas where transport to work is cheap.[6] In contrast, the 'idealized' North American grid city expands along its major axes and maintains a uniformity that avoids overstressing its original center, again using beltways to relieve congestion at intersections from clipping journeys. Although grid cities are superficially uniform, partitioning of rental value is often triggered by environmental factors (downwind, downriver, across the tracks) and agglomeration by local economies of scale. Both these urban configurations are characterized historically by capital investment in the city that matched the influx of population. Conversely, in many developing countries the migration rates from rural areas currently run ahead of capital formation, creating serious issues of energy access and infrastructure development (see Section 18.4.1).

18.2.2.4 Time and the City

While urban geography is naturally expressed as space, an urban settlement might equally be thought of as a complex time machine. Since the urban rationale is to bring specified people together at the same place at the same time to get things done, motion within the area needs to meet socially determined constraints in absolute time. Zahavi's rule (Zahavi, 1974) notes the rough constancy, in many countries over many decades, of the time spent traveling during a working day. This presumably reflects the constancy of many shared social norms, such as when work starts and ends and when entertainment begins. Since different modes of travel involve different amounts of physical work by the traveler, the social norm also sets upper limits on how tired the traveler can be on arrival (Kölbl and Helbing, 2003). The dynamics of land-use changes then 'solve' the consequent set of time constraints. Thinking of a city as a vast set of service connections self-consistently feasible within given absolute time windows is a complementary dynamics paradigm with some useful explicative power.

Transport improvements (or the prospect of them) tend to induce land-use changes and investment, and not save traveling time (as reviewed in Metz, 2008). In urban areas the local density of travelers on the move directly affects the average speed of travel and also indirectly decides safe speed limits. A city with high values of speed averaged over complete journeys can support journeys of longer length, within social

6 In cities of developing countries, economic pressures to relocate slums that enjoy a transport locational advantage are therefore high. Conversely, locating the poor far outside the city with poor (and expensive) transport access (as was the case in apartheid South Africa) further disadvantages them socially and economically.

norms, and so individual service points sweep larger areas of clients. Increased average speed supports larger agglomerations (e.g., large retail shopping malls) and so gains economies of scale. Higher speeds can give greater separation between incompatible land uses without breaking scheduling norms.

As a consequence of land-use adjustments, high-speed cities have longer average journey lengths, but this means their growth dynamics can relax to lower densities with greater local accumulation. An hour or so traveling time represents the effective limit to the radius of commercial activity of an urban settlement. The resulting dependency of transport-energy use on urban density is roughly linear when plotted against the mean interpersonal distance interpreted from two-dimensional urban density (Kenworthy and Newman, 1990), as might be expected from a largely traveler-interaction effect. Since the total start-to-finish journey time is the key determinant of location there are densities below which only individual motorized transport can provide a plausible service. By the same token, as urban density increases the interaction between travelers becomes increasingly significant and energy use ceases to fall as energy is wasted in congestion and traffic queues. Very high density centers offer little advantage to transportation because congestion is so severe (especially true in cities in which both the mass transit and private transit systems become embroiled in the same gridlock). Urban areas in this state tend to spill outwards and create a self-organizing critical density consistent with the underlying social norms.

18.2.2.5 Economic Complexity

The new insights of complex system 'econophysics' complement rather than displace traditional urban economics. The timescales and spatial statistics employed tend to be different. Ecophysics focuses on changes over long timescales and wide spatial averages, while traditional models the short-term dynamics that manage the scarcity and surplus of individual space. The overlap is the understanding of the dynamics of rents, both in the form of local taxation and 'ground' rents. These influence income distribution and the dynamics of investments and also change the economics of urban- versus rural-based activities (Irwin et al., 2009). Differences between urban settlement dynamics in different societies may also reflect institutional differences (e.g., as reviewed by Diamond, 2004).

18.2.2.6 Future Dynamics

The energy demand and energy mix of urban settlements normally follows rather than leads urban expansion (Seto and Shepherd, 2009). However, the historical generalities of urban growth hide the continual adoption and invention within the settlements themselves. Even new transport technologies that made such a fundamental contribution to urban form usually arose from solving a problem caused by an existing technology. So projecting the urban future on the basis of past trends is dangerous if attention is not paid to changes in detailed mechanisms. Indeed, some signs indicate that this new urbanized century might be different in character from the urban-rural mix that preceded it.

For example, the simplicity of Zipf's law is now retained for the world's largest cities only if the associated metropolitan region is treated with the city as one (see Figure 18.4 above). If airline connectivity is a new paradigm of interurban transport, the connectivity of the largest cities appears not to have caught up with expectations from a natural extension of the power law to describe airline connectivity of smaller towns (Guimerà et al., 2005). Indeed, scaling arguments (Kühnert et al., 2006) suggest that the frequency with which settlements need to find paradigm-shifting innovations must increase as they grow. Since breakthroughs are, by definition, unforeseeable there is a future scenario in which the growth of the world's largest metropolitan areas falters.

Urbanization forms part of the demographic transition and is expected to deliver a stabilization and then decline in world population around the middle of this century. As a consequence urban settlements may face retractions in some unspecified form. How built form relaxes to new configurations poses a fascinating question to a new understanding of urban structure.

18.2.3 Specifics of Urban Energy Systems

In principle, urban systems are not fundamentally different from other energy systems in that they need both to satisfy a suite of energy-service demands and to mobilize a portfolio of technological options and resources. However, urban systems also have distinguishing characteristic that sets them apart:

- A high density of population, activities, and the resulting energy use and pollution (see Section 18.4.2 for a more detailed discussion).
- A high degree of openness in terms of exchanges of flows of information, people, and resources, including energy.
- A high concentration of economic and human capital resources that can be mobilized to institute innovation and transitional change.

Urban areas are characterized by high spatial densities of energy use, which correspond to their high population concentrations, and by low levels of energy harnessed and extracted: cities are loci of resource management, processing, trade, and use, rather than of resource extraction or energy generation. All settlements depend on a hinterland of agriculture, forestry, mining, and drilling; in the present fossil-fuel economy, this hinterland has a global reach. Indeed, the same may be true of many rural areas, which, in developed countries, often focus on a few crops. These specialized rural areas also require imports of energy, goods, and services, which often may be on the same scale, per capita, as those of urban areas. Indeed, spatial division of labor is a characteristic of

modern societies, with consequences for local energy use and policies. In industrialized countries both urban and rural areas depend heavily on energy-intensive industry, which may be located in or outside cities. If heavy industry is located outside urban areas, urban energy use may apparently be lower than rural energy needs, even though urban dwellers also consume the products from industrial activities.

High levels of energy demand open possibilities to reap significant *economies-of-scale* effects in energy systems, in supply as well as in transport and distribution. (It is not a coincidence that, historically, many major, large hydropower resources were developed to supply electricity to large urban agglomerations, from Niagara Falls in the Unites States to Iguacu (Itaipu) in Brazil.) Simultaneous to cities being loci of a wide diversity of activities, significant *economies of scope* are possible. The wide range of different energy applications from high-temperature industrial processes down to low-temperature residential home heating, and even to the energy provision of greenhouses, allows the maximization of energy efficiency through better source-sink matching of energy flows in the system, be it through conventional cogeneration schemes or through more complex waste-heat 'cascading.' These can, however, only be realized if diverse energy uses in a city are sufficiently mixed and co-located to allow these concepts of 'industrial ecology' to be the implemented. On the negative side of density, typical urban agglomeration externalities are important: low transport efficiencies through congestion and high pollution densities add urgency to environmental improvement measures. Retrofitting a high-density built environment can also incur many transaction costs that would not apply in low-density developments. However, it is no coincidence that cities have always been the first innovation centers for environmental improvements (Tarr, 2001; 2005).

The latter perspective is perhaps the most fundamental for the transformation of energy systems. Urban agglomerations are *the* major centers and hubs for technological and social innovation (Kühnert et al., 2006), as they both dispose of and mobilize formidable resources in terms of human, innovation, and financial capital. Bringing these transformations to fruition may ultimately be of greater long-term environmental significance than any short-term environmental policies. So, energy and environmental policies in an urban context may have substantial leverage in inducing further much-needed innovation in the core, where such activities take place.

18.2.4 City Walls and Urban Hinterlands: The Importance of System Boundaries

18.2.4.1 Introduction

Measuring the energy use of cities is no easy task, compounded by the absence of widely agreed measurement concepts and data-reporting formats. And yet for reasons of scientific enquiry, policy guidance, and political negotiation the important issue of 'attribution' needs to be addressed. The seemingly easy question of "How large is the energy use (or associated GHG emissions) of a city and what can be done to reduce it?" can vary enormously as a function of alternative geographic and system boundaries chosen. Therefore, this section reviews the different issues that must be addressed in urban energy assessments and aims to clarify the various concepts and definitions and help make their differences more transparent. In a modification of an old adage that only what get's measured gets controlled, this chapter postulates that only what is measured correctly and transparently at an urban scale is useful for policy guidance.

As a simple example of the importance of boundaries in urban energy assessments consider the issue of the administrative/territorial boundary chosen for defining a given city. Barles (2009) studied the fossil-fuel use of Paris, its suburbs, and the larger Parisian metropolitan region. The per capita fossil-fuel use was lowest in the city of Paris, and increased as the region considered expanded. This phenomenon is caused by a combination of inherent and apparent factors: the inherent factor is the lower transportation energy required by areas of higher population density (in central Paris with its formidable Metro system, compared to its suburbs); the apparent effect is the changing of the system boundary to encompass more energy-intensive industrial activities located beyond the city center.

Generally, urban-energy assessments must be oriented either to physical, and hence local, energy flows (a 'territorial' or 'production' perspective) or, if trade effects are included, follow economic exchanges linked to energy use (a 'consumption' perspective). The joint consideration of the production and consumption perspectives is most likely to yield a full assessment of urban energy,[7] albeit to date the literature and data base for such a comprehensive perspectives is extremely limited.

In assessing a variety of local and upstream contributions to the urban metabolism, it is sometimes tempting to aggregate the disparate elements into one indicator. For instance, the ecological footprint (see Rees and Wackernagel, 1996) is increasingly used to describe the impact of urban resource use (e.g., in London, Barcelona, and Vancouver). The ecological footprint of an urban area is invariably larger than the surface area of the city itself, which leads to the facile (but erroneous) conclusion that the city is 'unsustainable.' Cities are part of an exchange process, whereby they produce manufactured goods and services while depending on a hinterland for their supplies – and the existence of this hinterland cannot of itself be unsustainable. Better indicators are the relative magnitude of resource use and emissions (per capita, household, or income), compared to rural or other urban populations, or environmental limits, like carbon accumulation in the atmosphere. Since the ecological footprint is, in any case, driven

7 The terms 'direct' and 'indirect' energy are avoided here, since they have a different meanings in each of the approaches considered. Instead, the terms 'final,' 'primary,' 'upstream,' and 'embodied' energy are used here.

Table 18.4 | Overview of urban energy-accounting frameworks.

Approaches	Data basis	Definition of energy users	Position along energy chain	Upstream or embodied energy	Territorial/Production or Consumption approach
Final energy	Physical	Final user (energetic)	Final	Not included, can be added using typical conversion efficiencies between primary to final energy for different energy carriers	Territorial Example: Regional energy statistics, Baynes and Bai, 2009
Regional energy metabolism	Physical	Region	Combination of final, secondary and primary	Not included, but can be added using typical conversion efficiencies	Territorial example: Schulz, 2007
Regional economic activity	Economic (physical extensions)	Final demand (economic)	Total Primary Energy Supply	Includes upstream & embodied energy of goods and services, no sectoral differentiation	Territorial Example: Dhakal, 2009
Energy Input-Output	Economic (physical extensions)	Final demand (economic)	Total Primary Energy Supply	Includes upstream & embodied energy of goods and services, no sectoral differentiation	Consumption Examples: Weisz et al., 2012; Wiedenhofer et al., 2011

by fossil-fuel carbon emissions, studying urban energy use directly appears to be a more constructive approach.

18.2.4.2 Energy Accounting Methods

Table 18.4 classifies the various methods used to estimate urban energy use. This classification utilizes two main criteria: the basis of the data and the definition of energy users. The first two methods are based on physical flows, and as such produce 'territorial' or 'production' oriented energy balances; the other two focus on economic flows, and are 'consumption' oriented. The economic-based models (regional economic activity and economic I-O (input-output) approaches) are further distinguished by the level of sectorial detail.

The 'final energy' method uses physical data, such as energy statistics from utilities or fuel sales, as the data basis. Users are defined as energetic end users within the city boundaries. Energetic end users are the "consumers" of final energy (such as electricity, heat, gasoline, or heating fuels). It is important that both producers and consumers (i.e., firms and households) use final energy. By disaggregating the final energy use by sector, one can differentiate between residential, commercial, and industrial uses. These sectorial accounts of urban final energy use also allow comparisons with national level data or data of other cities and can serve as a useful guide, e.g., for energy-efficiency 'benchmarking' that can guide policy.

The direct final energy account can further be extended by estimating the *upstream energy* requirements needed to provide the final energy, using e.g., lifecycle analysis. The upstream energy is the primary or secondary energy use *linked to the final energy* utilized by the end users within a city. Depending on the estimation method, the upstream energy may or may not include the energy required to extract and transport the primary energy itself. For clarity, it is crucial to specify which type of upstream energy is considered: secondary, primary, or primary, including energy for extraction activities themselves. To avoid confusion with other terms used for upstream energy, this section reserves the term 'upstream' for energy-linked direct energy flows (mobilized outside the geographic city boundary, but linked to a city's final energy use), and the term 'embodied' for goods and services linked to indirect energy flows (i.e., energy embodied in resources, materials, and goods traded).

Final and upstream energy uses are not the total primary energy required by urban activities, since they do not include the energy needed to produce goods and services *imported* into the city. Conversely, the final and upstream energy uses of a city also include energy uses to manufacture goods and provision of services *exported* from the city (and consumed in other cities or in rural areas). Care therefore needs to be taken to avoid double counting of energy flows, for example by adding imported 'embodied' energy flows to the final and upstream energy uses of a city, but ignoring the (final and upstream) energy embodied in goods and services produced in a city, but exported for consumption elsewhere. This double counting is averted in I-O methods but can be a problem in approaches that rely on lifecycle analysis (Ramaswami et al., 2008; Hillman and Ramaswami, 2010).

The difference between the final and upstream energy use can be considerable. Take the example of electricity: typically, for 1 GJ of electricity consumed in a city, up to 3 GJ of primary energy in the form of coal must be burned in a conventional steam power plant. (This ratio is substantially lower for combined-cycle power plants fired by natural gas, which illustrates the need to consider the *actual* urban energy system characteristics rather than aggregate 'upstream' adjustment factors.) Heating fuels, such as gas and fuel oil, also have upstream energy use through their extraction and transport. According to Kennedy et al. (2009), who applied this method to the GHG emissions of 10 global cities, the lifecycle GHG emissions associated with urban fuel use are between 9% and 25% higher than their local emissions. This approach is also that followed by the Harmonized Emissions Analysis Tool of the International Council for Local Environmental Initiatives (ICLEI, 2009), although since the software is proprietary (and not transparent),

Table 18.5 | Energy and material flows of selected cities showing the importance of energy flows in the total metabolism of cities.*

* Domestic material consumption = domestic extraction + imports – exports, which in the urban case is dominated by imports.

1 includes other products

geographically limited, and often applied only to municipal energy use, it is not clear how reliable or significant the results are.

The 'Regional Energy Metabolism' method also uses physical data, but defines the user as a geographic region (in this case, boundary of the urban area): thus, all energy flows that cross the regional boundary are measured. This method is based on a socio-metabolic understanding of the city, including energy, materials, water, important waste flows, infrastructure stocks, and other relevant physical attributes of a city. Indeed, a complete urban metabolism would include other energy flows, such as the calorific value of physical goods entering and leaving the city and biomass for human (and animal) nutrition, which are not included in other approaches. This method includes all the energy that is imported into the city, regardless of its conversion stage. In contrast to the final energy method, the primary energy used by the energy sector *within the city* is included in the regional energy metabolism. Thus, the location of a power plant inside or outside a city's boundaries has a large influence on the measurement of its energy use in this method. As a result, the regional energy metabolism of a city is always larger than its final energy. The mixture of primary and final energy, however, makes it difficult to compare this method's results with national level data and those of other cities.

So far, the urban metabolism approach has been applied to material flows rather than energy flows for Cape Town (Gasson, 2007), Geneva (Faist et al., 2003), Hong Kong (Newcombe et al., 1978), Paris (Barles, 2009), and Singapore (Schulz, 2006; 2010b; see also Chapter 1). Table 18.5 summarizes some findings from urban metabolism studies. Energy is extremely important in the urban metabolism: energy carriers represent a significant share (a quarter to a half) of domestic material consumption. Moreover, other materials consumed (biomass, construction and industrial minerals, and ores) also represent important flows of embodied energy.

The 'Regional Economic Activity' approach uses the urban final demand aggregate (defined in *economic* (monetary) terms, that is as gross regional product (GRP)) and a national or regional energy-to-GDP relationship to estimate the city-specific energy use. This method was used by Dhakal (2009) for major Chinese urban areas (see Section 18.5.2), and is the only possible approach when no city-specific energy data are available. However, the limitation of this method is that it ignores all city-specific drivers of urban energy use except income. The national or regional energy-to-GDP ratio usually uses total primary energy supply as the energy variable. This method is thus fully comparable with statistics on the national level.

'Energy I-O' accounting approaches are based on national economic I-O tables, which measure (usually in monetary terms) all sales and purchases of goods and services among the producing sectors and to final demand. These tables can be extended to account for physical energy flows or emissions. Based on I-O tables, the 'embodied' energy (i.e., the energy used throughout the whole production chain to produce the final goods and services) can be calculated. This approach allows allocation of energy use to specific sectors of economic activity. Using consumer-expenditure surveys for urban areas, I-O studies have assessed the energy use of Indian urban and rural populations (Pachauri et al., 2004; Pachauri, 2007), Brazilian urban households (Cohen et al., 2005), Sydney's energy use (Lenzen et al., 2004), as well as for postal district resolution maps of Australia (Dey et al., 2007). Illustrative results on direct versus embodied energy use in Asian megacities based on I-O analyses are given in Figure 18.5.

First, it is important to recognize how embodied energy flows compare with direct energy flows, particularly for high-income cities such as Tokyo. Second, the dynamics of energy flows are characterized by the

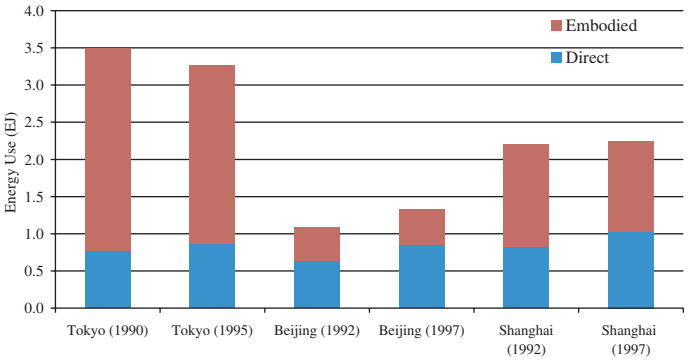

Figure 18.5 | Estimates of direct (on-site) versus embodied (via imports of embodied energy in goods and services) energy use of Asian megacities. Source: Dhakal, 2004, based on Keneko et al., 2003.

growth of direct energy flows (income growth leading to buildings and transport energy demand growth), whereas embodied energy growth remains comparatively flat. In these examples the income effect on direct energy use is larger than changes in trade flows into the city over the limited time period considered in the studies.

I-O avoids the thorny issue of double counting, as only the final demand (i.e., household consumption – and that of government, even though this is rarely reported) serves as the allocation unit of all direct (including upstream) and indirect energy flows, whereas industrial and service-sector energy uses are treated as intermediary uses, allocated to final consumption (in a city and elsewhere) based on expenditure levels and structure. Hence, this approach is often referred to as a 'consumption' approach, as opposed to the 'production' approach that focuses on apparent energy use. The I-O based 'consumption' approach can thus differentiate between cities with different incomes and final consumption patterns, but cannot capture differences in industrial and service energy use, not to mention differences in energy systems (e.g., degree of cogeneration) between different cities. The issue of the representativeness of national I-O tables for cities with different consumption structures, even within identical expenditure categories, and with different (usually higher) price levels has not been addressed by systematic studies. National I-O analyses do not provide information on embodied energy flows in commodities and goods traded internationally, which requires the use of multiregional I-O models, whose data quality is often weak. Studies performed for Norway (Peters et al., 2004), the United Kingdom (Wiedmann et al., 2007), and the United States (Weber and Matthews, 2008) show that a significant fraction of energy use can be attributed to imports, especially in industrial economies (Peters and Hertwich, 2008). The application of the I-O method to developing countries is, however, not straightforward, since the large informal sector is absent from the official I-O tables, which themselves exist in up-to-date versions only for a few developing countries. It has also been shown that uncertainties are very large for the GTAP (Global Trade Analysis Project) database used in multiregional I-O models (Weber and Matthews, 2008).

From the I-O studies, the largest categories in urban household energy use are housing, electricity, transportation, and food. Of these, food and electricity have the largest upstream and embodied energy "content." Thermal electricity generation involves heat losses up to two-thirds during transformation, plus transmission and distribution losses. Food has both nutritional and embodied energy components: a diet of 3000 kcal/day corresponds to 4.5 GJ/year in nutritional energy per person. The commercial primary energy required to produce food ranges from 2.5 to 4.0 GJ/capita for Indian urban households and from 6 to 30 GJ/household for Brazilian urban households (where the ranges correspond to low and high income brackets) to around 40 GJ/capita for European households (Vringer and Blok, 1995; Pachauri, 2004; Cohen et al., 2005). The majority of the energy embodied in food production is consumed outside city boundaries.

Comparison of energy-accounting frameworks

To compare and contrast the results from different accounting approaches Chapter 18 initiated a collaboration among various research teams to provide a quantitative illustration, applying two different methodologies ('final energy' and 'energy I-O') for two different cities: London and Melbourne. Recent (partial) results for Beijing are also included for comparison. These two approaches are often contrasted at the national level for energy or GHG, where they are generally known as 'production'[8] or 'territorial' (for the 'final energy' method), and 'consumption' (for the 'energy I-O' method) (see, for instance, Peters, 2008).

For the Melbourne study, Manfred Lenzen and his group at the University of Sydney used environmentally extended I-O methods coupled with household expenditure surveys to map direct and embodied GHG emissions of household consumption (Dey et al., 2007). This method was adapted to provide results in terms of primary energy use for the city of Melbourne (Australia). Baynes and Bai (2009) scaled state data down to the urban level, focusing on the (direct) final energy use of Melbourne city. The London study compares final energy use from official statistics (UKDECC, 2010) and results from a multiregional, environmentally extended I-O analysis with explicit representation of the household consumption vectors for the Greater London Authority. The yet unpublished study is based on a method of Minx et al., (2009) and was carried out by the Technical University of Berlin, the Potsdam Institute for Climate Impact Research, and the Stockholm Environment Institute.[9] The Beijing study (Arvesen et al., 2010) only considered household energy use (and hence misses the large industrial and service sector energy use) and combined both the final energy method (with additional approximate fuel-specific estimates of upstream conversion energy needs) with an I-O approach.

8 The term 'production' accounting as applied to household energy use is somewhat misleading, but to not introduce further terminological complexity, the term (well established in the national scale literature) is retained here.

9 Weisz et al., 2012.

Table 18.6 | Primary energy use for two different energy-accounting approaches for three cities for which (partial) data are available: Melbourne, London, and Beijing. All values are expressed in GJ/capita (permanent) resident population. Dashes (-) indicate categories of energy use that cannot be compared directly between the two different accounting methods.

Primary energy GJ/capita for:	Melbourne 2001		Greater London 2004		Beijing 2007 Household energy only	
	Pop.: 3.2 million		Pop.: 7.6 million		Pop.: 12.1 million	
	Prod. acc.	Cons. acc.	Prod. acc.	Cons. acc.	Prod. acc.	Cons. acc.
Residential heating	22	12	28	–	9	–
Residential electricity	28	30	17	–	9	–
Residential housing (heating + electricity)	50	42	45	35	18	11
Private cars	33–41	27	10	–	7	7
Nonresidential use	197	–	56	–	n.a.	–
Household consumption of goods and services	–	116	–	108	–	34
Total	279–288	184	111	143	25	52

Pop = population; Prod. acc. = production accounting; Cons. acc. = consumption accounting; n.a. = not available.

The results are summarized in Table 18.6. To enable comparison, the position along the energy chain has to be the same, so the primary energy equivalent of final energy is estimated where detailed statistics are unavailable (using standard conversion efficiency factors from Kennedy et al., 2010). To correct for different sizes of the cities, all values are expressed in GJ/capita.

The two methods cover different types of energy flows, some of which can be compared, and others cannot (denoted by dashes in Table 18.6). Energy I-O ('consumption accounting') focuses on the energy use of households within the city boundary, directly and embodied in the purchase of goods and services. A direct comparison with the territorial final energy ('production accounting') method is only possible, therefore, for the energy directly purchased by households: for residential housing (heating and electricity) and (in the case of Melbourne and Beijing) private transportation. The final energy method also measures urban nonresidential energy (for industry and commercial activities, as well a non-private transportation), which the energy I-O method does not cover. Conversely, the energy embodied in the household purchase of goods and services is not covered by final energy method.

The most interesting result lies in the (first ever) quantification of the differences between the two different accounting methods. As expected, the consumption-based accounting method yields much higher energy use for London (+30%)[10] and Beijing (+100%). Conversely, Melbourne's territorial energy use is significantly higher than the energy used directly and indirectly by its households. This is not because the Melbourne households consume less energy: in fact, in total, they consume almost one-third more than the London households, mainly through private transportation (cars). Instead, it is because Melbourne's nonresidential energy use is almost quadruple that of London's, on a per capita basis. Melbourne is still a major industrial production center, and this industrial activity results in more energy per capita than that of household consumption. London, in contrast, has very little industrial activity, with services dominating its economic activities, and so household consumption is larger than the territorial production-account energy use. The importance of industrial energy use is also illustrated in the case of Beijing. Total secondary energy use (all sectors) in Beijing in 2007 was some 145 GJ/capita (Beijing Government, 2010), i.e., three times larger than the total direct plus embodied estimated household energy use reported in Table 18.6. Taking upstream energy conversion losses into account, the primary energy use (the energy level directly comparable to the other cities in Table 18.6) of Beijing is approximately 200 GJ/capita, i.e., in the same ballpark as Melbourne or London (production accounting). The major difference is that average per capita income in Beijing is with 10,000 *purchasing power parity* dollars (PPP$) per capita, approximately a factor four lower than that of Melbourne and a factor of six lower than London's, suggesting the twin importance of economic structure and efficiency of energy end-use as determinants of urban energy-use levels, with the latter offering a substantial potential for improvement.

The above results confirm that production accounting of energy reflects the economic structure of urban areas, and their role in the international division of labor, whereas consumption accounting energy reflects a mixture of local conditions (climate and transit infrastructure) and expenditure levels (income and lifestyle effects). This exercise also demonstrates the power of applying and comparing different methods at the urban level. By showcasing the differences in production and consumption accounting of energy, the potential role of local policy measures (e.g., transport) versus broader consumption measures (consumption

10 CO_2 accounts for London (Hersey et al., 2009) suggest that the differences between the two accounting methods could be 100% (some 45 versus 90 million tonnes CO_2 for the production versus the consumption accounting, respectively), a difference that appears very large in view of the results form the energy comparison reported here. I-O techniques are used here (Table 18.3.6) whereas the London CO_2 study used a lifecycle assessment approach to estimate consumption based CO_2 emissions (but the method and data have not been published), so there might be an additional methodological explanation for the large differences in estimates of the energy and CO_2 consumption-accounting 'footprint' of London.

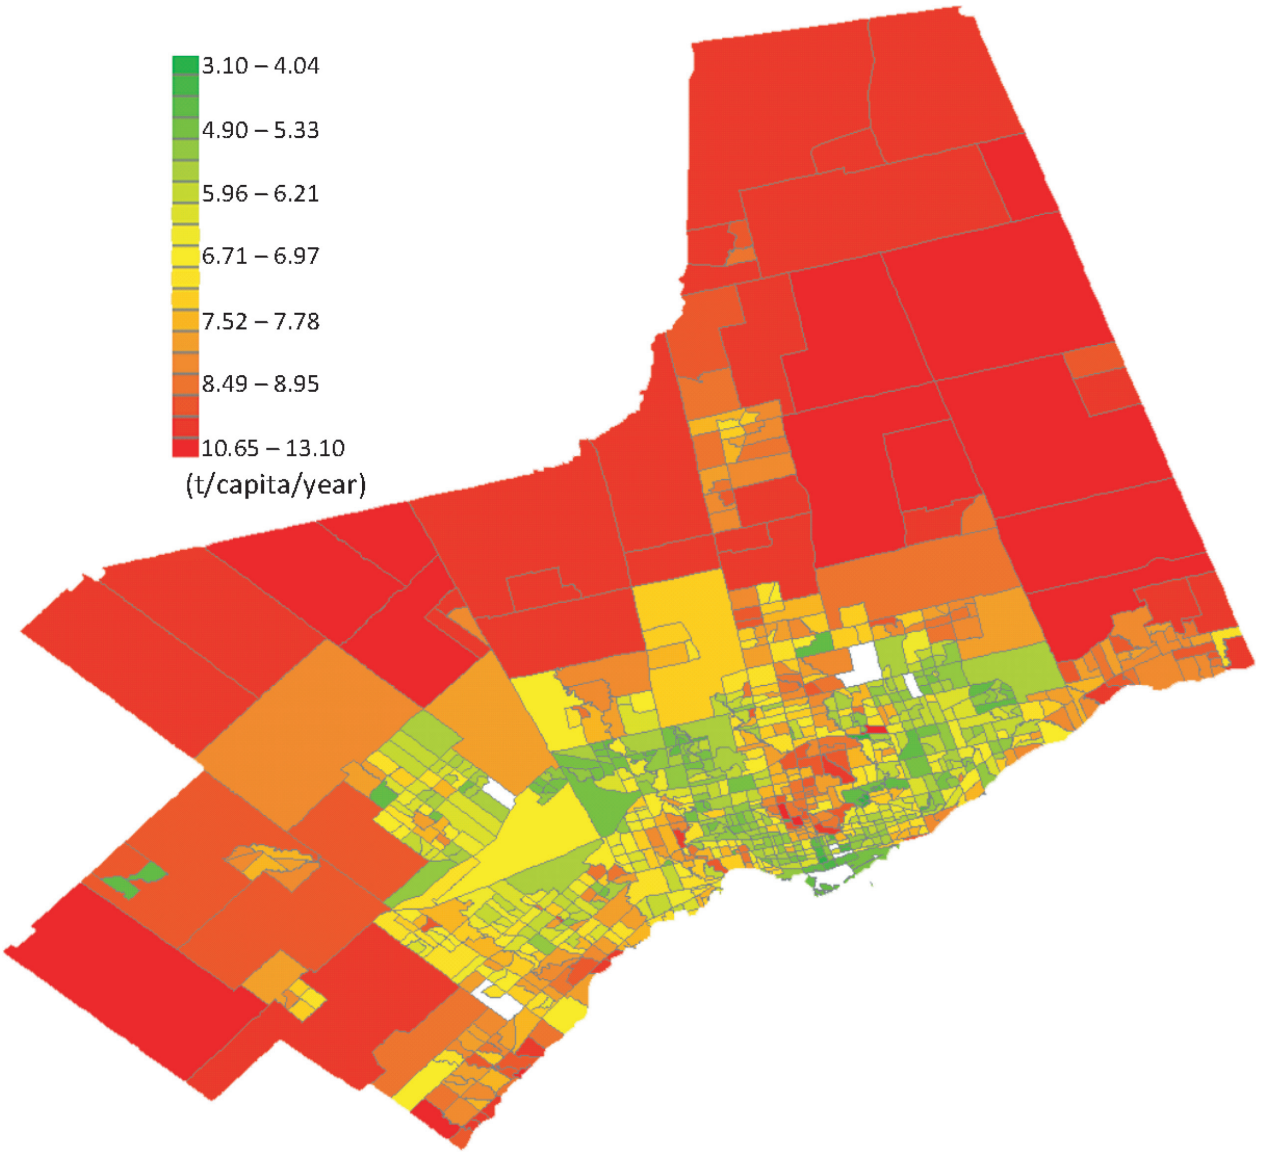

Figure 18.6 | Total GHG emissions from Toronto (tonnes CO_2-equivalent/capita/year). High-resolution images as well as maps for various energy-demand subcategories (residential, transport, etc.) are available from VandeWeghe and Kennedy, 2007.

reduction, or low energy/emissions supply chain management) can be made explicit.

The comparison of the two methods indicates two policy avenues. Local policy priorities should focus on housing, transit, and industrial energy savings. But these must imperatively be complemented by shifts and reductions in the energy embodied in household purchases of goods and services to avoid that savings at the regional level are offset by increased energy demand from the consumption of goods and services, which occurs somewhere else in the world. Such a policy agenda clearly goes beyond the local level and needs to be addressed on multiple scales.

18.2.4.3 Spatially Explicit Urban Energy Accounts

Spatially explicit energy-use studies may be the key to understanding the influence of urban form and periurban and urban specificities. For Sydney, Lenzen et al. (2004) disaggregated total primary energy use in 14 areas, and followed this up with a GHG emissions atlas of Australia at the postal district level (Dey et al., 2007). For Toronto, VandeWeghe and Kennedy (2007) derived spatially explicit direct-energy use based on transportation and energy-expenditure surveys (see Figure 18.6). Andrews (2008) analyzed direct energy use of several districts in New Jersey, ranging from rural to urban. A comprehensive spatial GHG account, including discussions of uncertainties, was

recently completed for the city of Lviv, Ukraine. An innovative study used the Vulcan emissions atlas to compare transportation and building emissions in urban, periurban, and rural counties of the United States (Parshall et al., 2010).

The Sydney and Toronto studies found higher energy and emissions in the outer, low-density suburbs. The US study also found a 'threshold' effect in per capita urban transportation energy compared to more rural counties. In Sydney and Toronto, building fuel use was higher in the center city. The causes for higher building energy in the center city could be the age and quality of the housing stock, the presence of an energy-intensive central business district, and higher incomes in those areas. In the Sydney study, where economic information is available, building energy use is highly correlated with income, but less correlated with population density. In Sydney, central districts tended to have higher incomes than the outer suburbs, a trend absent in the New Jersey study. Since these studies are of industrialized countries and automobile-based urban areas of North America and Australia, their results may not apply to urban areas more generally.

18.2.4.4 Recommendations for Urban Energy Assessments

The indeterminacy in defining 'urban energy' should not be misinterpreted as a flaw in the urban systems perspective. It reflects that the data are approaching the actual final-decision level at which the purpose of the decision, to some degree, can resolve many of the statistical and data ambiguities. For example, administrative boundaries and a production perspective are appropriate system boundaries if the decisions are to be undertaken by local administrations. Final energy-use data remain an essential and useful tool for analysis of energy efficiency and for crafting policies for improved efficiency. Conversely, a 'consumption' perspective on urban energy and GHG use helps to raise awareness that, ultimately, urban energy and GHG management cannot be relegated to an energy optimization task, but equally involve changing lifestyles and consumption patterns.

As urban energy statistics have a vital role in allowing agents to benchmark, it is essential to be sure that the methods are comparable and that 'gaming' is not taking place. Each of the methods described above can produce results that allow benchmarking and comparisons, as long as the method and data sources are described clearly, and consistent data, sectorial definitions, and system boundaries are applied and spelled out clearly. The method should also be as transparent and as open as possible, to guarantee reproducibility and fact checking. Moreover, examples of energy assessments that only account for some sectors are not measurements of urban energy. The sectorial distribution of energy use (residential, commercial, industrial, administrative) as well as purpose (transportation, heating) are essential complementary elements for informed analysis and decision making and should be an integral part of urban energy reporting.

Urban energy and GHG statistics should provide a basis for policy formulation, investment decisions, and further action toward climate protection. Therefore, it is essential that their origin and data quality is made transparent and methodologies are comparable. Suggestions to improve terminology are provided in this chapter. It is far too common to read 'the energy use of this city is *X* Joules,' without any qualification what type of energy (final or primary, including upstream or embodied energy) is referred to. There is also a rich field in enhancing the usefulness of urban energy accounts by expanded information on energy quality (e.g., separating heat demand by low, medium, and high temperature regimes), which can form the basis of extended energy efficiency studies, for example in the form of exergy analysis (see Box 18.6).

City energy assessments should also include clear definitions of the system boundary used. Currently, many urban energy assessments, in effect, arbitrarily choose the system boundary to reduce the reported energy use or GHG emissions, for instance by claiming their electricity comes from different sources than the average regional mix, or by excluding certain energy uses that are, nonetheless, central to the very functioning of cities, such as airports or a large tourist population. Arbitrary, or ill-defined, system boundaries defy the very purpose of urban energy assessments: to guide public and private sector policies and decisions and to allow comparability and credibility of the entire process.

18.3 Urban Energy Use

18.3.1 Current Urban Energy Use (Global and Regional)

How large is the urban fraction of global energy use? This seemingly simple question is hard to answer as, contrary to the data for countries, no comprehensive statistical compilation of urban energy use data exists. With 50% of the world population being urban, a range of (largely ballpark) estimates put the urban energy share between two-thirds to three-quarters of global energy use, but such global estimates have, until recently, not been supported by more detailed assessments. This Section reviews the two detailed assessments of urban energy use available to date: the estimate of the IEA published in its 2008 *World Energy Outlook* (IEA, 2008) as well as an estimate developed by a team of researchers at the International Institute for Applied Systems Analysis (IIASA) for this study.

In the absence of detailed, comprehensive urban energy-use statistics, two analytical approaches were pursued to derive global (and regional) urban energy use estimates. One technique, which might be labeled 'upscaling,' uses a limited number of national or regional estimates of urban energy use and then extrapolates these results to the global level. This is the approach followed by the IEA (2008) study that estimated (direct) urban energy use at the primary energy level. The second approach adopts 'downscaling' techniques in which national level statistics are 'downscaled' to the grid-cell level, and then combined with geographic information system (GIS)-based data sets on

Box 18.3 | Urban Energy Data: Measurement and Quality Issues

For urban energy data and assessments two major issues need to be spelled out in a clear and transparent way: (1) system boundaries, and (2) data availability and quality issues.

(1) Within the discussion of system boundaries two issues need to be considered:

  (a) What is the spatial or functional definition of the urban system under consideration? Does the city definition refer to the core city alone, or does the assessment include the larger metropolitan area? Does the system definition include recognition of bunker fuels[11] (transport fuels used outside of the spatial system boundary, e.g., in national and international territory) or not? Does it consider also the embodied energy associated with the use of material resources and goods other than energy carriers, or not?

  (b) What is the energy system considered? Is primary or final energy reported, and to what extent is a lifecycle perspective for the fuel provision followed (e.g., upstream energy conversion losses and associated emissions, or the costs of exploration, drilling, transporting, and refining fuels before import into the urban system are included or omitted in the analysis)?

(2) Quality and availability of energy data: are actual statistics used or extrapolated/downscaled data? Does the assessment include noncommercial energy?[12] Which spatial and temporal resolution was considered to calculate the fuel mix for electricity provision? Are differences in technology, efficiency, etc., of power plants and other energy conversion processes recognized?

In an ideal world, urban energy reporting should adopt as wide systems boundaries and complementary accounting frameworks as is reasonably possible and available data allow.

When narrower system boundaries are adopted, a simplified sensitivity analysis of the effects of inclusion of omitted system components can help to put reported numbers into a proper perspective (i.e., complementing final energy accounts with estimates of corresponding primary energy needs, or production-based accounts by estimates of consumption-based accounts based on national I-O tables).

Incomplete reporting (e.g., of only municipal energy use) should be avoided as only a comprehensive sectorial perspective of all urban energy uses can reveal the full potential for policy intervention and assure comparability across different urban energy accounts.

Finally, data disclosure and documentation of assumptions and methods are a 'must.' Particularly, the area of urban GHG inventories is replete with examples of glossy policy briefs that do not allow the reproducibility of the numbers presented (not to mention unreported uncertainty ranges). Transparency and data disclosure are not only key from the perspective of scientific integrity, quality, and reproducibility, but they are also the key for well-informed policy choices. A comparable effort to the standardization of energy and GHG accounts at the national scale along the OECD/IPCC model is long overdue for the urban scale as well.

urban extents is used to derive spatially explicit estimates of urban energy use. These are then aggregated to the national, regional, and global levels. This approach underlies the IIASA study that estimated urban energy use at the level of (direct) final energy, also reported in this section.

In the 2008 *World Energy Outlook* (IEA, 2008), a separate chapter is devoted to urban energy use and contains estimates of 2006 base-year urban primary energy use data and a reference scenario projection to 2030. Detailed urban energy use assessments were first commissioned for a limited number of countries and regions (China,

11 Bunker fuels, i.e. energy used for (international) air transport and shipping, can be a substantial fraction of urban energy use. In 'world cities,' like London and New York, air and maritime bunker fuels can account for about one-third of the direct final energy use, suggesting the importance of their inclusion in urban energy accounts.

12 For many cities in developing countries, noncommercial energy forms can account for a substantial fraction of urban energy use (one-third to half). Its reporting is therefore not only key for a comprehensive urban energy accounting, but also yields important information on the potential of fuel substitution with rising urban incomes and hence future energy infrastructure needs.

the United States, the European Union, and Australasia (i.e., Australia and New Zealand)). In these regions urban energy use is estimated to range from 69% (European Union) to 80% (United States) of the primary energy use of these regions, which reflects their high degree of urbanization. For China the estimate is 75%, despite a comparatively lower urbanization rate (41% compared to 81% in the United States), but is explained by the substantially higher urban energy use in Chinese cities compared to the national average because of higher urban incomes and industrial activities. The results of the 'upscaling' of these four regional sets of data to the global level are not reported separately by region by IEA, so only global totals are discussed here.

The IEA (2008) estimates urban primary energy use at the global level to amount to some 330 EJ in the year 2006, or 67% of world primary energy use. Using an average global primary-to-final energy conversion efficiency of about 69%, the estimate translates to 230 EJ urban final energy use worldwide, which is in good agreement with the IIASA study results reported below. Estimates are also provided by major primary energy source and for electricity, assuming that the primary energy mix of cities is the same as at the national or regional average. This assumption is problematic, especially for countries of low-income, low-urbanization, particularly in Asia and Africa, where available data suggest that urban energy use structures are, in fact, very different from rural and national averages. Urban energy use is invariably characterized by much higher shares of grid-dependent energy carriers (electricity and gas) and by much lower reliance on traditional biomass fuels. This simplifying assumption in the IEA (2008) study also diminishes the plausibility of the study's scenario projections by primary energy carrier to 2030, where total urban primary energy use is projected to grow by some 56% from 2006 to 2030. In the IEA reference scenario almost 90% of global energy growth to 2030 is projected to result from urban energy use.

The IIASA study follows a different approach. Drawing on methods and data sets (see Grubler et al., 2007) developed for spatially explicit GHG emission scenarios, the IIASA study used spatially explicit GIS data sets of urban extents, constrained to be consistent with the latest UN WUP statistics (see Section18.2.2 above) for the year 2005 as initial input. In a subsequent step, national level final energy use data by fuel (traditional biomass and electricity) as well as by end-use activity (primary, light and heavy manufacturing industries, households, and transportation) were downscaled to the grid-cell level in proportion to available spatially explicit activity variables (population, GDP, light luminosity, etc.) under a range of plausible algorithms (hence the study provides central as well as minima/maxima estimates to illustrate uncertainty). The scenarios of individual final energy use categories were then aggregated per individual grid-cell and overlaid with the urban extent map to derive the total estimated (direct) final energy use (including noncommercial traditional biomass fuels) in urban areas. Table 18.7 summarizes the results for the 11 GEA regions and five GEA world regions, as well as for the global total.

Globally, urban final energy use in the IIASA study is estimated to range from 180 to 250 EJ with a central estimate of 240 EJ, or between 56% and 78% (central estimate, 76%) of total final energy. So, in terms of final energy use (as opposed to primary energy use reported in the IEA study), cities use 240 EJ, or some three-quarters, of final energy worldwide. The absolute amounts are in good agreement with the IEA (2008) study discussed above, at least globally.[13] Readers should not be confused by the somewhat higher urban percentage (76%) of urban *final energy* use of the IIASA study when compared to the 67% estimate of the IEA for *primary energy* use. As discussed above, the assumed identity in urban fuel and energy mix with national and/or regional averages in the IEA study underestimates the level of high-quality, processed-energy forms in urban areas that entail correspondingly higher upstream energy-conversion losses. If this simplifying assumption in the IEA calculations could be relaxed, the corresponding urban primary energy estimate would become higher and much closer to the three-quarter benchmark of the IIASA study.

These observations are corroborated by commercial final energy use in urban areas, i.e., excluding traditional biomass use. For industrialized countries, estimates of urban commercial fuel use are identical to the totals reported in Table 18.7. Major differences exist, however, for some developing regions. For sub-Saharan Africa, estimates suggest that 4 EJ, or some 80% of all commercial energy use, can be classified as urban (compared to 8 EJ and 54% for total final energy, see Table 18.7). Differences for South Asia are also noticeable: 8 EJ, or 71% of final commercial energy, are classified as urban, compared to 10 EJ and 51% for total final energy. Differences for the other developing GEA regions are comparatively minor, as little noncommercial energy continues to be used in cities. The higher urban share in commercial energy results both from higher urban incomes and better urban energy access and infrastructure endowments, particularly the much higher degrees of electrification in urban areas.

Nonetheless, despite some uncertainties[14] (see Table 18.7), both the IEA and the IIASA estimates confirm a highly policy-relevant finding: While some 50% of the world's population is urban, *urban energy already dominates global energy use*, which means that the energy sustainability challenges need to be solved predominantly for urban systems.

13 The lack of available IEA regional estimates limits the possibilities for a more detailed comparison, but in the reported four IEA regions, urban energy use is within the respective minima/maxima regional values of the IIASA study.

14 The main source of uncertainty for the ranges reported in Table 18.7 is the fuzziness in delineating urban areas and population and hence the attribution of national energy use to the urban category. Conversely, the uncertainty in energy statistics is comparatively small, with the main uncertainty source being the lack of reliable data on urban noncommercial (traditional biomass) energy use, particularly in Africa.

Table 18.7 | Estimates of urban (direct) final energy use (including traditional biomass) for the GEA regions and the world in 2005 (in EJ and % of total final energy). See text for a discussion of urban commercial energy use and its corresponding (somewhat higher) urban share.

18.3.2 GEA City Energy Data and Analysis

18.3.2.1 The GEA City Energy Data Base

An effort to compile a database with literature values of energy use on the urban scale was conducted as part of this assessment to improve understanding of the variation in energy demand of urban areas (for an example of such analyses, see Steemers, 2003).[15] The study, therefore, chose a cross-sectorial approach to compare as large a number of urban areas from as wide range of regional settings, geographies, sizes, and functions as possible, with minimal definitional constraints with respect to urban system boundaries so as to maximize data availability. In terms of energy-use, data are reported at the level of *total (direct) final energy use*, as this level of analysis creates the least ambiguity in terms of energy accounting and is also the indicator most widely available and comparable among case studies. (Accounting for primary energy equivalents or GHG emissions requires assumptions on boundary definitions, conversion factors, and efficiencies, etc., which introduce additional uncertainties in the comparisons.) Given the extreme paucity of consumption-based estimates of urban energy use (e.g., via I-O techniques), the decision to focus the database on a production approach was also straightforward.

15 A more complete GEA Chapter 18 working paper on the GEA city energy data base and its data analysis is posted on the GEA website, www.globalenergyassessment.org.

18.3.2.2 Data Coverage

Three categories of urban statistical data were brought together in the GEA City Energy Data Base from a variety of sources: population statistics (UN, 2008), energy statistics (e.g., Dhakal, 2009; Kennedy et al., 2009; Kennedy et al., 2010), and economic statistics on gross regional economic output (or GRP, which is the urban-scale equivalent of national GDP) converted into a common 2005 denominator in purchasing power parity (PPP expressed in International$ – $Int_{2005}$$) terms, including Eurostat (2008) and PriceWaterhouseCoopers (2007). While population statistics are routinely collected at various levels of spatial resolution, this is rarely the case for both economic and energy data. Coherent data sets were, nonetheless, found for 200 urban units, of which 132 were from UNFCC Annex 1 (i.e., industrialized) countries and 68 were urban areas located in non-Annex-1 (i.e., developing) countries. Details on data-source limitations, as well as further statistical analyses, are reported in a GEA Chapter 18 Working Paper (Schulz, 2010a).

18.3.2.3 Analysis

Comparisons of urban scale and national scale data

This section compares data on energy use per capita, (urban) per capita income (GRP/GDP), and energy intensity of GRP/GDP at the urban scale with their national scale metrics.

Table 18.8 | Comparison of per capita urban final energy (GJ/capita), GDP (1000 $Int_{2005}$$/capita) and energy intensity (MJ/Int$) statistics (number of observations and indicator values) at the urban and national levels. Data cover 200 urban areas, of which 132 were located in Annex-1 countries. Reported data refer approximately to the year 2000, albeit different city studies report different base years. Average and standard deviations (SD) are presented for three sample groups: 'lower,' all those cities in which urban indicators are below the respective national averages; 'higher,' indicators are higher than the national average; and 'Total,' indicators for all cities in the sample taken together.

		count (# of cities) higher/lower than national average			statistical values in GEA city energy data base					
					average	SD	average	SD	average	SD
		Energy/cap.	GDP/cap.	Energy/GDP	GJ/cap.		GDP/cap.		MJ/$

	total	200	200	200	99	65.4	25643	13695	5.3	5.2
UNFCC Annex-1 countries	lower	107	67	93	93.5	23.2	33093	10274	3	0.9
	higher	25	65	39	171.9	132.3	29018	9677	6.4	4.6
	total	132	132	132	107.6	66.3	32360	10256	3.6	2.5
Non Annex-1 countries	lower	27	27	31	40.3	31	11453	8329	3.9	1.9
	higher	41	41	37	98.7	60.5	9792	4711	11.5	8
	total	68	68	68	79.5	59.2	10337	6114	9	7.5
Asia w/o Japan	lower	13	15	18	55.2	41.1	14538	14112	4	1.9
	higher	37	35	32	87.9	37.8	9938	4905	10.1	5.6
	total	50	50	50	83.3	41.3	10580	6851	9.3	5.6
Latin America, Middle East, Africa	lower	14	12	13	42.8	36.1	10121	4146	4.7	3.8
	higher	4	6	5	198.5	130.1	8446	2127	24.5	15.2
	total	18	18	18	70.5	89.7	9757	3933	8.4	11

Table 18.8 presents the overall results and a regional breakdown by status regarding Annex-1 versus non-Annex-1 assignation and geographic regions. Demographic data at the national scale are derived from UNDESA (2008; 2010), national energy statistics from IEA energy balances (IEA, 2010a; 2010b), and economic data from the International Monetary Fund (IMF, 2010).

Per capita energy use

An initial observation is that almost two out of three urban areas have a *lower than national average (direct) final energy use on a per capita basis*. This trend is more pronounced (107 out of 132) among Annex-I countries, which are overrepresented in this sample (132 out of 200). The main reason for this is the effect of urban economic structures (a higher share of less energy-intensive service activities compared to national averages) and, to a lesser degree, the effect of urban density on lower transport energy use (more public transport and soft mobility modes compared to national averages that reflect rural automobile dependence).

In non-Annex-I urban areas the reverse pattern is observed, with more than two out of three urban areas having *higher per capita final energy use* compared to their respective national averages. Among non-Annex-I countries there is pronounced *regional heterogeneity*: Africa and Latin America share the prevalence of *lower than national average urban per capita final energy use*, in contrast to Asia where urban per capita final energy use is predominantly (37 out of 50 cases) *higher than the national average*. These patterns reflect primarily the different influences of income with the urban-rural income differential, being particularly pronounced in Asia as reflected in a corresponding higher per capita final energy use gradient.

To explain these differences requires further analysis, but preliminary findings suggest that differences in levels of incomes and in economic structure (degree of service versus industry orientation of urban economies) are likely to be the main explanatory variables. In general, the number of observations in rapidly growing economies of non-OECD Asia is much larger in the sample than those of Latin America and Africa (50 vs. 18), illustrating the need for improved energy information in urban settlements in these regions particularly.

Figures 18.7 and 18.8 summarize this statistical analysis, showing all the city observations as a cumulative plot (over population) sorted by decreasing per capita final energy use. The color code indicates whether a city is above (red) or below (blue) its respective national average. The inverse per capita energy use pattern of cities in Annex-I versus non-Annex-I countries is clear from this comparison. On average, the *lower energy-use cities in Annex-I countries have a final energy use that is one-third lower than the Annex I national average*. For non-Annex-I countries the relationship is inverse: *most non-Annex-I cities have higher (about twice) per capita final energy use* than their respective national averages, being in the same ballpark as the lower energy use city sample in the Annex-I countries (at some 100 GJ/capita).

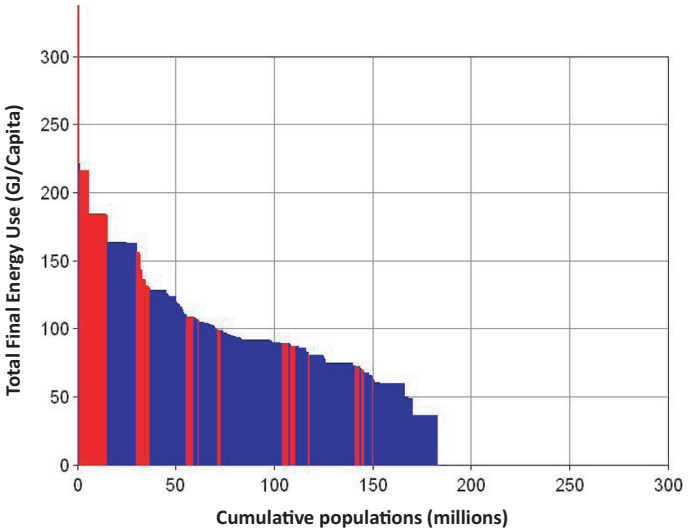

Figure 18.7 | Per capita (direct) final energy use (GJ) versus cumulative population (millions) in urban areas (n =132) of Annex-1 (industrialized) countries. Red indicates urban areas with per capita TFC *above* the national average. Blue indicates per capita final energy *below* the national average.

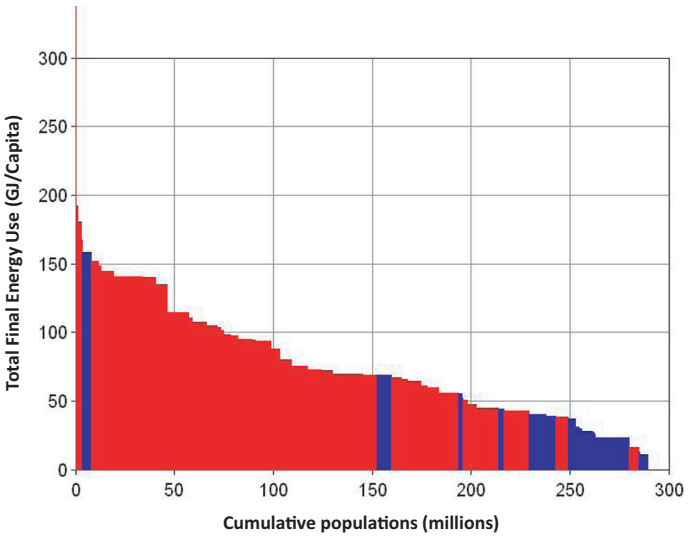

Figure 18.8 | Per capita (direct) final energy use (GJ) versus cumulative population (millions) in urban areas (n = 68) of non-Annex-1 (developing) countries. Red indicates urban areas with per capita TFC *above* the national average. Blue indicates per capita final energy *below* the national average.

These conclusions only refer to the (direct) final energy use metric adopted for the comparative analysis of our sample of 200 urban areas.

Evidence suggests that for Annex-I country cities the lower final energy use is likely to hold only for the production-accounting approach adopted for this comparison. Adding 'embodied' energy use (corrected for net trade of imports and exports of manufactured goods and services from and to urban economies) is likely to weaken the conclusion of a lower urban energy footprint in cities of Annex-I countries compared to the national average (see Section 18.2.4 above) as lower (direct) final urban energy use is likely to be (largely) compensated by higher 'embodied energy' use associated with higher urban incomes. And yet, the lower (direct) final energy use of many urban compared to rural areas in Annex-I countries illustrates well the *urban comparative advantage for a sustainability transition*: urban areas with their corresponding more energy-efficient compact settlement structures and lesser (energy-intensive) automobile dependence and greater potential for efficiency improvements through energy 'recycling' (i.e., cogeneration and heat cascading) have larger efficiency-leverage potentials compared to those of rural areas. The challenge to reduce the energy and environmental footprint from (over)consumption (i.e., embodied energy) is not unique to urban dwellers as it applies equally to rural ones in Annex-I countries.

The situation of cities in non-Annex-I countries, particularly in Asia, is markedly different. Compared to rural areas, cities not only have higher (direct) final energy use, they also have generally much higher incomes. Thus, the urban-rural gradient in terms of per capita (direct) final energy use is amplified yet more by higher urban incomes, which further increases the rural-urban energy gradient when considering the 'embodied' energy use associated with consumption. Given the dynamics of urbanization trends (see Section 18.2.1) it is thus fair to conclude that the sustainability 'hot spot' in the decades to come will reside particularly in the rapidly growing cities of non-Annex-I countries, especially in Asia.

Per capita income

Regarding per capita income the data sample reveals much more heterogeneity than the popular conceptions of invariably rich urbanites.[16] Almost half of the urban areas in our sample had per capita GRP/GDP values below the national average. Again, the patterns diverge between Annex-I countries (where this trend is driven by the large number of relatively deprived smaller UK urban centers in the data sample, but also by such prominent examples like the capital of Germany, Berlin) and non-Annex-I countries.

In non-Annex-I urban areas the majority showed above national average per capita GRP/GDP values. In Asia, two out of three urban areas had GRP/GDP above the national per capita average. In Africa and Latin America, just over one-third of the urban areas had GRP/GDP values that exceeded the national per capita average, but two-thirds ranked below it.

Energy Intensity

Regarding energy intensity of urban GRP/GDP, the majority of urban settlements studied showed lower than national average energy intensities,

16 GRP data is provided only by a limited number of statistical offices or other sources. They differ in methodology and are not always strictly comparable. A more detailed discussion of economic measurement issues at the urban scale is beyond the scope of this energy assessment.

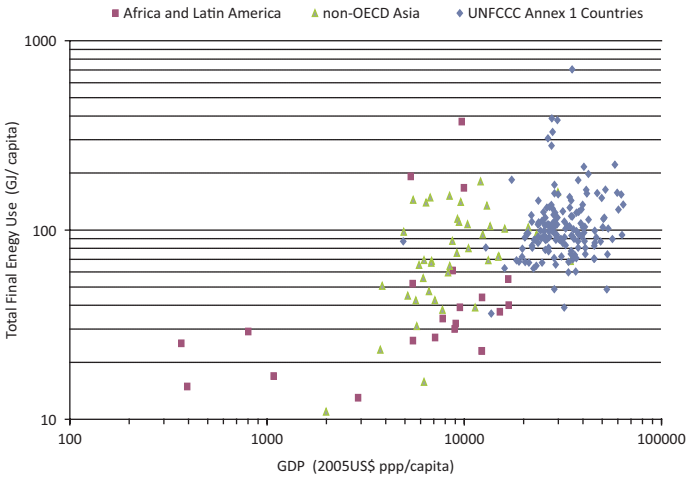

Figure 18.9 | Comparison of urban total final use (TFC) and urban income (GRP/GDP at PPP in $Int_{2005}$$) per capita for cities in Annex-I and non-Annex-I countries.

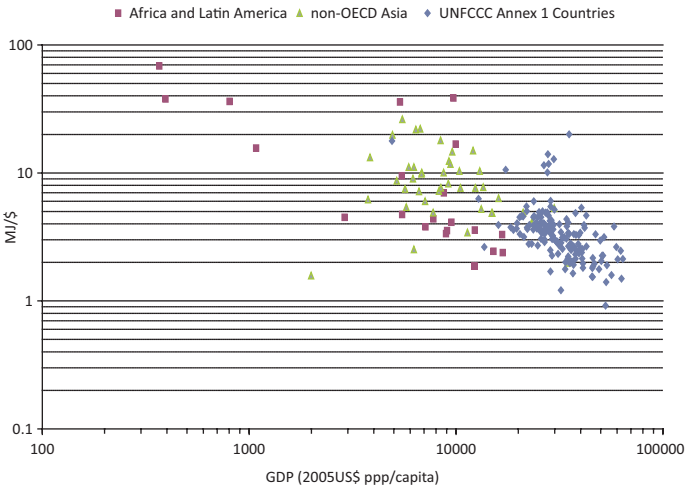

Figure 18.10 | Comparison of urban energy intensity and urban per capita income (at purchasing power parities) for cities in Annex-I and non-Annex-I countries.

which indicates the dominance of less energy-intensive tertiary sector activities in urban areas. In Annex-I countries more than two out of three settlements show lower than national level energy intensities of GDP. In the non-Annex-I countries the general trend is almost balanced, with just a few more cases of urban energy intensity that exceed the national average values. Again, the Asian urban areas show a very different pattern to those from the Latin America, Middle East, and Africa regions. Three out of four urban areas in non-OECD Asia have energy intensities that exceed the national average, while four out of five of the African, Middle East, and Latin American urban cases have the same pattern as OECD countries, with urban area energy intensities below their respective national average.

General observations

For the non-Annex-I urban areas at least three general patterns of energy use can be discerned.

One is the lower end, with final energy use under 30 GJ/capita. Per capita income is mostly less than 5000 PPP$/capita and energy intensity is, in many cases, also quite low, below 5 MJ/$. This low energy intensity in low-income, non-Annex-I cities does not necessarily suggest highly efficient energy systems, but rather different consumption structures (particularly lower private transport energy use). In all likelihood, the low energy intensities may also reflect an underreporting of noncommercial, traditional biofuels used by low-income urban households.

The medium range of per capita final energy use in non-Annex-I cities is from 30–100 GJ/capita and coincides with a wide range of incomes and energy intensities.

Heavy industrial urban areas show yet higher per capita final energy use of up to 350 GJ/year and over a highly variable range of income levels. In practically all urban settlements of the third group of non-Annex-I countries energy intensity is above 10 MJ/$ (up to 39 MJ/$ in the sample).

Patterns for Annex-I cities are markedly different. The Annex-I city panel in general appears more coherent in final energy use patterns. First, the correlation between higher urban incomes and higher final energy use tends to weaken significantly, with richer cities not necessarily using more (direct) final energy on a per capita basis (but highly likely to use much more embodied energy compared to poorer cities). Second, there is a strong and inverse correlation between urban incomes and energy intensity, with the latter falling with rising urban incomes. Only three out of the 118 Annex-I urban areas show energy-intensity values above 10 MJ/$ and the vast majority are below 5 MJ/$.

Variable correlations

Figure 18.9 presents the overall positive correlation between per capita incomes and (direct) final energy use. The general positive correlation, familiar from national level analyses, is also found at the urban scale. However, the variation appears to be larger at the urban level than at the national scale, which suggests a much broader spread for path-dependent urban development trajectories. Also, within the panel of Annex-I countries there is a large variation in energy use per capita (with some urban areas using more than 600 GJ/capita final energy). A proposed 'turning' (or saturation) point cannot be identified at a statistical significant level in this data set, which covers GRP/GDP ranges up to about 80,000 $Int_{2005}$$/capita (in PPP terms), despite a visible weakening of the income-energy use link for high-income cities.

Figure 18.10 presents the relation of GRP per capita and energy intensity of GRP. Trends in non-OECD Asian cities come closest to the often proposed 'hill' (Goldemberg, 1991), with a peak in energy intensity at about 10,000 PPP$/capita and a pronounced decline in energy intensity at higher per capita incomes. At lower income ranges, however, the data in our sample are sparse, and often also exclude the dominant noncommercial traditional biofuels, so the above findings are consistent with the observation of a 'hill' in the development of *commercial* energy intensity (Goldemberg, 1991) against a background of continuously

falling *total* (including noncommercial) energy intensities with rising incomes (see Nakicenovic et al., 1998) as evident in the cities of Africa and Latin America in Figure 18.10.

18.4 The Urban Energy Challenges

The urban energy challenges are embedded within overall social, economic, and environmental development challenges and their numerous interdependencies and linkages. This energy assessment focuses on the interdependencies that bear directly on urban energy. The linkages between development and energy are most straightforward in the area of the literature on 'energy poverty,' energy access, and adequate housing and transport access for the urban poor. Hence the discussion begins with a discussion of energy access and poverty within an urban context (Section 18.4.1). The discussion then moves on to the nexus of urban energy use and urban environmental quality and the challenges imposed by the high densities of energy demand and the corresponding need for efficient and low-emission energy systems (Section 18.4.2). Lastly, Section 18.4.3 discusses the challenges for urban energy infrastructures, including reliability and security.

Other urban development challenges with more indirect implications on energy, such as urban transport, land-use, and density planning, are discussed Section 18.5.

18.4.1 Energy Access and Housing for the Urban Poor

18.4.1.1 Introduction

In the development literature, energy is not generally recognized as one of the basic needs (Pachauri et al., 2004), although it is in discussions of poverty in high-income nations (where it is referred to as 'energy poverty,' see Boardman, 1993; Buzar, 2006). One reason for this absence is that one of the main indicators of 'energy poverty' in high-income nations is the substantial proportion of household income spent on fuels and electricity (typically more than 10%). However, this is not an appropriate measure for much of the urban population in low-income and some middle-income nations because their incomes are so low in relation to the costs of food and necessities other than food that their energy use is very low. This is both in the energy used within their homes (lighting, cooking, and, where relevant, space heating and appliances), in the energy implications of the transport modes they use, and, for those who are self-employed, in the energy used in their livelihoods. Thus, the main indicator for their 'energy poverty' is in the inadequacies of the energy they can afford and in the poor quality of the energy sources they use (Boardman, 1993; Buzar, 2006) which in this assessment is referred to as "energy access." Such individuals or households also have so few consumer goods that their individual embodied energy is also low.

Thus, for nations with a proportion of fuel use from noncommercial fuels and where low-income urban households keep energy expenditures down by using dirty fuels (including wastes) or cutting fuel use, the proportion of income spent on energy is not a good indicator of poverty. In addition, an analysis of poverty in relation to energy should also consider the time and effort used to obtain needed fuels, the health implications (including those that arise from indoor air pollution and the risks of fire and burns), and the quality and convenience of the fuels used to meet daily needs (i.e., in space heating or cooling, and for hot water). Pachauri et al. (2004) suggest that, ideally, the analysis of the adequacy of energy should include primary energy use, end-use energy (especially electricity), useful energy (e.g., whether the primary or end-use energy delivers the energy needed), and the quality and adequacy of energy services for households (including transport). However, data are often only available for the first two of these. Moving out of poverty involves shifts away from the dirtier and less convenient fuels[17] and obtaining access to electricity, as well as keeping down total monetary expenditures on energy.[18]

Thus, the two most common implications of poverty in regard to energy use among urban populations in low- and most middle-income nations are, first, use of the cheapest fuels and energy-using equipment (including stoves, which bring disadvantages, especially in regard to indoor air pollution, inefficient fuel combustion, and convenience) and, second, no access to electricity. Low-income households may also limit the number of meals (in extreme circumstances to one a day) to save money both on food and cooking fuel. Poverty is also evident in the lack of space heating within cold climates or seasons – although this is difficult to measure as expenditure surveys cannot identify what consumers forgo. Owners of home-based enterprises often make significant energy purchases. Urban poor households often face much higher risks of burns and scalds for household members (especially children) and of accidental fires, underpinned by a combination of extreme overcrowding (often three or more people to each room), unsafe fires or stoves, the absence of electricity for lighting (candles and kerosene lights are used), housing built of flammable materials, high-density settlements, a lack of firebreaks, and no emergency services, including fire services (Hardoy et al., 2001; Pelling and Wisner, 2009). All the above are also often associated with homes and livelihoods in informal settlements – which helps explain the lack of electricity (with electricity utilities unwilling or not allowed to operate there), the poor-quality housing, and the lack of provision for fire-prevention and emergency services.

17 This includes a shift to 'clean' fuels – clean in the sense of minimizing raw pollution and health impacts for the users – for instance, with electricity and gas or energy derived from renewable energy sources being 'clean' and coal and raw biomass being 'dirty' (how dirty these are depends on the technology used in the home). Kerosene and charcoal fall between these two extremes. The term 'clean fuels' is ambiguous in that it is used to mean different things – for instance, for fuels or energy sources that have low or no CO_2 emissions rather than lower health impacts for users. In addition, electricity at the point of use may be 'clean,' but it often comes from coal-fired power stations that have high CO_2 emissions and often high levels of pollution.

18 For a more detailed discussion see also Chapter 4.

Table 18.9 | The housing submarkets used by low-income urban dwellers and their energy-use implications.

Housing type	Energy implications in the home	Energy implications for transport
Rooms rented in tenements	Typically one room per household; often electricity available, but usually too expensive to use for cooking and space heating	Usually close to sources of livelihood or demand for casual work (hence this type of accommodation is in demand)
Cheap boarding houses/dormitories (including hot beds)	Very low energy use; no provision for cooking?	As above
Informal settlement 1: squatter settlements (in many cities these house 30–60% of the entire population)	In low-income nations, usually reliance on dirtier fuels and lack of electricity; in many middle-income nations less so; for many households, part of fuel/electricity expenditure is for livelihoods in the home; illegal electricity connections may be common; often high risks from accidental fires	Many in peripheral locations, which implies high transport costs in time and money; better located squatter settlements often become expensive through informal rental or sale
Informal settlement 2: housing in illegal subdivision	More expensive than illegal land occupation, but less at risk from eviction and often with more provision of infrastructure (including electricity) or at least more possibilities of provision as the land occupation is not illegal	Many in peripheral locations which implies high transport costs; in large cities, the cheapest illegal subdivisions can imply several hours traveling a day to and from sources of income
Accommodation at the workplace	Common for single men in some cities; extent not known and includes apprentices	
Pavement dwellers and those who sleep in open or public spaces	Very low incomes so very low fuel use	Walk to work

Source: Hardoy and Satterthwaite, 1989; Yapi-Diahou, 1995; Harms, 1997; Mitlin, 1997; Mwangi, 1997; Bhan, 2009.

However, it is important to also consider the cost burdens of energy to low-income households who have access to electricity and who use cleaner, more convenient fuels. For instance, in cities such as Mumbai (India), low-income households who move from informal to formal housing benefit from access to electricity, but often find it difficult to pay the bills. Here, there are more parallels with what the literature refers to as 'energy poverty' in high-income nations. Buzar (2006) notes that increasing numbers of households in former communist states in Eastern and Central Europe[19] face difficulties in affording energy, in part because of significant energy-price increases as subsidies are removed, and in part because of the failure of the state to develop safety nets to protect low-income groups. This leaves many families with no option but to cut back on energy purchases, a problem further aggravated by cold climates and the poor energy efficiency of the building stock.

18.4.1.2 Housing Quality and Location

Around 800 million urban dwellers in low- and middle-income nations live in poor-quality, overcrowded housing with inadequate provision for basic services (UN HABITAT, 2003; 2008). A taxonomy of their housing submarkets with associated energy implications is given in Table 18.9.

Low-income groups in urban areas face limited choices in renting, buying, or building accommodation that they can afford and so have to make trade-offs between a good location, housing size and quality, infrastructure and service provision, and secure tenure (see references Table 18.9). Good locations in relation to income-earning opportunities mean that transport expenditures can be kept down and more central locations usually have more possibilities of infrastructure and service provision. But they are also more expensive and generally have less possibility of space and of keeping down housing costs through illegally occupying land and self-built homes. At their most extreme, to obtain central locations, low-income groups live in shacks built on pavements or waste dumps or in small rooms with more than three people to a room or share beds (so a single person pays to sleep in a bed in a shared dormitory with each bed serving two or three people over a 24-hour period, known as hot beds).

One of the most extreme examples of this are the tens of thousands of pavement dwellers in Mumbai, where the choice to live on the pavement (and usually with low lean-to shacks too small to sleep in) is from a combination of their very low incomes, the central location of where they earn their incomes (they walk to work), and the impossibility of affording transport costs from less central locations (SPARC, 1990). Another example are households in Indore (India) who choose to live on land sites adjacent to small rivers that flood regularly. These have economic advantages because they are close to jobs or to markets for the goods the households produce or collect (many earn a living collecting waste). The land is cheap and, because it is public land, the residents are less likely to be evicted. These sites have social advantages because they are close to health services, schools, electricity, and water, and there are strong family, kinship, and community ties with other inhabitants (Stephens et al., 1996).

Rented accommodation or land on which houses can be built is cheaper in more peripheral locations and often more distant from income-earning opportunities – the cheaper the cost and the greater the possibility of

19 This section does not cover high-income nations and low- and middle-income nations that were formerly part of COMECON (termed countries undergoing economic reform in GEA).

Table 18.10 | The proportion and number of the urban population that lacks electricity and access to 'modern fuels' in developing countries, least-developed countries, and sub-Saharan Africa.

Percentage and number of the urban population	Developing countries	Least-developed countries	Sub-Saharan Africa
Lacking access to electricity	10% (226 million)	56% (116 million)	46% (124 million)
Lacking access to modern fuels	30% (679 million)	63% (130 million)	58% (156 million)

Source: UNDP and WHO (2009).[20] Statistics on the urban population are drawn from UN Population Division (UN DESA, 2008) and are for 2005. The dates for the statistics on access to electricity and modern fuels vary by country, with most being between 2003 and 2007.

building a home illegally (and so avoid paying a full rent, which is often among the main reasons why distant informal settlements develop). But this means high time- and monetary-transport costs, and it is difficult to establish the high transport costs for those living in peripheral locations because most of the data on the proportion of income spent on transport are averages for cities. In addition, it is likely that many household surveys under-represent those who live in informal settlements – for instance, a lack of formal addresses and maps makes it difficult to include their inhabitants in surveys or those responsible for collecting data fear to work in informal settlements (for an example of this, see Sabry, 2009). Peripheral locations also constrain the inhabitants' access to economic opportunities, as many locations are too distant or too expensive to commute to.

18.4.1.3 Urban Populations and Energy use in Low- and Middle-Income Nations

There are some general statistics on the forms of energy use for urban populations – for instance, in what fuels (and mix of fuels) are used and whether or not they have access to electricity (Table 18.10). However, there are no general statistics on how fuel use and access to electricity vary within nations' urban populations or within cities by income group. In part, this is because many 'energy' statistics for individuals or households are only available for national populations. Where these are disaggregated, it is often only as averages for 'urban populations' when there are very large differences between different urban centers and between different income groups within each urban center. In part, this is because the documentation of 'energy' provision deficiencies has not been given the same level of attention as, say, deficiencies in provision for water and sanitation. The only exception is the very considerable documentation on the health impacts of pollution from the use of 'dirty' fuels (and other factors, including poor ventilation and inefficient stoves), although much of this literature is for rural households and perhaps underestimates the extent of this problem among urban poor households.

Table 18.10 highlights the very considerable proportion of the urban population in low- and middle-income nations that lacks access to modern fuels – 30% (which implies close to 700 million urban dwellers). A higher proportion has access to electricity, but about half the urban population within the least-developed nations and within sub-Saharan Africa lack access to electricity. In sub-Saharan Africa alone, this implies that around 120 million urban dwellers lack access to electricity. For all developing countries taken together some 230 million urban residents lack such access.

Particular studies suggest that it is common for urban poor households in Africa and Asia to use a mix of fuels – for instance, different fuels for different kinds of food and fuel-switching at certain times of year when fuel prices or household incomes change (see Pachauri and Jiang, 2008 for China and Meikle and North, 2005 for Arusha). Regional and seasonal differences may be significant, and households are also influenced by subsidies and incentives, fuel availability, and cultural preferences. Policymakers rarely understand these complexities.

The available data on energy use by low-income urban dwellers range from very large numbers who use little or no fossil fuels and electricity (i.e., wood, dung, straw, and charcoal) through those who use kerosene and coal or coal-based fuels to those who use gas (bottled or piped) and electricity. For electricity, in some nations almost all urban households (including low-income households) have electricity and in others only a very small proportion of urban households have electricity.

Available studies also give examples of the scale of the differentials in energy used between high-income and low-income households within particular urban centers; some show that these can vary by a factor of 10 or more, but of course the scale of the differentials depends, in part, on how 'the urban population' is divided for this comparison (e.g., differentials will be greater if the richest and poorest deciles are compared instead of the richest and poorest quartiles).

The two nations with the world's largest urban populations are China and India (by 2010 these accounted for more than a quarter of the world's urban population). In India, fossil-fuel based energy sources increasingly dominate the energy mix of urban households, although biomass (including firewood and dung) continues to be used, especially by the lowest income groups. In addition, during the mid-1990s there was an evident rise in the use of liquefied petroleum gas (LPG) and

20 This source is inconsistent in how it reports some of the figures for access to electricity; the figures above for the least-developed countries and sub-Saharan Africa are from Figure 3, but the accompanying text (page 12) says that 46% of the urban population of least-developed countries and 56% of urban dwellers in sub-Saharan Africa lack electricity access. The report does not specify where its population figures come from, although it lists the UN Population Division's *World Population Prospects: the 2006 revision* in its sources.

electricity among urban households (Pachauri and Jiang, 2008). In China, among urban households there has been a shift away from the direct use of coal to gas and electricity (although coal is still important for a significant proportion of urban households). Energy use among urban households declined from 1985 to 2002 (from 9 GJ/capita to around 5 GJ/capita), because of a shift to more-efficient fuels (Pachauri and Jiang, 2008). Also, dependence on coal may not be reduced if coal-fired power stations are an important part of meeting the consequent rising demand for electricity.

Table 18.10 shows how most (90%) of the urban population in 'developing countries' had access to electricity and 70% had access to modern fuels (mostly gas) in 2007 – but also how the picture on energy access for urban populations was very different for the least-developed countries and for sub-Saharan Africa. When considering fuel use among urban poor households in all low- and middle-income nations, this varies from, at one extreme, continued reliance on fuelwood, charcoal, and waste materials (and no electricity) through to greater use of solid or liquid fossil fuels (coal and/or kerosene, often called transition fuels) and a proportion of households with electricity, and on to the use of cleaner fuels (LPG or connection to gas) and electricity.

This diversity in the forms of energy used is also likely to be present between urban poor households within most (but see above). The only obvious characteristics that all urban poor households share is limited purchasing power for energy (for all uses) and a desire to keep costs down, so their fuel use and fuel-energy mix is much influenced by the price and availability of different fuels and electricity. Having access to electricity at prices that low-income households can afford obviously represents a major advantage – for lighting and for key appliances (including fridges and, where needed, fans) and for the reduced risk of accidental fires. However, they will keep electricity use down (for instance, where it is expensive in comparison to other fuels, they may not use it for cooking or space heating) unless there is no better alternative (or they have made illegal connections to power grids that keep costs down).[21] Having gas for cooking and hot water (and, where needed, space heating) has great advantages of convenience and of low generation of indoor air pollution, but in many urban contexts it is only available as LPG canisters (and so less convenient and more expensive than gas piped to the home). This often makes it too expensive for large sections of the urban population.

Among the low-income households in urban centers in the lowest-income nations, fuel use is dominated by charcoal, firewood, or organic wastes (e.g., dung). The more access to fuels is commercialized, the less fuel is used. In many small urban centers in low-income nations, it may be that certain fuels (wood, dung, agricultural wastes, etc.) are cheap and that a proportion of the urban population can gather fuel rather than pay for it – but probably the larger the city, the greater the commercialization of all fuels. Also, the very limited space within the homes of most low-income urban households – especially those that live in central areas with, in many cases, less than 1 m^2/person – limits the capacity to store bulky solid fuels.

Table 18.11 | The main fuels used for cooking in urban areas in developing countries, least-developed countries, and sub-Saharan Africa (in percent of urban population using particular fuels).

Percentage of the urban population	Developing countries	Least-developed countries	Sub-Saharan Africa
Using wood, charcoal, and dung for cooking fuels	18	68	54
Using coal for cooking	8	3	2
Using kerosene for cooking	7	4	20
Using gas for cooking	57	20	11
Using electricity for cooking	6	4	11

Source: UNDP and WHO, 2009.

Fuel use for cooking

Table 18.11 shows the contrast between the proportion of the urban population using wood, charcoal, and dung in developing countries (less than one-fifth of households), in the least developed nations (two-thirds of urban households), and in sub-Saharan Africa (more than a half). In developing countries close to two-thirds of the urban population use gas or electricity for cooking; for the least-developed nations and sub-Saharan Africa, this is less than one-quarter. There are large differences in this within the least-developed nations and in sub-Saharan Africa. For instance, for many of these nations only a small percentage of the urban population has access to electricity.

For most nations with per capita GDPs under $1100, 85% or more of their urban population use wood and charcoal for cooking – and all these nations are in sub-Saharan Africa, except Haiti. For nations with per capita GDPs above $14,000 virtually all urban households do not use wood or charcoal. For nations with per capita GDPs of $1100–4000, the variations in the percentage of the urban population that use wood or charcoal are very large (UNDP and WHO, 2009).

Households select fuels for food preparation for reasons that include cost, availability, convenience, type of food, and cooking equipment, as illustrated by a study in Ibadan (Nigeria). Kerosene was the major cooking fuel for low- and middle-income households until subsidies on petroleum products were withdrawn in 1986. As a result of the increased kerosene and cooking-gas prices, surveyed households in 1993 had begun to use fuelwood, sawdust, and other cheaper energy sources. A follow-up in 1999 discovered that households had switched back to kerosene, while also reducing the frequency of cooking, eating cold leftovers, and substituting less nutritious but faster-cooking foods (Adelekan

21 Care is needed here: illegal connections are often not providing electricity free as the connection is through another household that charges for this or the occupants are tenants and have to pay the landlord extra for electricity.

and Jerome, 2006). A study of energy use in an informal settlement in the Cape Peninsular in South Africa showed how households that had legal electricity connections and meters could access 50 kWh/month free basic electricity, which encouraged them to cook with electricity rather than paraffin (Cowan, 2008).

Low-income urban households often cook with solid fuels that pose serious health threats to household members from indoor air pollution, especially for those with the longest exposure (see Chapter 4 for details). Among urban populations in many sub-Saharan African nations, wood and charcoal are still the most widely used cooking fuels (see, for instance, Ouedraogo, 2006 on Ouagadougou; Boadi and Kuitunen, 2005 on Accra; Kyokutamba, 2004 on Uganda; and van der Plas and Abdel-Hamid, 2005 on N'Djaména).

This reliance on charcoal by large sections of the population of major (and often rapidly growing) cities generated concerns regarding its contribution to deforestation, although a detailed study in several African nations in the late 1980s found very little evidence of this (Leach and Mearns, 1989) and a more recent review suggests that fuelwood is seldom a primary source of forest removal, although "in some of the areas where charcoal production is concentrated, this may be the case" (Arnold et al., 2006).

Urban dwellers in India are shifting to cleaner cooking fuels, although the shift between 1983 and 1999 was most evident among higher income groups. In 2000, less than 40% of the bottom two urban deciles cooked with clean fuels. And among the poorest urban groups, adoption of clean cooking fuels hardly increased from 1983 to 2000 (Viswanathan and Kavi Kumar, 2005). LPG and kerosene are highly subsidized in India, but nonpoor groups are the main beneficiaries and many low-income urban residents continue to cook with dirtier energy sources (Gangopadhyay et al., 2005; Pohekar et al., 2005).

Cooking with LPG is common in the Philippines, but poor urban households also buy kerosene or biomass fuels to keep costs down. In a survey of two low-income districts in metro-Manila, LPG was the main cooking fuel in 75% of households (APPROTECH, 2005). However, as LPG prices increased in 2004, low-income groups also began to cook with kerosene, fuelwood, or charcoal. Although residents intended to reduce expenditures, they still paid higher unit prices because they could only afford to purchase small quantities (APPROTECH, 2005).

High expenditures on energy

A considerable range of national and city studies and studies of particular settlements show how expenditures on fuels for household use are consistently burdensome for low-income households (but may not show up as high expenditures or high proportions of income spent on fuel, as discussed above). Examples of high expenditures on energy are:

- In Guatemala, cooking and lighting took up about 10% of household expenditures for the three poorest urban deciles in 2000 (ESMAP and UNDP, 2003).
- In Thailand, slum dwellers spent about 16% of their monthly income on energy (cooking, electricity, transport) in Bangkok and about 26% in Khon Kaen. Households in these slums with incomes below the poverty line spent 29% of total household income on energy in Khon Kaen and 18.5% in Bangkok – mainly because of the high cost of electricity (Shrestha et al., 2008).
- In Ethiopia, fuel and power took 11% of expenditure among urban poor (Kebede et al., 2002).
- In Sana'a, the capital of Yemen, the bottom two deciles spent over 10% of their incomes on electricity alone (ESMAP and UNDP, 2005).
- In Kibera, Nairobi's largest informal settlement, for over 100 households surveyed energy expenditures reached 20–40% of monthly incomes (Karekezi et al., 2008).
- In Rio de Janeiro (Brazil), many households in surveys in informal settlements were spending 15–25% of their incomes on energy (WEC, 2006).
- In Cairo (Egypt), households with incomes at the lower poverty line spent 8–20% of their income on electricity (Sabry, 2009).

Low-income households who obtain electricity through shared electricity meters can be charged higher rates because of rising block tariffs (examples in Kumasi (Ghana), Mumbai, and an informal settlement in South Africa are given by Devas and Korboe, 2000 and Cowan, 2008).

Space heating

Data on heating expenditures are limited, but it is clear that where space heating is needed, low-income urban dwellers can face high costs to keep warm. For instance, surveys in 1999 found that low-income city-dwellers in Armenia, Moldova, and the Kyrgyz Republic devoted 5–10% of their household incomes to heating (Wu et al., 2004). Poor households may also heat their homes with inefficient, polluting fuels to reduce expenditures. During the winter of 2002, Tbilisi's poor households who were not on the gas network resorted to using wood for heating and cooking (ESMAP, 2007). Wood prices were cheaper than those of other fuels, except natural gas. In Buenos Aires' peripheral settlements of Villa Fiorito and Budge, the average household relies on charcoal for space heating and cooking, with space heating taking up nearly 13% of household annual net energy use (Bravo et al., 2008). In the heart of South Africa's coal-mining country, residents of Vosman Township rely on coal for space heating, water heating, ironing, and cooking (Balmer, 2007). Even in the United Kingdom, four million households were deemed to live in fuel poverty in 2007 (defined by spending 10% or more of income on maintaining an adequate level of warmth) (UKDECC, 2010).

In China, coal is a key heating fuel for the poor, particularly in cold northern cities where heating may take up as much as 40% of households total energy needs (Pachauri and Jiang, 2008). Although data are not

specifically available on coal use for heating, national surveys indicate that 65% of the poorest urban households utilize coal (Pachauri and Jiang, 2008). Coal-using urban residents are exposed to extremely high levels of indoor air pollution (Mestl et al., 2007).

Lighting and access to electricity

There is a clear association between the percentage of the urban population with electricity and a nation's per capita GDP (UNDP and WHO, 2009). Almost all nations with GDPs per capita of US$6000 or more have 95–100% of their urban population with electricity. For nations with per capita GDPs below US$3000, there is a quite consistent picture of rising proportions of urban households with electricity, with some variation. There is more variation between US$3000 and US$6000.

However, were the sample frames for the urban households interviewed in the surveys from which this data comes rigorous in including the needed proportion of households that are in informal or illegal settlements? For instance, half of Kenya's urban population is said to have access to electricity in 2003, yet a survey in 1998 of informal settlements in Nairobi (which house half of Nairobi's population) found that only 17.8% had electricity (APHRC, 2002).

In most middle-income nations and some low-income nations, most of the urban population has access to electricity. By 2002, there was near-universal access to power in Caracas, Buenos Aires, and Rio de Janeiro (WEC, 2006). India's household surveys in 2004–2005 found that 91% of urban households used electricity; for Chinese city dwellers, household surveys reported that 96% used electricity in 2001 (Pachauri and Jiang, 2008). Many nations, including Colombia, Dominican Republic, Egypt, Indonesia, Jordan, Pakistan, and Ukraine, report that more than 98% of their urban population has electricity (UNDP and WHO, 2009). These positive developments illustrate that the proximity to existing energy infrastructure in urban areas enables rapid progress when dedicated policies of connecting urban poor are in place. Barriers of low income and limited grid extensions therefore can be overcome.

Thus, many cities and national urban populations have a high proportion of urban poor households with access to electricity. For instance, a study of energy-use patterns in slums in Bangkok and Khon Kaen in Thailand found almost 100% with electricity connections (Shrestha et al., 2008), although in Bangkok 32% of households were connected through their neighbors (Shrestha et al., 2008). Almost all 'slum' dwellers in Cairo have electricity connections (Sabry, 2009). In Mexico in 2000, access to electricity was enjoyed by 91–97% of the lowest-quartile households in cities along the US border (Peña, 2005). National surveys in 2001 found that over 80% of Pakistan's poorest urban deciles had electricity (ESMAP, 2006).

Access to electricity is not only an issue of quantities. Quality of service in terms of regularity, reliability and the duration of provision are of equal importance.

Table 18.12 | The cost per household (in current US$) of providing electricity in different cities.

City	Cost per household (US$)
Ahmedabad	114
Manila	154
Rio de Janeiro	226
Salvador	350
Cape Town	417

Source: USAID, 2004.

The costs of electricity access for the urban poor are generally low (Table 18.12). Nonetheless, some caution is needed in using the figures in Table 18.12 because it is not clear whether these are just the cost of extending electricity to these households or also include other costs, such as the costs of extending overhead lines and upgrading the power-generation system (USAID, 2004).

A study of the costs of different 'slum' upgrading programs in Brazil showed that the provision of electricity and lighting was 1–3% of total costs, although these were comprehensive upgrading programs that included provision of water and sewer connections for each house, and building homes for those that had to be rehoused (Abiko et al., 2007). The costs would be higher as a proportion of total costs within a more minimalist upgrading program – for instance, one that only provided communal water provision and drainage and not piped water and sewer connections to each household.

Further discussion on energy access issues beyond electricity is contained in Chapter 4.

18.4.1.4 Transport

When choosing where to live, low-income individuals or households have to make trade-offs between good locations for access to income-earning opportunities, to housing quality, size, and tenure, and to infrastructure and services. In most cities in low- and middle-income nations, a significant proportion of low-income groups live in peripheral locations because it is cheaper (and often less crowded) or there are more possibilities of obtaining land on which to build housing (although usually illegally). But peripheral locations usually mean high monetary and time costs in traveling to and from work and services. Thus, transportation costs can eclipse household spending on cooking, heating, and lighting.

Various studies of transport use and expenditures in cities or of urban poor communities show that public transport costs represent a significant part of total household expenditure. For instance, for the inhabitants of eight informal settlements in Cairo transport costs were a major burden. Many such settlements on the outskirts are not adequately served by the public bus network or the metro. Many inhabitants have to use more expensive privately operated microbuses for part of the journey

and a high proportion have to change to other buses or the metro for their journey. High travel costs were one reason why few children went to secondary school (Sabry, 2009). Other examples include:

- In Karachi, interviews with 108 transport users who lived in one central and four peripheral neighborhoods found that half were spending 10% or more of their income on transport (Urban Resource Centre, 2001).
- In Bandung City (Indonesia), interviews with a sample of 145 *kampong* residents found that nearly 7% of their monthly income was devoted to transport costs (Permana et al., 2008).
- In Buenos Aires, a 2002 survey found that the bottom quintile walked to work for 53% of their journeys, but they still spent over 30% of their family incomes on public transit (Carruthers et al., 2005).
- In Sao Paulo, a 2003 survey found that low-income groups spent 18–30% of their incomes on travel (Carruthers et al., 2005). Wealthy residents spent just 7% of their incomes on transport, but were able to travel far more frequently. The number of trips completed by Sao Paulo's poor was less than one-third of those completed by the highest-income residents.
- In Salvador (Brazil), low-income residents often live in the urban periphery and a survey of over 500 households in the poor neighborhoods of Plataforma and Calavera found that transport expenditures averaged 25% of monthly expenditures (Winrock International, 2005).

Thus, it is common in cities for low-income groups to face high transport expenses that curtail their travel possibilities and leave them with onerous journeys, often on foot. Transport costs also limit livelihood opportunities for low-income groups that live in peripheral locations, as the cost and time to reach parts of the city are too high. A 2003 survey in Wuhan, China, showed how prohibitively high transit costs resulted in the poor rejecting jobs far from their homes (Carruthers et al., 2005).

Some studies show how many low-income groups walk long distances to keep their transport expenditures down (see, for instance, Huq et al., 1996 for various cities in Bangladesh, and Barter, 1999 for central Bombay/Mumbai and Jakarta). So, while such individuals may pay little for transport costs, they 'pay' through long journey times and extra physical effort. In the survey of Wuhan, China (Carruthers et al., 2005), the bottom quintile reported walking for almost half of their journeys, while 27% of their travel was by public transit and 22% by cycling.

Marginalized neighborhoods may not be served by public transit, and low-income women can face particular challenges in accessing secure, efficient transportation (Watkiss et al., 2000). Informal buses have proliferated in many cities, and can help alleviate transport shortages (Zhou, 2000). However, in this unregulated sector vehicles are usually old and overcrowded, accidents are common, and customers are vulnerable to rising or erratic fares.

Table 18.13 | Grouping households in India by the amount of energy they use and the energy services available to them (average household of five persons) in Watt-years (1 Wyr = 31.55 MJ).

Energy services of households	Useful energy use per capita (Wyr)
Associated with extreme poverty: up to one warm meal a day, a kerosene lamp, possibly a little hot water	<15 W
Associated with poverty: 1–2 warm meals per day, a few kerosene lamps or one electric bulb, some hot water	15–30
Associated with above the poverty line: two warm meals a day, hot water and lighting, some small electrical appliances for groups with electricity, possibly a scooter	30–60
Associated with a comfortable level of well-being: two or more warm meals a day, hot water, lighting, some space heating, for groups with electricity possibly some space cooling and electric appliances, possibly a scooter or an automobile	60+

18.4.1.5 Differentials within Urban Populations

Various studies show how it is common for low-income urban households in low- and middle-income nations with electricity connections to use 20–50 kWh/month (see Kulkarni et al., 1994; Karekezi et al., 2008). This is a small fraction of average household use in the United States (640–1329 kWh/month depending on the region) or Europe (341 kWh/month). So it is likely that differentials of the order of 100 or more are present between the world's wealthiest and least wealthy households with electricity. Pachauri et al. (2004) considered how the amount of energy used and the quality of energy services available varied by income-group (Table 18.13).

18.4.1.6 Summary

Development literature focuses principally on provision of water and sufficient food, not on clean energy and electricity. Several hundred million urban dwellers in low- and middle-income nations lack access to electricity and are unable to afford cleaner, safer fuels such as gas or LPG (or even kerosene). Most are in low-income nations in Asia and sub-Saharan Africa. In many such nations, more than half the urban population still rely on nonfossil fuel cooking fuels with obvious consequences for health problems (and large health burdens) and for the time needed to obtain fuels. In many low-income nations, more than half the urban population also lacks access to electricity, even though urban population concentrations lower unit costs for providing electricity and gas (or LPG gas distribution). For a large part of the urban population that lacks clean fuels and electricity, the reasons are not that they cannot afford

these but that they face political or institutional obstacles to accessing them. Most live in informal settlements with no legal addresses and legal tenure, where they are also denied paved roads and provision for water, sanitation, and drainage, and often healthcare, schools, and emergency services.

A high proportion of urban dwellers in low- and middle-income nations find it difficult to afford their 'energy bills' (for fuel and, where available, electricity and expenditure on transport); these often take 10–15% of household income and for many a higher proportion.

However, in many middle-income nations (and all high-income nations) nearly all low-income urban dwellers have legal electricity connections and can afford clean fuels. The shift to clean fuels and the availability of electricity bring many advantages in terms of health, convenience, and time saved in accessing and using energy. If the cost of a legal connection to electricity and to natural gas supplies can be afforded and supplies are affordable and reliable, no time is needed to purchase or gather fuels, and then carry home solid or liquid fuels or LPG cylinders. Also, no space in the home is needed to store these. Reliable electricity supplies also bring many other obvious advantages – reliable, cheap, and safe lighting at night, the possibility of fridges, televisions, and electric fans, support for home enterprises, and a very large reduction in fire risk.

The costs of connection to an electricity grid and the use of electricity can be burdensome for low-income groups, but innovations have reduced these costs – for instance, rising tariffs with low prices for 'lifeline' electricity use (or in South Africa no charge for up to 50 kWh/month), pay-as-you-use meters, and standard 'boards' that remove the need for household wiring.

Climate change implications may pose problems for low-income urban dwellers obtaining electricity and clean fuels. However, the shift from dirty fuels to clean fuels produces a lower than expected contribution to global warming because of the inefficiencies in how dirty fuels are consumed and in the reduced contribution of fuel use to black soot aerosols. Thus, a shift to clean fossil fuels leads to major improvements in the global impacts associated with non-CO_2 emissions. In addition, current differentials in electricity use per household or in CO_2 emissions per household are likely to vary by a factor of at least 100 between the wealthiest households and the least-wealthy households.

The constraints on supporting the shift to clean fuels and providing all urban households with electricity are less in energy policy and far more in government policy and daily practice in regard to those who live in informal settlements and work in the informal economy. A large part of the population that lacks clean energy and electricity also lacks reliable piped water supplies and good provision for sanitation and drainage. They often lack access to schools and healthcare. Governments often ignore them, even though their settlements house 30–60% of the city population, most of its low-wage labor force, and many of its enterprises. It is mostly in nations where relationships between local government and the inhabitants of these informal settlements are not antagonistic, with widespread public support for 'slum' and squatter upgrading, that clean energy and electricity reaches urban poor groups.

18.4.2 Energy Demand and Air Pollution Densities, including Heat Island Effects

18.4.2.1 Introduction

The concepts of energy demand and pollution densities refer to the *quantity of energy* used and/or produced or the pollution emitted *per unit of land*. Their common denominator and driver is urban population density. Despite being of fundamental importance in an urban context, the literature on energy or pollution densities is surprisingly limited, apart from that on urban heat island effects, reviewed in detail in Section 18.4.2.4 below.

18.4.2.2 Urban Energy Demand Densities

This Section illustrates the concept of energy supply and demand densities both generally and by drawing from contrasting examples of two high-density megacities (Tokyo and London), as well as a small, low-density city (Osnabrück, Germany). A brief discussion of associated policy issues follows.

The classic reference on energy demand and supply densities remains Smil (1991), from which Figure 18.11 is adopted in modified form.

The customary unit for energy densities is Watts per square meter (W/m^2), referring to a continuous use of the power of one Watt over a year.

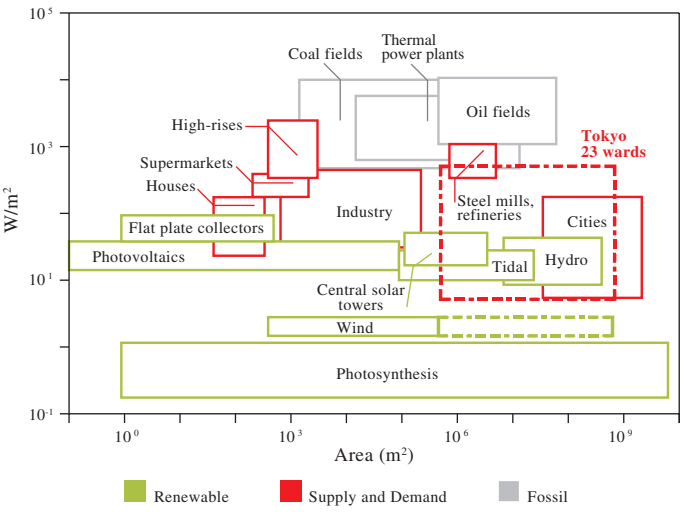

Figure 18.11 | Energy densities of energy supply from fossil (gray) and renewable sources (green) versus density of energy demand (red) for typical settings, in W/m^2 and m^2 area. Source: modified from Smil, 1991.

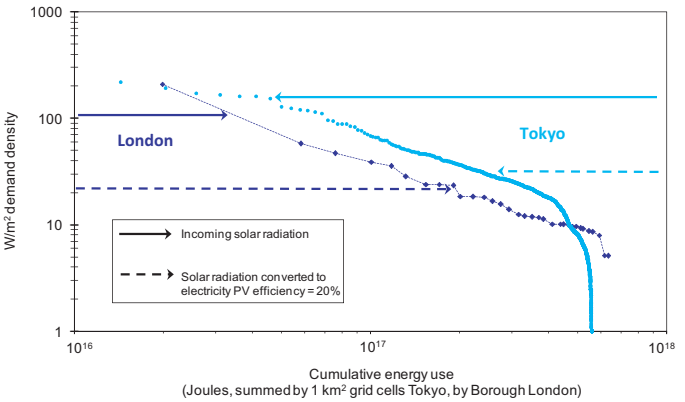

Figure 18.12 | Energy-demand densities (W/m²) for London (33 boroughs) and Tokyo (1 km² grid cells, 23 wards) versus cumulative energy use of these spatial entities (in Joules). For comparison the energy flux of incoming solar radiation (W/m²) and the electricity that could be generated (assuming photovoltaics (PVs) with a conversion efficiency of 20%) is also shown. Source: Dhakal et al., 2003; UKDECC, 2010.

Within an urban context particularly, energy demand densities are of significance. The twin influences of high population and high income mean that the spatial density of energy demand of cities typically ranges from 10–100 W/m², a range exemplified by cities such as Curitiba (Brazil) and Tokyo. Energy-demand densities in smaller portions of urban areas can approach values of 1000 W/m², as in sub-sections of the 23 wards of central Tokyo (Dhakal et al., 2003).

The significance of urban energy-demand density arises in three areas. First, the higher the energy density, the larger the impact of emissions, either as air pollutants or as waste-heat releases. Second, from an energy-demand perspective, high energy densities suggest opportunities for waste-heat recycling and economic provision of clean district heating and cooling services. Third, energy-demand densities are significant constraints for the provision of energy services through renewable energies, which (with the exception of geothermal) typically range from 0.1 to 1 W/m² and thus yield a significant mismatch between demand and supply at the urban scale.

From an energy-systems perspective it is important that the prevailing high energy-demand densities characteristic of urban areas are much in line with those of fossil fuel infrastructures and conversion devices (Grubler, 2004). The general mismatch between (high) urban energy demand and (low) renewable energy supply densities is shown with actual energy demand data for London and Tokyo in Figure 18.12.

The typical order of magnitude of energy use of a megacity is in the order of an exa-Joule (10^{18} J), a unit normally reserved reporting the energy use of entire countries. The (direct final) energy use of Tokyo's 23 wards is estimated to be about 0.6 EJ and that of the larger Tokyo Metropolitan area as 0.8 EJ (Tokyo Metropolitan Government, 2006), compared to 0.6 EJ for London (33 boroughs) and 0.8 EJ for New York City[22] (Kennedy et al., 2009). Energy-demand densities in Tokyo and London typically span a range from a few W/m² to >200 W/m², as in the City of London or in the top 25 grid cells (i.e., top 25 km²) of the Tokyo wards that use close to 18% of Tokyo's total final energy. Such high energy-demand densities are comparable to the entirety of the solar influx, which equals 157 W/m² in Tokyo and 109 W/m² in London. Mean energy densities, 28.5 W/m² for the Tokyo 23 wards (621 km²) and 27.4 W/m² for Inner London (319 km²), are similar. (For Greater London with its larger size (1572 km²), lower population densities, and greater extent of green areas, energy densities are naturally lower, at 13 W/m².)

Assuming that all the incoming solar radiation could be converted for human energy use (e.g., to electricity with 20% efficient PV panels), the maximum renewable energy supply density would range from 22 (London) to 31 (Tokyo) W/m² in line with average demand densities in the two cities, but only under the assumption that the entire city area could be covered by PV panels! Even assuming an upper bound of potential PV area availability (roofs, etc.), the results from a low-density urban area (Osnabrück, Germany, see below) of 2% of the city area, solar energy could provide a maximum of between 0.4 (London) and 0.6 W/m² (Tokyo), which would cover between 2% (Tokyo's 23 wards) and 1–3% (Inner to Greater London) of urban energy use in the two cities. *Local renewables* can therefore only supply urban energy in niche markets (e.g., low-density residential housing), but can provide *less than 1%* only of a megacity's energy needs.[23]

Given that local renewables in large cities are at best marginal niche options (because of the density mismatch between energy demand and supply), what is their potential in small, low-density cities? Using aerial survey techniques, Ludwig et al. (2008) performed a comprehensive assessment of suitable application of rooftop solar PVs for Osnabrück (Figure 18.13). Osnabrück, with an area of 120 km² and a population of 272,000 (a density of 23 people/ha) is characterized by an incoming solar radiation of 983 kWh/m² (112 W/m²). In the study, all suitable roof areas of some 70,000 buildings in the city were assessed (considering optimal inclination as well as shadowing by adjacent buildings) and the results published for local residents in a database per individual dwelling.

22 Final energy use within the city limits and excluding bunker fuels (aviation, shipping). The latter are reported to be 0.28 EJ (0.2 EJ aviation fuel and 0.08 EJ marine bunkers) for New York City compared to 0.76 EJ final energy use in 2005 (Kennedy et al., 2010). For London, aviation fuel also accounted for some 0.2 EJ for the year 2000 (Mayor of London, 2004).

23 This mind experiment considers a highly efficient conversion route of solar energy via high-efficiency PVs (with 20% net conversion efficiency). Assuming biomass as an alternative reduces the energy yield by a factor of up to 20, as the average conversion efficiency of solar energy via photosynthesis is only around 1%. Conversely, considering solar hot-water collectors (with a maximum efficiency approaching 100% of incoming solar energy) also does not change drastically the conclusion of the extremely limited local renewable potentials in high density cities, as solar hot water typically provides only a few percent of energy demand (hot water accounts for 2% of final energy demand in Europe (Eurostat, 1988)). Even if this were provided entirely by solar energy where feasible (in low- to medium-density housing, as high-rise buildings do not offer sufficiently large roof areas) the yield is less than 1% of energy demand in a densely populated large city.

Figure 18.13 | Example of assessing local renewable potentials: roof area (left panel) and suitable roof-area identification for solar PV applications (right panel) for the city of Osnabrück, Germany. Red: roof area well suited for PV; orange: suitable; yellow, only conditional suitability for PV applications; grey: shadowed roof area (unsuitable). Source: modified from Ludwig et al., 2008.

The study identified a total of two million m^2 of suitable PV roof area for Osnabrück (corresponding to 1.6% of the city area), which if used completely for PV applications could provide some 249 million KWh of electricity, or about the entire *residential* electricity demand of the city (235 million kWh) or up to 26% of the total electricity demand of Osnabrück (940 million kWh). It is of particular interest to interpret the Osnabrück results in terms of their corresponding renewable energy supply density, which adds up to some 0.2 W/m^2 and can be considered a realistic upper bound of the local renewable energy potential for low-density urban areas. In the example of Osnabrück, local renewables could provide some 3.3 GJ/capita or 2% of the average German per capita final energy use of 154 GJ/capita.

This example shows an important trade-off between population density, transport energy demand, and the potential for local renewables. Generally, the areas available for harvesting local renewable energy flows are higher for a *lower* population density in an urban area. Osnabrück, with a population density of 23 inhabitants/ha and a high proportion of low-density residential housing (single-family homes) evidently offers larger potentials to harness solar energy compared to a megacity with population densities of 130 people/ha and predominantly high-rise buildings (as for Tokyo's 23 wards). However, this higher potential for harnessing local renewables at lower population densities is at odds with the potential to lower the dependence on energy-intensive individual transport modes (automobile usage) in urban areas via public transport. Public transport systems require relatively high population densities to offer an attractive and economically viable alternative to private automobiles, with the minimum population density threshold required typically above 50–100 inhabitants/ha (see Section 18.5.3). In terms of energy, there is thus an inherent trade-off between urban form, transport choices, and the potential of harnessing local renewable energy flows. Put simply, the positive energy implications of an 'active' building (e.g., a 'Passivhaus' standard energy-efficient home with PV panels on the roof that produce electricity both for its own use and for the grid) can quickly turn negative if the building is situated in a low-density, suburban setting with a high automobile dependence.

Therefore, if renewable energies are increasingly to supply the urban energy needs on a large scale, the resulting needs for conversion and long-distance transport, as well as very large energy 'catchment' areas (the 'energy footprint' of cities), needs to be taken into account.

In an attempt to quantify the implications of the energy supply and demand-density mismatch, IIASA researchers used spatially explicit energy-demand estimates for Europe to calculate related energy-demand density zones (Figure 18.14). The study found that about 21% of final energy demand in Western Europe is below the supply density threshold of 1 W/m^2, a characteristic upper bound for locally harvested renewable energy flows. The corresponding value for Eastern Europe is somewhat higher, with 34% of energy demand below 1 W/m^2. Nonetheless, in all densely populated, highly urbanized regions, the majority of renewable energy supply has to come from areas of low population and energy-demand densities, where renewable energy flows can be harnessed and transported to the urban energy-use centers, which represents a formidable infrastructure challenge.

The findings of the IIASA study are also confirmed by a detailed, spatially explicit assessment of solar electricity (PV) potentials for all of Western Europe by Scholz (2010; 2011) (see also Chapter 11).

The Scholz study identified a total solar (rooftop)[24] PV generation potential of 638 TWh (equivalent to 2.3 EJ, or some 40% of the residential

24 Adding also building facades to the potential PV areas does not change the results significantly. In a study of solar PV potentials considering the entire building envelope Gutschner et al., (2001) estimated a total electricity potential of 600 TWh for a sample of 10 European countries, which is good agreement to the Scholz study (638 TWh). Facades were estimated to add another 25% to the rooftop PV potentials by Gutschner et al. (2001).

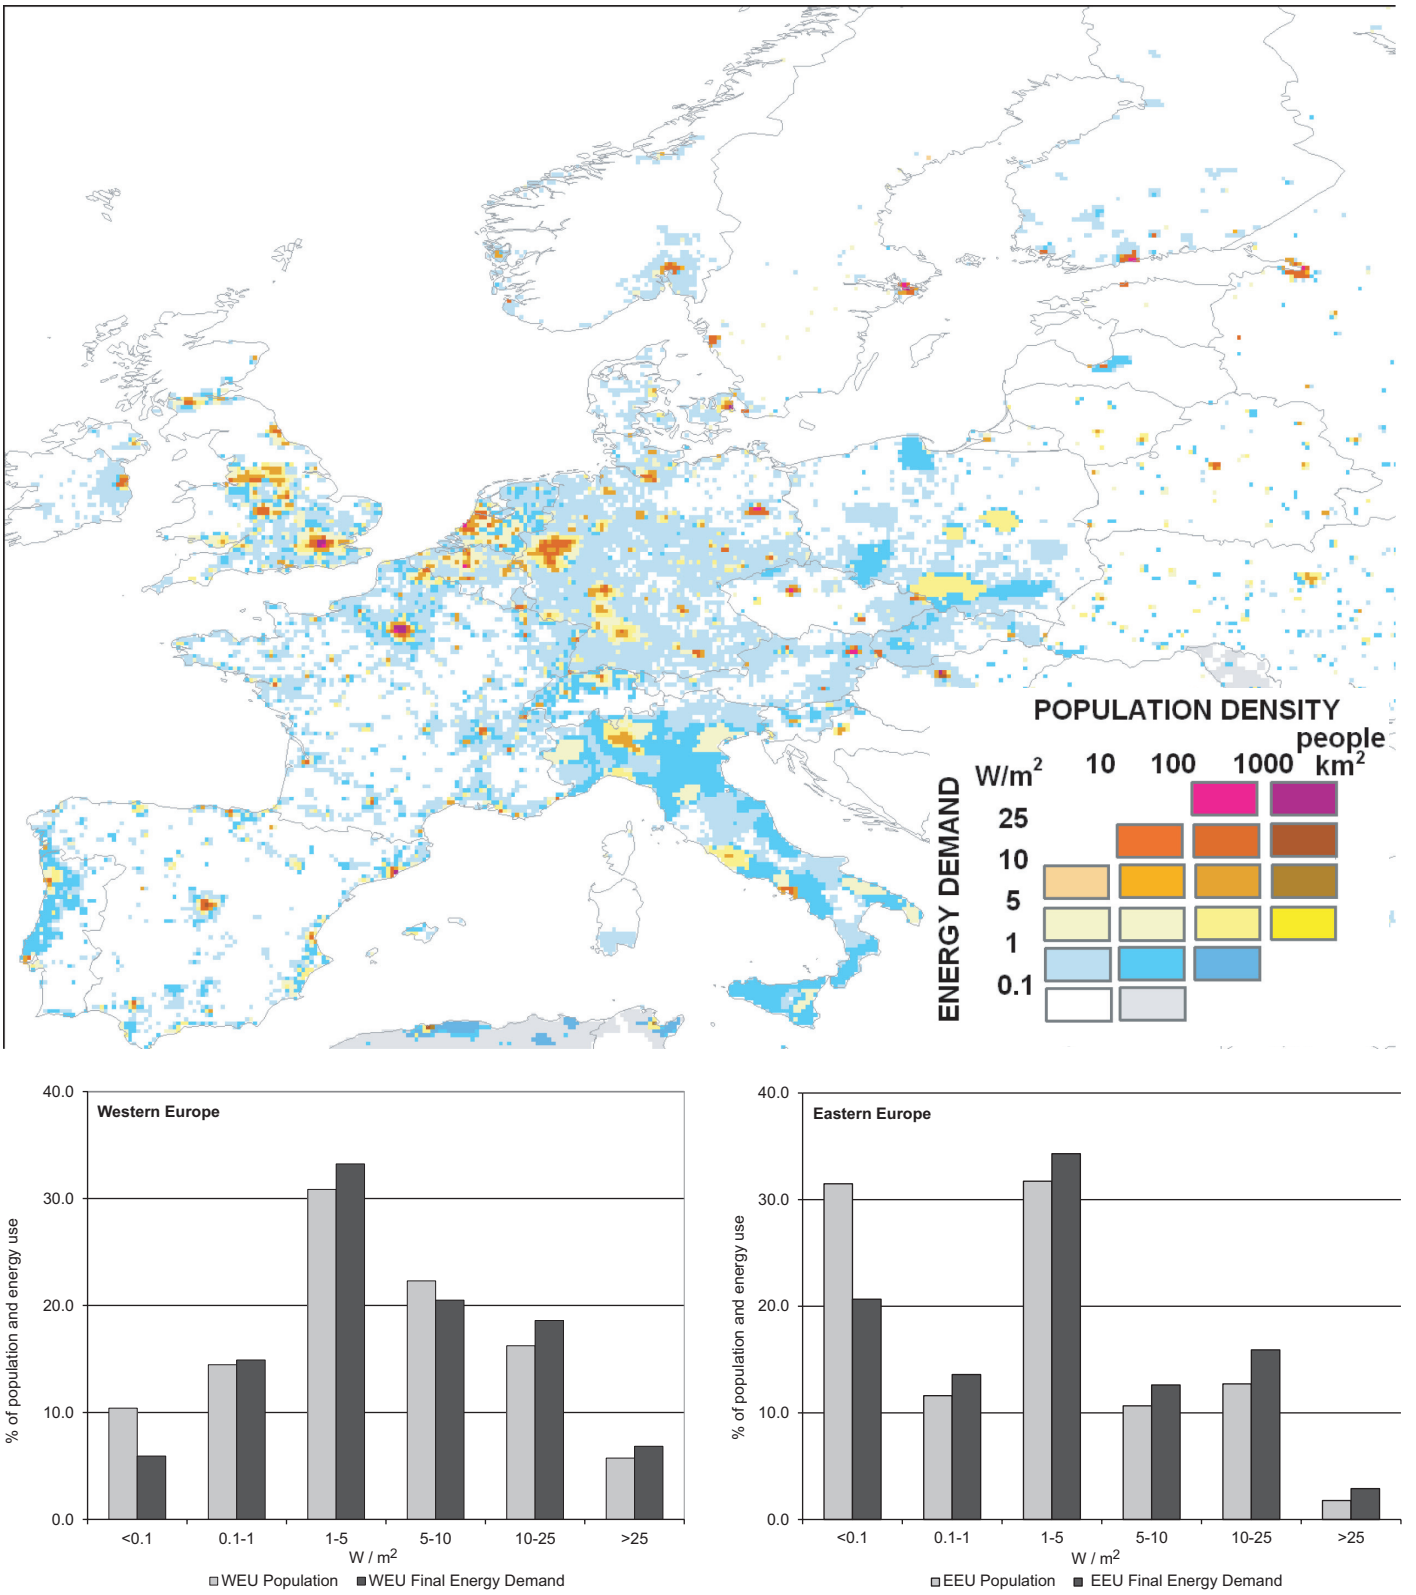

Figure 18.14 | Top: Spatially explicit energy demand densities in Europe (W/m²): Blue and white areas indicate where local renewables can satisfy low-density energy demand (<0.5–1 W/m²). Yellow, red and brown colors denote energy demand densities above 1, 5, 10, and 25 W/m² respectively.

Bottom: Distribution of population (grey) and final energy demand (black) (in percent) as a function of energy demand density classes in W/m² for Western Europe (left panel) and Eastern Europe (right panel). Only 21% (Western Europe) and 34% (Eastern Europe) of energy demand is below an energy demand density of 1 W/m² amenable to full provision by locally available renewable energy flows. The high energy densities of cities require vast energy 'hinterlands' that can be 100–200 times larger than the territorial footprint of cities proper requiring long-distance transport of renewable energies. Source: IIASA calculations commissioned by Chapter 18.

Table 18.14 | Global exposure equivalents to particulate emissions. Note, in particular, the continued dominance in developing countries of indoor air pollution from traditional biomass cook stoves compared to the urban outdoor air pollution exposure.

	Concentrations (μg/m³)		Exposures (GEE)[a]

Developed					
Urban	100	70	5	<1	**6**
Rural	60	40	1	<1	**1**
Developing					
Urban	255	278	19	7	**26**
Rural	551	93	62	5	**67**
Total			**87**	**13**	**100**

a GEE = Global Exposure Equivalent

Source: adapted from Smith, 1993.

electricity demand in Western Europe, and 23% of the total electricity demand in the region). 637 TWh (99.8%) of that solar PV potential is below a maximum energy supply density of 0.5 W/m², and 563 TWh (88.2%) below a energy supply density level of 0.2 W/m² (Scholz, 2011). Renewable energy supply densities in urban areas are therefore maximum in the range of 0.2 to 0.5 W/m² which are thus between 2 to 5 percent of characteristic urban energy demand densities of 10 W/m².

18.4.2.3 Pollution Densities

A corollary of energy densities is that of pollution density. High population density also leads to high *exposure*[25] density to pollution risks.

However, at least for traditional air pollutants such as particulates, urban pollution exposures also need to be seen in context, as only approximately one-third of the global pollution exposure is urban, whereas two-thirds are rural, because of the dominance in global particulate pollution exposure of indoor air pollution in rural households of developing countries (Table 18.14 and Chapter 4). Smith (1993) developed the concept of global exposure equivalent (GEE), which represents a renormalized index of the global summation of pollution exposure (pollution concentration times population exposed) calculated for a range of human environments. According to Smith (1993), global human exposure to traditional pollutants is dominated by indoor air pollution in rural and urban households in developing countries as a result of the continued use of traditional biomass for cooking.

For more modern forms of pollution (sulfur and nitrogen oxides (SO_x and NO_x) and ozone (O_3)), the corresponding GEEs have not been calculated, but it is highly likely that the respective role of indoor versus outdoor air pollution as the main source of a population's pollution exposure risk is reversed; that is outdoor air pollution and urban settings comprise the dominant form of pollution exposure. As an example, consider emissions of sulfur dioxide (SO_2). The 'hotspot' of sulfur emissions and pollution, which has for decades been the 'black triangle' (the coal-rich border area of Poland, the Czech Republic, and East Germany) in Europe, was remediated by successful European sulfur-emission reduction policies. The current sulfur-emission hotspot is now in China (Figure 18.15), where high elevated levels of sulfur emissions particularly affect the urban populations and triggered policy responses (see also Section 18.5.5 below).

From an environmental perspective high urban energy demand and the resulting pollution densities hold two important implications. First, energy use usually involves heat losses at well above ambient temperatures and high densities of urban energy use also imply high densities of urban waste-heat releases. These combined with the (high) thermal mass of buildings in densely built-up urban land give rise to the 'urban heat island effect' (see below) in which urban mean temperatures are several degrees higher than those of surrounding hinterlands.

Second, fuel choice becomes of paramount importance: pollution-intensive fuels (biomass or coal) used at the high demand densities of urban areas quickly result in unacceptably high levels of pollution concentration (such as the London 'killer smog' of 1952 or the current air-quality situation in many cities, especially in the developing world). Even low-pollution fuels, such as natural gas, can quickly overwhelm the pollution dissipative capacity of urban environments. So, high energy-demand density requires zero-emission fuels: electricity and perhaps, in the long run, hydrogen.

18.4.2.4 Urban Heat Island Effects

Formation of urban heat islands

Urban heat islands describe the frequently observed pattern of urban air temperatures that exceed those of neighboring, more rural areas. In temperature maps, which delineate neighborhoods of similar temperature with contour lines ('isotemperatures'), urban areas stand out as 'islands' that form 'heat domes.' For example, Figure 18.16 shows these for Tokyo, the city for which most literature on the heat island effect is available.

Urban temperatures typically peak some hours after midday, but the absolute temperature difference against rural areas can be even larger during the night under cloud-free conditions. Heat islands are facilitated in climatic situations of low air movement. Wind otherwise disperses temperature plumes. Heat islands are similar to air-pollution concentrations and they can be enhanced by local topography and climate patterns that prevent mixing of the boundary layer. In terms of average temperature difference, urban areas are often 1–3°C warmer than the

25 Exposure risk: product of population × pollution level × exposure time of population to pollution.

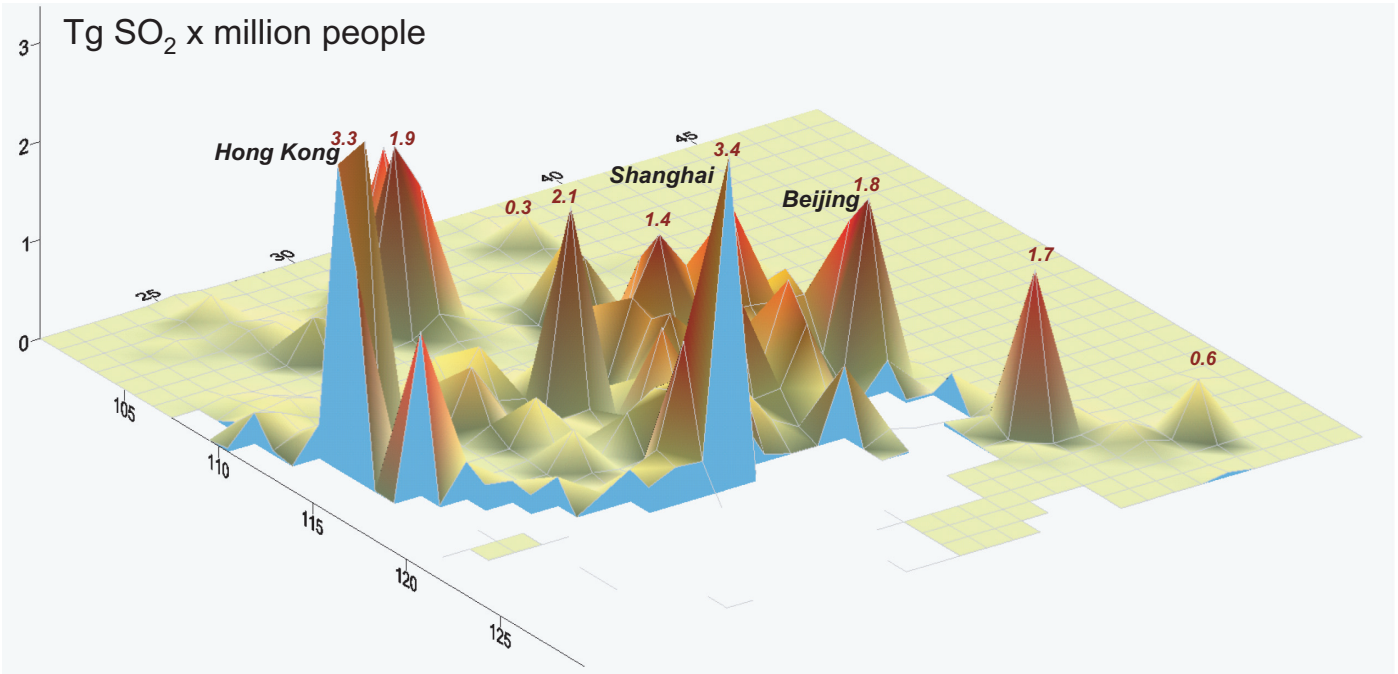

Figure 18.15 | Human exposure to sulfur emissions (population × emissions in million x Tg SO_2, z-axis) in China (2000), based on an analysis of gridded socioeconomic and emission data. (Units on x, and y-axis refer to geographical longitude and latitude). Note the high pollution exposure in major urban areas of China. Source: IPCC RCP scenario database (IIASA, 2010).

surrounding air, and at individual locations in calm and clear nights temperature differences can exceed 12°C (Klysik and Fortuniak, 1999). With increasing energy use, the extent of urban heat island effects increases (Figure 18.17), which results in local warming.

Heat islands are, among other factors, caused by urban energy use through anthropogenic heat release. Without planning or intervention strategies there is a risk of maladaptation feedbacks, in which heat island countermeasures trigger increasing energy use, which amplify

26 Sensible heat flux: air is heated directly by the heated ground surface. Latent heat flux: evaporation from wet ground surface or from cooling towers settled on top of buildings and evapotranspiration from vegetation. This type of energy exchange does not change air temperature. Its energy is consumed in the phase change from water to moisture.

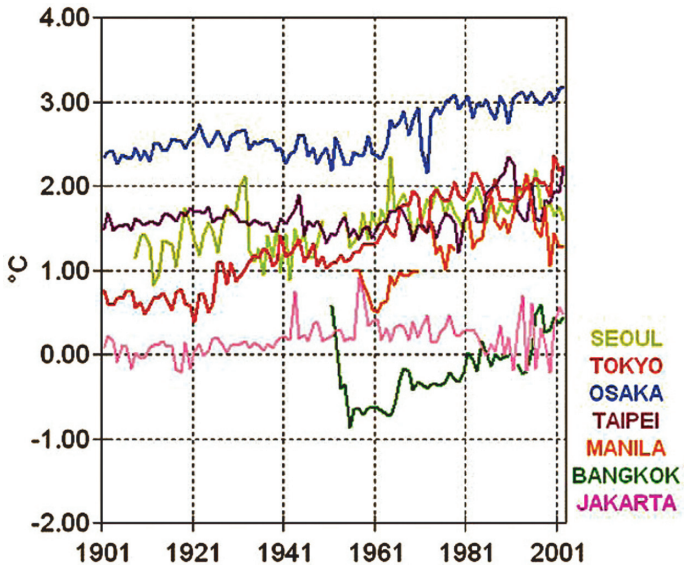

Figure 18.17 | Estimated urban heat island intensity in large Asian cities. Source: Kataoka et al., 2009.

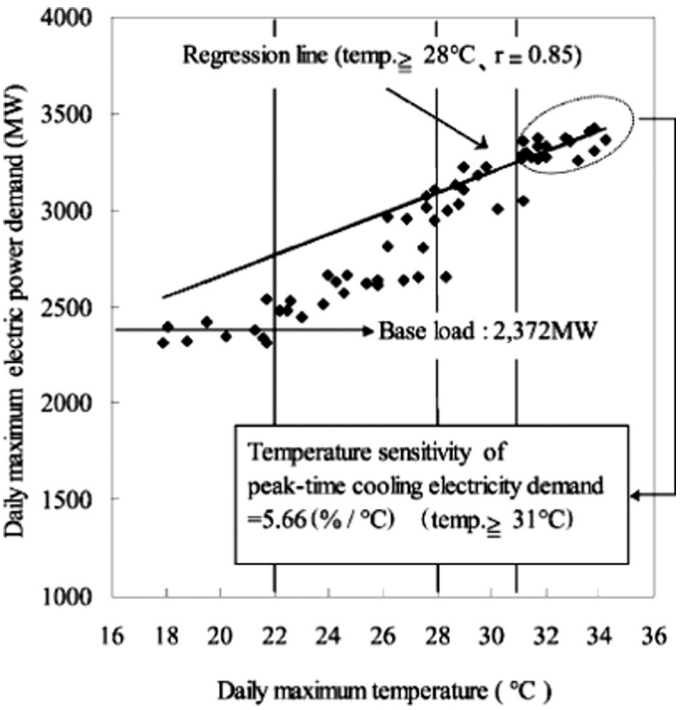

Figure 18.18 | Daily electric power demand and maximum temperature in Tokyo, June to August 1998. Source: Kikegawa et al., 2003.

the heat island (Figure 18.18). The increasing use of air-conditioning equipment in buildings and automobiles (which dump waste heat into the atmosphere) are one such example (Kikegawa et al., 2003; Crutzen, 2004).

Urban heat islands also affect the energy system directly. Elevated environmental temperatures reduce the efficiency of thermal power plants. Also, the availability of cooling water for thermal or industrial plants can be reduced as water bodies warm up.

A range of factors contribute to the formation of urban heat islands and their relative contribution varies among urban areas (Seto and Shepherd, 2009):

a) The geographic context defines the natural radiation balance across seasons, temperature, precipitation patterns, topography, and exposure to prevailing wind patterns. In humid climate regions, the natural vegetation is often forest dominated. Urban surface-temperature variation is then, at least partly, moderated by the latent-heat transfer through evapotranspiration of adjacent vegetation (Oke, 1987). Parks with water bodies and extensive vegetation cover reduce heat island formation. In more arid climate regions with low vegetation cover, daily temperature variation is more pronounced and heat island formation is more likely.

b) The replacement of natural vegetation with artificial surface materials for buildings, squares, and transport infrastructure results in more incoming radiation being stored during daytime, particularly if materials are dark, such as bitumen and asphalt. The albedo changes and differences in specific heat capacity of construction material result in more incoming energy being accumulated in surface material during daytime, which is later emitted as infrared radiation (Taha, 1997). Thermal insulation of buildings can reduce their specific heat capacity drastically.

c) Urbanization modifies the local hydrology. Natural groundwater recharge is typically prevented by the extensive use of impermeable surface materials. Rain gutters, drainage systems, sewers, and canals channel precipitation rapidly away to avert urban flooding. Additionally, the extraction of water from local wells and for construction projects often lowers water tables, which results in lower water availability for the remaining vegetation, and consequently lower evapotranspiration and associated cooling through latent heat transfer.

d) Also, structural characteristics of the urban form (Weng et al., 2004) affect the efficiency of heat loss through radiation and convection. Narrow street canyons with a limited sky view prevent heat loss through direct radiation upward. The urban layout and orientation of street corridors in relation to prevailing wind patterns affect the efficiency of heat transfer through convection and boundary layer mixing. These factors can be addressed through planning regulations. In Germany, for example, the concept of urban ventilation pathways ('Luftleitbahnen') aims to maintain radial corridors of cold winds to reach urban centers.

e) The metropolitan area size (extent) amplifies the magnitude of the urban heat island effect. For some rapidly growing urban areas,

such as Los Angeles or Kobe, a continuous increase in urban heat island temperature of up to 0.5°C/decade occurred over the past 60 years. This trend is partly amplified by changes in energy-use patterns (Böhm, 1998) and needs to be compared against general trends of global surface temperature warming of about 0.7°C over the past century (Oke, 2006; IPCC, 2007; Kataoka et al., 2009) (see Figure 18.17).

f) As energy demand is concentrated particularly in urban centers, the consequential release of anthropogenic heat is similarly dense in these areas. Industrial and service-sector activity, residential housing, and transport functions are typically clustered in close proximity. Electricity use and combustion processes in buildings and vehicles, for heating and cooling, lighting, or motion, all result in vast quantities of waste heat being released (Rosenfeld et al., 1995). To a small extent, the metabolic activity of biological body functions of the human population also contributes to this.[27] Global average estimates attribute a resulting climate forcing of about 0.028 W/m^2 to anthropogenic heat release (technical and biogenic). In North America and Europe these figures are estimated to be higher, at +0.39 and +0.68 W/m^2, respectively (Flanner, 2009). For the Ruhr area in Germany, average anthropogenic heat-related forcing values of 20 W/m^2 were calculated by Block et al. (2004). At higher spatial and temporal resolution, the values are much larger, often between 20 and 100 W/m^2. Numerical simulations for heat discharge of individual neighborhoods in the Tokyo metropolitan region, for example, indicate radiative forcing values of up to 700 W/m^2 during the day and in summer time (Dhakal et al., 2003). However, urban heat islands do not always increase urban energy demand. In higher latitudes the resulting reduction in heating demand in winter can more than compensate the additional cooling energy demand in summer. Integrated climate-energy system models increasingly aim to capture such effects (Kanda, 2006; Oleson et al., 2010).

Mitigation

Strategies for heat-island mitigation include behavioral and technological solutions. They can provide various co-benefits, including energy savings, peak-load reduction, air-quality improvements, and beneficial health, psychological, and socioeconomic effects.

Building design and layout allow solar gains of houses in summer to be minimized and increased passive gains during winter (e.g., in Passivhaus designs). Reduction in cooling demand can also be achieved through the use of deciduous vegetation for shading (including vertical greening of facades) or the application of mechanical shades, shutters, or 'smart glass windows,' with modified transmission properties of heat and light on demand. Albedo changes and the use of reflective paint and surface material on roofs and transport infrastructure is another particularly cost-effective mechanism to reduce heat absorption in urban areas. Improving the insulation of the building stock to prevent the warming and storage of solar influx in material of high specific heat capacity, such as concrete, is another measure, just like the expansion of shading structures (vegetation or textile) in general. The shading of parking lots, for example, not only provides thermal comfort, but also reduces emission of volatile organic compounds (significant precursors of low-level O_3 formation) from parked vehicles.

Active cooling via enhanced evapotranspiration can be induced through ponds or fountains, green roofs, and tree planting, or through the generation of artificial mist (microdroplets of water) to create local cooling clouds. In preparation for urban heat waves, the city of London considered the need to prepare 'cooling shelters' for vulnerable or elderly population, as the typical UK housing stock is not equipped with air-conditioning (City of London, 2007).

Changing the timing of activity patterns to avoid the hottest hours of the day was a traditional response to hot climates. In peak-load management programs some of this rationale is revived. Operators of office space in New York City are given price incentives to start air-conditioning in the early hours of the day to reduce demand during peak hours of electricity demand (Bloomberg, 2007). While the primary motivation was to reduce peak power demand in a grid of constrained capacity, this measure also reduces the peak in waste-heat emission in the early afternoon hours. While probably not the most suitable for dense, high-rise developments like Manhattan, solar cooling devices that provide a maximum cooling output at periods of peaking outdoor temperatures appear to be suitable for low-density cities.

In 2005, the Japanese environmental ministry started a campaign titled 'Cool biz' to restrain the use of air-conditioning units to an indoor temperature of 28°C. The campaign aimed to loosen the strict dress code of full-suit, tie, and long-sleeved shirts for office workers during the hot season (June 1 to September 30) and promoted a more heat-tolerant dress code of short-sleeved shirts without ties (Pedersen, 2007).

18.4.3 Supply Constraints, including Reliability and Security

Cities depend on extended energy networks and failures can occur on a regional and national scale. On August 14, 2003, a cascading outage of transmission and generation facilities in the North American Eastern Interconnection resulted in a blackout of most of New York State as well as parts of Pennsylvania, Ohio, Michigan, and Ontario, Canada. On September 23, 2003, nearly four million customers lost power in eastern Denmark and southern Sweden following a cascading outage that struck Scandinavia. Days later, a cascading outage between

27 Assuming about 100 W of biological energy use per person and maximum population densities of 40,000/km^2 in some cities in developing countries, this factor can contribute up to 4 W/m^2 additional forcing. Typical urban population densities are lower.

Italy and the rest of central Europe left most of Italy in darkness on September 28. These major blackouts are among the worst power-system failures in the past few decades. They had a profound effect on power-system philosophy because these networks were some of the world's most sophisticated power-generation distribution systems. In particular, the US failure was promoted by an early underlying failure in software used to control networks, which meant the scale of the emerging problem was recognized too late to protect the cascading failure.

Energy efficiency and resilience are not coincidental outcomes. Thus, a low-energy settlement might be even more sensitive to disruptions in supply than a settlement with some slack in its energy system. A dense city with no power for its elevators may be in a worse state than a low-density urban settlement without power. Renewable power sources based on wind or solar alter the reliability profile. As they are of a much smaller unit size, they do not induce major dropouts, as happens when a large nuclear power station needs to come offline very rapidly. Conversely, the variability in available power they supply may require them to be shadowed by a rapid-response plant. They may also exacerbate failure cascades because of switching out for self-protection when the power system is stressed heavily.

The increasing dependency on power even for simple clerical work, let alone for critical functions like hospitals, means that stand-by power supplies could be an increasing feature in urban systems. One suggestion (Patterson, 2009) is that it is possible for the local distributed power generation to become dominant and the national distribution systems only handle back-up. This is already effectively the case for dwellings that use microgenerators for power and heat. Another suggestion is that more sophisticated metering and tariffs could incentivize the extension of demand-side load management from large facilities of 'interruptible supply' at the microscale. In line with the efficiency-resilience argument it is expected that vulnerability to societal interruption is higher in countries with generally very secure supplies in which the economy has sought an equilibrium that assumes secure power supplies than in countries with frequent brownouts and blackouts in which the economy has adjusted to coping with the risk.

The winter of 2008/2009 in Europe showed the vulnerability of gas-supply networks to urban areas. Gas can be stored both in the mains and in dedicated storage facilities, but gas is currently supplied directly to consumers and power generation, and so indirectly to mass-transit systems. Thus, a failure of supply pressure has wide implications. Coastal cities can increase their robustness with liquid natural gas (LNG) terminals, but LNG is a world-trade product and may come at a high price in a regional emergency.

Liberalization of gas and electricity market pressures gives the lowest prices to consumers, but the effect is to incentivize producers to 'sweat' their existing assets (e.g., Drukker, 2000). It may then become necessary to introduce further complexity into tariffs to incentivize investment and reflect the value to the consumer of lost load. Undercapitalization of energy networks, many of which were built in the 1960s, remains a real risk over the next 20 years in developed world systems.

Possibly the greatest vulnerability in an urban context is the supply of transport fuels. The weakness of the low-density settlement is its complete dependence on oil at a density below around 30–40 persons/ha (Levinson and Kumar, 1997). There are ways to save oil quickly (IEA, 2005), largely based on increasing load factors, but there is a mounting recognition of the advantages of diversifying the transport energy vector away from oil.

18.5 Urban Public and Private Sector Opportunities and Responses

18.5.1 Introduction

18.5.1.1 Concepts of Sustainable Cities and Designs

The term 'sustainable city' dates from the 1990s. The term 'sustainable development' is usually dated from the World Commission on Environment and Development Report (WCED, 1987), which devotes a chapter to 'the urban challenge.' The WCED concern was principally about issues of the urban poor in rapidly growing large cities of the South. The term sustainable development is now used more frequently in the narrower context of the need to protect the environment that underpins social and economic capital. For this reason the term 'sustainable cities' is more often associated with civic initiatives in cities of the North, addressing what is perceived as the unsustainable impact of their citizen's lifestyles, especially the generation of large volumes of waste and GHG emissions. It is largely coincident with the earlier idea of an 'ecocity.' Ecocities essentially try to contain their 'ecological footprint' (Andersson, 2006; Jabareen, 2006; Kenworthy, 2006; Pickett et al., 2008). This focus means that some projects are not always more broadly sustainable, especially as economic units.

Attempts to achieve an optimal 'sustainable urban system' in new settlements invariably resorts to some form of spatial organization. This may be provided by a city authority, but it could equally be the covenants imposed by a land developer. The intention is to gain from bringing the various strands of urban activity together into a more integrated whole. For example, reducing urban traffic noise through less need to travel by automobile and the use of quiet road surfaces or electric vehicles enables citizens to keep windows open in summer. This provides the opportunity to avoid mechanical ventilation by recovering the opportunity for natural ventilation. 'Sustainable' urban configurations are often expressed in terms of optimal residential densities linked to low-profile transport networks. This fairly crude metric is often employed in zoning regulations. The optimal configuration then seeks to avoid a very high density with highly congested services and a very low density automobile-dependent networks. This configuration is expected to induce a stronger sense of

community by providing some local retail and commercial space with local interaction, itself reducing the need for automobile travel.

Energy implications of 'sustainable cities' arise naturally from their move away from automobile dependency. But overlaid is an attempt to exploit the area of the city as a source of renewable energy. At the current state of technology, most 'zero-carbon' developments are essentially *net* zero carbon, and rely on the existence of a market for surplus renewable electricity at some time of the day and the ability to import electricity at others. The installed PV capacity for the proposed new Masdar city in Abu Dhabi is nearly 200 MW within its city boundary of 6 km^2. Wind is less likely to be exploited in a sustainable city, except as an aid to natural ventilation, because of the ground-effect drag in urban environments. For the purist to import green electricity is wrong. While wind generators sometimes appear in iconic building structures, drag resistance of the urban surface makes them a less compelling investment than wind generators in more exposed localities. However, while the proposed ecocity at Dongtan outside Shanghai uses local agricultural wastes as an energy supply, it is not obvious how this differs from using waste collected from a wider area.

Waste is a particular issue for all cities. Cities of the ancient world produced little nonbiodegradable waste, in contrast to the large volume of solid waste that large urban settlements currently need to dispose of. 'Sustainable city' discourses thus focused on reducing waste sent to land fill by providing recycling and incineration facilities. In ironic contrast, the large cities of the developing world already have an informal economy in the periurban areas that pick clean the waste of the formal urban centers. Sustainable cities frequently try to capture waste heat from electricity generation by locating combined heat and power (CHP) sets within the city or encouraging microgeneration. For large urban areas this strategy can only maintain urban air quality if other measures designed to reduce air pollution are successful – which emphasizes the importance of treating issues and systems holistically (Box 18.4).

Box 18.4 | Zero-Carbon Cities

Planners are exploring new urban paradigms in which urban energy use is not entailed by urban form, but in part defines the urban master plan. Dongtan near Shanghai and Masdar in the Arab Emirates are two recent high-profile design studies that exemplify this.

Both Masdar and Dongtan represent a new development strategy whereby the creation of the city forms its own economic rationale. This reflects the delocalization of some classes of economic activity and hence the ability to bring these together in a desirable location. This is the theory behind the creation of Dubai as a global financial sector from scratch. Less ambitiously, Dongtan was to be a service center outside of Shanghai. Masdar was to be a knowledge center that specialized in renewable energy technologies. The master plans of both complexes are polycentric so that 'quarters' or districts are often defined by a locally dominant economic or social function. Whether the loss of monocentricity is significant is hard to tell. The cellular nature of both development plans enables stable modular growth in uncertain economic times. Both designs have a substantial external energy supply from local renewable resources and so 'to first order' are formally 'zero carbon.' The designs themselves sought to reduce energy demand substantially without affecting service delivery.

Dongtan was designed as a 'zero-carbon' development. The initial settlement study was for 80,000 inhabitants, but with expansion possibilities to over half a million. Its external supply of energy is regional biomass waste from rice production, along with solar power panels. In delivered energy terms, it is an all-electric city. Electric vehicles provide all motorized transport within the city. These can either be conventional battery-powered or fuel-cell powered vehicles that use hydrogen, but the short range is less important in Dongtan because the city is spatially organized to reduce distances for essential travel. Conventional transportation to the outside world has to be parked at the city boundary. The master design features not only low-energy concepts, but also self-sufficiency in water and waste recycling. A particular feature was the exposure of system synergies. For example, by switching to quiet clean electric vehicles, it became possible to revert to natural ventilation and day lighting for housing and offices. The estimated 'eco-foot print' for Dongtan was 1.9 ha/capita, only slightly above the WWF target (Cherry, 2007).

Masdar faces a notably different climate to Dongtan, dominated by cooling load. This demand is reduced by recourse to traditional Arabic architectural approaches that protect building facades and access routes from the sun, with narrow access spaces that still provide daylight penetration into occupied spaces. Like Dongtan, Masdar is a zero-carbon urban development. The scheme's energy supply is provided by a large solar-power energy park. Indeed, Masdar's economic rationale is as an international center in advanced renewable energy technology. Its first districts are already established and it hosts the International Renewable Energy Agency supported by over 130 nations. Industrial zoning places production facilities at the periphery of the neighborhood complex, where more conventional freight transport has access. Novel electric personal transport aims to shuttle residents between centers. As with the Dongtan design, there are no private vehicles within the city. The planned scope of the city is around 6 km^2.

Both Dongtan and Masdar were designed as showcases of a new vision of future master planning focused on low environmental impact, especially of energy. The focus on zero carbon and sustainability reflect the kind of private investment that the developments were intended to attract. The common theme is the value of integrated design in reducing the overall impact of urban processes. It is yet to be demonstrated whether less well-endowed and less well-organized new urban settlements can achieve similar impressive potentials. Given Masdar's initial investments of well above US$20 billion, the sheer magnitude of the investments need for housing some three billion additional urban dwellers in radical new zero-carbon city designs is staggering: well above US$1000 trillion, or some 20 years of current world GDP (Kluy, 2010)!

Whereas the Masdar project has completed at least its first phase, the Dongtan design has been set aside for the moment, although a number of new, perhaps less ambitious, settlements are under construction around Shanghai (Larson, 2009). In many ways the Dongtan design exercise has served as a valuable learning experience in 'holistic' master planning and is widely influential. As important as both projects are as showcases and experiments in new thinking and planning, the actual urban development reality is rather one of incremental, continuous change within an existing urban fabric that needs to incorporate the lessons learned from bold 'greenfield' ecocity design experiences.

The 'sustainable city' as currently conceived is not without its critics. The discourse is often so concerned with environmental factors that the local robustness of social and economic capital is unwisely taken for granted. However, examples that have been partially implemented show reductions in final energy use against normal benchmarks of 10–15% without any substantial changes in lifestyle norms. While sustainable urban form can often require significant capital 'up front' and is thus a serious obstacle under capital constraints, a possibly more fundamental issue is *institutional*. Is it possible that stakeholders within an urban context who are used to working independently can find an institutional structure where they can work together in an integrated manner. This may be easily done at the master planning stage, at which broad-brush issues are under the control of a single land-use planner, but to maintain the integrity of the master plan can be a challenge. If the problem can be solved, it would be a major disruptive technology to conventional urban planning and development and for which prototype design software is already in existence (Keirstead et al., 2009).

Summary

Urban planning measures have the potential to be very powerful methods of integrating urban services that minimize urban energy use and other ecological impacts. Nonetheless, many of the recent design exercises in 'sustainable cities' are for premium urban centers. The technology may be transferable with further development, but the systems are presently too expensive to treat them as realistic new paradigms for the urban built environment in the decades to come.

18.5.1.2 Overview of Main Policy Instruments of Relevance for Urban Energy Systems

The policy players

Policy instruments that apply to urban settlements are generally exercised through several layers of government, often as many as five or six. In theory, this plurality is to ensure that policy powers have an appropriate geographic reach for the issue at hand, and to ensure that destructive competitiveness between settlements does not undermine the quality of specific policy interventions (e.g., Baumol and Oates, 1975). Parallel arguments are deployed to explain the distribution of tax raising, tax collection, and spending powers at different levels of government. The system is extremely effective, but it can be prone to problems of coordination and regional politics. The universal tendency is to decentralize responsibility without decentralizing resources. Urban administrations are more often the delivery agent rather than the tax raiser and this frequently leads to accusations by lower tiers of government of 'underfunding' by higher levels. From time-to-time many of the cities, even in the richest nations, operate close to bankruptcy, which can limit their ability to obtain capital for projects. Generalizations are otherwise dangerous. Urban settlement patterns of governance are, in part, an accretion of local history.

The degree to which public policy is a meaningful term in an urban energy context varies greatly from the highly organized urban society of Singapore to the current chaos of Mogadishu. The issues important to energy use, such as regulation of construction standards for stationary infrastructure, are found at all levels. Control of transport provision also occurs at all levels, although land planning, infrastructure standards, and transport can be dealt with by distinct silos within several layers of public administration. Also, landowners, both private and public, often hold important powers through ownership rights that help define the urban form and its physical emergent properties. Houston is possibly the extreme with no state zoning, but relies largely on land covenants. Other relevant powers can reside with the public or private bodies that provide the utility services.

Energy use is currently an 'emergent' property of a complex urban system. Current governance structures were not designed specifically to

manage energy outcomes. In any long-term perspective that embraces a very uncertain future in which energy and related environmental issues become important, it seems likely that greater clarity and effectiveness of governance-relevant structures is highly desirable. Increasingly, major cities in the world have developed 'energy plans' or 'energy strategies' (e.g., Mayor of London, 2004).

The policy instruments

Policy instruments are conveniently arranged in a hierarchy of leverage effects, with land-use planning at the base and control of infrastructure use at the apex. Sometimes the whole hierarchy is delivered at one stroke, as in a major rapid expansion of an economic zone, and energy optimization or 'zero carbon' has featured in a number of recent expansions (e.g., Masdar (Biello, 2008), Dongtan (Normile, 2008), and Incheon (Kim and Gallent, 1998)). These large enterprises are usually led by a development corporation or similar entity with powers to integrate the various s tiers of provision and exceptional access to capital. While impressive in concept, to devise a master plan durable against changes in external circumstances over decades is no mean feat (as the unrealization of the Dongtan project illustrates).

Normally, land-use planning is less ambitious and sets aggregate parameters for zones, such as permitted functions, density, or maximum building height, that guide rather than direct public and private investment. This is the pragmatic solution for the incremental redevelopment of an area. This means that upgrading and refurbishment frequently takes place in patchworks such as '22@' in Barcelona or 'Thames gateway' in London, usually within the framework of a local or regional government 'master plan.' This approach is potentially very powerful for realizing some of the advantages of economies of scale in low-energy or low-carbon technologies, but there is as yet relatively little experience as to how to exercise it effectively. There are some impressive examples in European towns, like Malmo and Freiburg, and US towns like Portland or Davis. These examples influenced recent thinking in urban design, but are apparently not impressive enough to induce widespread replication at current (low) energy or 'carbon' prices.

In many jurisdictions the planning authority has the power to apply conditions to new developments, such as mandatory connection to a district-heating scheme. These conditions can be overwritten by other energy-policy objectives. For example, in Europe a development might be required to install a renewable energy source, but energy competition policy would prohibit the imposition of an additional requirement for its exclusive use by tenants. Planning control can be effective in eliminating the most excessive energy use and giving some certainty to capital investment. However, because so much of the final energy use is delivered by instruments at lower levels in the hierarchy, planning control can seldom deliver very low-energy solutions on its own. Where a low-energy solution collides with other environmental factors, such as appearance or noise, it can militate against it.

The next level 'down' from planning control conventionally contains instruments that relate to the economic framework of the urban settlement. Since the 1980s the trend has been for local services to be provided by the private sector within a regulatory framework. Energy prices are usually regulated (or subsidized) at the national level, and not always in a manner conducive to good outcomes. Removing energy subsidies is theoretically a low-hanging fruit. In practice, the objections of those who benefit from them make such action politically contentious. However, lower tiers of government still have a number of economic instruments at their disposal, especially for transport. Thus, parking charges and more ambitious road-user charging can be used to favor or subsidize mass-transit systems. As these instruments are often redistributive, even when effective, their application can require considerable political skill. The London Congestion charge is a case in point (Taylor, 2004). More broadly, the price of land and stationary infrastructure is an important factor in all that goes on in urban settlements. Property taxes and taxes on sales can incentivize upgrading of the energy efficiency of the building stock. Where land ownership is heterogeneous, local government can facilitate the roll out of refurbishment programs, often working with large property developers. Programs of this kind can make up a substantial part of the work of 'energy-service companies' or ESCOMs (Dayton et al., 1998). The lowest tier of policy instruments relates to individual components and their direct use. Construction standards when coupled with standards for energy-control provision have a long history of application. The diffusion of new technologies is *inter alia* influenced by social networks (Fisk, 2008) and local networks, of which local government is a part and can accelerate take-up.

The provision of a mass-transport system is an important option when travel densities are sufficiently high to provide savings over private transport. However, success depends, in part, on delivering a service that is universal rather than just for the most disadvantaged. That, in turn, implies a system with sufficient coordination to ensure feasible journey times for a wide range of journeys.

Finally, urban administrations have an important role to play in administration during energy-security events (IEA, 2005).

18.5.2 Drivers of Urban Energy Use and Main Policy Leverages

18.5.2.1 Introduction

This section synthesizes existing knowledge of the main drivers of urban energy use and related policy considerations. Traditionally, comparisons and analyses of energy use and the drivers of differences are carried out at the national level. In comparison, research on the factors that determine urban energy use is still in its early stages, severely hampered by the limited availability of comparable city-level data.

Keeping the above caveats in mind, the factors that determine urban energy use can be classified into a few major groups: *natural environment* (geographic location, climate, and resource endowments), *socioeconomic characteristics* of a city (household characteristics, economic structure and dynamics, demography), *national/international urban function and integration* (i.e., the specific roles different cities play in the national and global division of labor, from production and a consumption perspectives), *urban energy systems characteristics including governance and access* (i.e., the structure and governance of the urban energy supply system and its characteristics), and last, but certainly not least, *urban form* (including the built urban environment, transportation infrastructure, and density and functional integration or separation of urban activities).

These factors do not work in isolation, but rather are linked and exhibit feedback behavior, which prohibits simple linear relations with aggregated energy use. The interaction between the driving factors may change from city to city – moreover, many of the factors are dynamic and path dependent, i.e., are contingent on historical development. There is, however, one factor that underpins all these determinants in a complex and nondeterministic way: the *history* of a city. The location of a city and the initial layout of its urban form are determined historically: witness the difference between sprawling North American cities that developed in the age of the automobile and older, compact European cities that developed their cores in the Middle Ages. Likewise, the economic activities of a city often stem from historical functions, whether as a major harbor, like Cape Town and Rotterdam, an industrial center, like Beijing now and Manchester historically, or a market and exchange center, like London, New York, and Singapore. These historical legacies may have long-term implications on urban energy use. However, there are also cases in which relatively rapid changes in the historical layout and/or the economic role of a city occur. This can be the result of war, natural disasters, or rapid socioeconomic transitions, such as industrialization or deindustrialization. Examples are Tokyo after World War II, Beijing in the past decade as transformed by China's accelerated transition from an agrarian to an industrial society, or many Eastern European cities after the fall of the iron curtain in 1989 and the subsequent economic restructuring from a centrally planned toward a market economy.

18.5.2.2 Geography, Climate, and Resource Endowments

Climate is an important factor in determining final energy use, especially for heating and cooling demands. Its influence on energy use can be measured through the metrics of heating and cooling degree days, which, in combination with the thermal quality of buildings and settings for indoor temperature, determine energy use. Urban energy demand is, in principle, not markedly different in its climate dependence than that in nonurban settings or national averages, but it is structured by the influence of other variables, such as urban form (e.g., higher settlement densities lead to smaller per capita residential floor areas), access to specific heating fuels, or income (e.g., more affluent urban households use more air conditioning), that can amplify or dampen the effect of climate variations on urban energy demand.

National studies illustrate the quantitative impact of climate variables on energy demand. For example, Schipper (2004) reports differences in space-heating energy use (measured as useful energy) normalized to heating degree days and square meters living space for seven industrial countries. This analysis reveals substantial ranges from 50 kJ/m^2/degree-day for Australia to 250 kJ/m^2/degree-day for the United States in the early 1970s, and from 60 (Australia) to 160 kJ/m^2/degree-day for Germany in the mid 1990s. Assuming a residential floor space of 100 m^2, a difference of 1500 heating degree-days, which is characteristic between northern (Denmark) and southern (Greece) Europe, translates into a variation in residential energy demand between 9 and 24 GJ, which is significant compared to a typical European household residential energy use of some 60 GJ, but nonetheless only constitutes between 9% and 24% of the typical 100 GJ/capita western European total urban final energy use. Conversely, little is known on the differences in the demand for thermal comfort as reflected in ambient indoor temperatures. A case study carried out for Metro Manila indicated that people in the highest income brackets have much lower indoor room temperature setting preferences, which leads to an increased air-conditioning demand (Sahakian and Steinberger, 2010).

The relationship between climate and urban energy use is a two-way street: climate not only influences urban energy demand, but urban areas also influence their local climate through the 'urban heat island' effect (see Section 18.4.2.4). This effect can reduce the heat demand during winter, but also enhance the need for cooling in the summer, especially in warm and humid climates. Studies show increases in the summer time cooling load in tropical and midlatitude cities (Dhakal et al, 2003). A series of studies on California show that a 0.5°C increase in temperature causes a 1.5–3% increase in peak electricity demand (Akbari et al., 1990; 1997).

To a certain extent cities inherit the resource dependencies of their respective countries, which explains, for instance, the continued use of coal in urban areas in countries endowed with large coal resources. The connection to national energy systems and their dependence on the resource base is especially pronounced for power generation, since cities often draw electricity from the national grid. In some cases, urban power plants are designed to use local resources, such as hydropower, geothermal, or wastes, but these potential resources are usually extremely limited in urban areas and provide only a small contribution to the high energy demand associated with high urban population and income densities. On the distribution and end-use side, district heating and cooling infrastructures, which allow large economies of scale, cogeneration, and energy-efficient 'cascading' schemes, are specific urban-efficiency assets, but only economically possible when the density of demand is above a threshold that warrants the investment.

18.5.2.3 Socioeconomic characteristics

The positive correlation between income and (final) energy use is long established in the traditional energy literature, especially for analyses at the national level. For the household level, correlations between income and energy use have been shown for the Netherlands (Vringer and Blok, 1995), India (Pachauri and Spreng, 2002), Brazilian cities (Cohen et al., 2005), Denmark (Wier et al., 2001), and Japan (Lenzen et al., 2006), with similar results for GHG emissions in Australia (Dey et al., 2007) and CO_2 emissions in the United States (Weber and Matthews, 2008). For Sydney, Lenzen et al. (2004) showed that urban household energy increases with household expenditure, and that most of this increase results from the energy embodied by goods and services, since direct final energy use, in contrast, increases only slowly with expenditure (albeit from high baseline levels).

Based on a production approach, urban per capita energy use is very often lower than nonurban energy use or the national average, particularly for postindustrial, service-sector oriented cities in the OECD countries (see Section 18.2.4; Brown et al., 2008; Parshall et al., 2010).

Figures 18.19 and 18.20 show the urban income-energy relationship from a production perspective. The GRP/resident is plotted in a cross-sectional analysis against energy use for a sample of Chinese cities (Figure 18.19). Figure 18.20 complements the Chinese cross-sectional analysis by a longitudinal analysis for six megacities. For both cases, income and energy increase together, albeit along distinctly different trajectories, which illustrates *path dependency*. Income is therefore far from the sole determinant of the level of energy use: for instance, Beijing and Shanghai have a higher average energy use than Tokyo, despite a lower per capita income.

In addition to income, demographic factors play a role in determining urban energy use (Liu et al., 2003; O'Neill et al., 2010). For instance, studies suggest that household size, that is the number of people living in one household, plays a role in energy use: above two people per household, economies of scale can reduce the energy used per capita (see above). This phenomenon is observed in India (Pachauri, 2004), Sydney (Lenzen et al., 2004), the United States (Weber and Matthews, 2008), and Denmark and Brazil (Lenzen et al., 2006). In Japan, in contrast, larger household sizes correlate with slightly larger energy use (Lenzen et al., 2006). Urban populations often have significantly smaller household sizes than rural populations because of smaller families and a larger generation gap, as well as smaller dwellings, and so shelter for extended families or many generations under the same roof is less likely.

The evidence for age is mixed. In Sydney, increasing age is correlated with higher residential but lower transportation energy use (Lenzen et al., 2004). Larivière and Lafrance (1999) found a positive correlation between residential electricity use with age for Canadian cities. At this point, not enough is known regarding the influence of age to make any general statement, much less predictions, applicable to cities with very diverse age pyramids that range from young and growing, to old and declining populations.

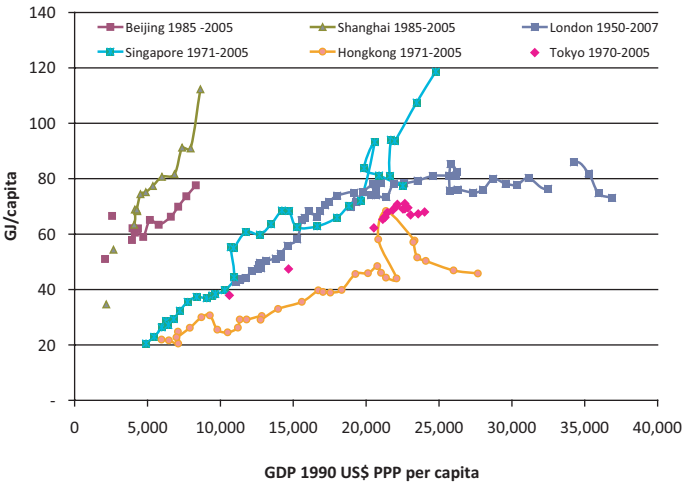

Figure 18.20 | Longitudinal trends in final energy (GJ) versus income (at PPP, in $Int_{1990}$$)[28] per capita for six megacities. Note the path-dependent behavior. Source: Schulz, 2010a.

18.5.2.4 Role of the City in the National or Global Economy

A city's function in regional, national, and international economies has a strong bearing on its energy signature when measured from a production perspective. In the extreme case of Singapore (Box 18.5), a major center for oil refining and petrochemical production and a major international transport hub, the energy use associated with international trade in oil products, shipping, and air transport (usually subsumed[29] under 'apparent consumption' of the city's primary energy use) is four times larger than the direct primary energy use of Singapore and more than eight times larger than the final energy use of the city.

28 For comparison: per capita GDP (in PPP terms) in 2005 and in Int_{2005}$ are: Beijing: 9238, Hongkong: 34574, London: 53145, Shanghai: 9584, Singapore: 29810, and Tokyo: 33714. (Note that a change in base year for the PPP metric changes the relative position of urban incomes in a non-proportional way.)

29 International bunker fuels are an important exception that, by simple definition, are excluded in national energy-use balances and the resulting emission inventories.

Box 18.5 | Singapore: The Importance of Trade

The case of Singapore illustrates the intricacies of energy (and emissions) accounting in trade-oriented cities that import primary energy, such as crude oil, re-export processed energy (fuels), energy-intensive products (petrochemicals), refuel ships and aircraft (bunker fuels), and import and export numerous other products and services that all 'embody' energy (see Figure 18.21). In terms of energy or CO_2-emission accounting, this extreme example amply illustrates the limitations of applying current inventory methodologies developed for national applications to the extremely open economies of cities. New, internationally agreed accounting standards are needed, as otherwise the risk of either misinforming policy or drawing arbitrary system boundaries is significant. There is a risk of 'defining away' energy use and emissions (e.g., international bunker fuels for aircraft and ships) associated with the inherent functioning of spatially defined entities (cities, city states, even small national open economies) whose interdependencies and energy/emissions integration into the international economy provide for their very *raison d'être* and therefore need to be included in energy and GHG emission inventories.

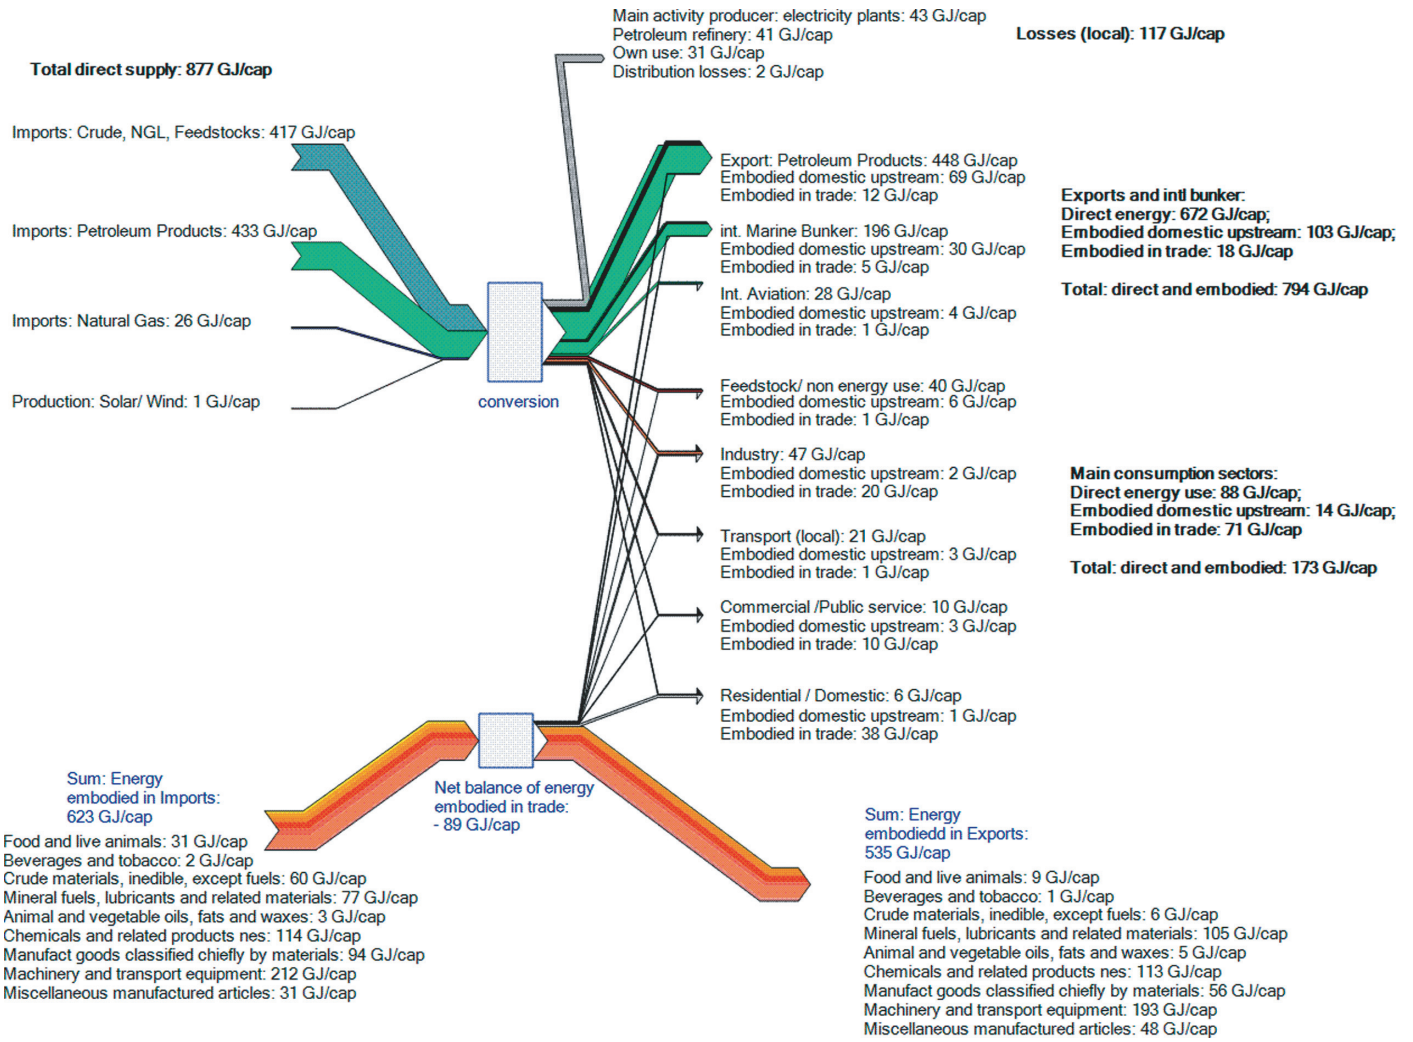

Figure 18.21 | Full per capita energy accounting for both direct and embodied energy flows of a large urban trade city, Singapore (in GJ/capita). Domestic direct and embodied energy use is 173 GJ/capita, but is dwarfed by the total energy imports to the city of 1490 GJ/capita. Total energy re-exports (direct and embodied) are 1225 GJ/capita. Source: Schulz, 2007; 2010b.

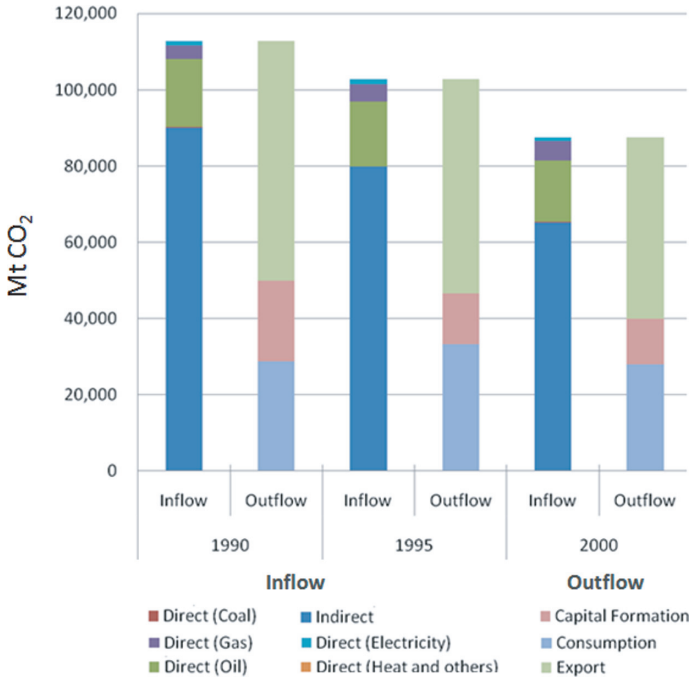

Figure 18.22 | CO_2 balance of Tokyo 1990, 1995, and 2000 using I-O analyses, in million tonnes CO_2. Source: Estimates by Shinji Kaneko and Shobhakar Dhakal.

That urban areas are usually in an intense process of energy exchange (imported and exported) with surrounding markets is again shown dramatically in Figure 18.22 for Tokyo in terms of CO_2 emissions. Emissions attributable to the direct and indirect energy and resource uses of Tokyo ('inflows') are balanced with the final consumption categories of these inputs as well as exports ('outflows'). Embodied energy and emission flows have gained increasing importance, comprising some 80% of Tokyo's 'inflows' and still slightly half of its 'outflows,' which illustrates Tokyo's embeddedness in the global economy. The Tokyo example also indicates the importance of energy and emissions embodied in maintaining and expanding the physical infrastructures and capital goods (reported under capital formation in Figure 18.22). Generally, private households only account for a small fraction of total capital formation (dominated by government, industry, and commerce). A consumption-based accounting that only uses household expenditures (as frequently done) therefore misses these important embodied energy and emission flows.

The 35 largest cities in China (China's key industrialization and economic drivers) are responsible for 40% of the nation's GDP and contribute overproportionally to national commercial energy use (Dhakal, 2009). Cities often specialize in certain types of manufacturing, commercial, or administrative functions. Some urban areas are also large transport hubs, such as London for air transit, or Cape Town and Rotterdam for shipping, that adds significantly to urban energy use, and is too often omitted from urban energy and GHG accounts. For instance, London's twin functions as a major international airport hub and as a global city result in an energy use from air transport that corresponds to one-third of London's total (direct) final energy use (Mayor of London, 2004).

A service-based economy can generate the same income with less energy than an economy based on the production of goods, which is one reason city per capita energy use in advanced, service-oriented economies is lower than national averages. This is also why Shanghai and Beijing have higher energy use per capita than Tokyo (see Figure 18.20 above), despite their lower GDP/capita.

If the economic activities located within a city determine its local energy use, its economic transactions with other areas entail energy use in those areas. Any product or service bought or sold entails energy use, and for service-oriented cities it may well be that the energy used, indirectly, through their economic transactions is larger than the energy used locally by their services industry. This phenomenon was shown at the level of urban household expenditures: rich households consume more energy indirectly than they do on housing, utilities, and local transit (Lenzen et al., 2004).

In addition to economic globalization, cultural globalization encourages urban upper and middle classes to adopt consumption patterns from global elites. Globalization-influenced urban development tends to favor private automobile-based individual transport modes and suburban sprawl for those who can afford it. Foreign direct investments (FDIs) and trade agreements affect the location and technology of manufacturing and commercial activities and labor reorganization (Romero Lankao et al., 2005). In China, individual cities compete with each other to attract FDIs and compromise their local environmental conditions and tax policies (Dhakal and Schipper, 2005). This type of intranational competition also occurs in other countries, such as Vietnam and India.

18.5.2.5 Energy Systems Characteristics: Governance, Access, and Cogeneration

The organization of energy markets and their controls at the urban level also influence urban energy use. Alternative organizational forms, such as state or municipal monopolies, cartels, or free-markets, impact access, affordability, and the possibility of implementing energy-saving policies. Localized energy monopolies may work closely with urban governments to further local policies, whereas free-market structures often challenge the enactment of environmental or social policies, such as renewable mandates, or the possibility of performance contracting. New York City requires (because of energy security and reliability concerns) 80% of electricity-generating capacity to be located within its territory; this means that the ability to influence the energy system is different to that in other cases. Vienna city owns its respective electricity, gas, and district-heating utility companies, and thus may have greater influence compared to cities with completely privatized and deregulated utilities. In Chinese cities, where energy companies are state-owned enterprises, the city government policies can exert strong influence on the suppliers, albeit less on the energy demand side. Many industrialized cities have put in place City Climate Actions Plans, which are expected to reduce or dampen energy use or promote shifts to renewables in the coming decades, but their success will depend on the links between city government and local energy providers. In many

cities across the world, the local government is hardly able to influence the energy-supply side (because of jurisdictional and capacity limits), but may be in a position to address demand-side energy issues.

In developing countries, urban populations generally have higher levels of access to commercial energy forms than rural populations. This affects the efficiency and the intensity of the environmental impacts of energy use (Pachauri, 2004; Pachauri and Jiang, 2008): rural populations consume (often self-collected) fuels such as fuelwood, biomass, and coal; urban populations consume commercial and cleaner energy forms: electricity, oil, and gas. Owing to the low level of efficiency of biomass use, the quantity of primary energy use per capita may be similar in urban and rural settings (Pachauri and Jiang, 2008), but the different fuel structure in urban, higher income settings provides for much higher levels of energy service provision. In this sense, urban populations benefit from the high efficiency of energy-service delivery of modern fuels and distribution systems, such as electricity, gas, or bottled LPG. Access to commercial energy is much less an issue in industrialized or industrializing countries, which already have electrification levels at 100% (IEA, 2002) and where gas-distribution networks connect a majority of urban households.

Many European countries also have a long tradition of urban district heating (and more recently of district cooling) networks that either use district heating plants or CHP energy systems. CHPs, in particular, offer potential energy-efficiency gains as waste heat from electricity generation can be used for low- and medium-temperature heat demands in urban areas, with steam-driven chillers that also provide cooling energy. Traditionally, such centralized systems are capital intensive and only economic in higher density urban settings that provide for sufficiently high demand loads to warrant the investments. The recent advance in more decentralized energy solutions, including microgrids, allows such systems to be extended to lower density urban settings. Typically, cities with significant energy cogeneration have primary energy needs that can be 10–20% lower compared to systems in which all energy demands are provided by separate, individual conversion devices.

A key issue for the improved efficiency of urban energy systems is therefore an optimal matching between the various energy-demand categories and forms to energy-conversion processes and flows, usually achieved by exergy analysis (see Box 18.6).

Box 18.6 | Urban Exergy Analysis: Efficiency – How Far to Go?

An analysis of the efficiency of urban energy systems is far from a trivial task, but it is fundamental to identify options and priorities for improved efficiency in energy use. With respect to the system boundaries of the analysis, should the analysis extend to final energy (the usual level of market transactions in the energy field), to the level of useful energy, or to energy services? Should only simply energy outputs/inputs relationships be considered in defining efficiency (referred to as First Law analysis in the literature, after the First Law of Thermodynamics) or the analysis be extended to consider quality differences in energy forms (which energy form is most adequate for delivering a particular task) and efficiency, not in absolute terms (as in First Law analysis), but in relation to what thermodynamically represents an upper bound of energy conversion efficiency (as no conversion process that operates under real-world conditions can achieve 100% efficiency)? The latter concept is referred to in the literature as Second Law (after the Second Law of Thermodynamics), or *exergy* analysis (e.g., Rosen, 1992).

The literature (e.g., Nakicenovic et al., 1990; Gilli et al., 1995) identifies the value of both types of analyses (First and Second Law analysis), but also concludes that Second Law analysis enables us to extend the system boundaries to include also energy *service efficiency* (which cannot be captured in First Law analysis as it lacks a common energy denominator) and important quality characteristics of different energy forms and their adequacy to deliver a particular energy service. Therefore, an illustration of the value of exergy analysis to assess the efficiency of urban energy systems is provided here using the example of Vienna, which is compared to a few fast-track European urban-exergy analyses obtained from various research groups.

The energy system of the city of Vienna is characterized by a number of unique features. First is that the city generates much of its electricity needs within the city itself with the use of resulting waste heat through a district-heating network (recently also extended to a district-cooling network). As a result, the corresponding First Law efficiencies of Vienna's energy system are very high: 85% of secondary energy is delivered as final energy and about 50% can be used as useful energy to provide the energy service needs of the city (see Figure 18.23). The impact of cogeneration on the city's energy needs is also noticeable: without cogeneration Vienna's secondary energy use would be some 13% higher. The high First Law efficiencies suggest limited improvement potentials. However, this is not the case as revealed by a Second Law analysis of Vienna's energy system, which shows the efficiency between secondary and useful exergy is only some 17%. This suggests significant improvement potentials, for example via heat-cascading schemes that better match the exergetic quality of energy carriers with the required temperature regime of energy end-uses.

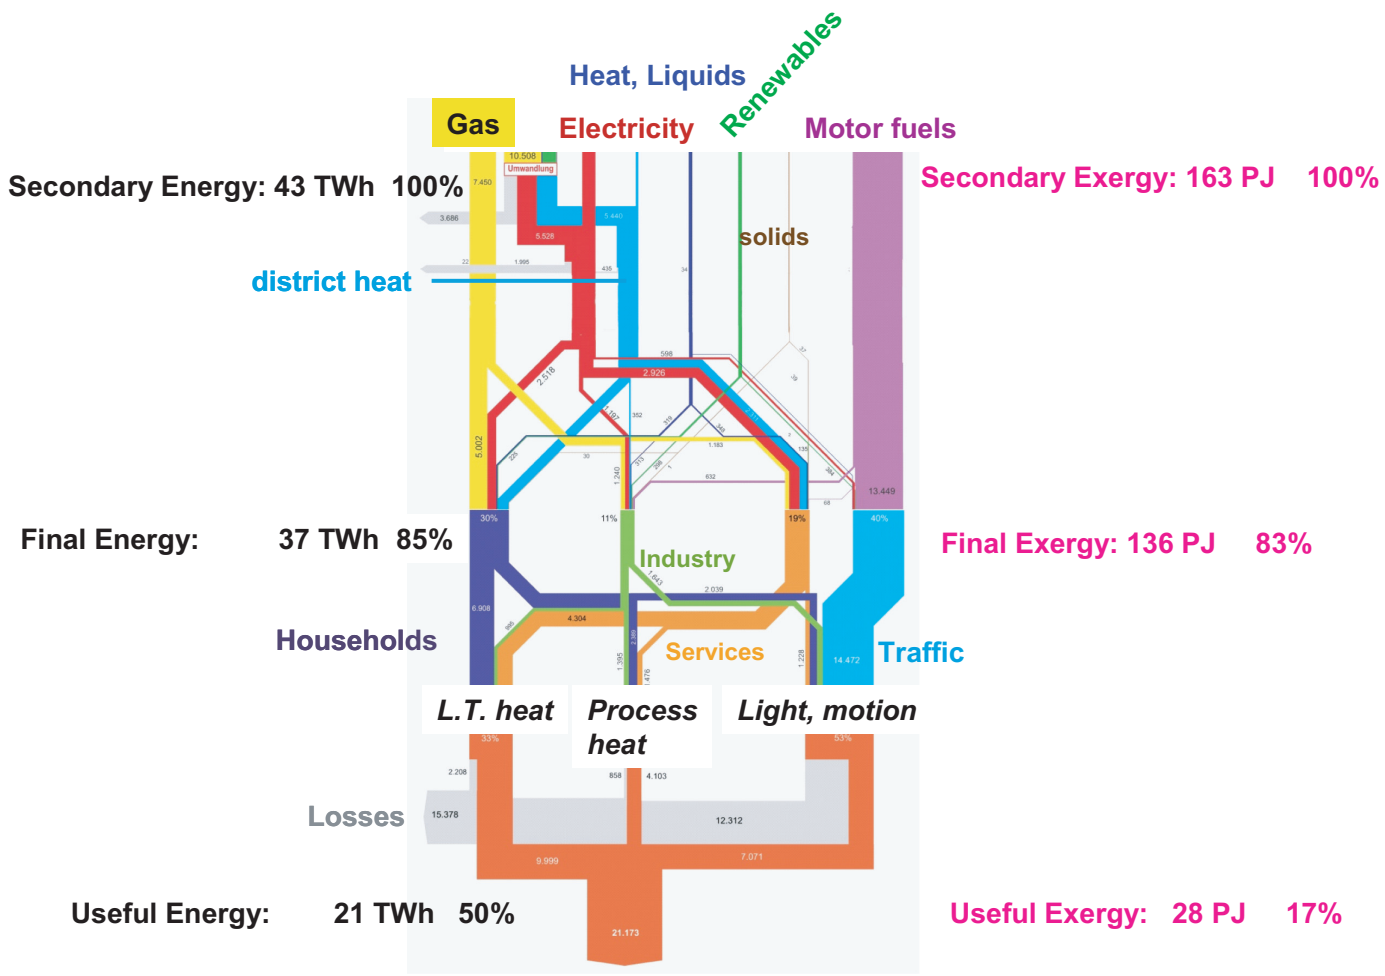

Figure 18.23 | Energy and exergy flows in the City of Vienna in 2007 between secondary and useful energy/exergy. Source: Energie Wien, 2009, (approximate) exergy efficiencies based on Gilli et al., 1996.

This assessment obtained the results of similar exergy analyses for Geneva, Switzerland (Giradin and Favrat, 2010), the Swedish city of Malmo, and London (Fisk, 2010). The results of the comparison in terms of the efficiency of useful exergy to that of secondary and primary exergy are summarized in Table 18.15.

Table 18.15 | Comparison of the efficiency of useful exergy to that of secondary and primary exergy.

	Useful exergy as % of:	
	secondary	primary
Geneva (CH)	23.2	15.5
Vienna (A)	17.2	
Malmö (S)	21.2	12.7
London (UK)	11.3	6.2
trad. Mexican village	5.7	

The results confirm earlier conclusions that, thermodynamically, urban energy systems could, in theory, be improved vastly, perhaps by as much as a factor of 20 (a similar order of magnitude as suggested by Nakicenovic et al. (1990) for OECD countries), and thus leave ample opportunity to realize feasible measures under real-world conditions and constraints that might deliver an improvement by at least a factor two. That modern urban energy systems are – despite their comparatively low exergy efficiencies – vastly more efficient (by a factor of 2–4) than traditional rural energy systems is also shown in the Masera and Dutt (1991) analysis of a traditional Mexican village with 2400 inhabitants using mostly preindustrial energy forms and conversion technologies (draft animals and fuelwood) for the provision of their energy services yielding an exergetic efficiency of only some 6%, compared to 11–23% for modern urban energy systems and uses.

18.5.2.6 The Urban Form: The Built Urban Environment and its Functions[30]

The built environment

The built urban environment comprises the totality of the urban building stock: residential, commercial, administrative, and industrial buildings, their thermal quality and spatial distribution (for a detailed exposition of building energy use, see Chapter 10). It also includes built urban infrastructures for transport, energy, water, and sewage. This environment is one of the key components for understanding the special characteristics of urban energy use as compared to rural, economy-wide, or global patterns. The unique concentration and overall scale of the built urban environment allow both economies of scale and economies of scope to occur, and thus provide options for energy-efficiency gains.

Building design

The design and thermal integrity (e.g., insulation levels) of buildings are essential for the amount of energy intensity (energy/m^2) needed for heating and cooling. Reducing the energy associated with heating has been a strong focus in northern European countries, but midlatitude countries have to attempt a design a balance between heating and cooling energy demands. In many cases, newer buildings have better thermal standards, but in some cases they are poorly adapted to their climate (e.g., European- and US-style villas and apartment buildings in tropical climates, which do not have adequate shade and ventilation). Old buildings may suffer from lack of renovations, or renovations that do not apply the best possible standards. The influence of building technology on the energy used for space heating is huge: a Passivhaus standard requires that energy use for space heating be no more than 15 kWh/m^2 floor area per year; for low-energy houses the corresponding number is around 50 kWh/m^2, whereas poor thermal insulation may cause energy use for space heating of 200–400 kWh/m^2 in mid-European latitudes.[31]

The energy involved in the maintenance and replacement of components over a building's life should also be taken into account in assessing the energy performance of a building. For a 50+ year lifetime of office buildings, the embodied energy in construction materials plus the energy needed for decommissioning is estimated to range from 2.5 to 5 years of the building's lifetime operational energy use (Cole and Kernan, 1996; Scheuer et al., 2003; Treberspurg, 2005), with a typical value of embodied energy being between 5% and 10% of direct, operational energy needs of buildings. Including single and multifamily houses somewhat expands this range. The detailed literature review of Sartori and Hestnes (2007) reports a range from 4 to 15% embodied energy in total lifecycle energy use of buildings. Only in extremely low energy-use buildings (e.g., Passivhaus-standard or even below), with their extremely low operational energy use, does embodied energy play a somewhat greater role, reaching between 25% (Sartori and Hestnes, 2007) and 29% (Treberspurg, 2005): typical values of 20–30 kWh/m^2 building floor area/year of embodied energy compare to 50–60 kWh/m^2 building floor area/year for operational energy (heating plus electricity).

Type of buildings and uses

Next to the energy characteristics of an individual building, also the mix of building types and their density are important determinants of urban energy use.

The specificities of the urban built environment are usually a large existing stock, which requires renovation and maintenance, and new buildings in growing cities. The improvement in building stock to lower heating and cooling demands is counterbalanced by the increase in surfaces necessary to house new populations in growing cities, along with the demand of inhabitants for larger and larger apartments – even as the average household size decreases. Residential floor space per capita is known to be strongly correlated with income (e.g., Schipper, 2004; Hu et al., 2010). National averages in industrial countries range from 30 m^2/person in Japan to 50 in Canada, 55 in Norway, and 80 in the United States (Schipper, 2004; US DOE, 2005). Typically, urban residential floor space per capita is lower than the national averages (to a degree counterbalanced by smaller household size), particularly for high-density cities with their corresponding high land and dwelling prices, but comprehensive statistics are lacking. For urban China, Hu et al. (2010) estimate 5 m^2/person in 1990 and approximately 25 m^2/person in 2007.

Newton et al. (2000) evaluated and modeled the energy performance of two 'typical' dwelling types – detached houses and apartments – across a range of climatic zones in Australia. Two main conclusions were drawn: (1) annual heating and cooling energy and embodied energy per unit area were similar for apartments and detached houses; (2) per person, however, the lifecycle energy of apartments was significantly less (10–30%) than that of detached houses in all circumstances, because the area occupied per person was much less. Norman et al. (2006) used a lifecycle analysis approach to assess residential energy use and GHG emissions, contrasting 'typical' inner-urban, high-density and outer-urban, low-density residential developments in Toronto. They found that that the energy embodied in the buildings themselves was 1.5 times higher in low-density areas than that in high-density areas on a per capita basis, but was 1.25 times higher in high-density areas than that in low-density areas on a per unit living area basis. Salat and Morterol (2006) compared 18th century, 19th century, and modernist urban areas in Paris, assessing five factors in relation to CO_2 emissions for heating: (1) the efficiency of urban form in relation to compactness; (2) a building's envelope performance; (3) heating equipment type, age, and efficiency; (4) inhabitant behavior; and (5) type of energy used. Salat and Morterol (2006) asserted that an efficiency factor of up to 20 could be achieved

30 A working paper on urban form and morphology contains a more extended discussion and is accessible at www.globalenergyassessment.org.

31 See http://energieberatung.ibs-hlk.de/

from the worst-performing to the best-performing urban morphology by taking these five factors into account. Salat and Guesne (2008) investigated a greater range of morphologies in Paris and found that when considering heating energy, the less dense the area, the greater the energy required for heating (see also Ratti et al., 2005).

Urban form and functions

Urbanization patterns affect the extent and location of urban activities and impact the accompanying choice of infrastructures. Newton (2000) summarized key alternative urban forms or 'archetypal urban geometries,' namely the dispersed city, the compact city, the edge city, the corridor city, and the fringe city. The merits of dispersed and compact cities ('suburban spread' versus 'urban densification') have been debated since the 19th century and a strong divide exists between the 'decentrist' (the dispersed city model) and 'centrist' (the compact city model) advocates (Brehny, 1986).

Nonetheless, one the most important characteristic of cities is density. Overall, a certain density threshold is the most important necessary (although not sufficient) condition to allow efficient and economically viable public transit (see Section 18.5.3 below). In addition, in a dense environment distribution networks are shorter, infrastructure is more compact, and district-heating and -cooling systems become feasible. Unconventional energy sources, such as sewage and waste heat, are also more accessible. High density may thus help curb urban energy use (Rickaby, 1991; Banister, 1992; Ewing and Cervero, 2001; Holden and Norland, 2005).

Most importantly, a compact city brings the location of urban activities closer. In the context of transportation, from cross-city comparisons it is well established that higher urban densities are associated with less automobile dependency and thus less transport energy demand per capita (Newman and Kenworthy, 1989; Kenworthy and Newman, 1990; Newman and Kenworthy, 1991; Brown et al., 2008; Kennedy et al., 2009). Intracity studies for Sydney (Lenzen et al., 2004), Toronto (VandeWeghe and Kennedy, 2007), and New Jersey (Andrews, 2008) also show that denser neighborhoods have lower per capita transportation energy needs. As a result, in many low-density cities, per capita energy use has grown at approximately the same rate as that in suburban areas (sprawl) (Baynes and Bai, 2009).

In many of the less-compact cities, transportation[32] by automobile is the biggest contributor to energy use (Newman and Kenworthy, 1999). The data suggest that cities with a density of 30–40 people/ha or greater developed a less automobile-based urban transport system with typical density thresholds for viable public transport systems given as above 50–100 people/ha (see Section 18.5.3). On average, residents who live at a distance of 15 km from an urban center use more than twice the transport energy compared to residents living 5 km from the center (Stead and Williams, 2000). Nijkamp and Rienstra (1996) note that the private automobile has brought low-density living within the reach of large groups of upper and lower middle-class families. Moreover, correlations between automobile ownership and income suggest that more affluent automobile owners have a higher propensity to travel longer distances by energy-consumptive modes (Banister et al., 1997).

Diversity of function may also play a role in managing urban transport demand (Cervero and Kockelman, 1997). When strict zoning is enforced so that residential areas are separated from commercial, education, services, and work areas, private transportation is maximized. Mixed land uses and concepts of self-containment are important in reducing energy use in transport. Nevertheless, local jobs and local facilities must be suitable for local residents, otherwise long-distance, energy-intensive movements will continue (Banister et al., 1997). This coordination of land-use and transportation policies is termed transit-oriented development. The idea of location efficiency emphasizes the accessibility of opportunities, rather than how mobile one must be to find them (Doi et al., 2008); this is a central concept in recent approaches to transit-oriented development and other forms of sustainable urban development.

Also, urban density is an indicator of *potential* energy savings, especially in transportation. If infrastructure is inadequate to support the volume of traffic flow the resulting congestion can lead to higher energy use, even in high-density, built-up areas. For energy efficincy potentials of urban densities to be realized, a chain of interdependent, appropriate infrastructure, technical, and consumption decisions must be made. The correct level of public transit infrastructure requires large up-front investment and maintenance, from light rail to subways, trams, or dedicated bus routes. Adopting public transit also requires appropriate consumer behavior. In many North American cities, public transit is associated with lower economic status, and thus avoided by most people who can afford to drive, which reinforces the initial perception. A contrary example is Tokyo where the per capita energy use is smaller than in many East Asian megacities; one of the key reasons for this is the efficient rail-based public transport in Tokyo (Dhakal, 2004; 2009).

Another important energy implication of the urban form is the choice of urban energy-supply systems. District-heating and -cooling infrastructures, which allow large economies of scale and efficiency gains through cogeneration, are only possible when the density of demand is high enough to warrant the capital-intensive investment, unless such systems are mandated (and costs added to land prices). Compact urban form may also play a role in the energy used for buildings. Apartment buildings generate economies of scale compared to single-family homes, but apartment buildings may compromise decentralized low-energy design practices, such as natural lighting, ventilation, and decentralized use of PVs. Another important influence of density is at the personal consumption level. Apartment size per person tends to decrease with population density (with Hong Kong and Manhattan representing extreme examples). Effectively, the high competition for central urban space creates rents that contract floor space. However, in cities without

32 For a more in-depth discussion of transport energy use and its drivers see also Chapter 9 of GEA.

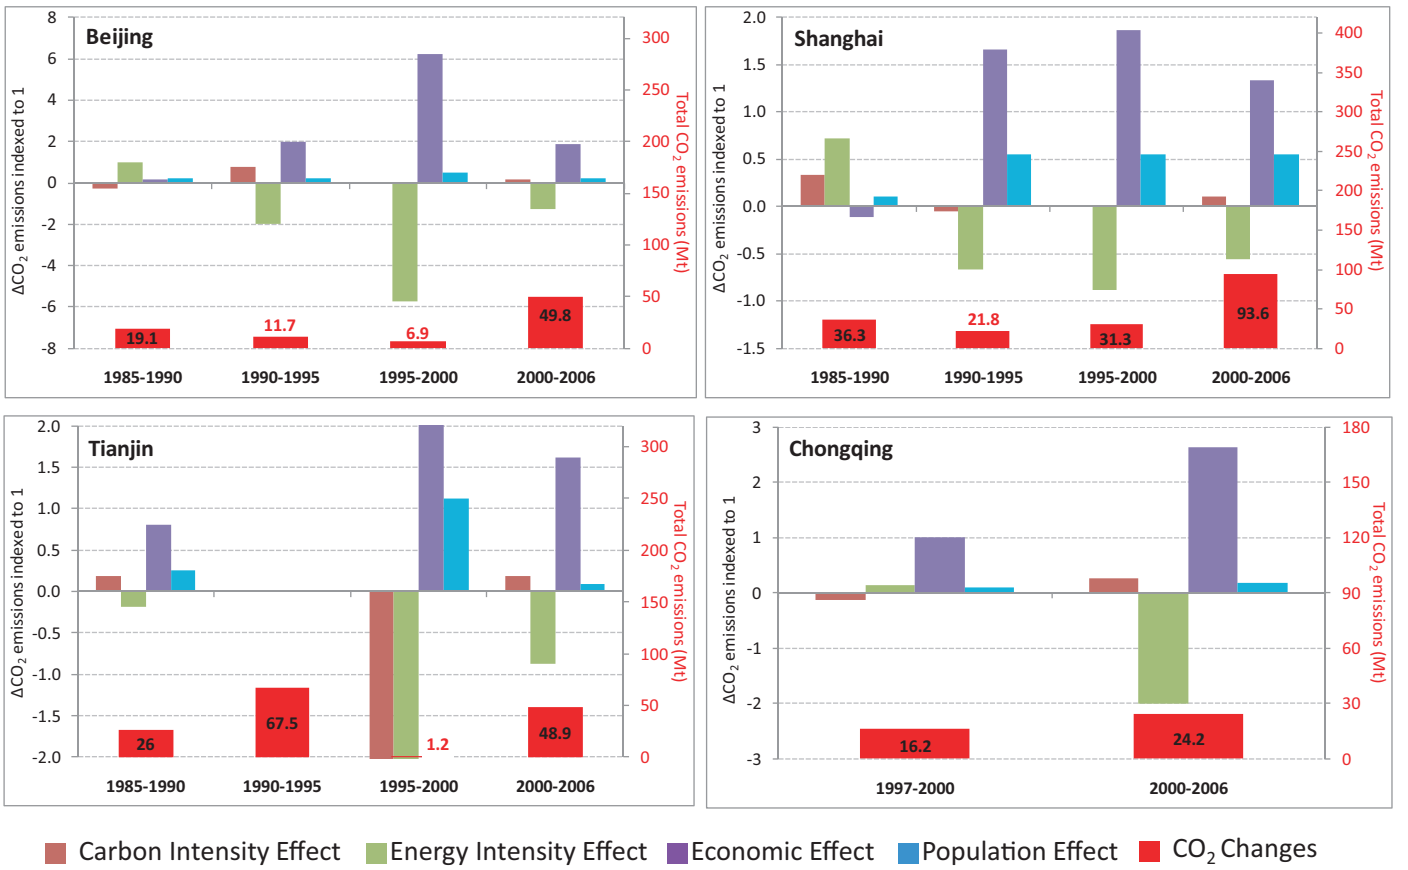

Figure 18.24 | Contribution of factors (indexed, left axis) to the changes in energy-related CO_2 emissions (million tonnes CO_2, right axis) for four Chinese cities. Source: Dhakal, 2009.

sufficient low-rental housing, even the smallest apartments can be out of reach for the poorer populations, who are forced to live in distant suburbs with poor transit connections. In many cities, suburbanization is also caused by industrial relocation from urban cores and the unplanned settlement of migrants and urban poor in the urban periphery.

More compact cities, however, may require special management to avoid the ill-effects of congestion and higher concentrations of local pollution (e.g., see Jenks et al., 1996). Urban heat island effects, for instance, may be exacerbated in dense urban cores. There may be a trade-off between the transport energy savings achieved with higher urban density versus the higher energy use of high-rise buildings. There are also trade-offs between urban density, dwelling type, block size, and the ecosystem services provided by vegetation. Both theoretically and empirically, it is by no means clear that there is an ideal urban form and morphology that can maximize energy performance and satisfy all other sustainability criteria.

18.5.2.7 Relative importance of the drivers of urban energy

No study so far has investigated the relative importance of all the factors known to influence urban energy use as described above. Existent approaches rather contrast energy and/or CO_2 emissions with such macrodrivers as population, income, and technology, and thus follow the classic IPAT decomposition approach.[33] Such decomposition analysis has, for example, been carried out for several Chinese cities (Dhakal, 2009), where the relative changes in urban CO_2 emissions are decomposed into the factors population change, income change (measured as GDP/capita), and two technology factors: the carbon intensity of the energy system (measured as CO_2 emissions per unit of primary energy demand) and energy intensity (measured as primary energy demand per unit of GDP) for several periods of time. Although the relative contribution of these factors varies across cities and time periods, overall income is shown to be the most important driving factor for increases in carbon emissions (by far outpacing population growth), and improvements in energy efficiency to be the most important counterbalancing factor. The net result is, in all cases, an increase in carbon emissions, which indicates that economic growth has, to date, outpaced technology and efficiency gains (Figure 18.24).

Earlier work by Dhakal and Hanaki (2002) and Dhakal et al. (2003) for Tokyo using 1970–1998 data and for Seoul using 1990–1997 data also

33 IPAT: Impacts = Population × Affluence × Technology. For a history and discussion of the concept see Chertow, 2000.

shows that the income effect was primarily responsible for the majority of energy-related CO_2 emissions growth in Tokyo and Seoul in their respective high growth periods, that is 1970–1990 for Tokyo and 1990–1997 for Seoul. The analysis also showed that, despite an economic recession, energy-related CO_2 emissions continued to grow in Tokyo in 1990–1998, largely because of a drastic decline in the energy-intensity improvement rate (often observed in periods of economic growth stagnation or recession caused by the slower rate of capital turnover and hence the slowing introduction rate of more energy-efficient technologies and practices).

18.5.3 Transportation Systems[34]

18.5.3.1 Urban Travel Behavior

Introduction

To a large extent, traveling and mobility are a means to an end; they are necessary to enable people to fulfill essential functions (e.g., living, working, gaining education, acquiring necessary supplies, and relaxing) in the most suitable places. The situation is similar for the production of goods and services: fragmentation of the production process of goods and services implies different stages of the production chain, provided by different, more specialized enterprises at different sites, which improves the efficiency of the production at all. This causes travel demand, which is measured in different ways depending on the reasons for travel:

Frequency of trip making

This metric is a basic indicator for the degree of mobility and concurrent degrees of economic development and lifestyles. In urban settings the mean value of this figure ranges from 2.2 trips/day for people in low-income cities of developing countries (Padam and Singh, 2001) to up to 4.0 trips/day in industrialized countries (Hu and Reuscher, 2004; Sammer et al., 2009). It is expected that, in future, the frequency of trip making will rise slightly, particularly in developing countries. Generally, the frequency of trips is higher in cities than in rural areas because of higher degrees of specialization and division of labor and the higher number of attractive destinations with good accessibility, characteristic of urban areas.

Distance traveled per day

This metric reflects the transport modes used and the spatial structure and settlement density (NRC, 2009). The lower the settlement density and the more automobile-oriented an area, the longer the distances traveled per day. Globally, the mean values of these distances vary considerably, from 10 to 60 km/person/day in developing and industrialized countries, respectively (Salomon et al., 1993). In rural areas of developed countries the average distanced traveled per day is *higher* than that in cities. In developing countries the opposite is true: in rural areas distances traveled are generally very low (significantly below 10 km/person) and are significantly higher in urban areas because of both higher urban incomes and better availability of urban infrastructures and transport options. There is a close positive correlation between the distance traveled per day and transport energy use (Pischinger et al., 1997).

Travel time budget per day

This metric is an indication for the time spent traveling. For long periods this figure was comparatively stable with a small tendency to increase; it is currently on average around 70 minutes per person and day and 90 minutes per mobile person and day in countries with high motorization and automobile orientation (Hu and Reuscher, 2004; Joly, 2004). Assuming that, in the long run, working hours will decrease through continued productivity gains, this figure is expected to increase somewhat in future.

Traffic and mobility surveys help to determine the travel behavior, which is typical for various sections of the population and for different settings. Caution is, however, advised when comparing different mobility surveys because of differences in survey coverage and methods (e.g., does the survey include non-motorized modes?) and differences in sampled populations (commuters to work versus total population) and other methodological intricacies (e.g., weekday vs surveys that also include weekends). Therefore, there remain serious data gaps for comparable and up-to-date mobility surveys across a wide range of settlements and with comprehensive geographic coverage. The next sections summarize the current state of knowledge, with special emphasis on survey comparability rather than on how recent the survey date is. Despite important data limitations, some robust generic patterns can be discerned.

Modal split of cities

The modal split is an expression for the shares of different transport modes in the overall travel demand – usually measured as shares in total number of trips performed. It is a reasonable proxy for the evaluation of the environmental soundness of an urban transport system and its associated energy use. Higher shares of 'ecomobility' transport modes (including non-motorized modes like walking and cycling, as well as public transport) and corresponding smaller shares of private motorized transport imply a more environmentally friendly and energy-efficient transport system. The modal split can be conveniently depicted in a triangular diagram (Figures 18.25 and 18.26) that plots the respective shares of non-motorized modes (walking and cycling), public transport, and private motorized transport (automobiles, two-wheelers, etc.), respectively. In cities or towns with a modal-split point close to the center of the triangle, the three transport modes have fairly similar shares. In Figure 18.25, public transport dominates in the case of modal-split points close to the top of the triangle (e.g., New Delhi in 1994), private motorized transport is dominant in the lower right-hand corner (e.g., Chicago in 2001), and non-motorized transport in the lower left-hand corner of the triangle (e.g., Lackhnow in 1964). This

34 See also Chapter 9 for a review of transport energy.

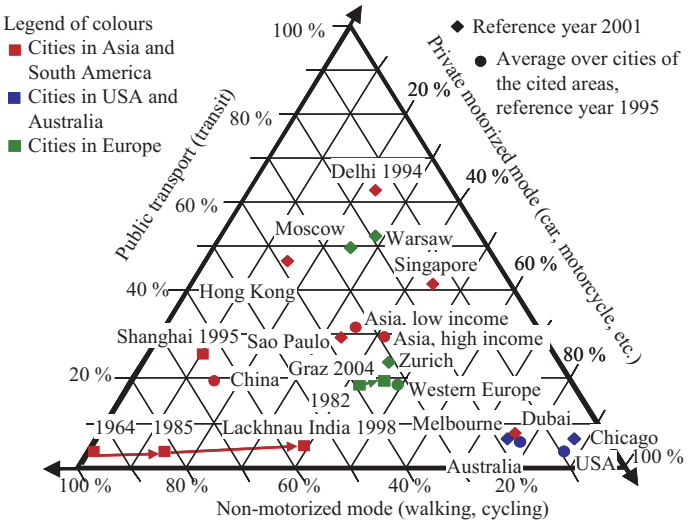

Figure 18.25 | Modal split for cities and towns on all continents (shares in trips). Source: Kenworthy and Laube, 2001; Padam and Singh, 2001; Zhou and Sperling, 2001.

representation enables the display of both cross-sectional and longitudinal observations.

Private motorized transport has a very high share between 88% and 79% in cities in the United States and Australia, where ecomobility has only a very low share of 12–21%. Thus, in these cities and towns transport systems depend strongly on private automobiles and so on fossil fuels. Cities and towns in Western Europe and well-developed Asian economies are roughly in the center of the diagram. There motorized private transport holds a share between 36% and 50%, that is transport systems are less automobile-oriented, and ecomobility holds a remarkably high share of 10–50%. In the cities and towns of China private motorized transport has thus far been fairly insignificant with a share of about 15%, but it is growing rapidly in importance.

Figure 18.25 indicates that with growing economic development and increasing incomes, the share of private motorized transport increases while the share of ecomobility decreases. This development is illustrated well by the longitudinal time trends of the modal split of the city of Lackhnau in India over the period 1964 to 1998. The United States and Australia seem to have reached a saturation level in this development; Western Europe and Asia have still some potential to develop further in this direction, unless they take countermeasures. This development does not follow any laws of nature: it is the result of transport policies and human behavior.

While Figure 18.25 shows the average modal split of cities and towns, Figure 18.26 shows the modal split for *commuter transport* in economically highly developed cities on different continents. These cities are divided in two groups: those with less and those with more than one million inhabitants.

For some selected cities the development of the modal split over time is also indicated, where comparable data are available. From the modal split for these cities and towns it is obvious that the range for individual elements is quite large, despite similar economic conditions and a high automobile-ownership rate. For example, non-motorized transport ranges from 4–50%. For walking as a separate mode, the range is from 4–21%, while cycling ranges from 0–39%. The range for public transport is also high, from 5–63%, while private motorized transport ranges from 24–80%. Thus, a high share of private motorized transport in towns and cities and an extensive use of automobiles are not an unavoidable outcome for cities in high-income countries, which illustrates the importance of urban form and transport policy choices.

The modal split of commuter transport (Figure 18.26) also shows a significant difference compared with all-travel purposes (Figure 18.25). The share of non-motorized modes is significantly lower and that of public transport higher, which is caused mainly by the longer journeys for working trips. There is no significant difference between large (over one million inhabitants) cities and smaller towns. The development of the commuting modal split over the long term shows a clear trend: motorized modes gain shares at the expense of non-motorized modes.

A considerable range for the modal split and the associated energy use can thus be observed in towns, cities, and urban agglomerations of industrialized countries, a range influenced by several factors: lifestyles, awareness of environmentally friendly and energy-saving travel behavior, objectives of urban transport policy and the willingness to implement such policies, spatial structures and settlement density, fuel prices, parking management, provision and operation of transport infrastructures for walking, cycling, public, and automobile traffic, pricing of the various transport modes (fees for both moving and stationary traffic, public transport prices), and priorities accorded to the various transport modes. Counter examples are easily found to the myth that a modern and economically viable city with a high quality of life can only be achieved with automobile-oriented private transport modes (Newman and Kenworthy, 1999; Directorate-General for Energy, 2007; Susilo and Stead, 2008).

Modal split and energy use

There exists a specific characteristic amount of energy use for every mode of transport, usually measured in terms of liters of fuel or in megajoules per passenger-kilometer traveled. The specific energy use of each mode is determined by the respective vehicle technology (e.g., size and/or weight of vehicle, engine efficiency, etc.), the vehicle occupancy rate (passengers per vehicle), and traffic conditions (degree of congestion). Overall, the specific energy use is highest for private automobile transport (Table 18.16 and Figure 18.27).

A robust finding, illustrated in Table 18.16, is that the choice of transport modes (i.e., the modal split) is a more important determinant of overall transport energy use compared to the specific energy

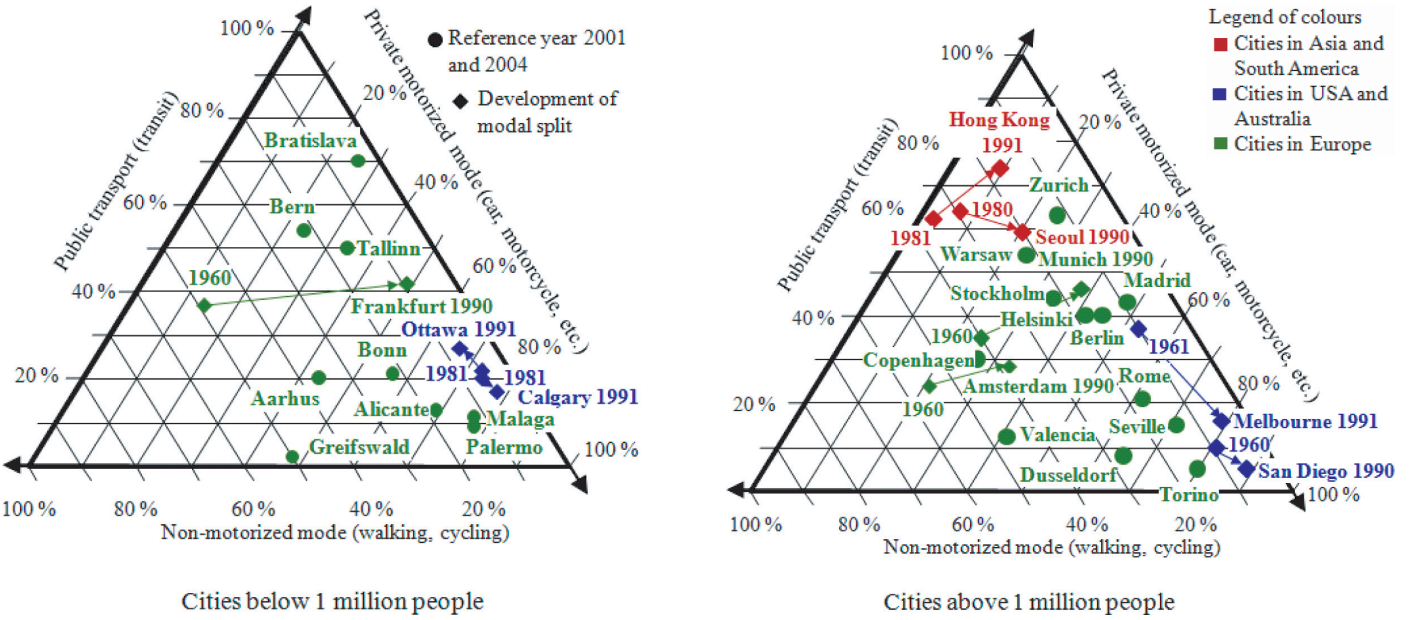

Figure 18.26 | Modal split of journeys to work in medium-sized towns with a population below one million people (left panel) and in cities with a population above one million people (right panel) in high-income economies for reference years 2001 and 2004 and selected time trends since 1960. Sources: Vivier, 2006; Steingrube and Boerdlein, 2009; Urban Audit, 2009; Wapedia, 2009.

Table 18.16 | Primary energy use per passenger-kilometer traveled for different modes, characteristic ranges for reference year 2005. Calculation based on Pischinger et al., 1997.

	Energy use per passenger-kilometer traveled	
	Fuels (liter/passenger-kilometer)	Energy (MJ/passenger-kilometer)
Private automobile traffic	0.050–0.075 (100%)	1.65–2.45 (100%)
Private motorbike	0.028–0.038 (55%)	0.92–1.25 (55%)
Public bus	0.009–0.013 (20%)	0.32–0.40 (20%)
Electric railways and public transport	0.002–0.004 (5%)	0.53–0.65 (35%)

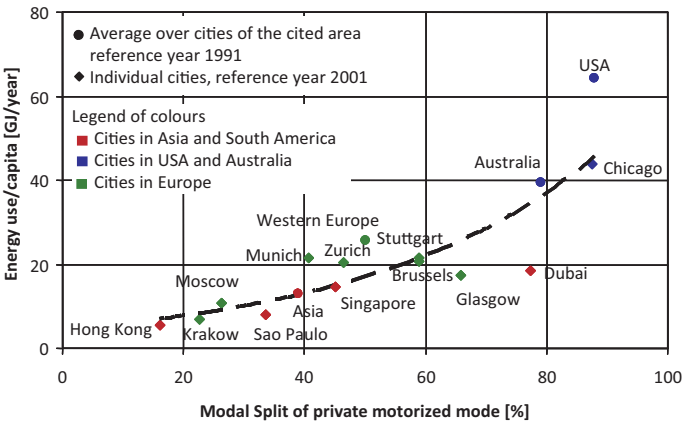

Figure 18.27 | Average energy use per capita in transport (average for countries and regions in 1991 and for selected global cities in 2001) versus share of private motorized transport in modal split. Source: data based on Kenworthy et al., 1999; Kenworthy and Laube, 2001; Vivier, 2006.

use of individual transport technologies. Put simply, using an (even energy-inefficient old) public bus is a more energy-efficient mode of transport than using a 'cutting-edge,' energy-efficient hybrid private automobile if the occupancy rate of the public bus is high (and that of the car is low). Policywise, this implies that if the objective is to minimize energy use, towns and cities should attempt to achieve a position for their modal split that favors 'ecomobility,' that is non-motorized and public transport, rather than incremental improvements in vehicle efficiency or biofuel supply for individual passenger automobiles, even if the latter may constitute important complementary options for sustainable transport planning in the interim before policy measures in urban form, traffic planning (especially for non-motorized mobility), and improved public transport systems take a long-term effect.

18.5.3.2 Specifics of Urban Transport Systems

Compared to rural and long-distance traffic, urban transport systems have some unique characteristics. Towns, cities, and urban agglomerations are places of high population and facility density. Their communication needs are high. This leads to a high density of travel demand within a limited space. Therefore transport modes are needed that require little space while offering high performance (Table 18.17). Pedestrians need the smallest amount of space, followed by public transport, cycling, shared taxis, and private motorized transport. The space required by the different transport modes and their capacity also depends critically on

Table 18.17 | Comparison of characteristic capacities of modes (assuming free-flowing traffic), space required with typical occupancy rates at peak traffic hours, infrastructure costs in urban settings, and maximum accepted distance for daily trips (ÖVG, 2009; Sammer et al., 2009).

	Non-motorized mode		Motorized mode			
	Walking	Cycling	Motorbike, two wheeler	Automobile	Shared taxi	Public transport
Capacity of a 3 m lane (person/h)	3600–4000	3600–4000	4300–5000 (max. 7200–8500)	2300–3000* (max. 9500–12,000)	5000–9000	Bus: 8000–16,000 Tram: 18,000–24,000 Underground: 30,000–60,000
Space required per person (m^2/person)	0.7–0.8	6.0–7.5	13.0–15.0	21.0–28.0	7.0–12.5	Bus: 1.25–2.5 Tram: 1.7–2.3 Underground: 0.75–1.50
Infrastructure investment costs for the space required per person (€/person)**	50–150	50–150	1500–3000	Urban road: 2500–5000 Urban motorway: 50,000–200,000	1250–2500	Bus: 200–500 Tram: 2500–7000 Underground: 15,000–60,000
Accepted distance for daily trips (km)	1–2	5–10	10–20	Practically unlimited	10–20	Practically unlimited
Type of mobility service	Door-to-door service, Temporarily unrestricted service					No door-to-door service, Scheduled service

* Average occupancy rate of 1.2 people/automobile at peak hours. **1 Euro = 1.245 US$ in 2005.

occupancy rates (load factors). The figures provided in Table 18.17 refer to peak-hour traffic, which means full occupation of public transport and about 1.2 people per automobile in private motorized transport, characteristic for average load factors during peak commuting times in high-income, high automobile-ownership cities.

With respect to energy use, emissions, required space, and noise, public transport is significantly superior to private motorized transport, if a sufficiently high occupancy rate of public transport modes can be assured. From the transport user's point of view, public transport has certain disadvantages compared to private motorized transport that can only partly be compensated for. Such disadvantages are the limited spatial and temporal availability because of a scheduled service with specific stops. To make public transport attractive, a dense public transport network and a high service frequency with short intervals is necessary. A headway of service of less than 10 minutes needs to be achieved so that passengers are able to use public transport spontaneously. To make access and egress attractive, the catchment area of a public transport stop should span not more than 300–500 meters. This can only be guaranteed if the densities of development of residential areas in cities (including traffic areas) are considerably higher than roughly 100 people/ha (10,000 people/km^2) and densities of development within the whole urban area are higher than 50 people/ha (5000 people/km^2). The large amount of space required for road areas and the low density housing types (e.g., single family dwellings) that preordain private

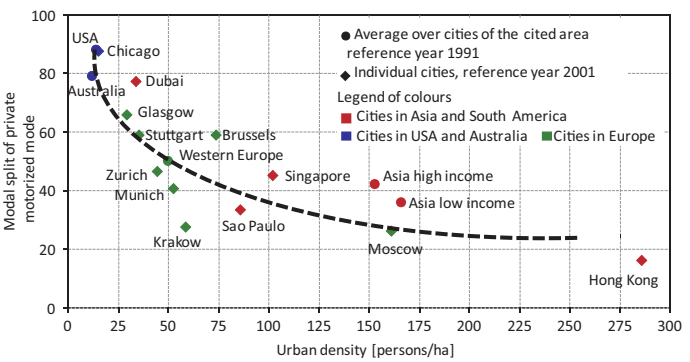

Figure 18.28 | Relation of urban density and share of private motorized transport modes (calculated from total mobility, including non-motorized modes) for individual cities and regional average cities. Source: Kenworthy et al., 1999; Kenworthy and Laube, 2001; Vivier, 2006.

automobile use mean that automobile-dependent urban settings typically have population densities far below these critical threshold levels (Figure 18.28) making attractive public transport not viable. An increasing share of private motorized transport modes causes a progressive increase of urban space and a progressive decrease of urban density. Since their density of development is unsuitable for offering attractive and economically viable public transport systems, automobile-dependent cities are Modd split of private molorized modes 'locked in' into high energy use and emissions.

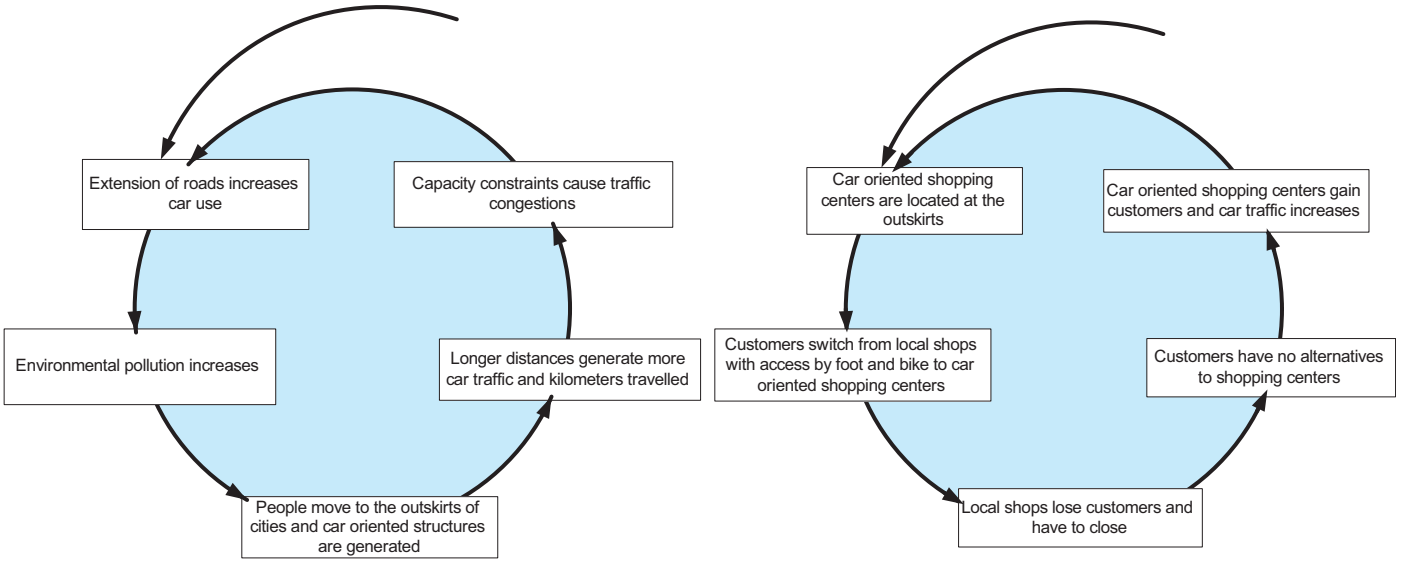

Figure 18.29 | Dynamic negative feedback effects between urban sprawl, automobile traffic, the quality of the environment, and viability of neighborhood stores in urban areas. Source: Sammer et al., 2009.

In terms of spatial planning, clear objectives with respect to sustainable urban-transport systems can be derived: stores for items of daily use need to be in locations that can be reached by non-motorized transport modes. The catchment area of such stores needs to be characterized by a sufficient density of use and compact settlement structures to make these stores economically viable. Thus, a concentration of stores for daily needs in shopping centers in automobile-oriented locations at the city perimeter should be avoided. The growth of decentralized shopping and other facilities leads to a negative feedback loop that further reinforces automobile dependence: fewer neighborhood stores, rising demand for shopping centers, increasing use of automobiles, and yet fewer customers for local stores (Figure 18.29). A similar negative feedback loop can be observed in the cause-effect chain from road-infrastructure development: the generation of more automobile traffic leads to environmental damages, lower urban quality of life, migration to suburbs, and then to yet further generation of more automobile traffic. Contrary to popular conception, any additional supply of urban road infrastructure (a frequent popular response to congestion by dense automobile traffic) inevitably also increases demand and entails more use of automobiles, ultimately simply shifting the point of congestion to higher levels of road and automobile traffic densities (Sammer et al., 2009).

Since trip lengths in local traffic are considerably shorter than those in long-distance traffic, high transport capacities at more moderate speed but with high traveling comfort are most important for short-distance, that is urban, traffic.

From an economic point of view, private motorized transport and public transport do not compete on an equal-level playing field, since the external costs of the two transport modes differ considerably. Table 18.18 offers an illustrative comparison of the external costs of road traffic and rail transport in Austria and Germany, where available data and estimation methods allow for one of the few 'apples-to-apples' comparisons possible in the extremely heterogeneous external-costs literature. Compared to rail transport, road traffic generally causes five to six times more external costs. The overall results for Austria and Germany are quite similar, but there are significant differences in some of the cost components, mostly caused by different assumptions with respect to external cost rates per externality category. (Thus, even in this case a fully consistent comparison of external costs is not possible. In the relevant literature (e.g., UNITE, 2003; Maibach et al., 2008), external cost estimates from transport vary considerably, which suggests the difficulty in arriving at widely agreed consensus values useful for policymakers.) The external costs caused by private automobile uses have to be paid for by other people. As far as the health costs of noise, emissions, and accidents are concerned, the people who finance the healthcare system have to pay for them, irrespective of whether they use an automobile frequently, infrequently, or not at all. The resulting costs of GHG emissions caused by fossil-fuel use in automobiles have to be paid by future generations that will face the consequences of climate change. From the perspective of sustainable transport systems and from an economic perspective of a fair competition among different transport modes, the externalization of costs needs to be overcome by *internalization.* Polluters should bear the resulting external costs by making them pay suitable fees or taxes. In reality this translates into an economic effect equivalent to a fuel price increase of at least a factor of 2–3, which does not look politically feasible at present. This suggests a more incremental policy strategy of a gradual phase in of external costs.

Table 18.18 | Estimates of external costs of road traffic and rail transport for passengers and freight in Austria and Germany, reference year 2005 (Pischinger et al., 1997; Sammer, 2009a) in €2005 cents per person- and tonne-km (1 Euro = 1.245US$ in 2005). For comparison, average total automobile operating costs (including taxes) per person-kilometer (paid by the driver) are about 24 €-cent per person-kilometer, including fuel cost of 6.5 €-cent (Austria, reference year 2005). External costs are thus at least up to twice the direct fuel costs (which, as mobility surveys show, dominate individual transport mode choices as few automobile drivers are aware of the total direct automobile mobility costs, including depreciation, maintenance, and operation).

External costs in €-cent per person-kilometer and ton-kilometer	Austria		Germany	
	Road traffic	Rail transport	Road traffic	Rail transport
Environment costs (caused by greenhouse and exhaust gas emissions, noise)	8.6	0.6	3.3	?
Accidents	3.1	1.5	5.1	?
External costs, Total	11.7	2.1	9.4	2.0

18.5.3.3 Strategies and Frameworks for Effective Policy Measures in Cities

This section summarizes the strategies, basic conditions, and measures to consider in policies for the effective reduction of urban transport energy use. Issues of vehicle technology and alternative fuels and the basic conditions for their use are not addressed here as they are covered in Chapter 9.

Strategies to encourage energy-efficient travel behavior need to be based on a systematic approach that takes into account the interaction of human behavior and travel demand with transport infrastructure supply, vehicle technologies, the environment, and financing.

The starting point is human decision-making which has a significant impact on urban transport systems and their energy use. Eight types of decisions by transport users have a crucial impact on urban transport systems and their effect upon the ecology, economy, and society. These decisions are usually taken in some sequence, with feedbacks taking place. Every decision taken has an impact upon subsequent decisions:

(1) **Selection of the place of residence and place of work.** The closer these two locations, the better equipped with local stores and other facilities, the more ecomobility transport choices are possible, mean less frequent motorized private transport and lower transport energy needs. To make this possible, compact settlement structures are needed; a minimum aggregate urban settlement density of well above 50 inhabitant/ha (5000 inhabitants/km^2) should be the policy objective.

(2) **Selection of the availability of vehicles.** Ownership, availability, and types of vehicles (bicycle, motorbike, automobiles with different drive technologies and fuel use, season tickets for public transport, membership in an automobile-sharing organization, etc.) have a significant impact on travel behavior and energy use.

(3) **Trip generation choice.** This is to decide whether some physical distance needs to be covered (trip) or whether an activity can be done at the place of residence or handled with the help of telecommunication technologies: good facilities at the location, for example broadband information and communication technology infrastructures and/or a garden, can help to reduce the need to travel any distances.

(4) **Decision about the time of travel.** Flexibility regarding the time of travel helps to save time, money, and energy, and to use resources in an environment-friendly way, because traffic jams and overcrowding of public transport can be avoided. This implies that wherever possible 'oversynchronization' of social activities should be avoided, for example through 'stacked' timing of school and of workplace operating hours..

(5) **Choice of destination.** A good retail, work, and school infrastructure close to the place of residence and a compact settlement structure help to avoid long commuting and shopping trips and the need to use motorized transport.

(6) **Modal choice.** Compact developments with good public (e.g., schools) and private (e.g., retail) infrastructures at the place of origin and destination, as well as good connections between the two with an attractive ecomobility offer (walking, cycling, and public transport) or a suitable offer of intermodal transport (bike-and-ride, park-and-ride, park-and-drive, park-and-bike, etc.) help to avoid unnecessary automobile trips. The quality of door-to-door connections is crucial for modal choices.

(7) **Route choice from origin to destination.** The concept of environmental zones (i.e., protected zones for residential areas, etc.) in connection with a hierarchical road network for motorized private transport and transport of goods structured according to the principles of traffic calming improves the quality of the urban environment. It helps to avoid through traffic of motor vehicles in protected areas and supports a high quality of housing and traffic safety.

(8) **Travel behavior reflection.** Reflection about previous travel behavior analyses the appropriateness of the realized choices and suggests a possible revision of the previous travel behavior in regular intervals. Global positioning system technology in connection with new traffic-information technologies will soon make it possible to check automatically whether decisions about traffic behavior are appropriate for the specified objectives (time requirements, environmental friendliness, cost of transport, etc.) or whether alternatives are preferable. This kind of individual

mobility-information system can lead to more sensitivity and awareness of transport-related decisions.

Principles and frameworks to reduce the fossil energy use in transport

- Traditional 'supply-side' measures that focus only on private vehicle infrastructure ("more and better roads") are insufficient to solve urban transport problems and risk significant consumer 'take-back' effects (i.e., induce additional automobile mobility rather than reduce congestion).

- A new fact-based systemic decision-making culture is needed for urban transport policy. Policymakers must be prepared to suggest and implement unpopular but necessary measures (e.g., internalization of external costs). It is essential that mere reactive and adaptive planning by individual measures without consideration of systemic effects and feedbacks (e.g., demand responses), such as the often ill-considered simple extension of road networks in urban areas ('adaptive planning'), is replaced by systemic and goal-oriented planning.

- As long as the true cost of various transport modes, particularly motorized private transport and public transport, are not transparent to the users through the lack of internalization of external costs, an unfair competition between transport modes is perpetuated. The 'push-and-pull principle' of restricting automobile traffic while simultaneously enhancing ecomobility modes can help to compensate for the lack of internalization of external costs.

- Cost-effectiveness criteria should be used to select policy measures to reduce fossil-fuel use and to make effective the use of limited available financial resources.

- An effective program to reduce urban transport energy use can only work as an integrated concept that takes all modes of transport into account. For the concept to be successful, regularly supervised and adapted quantitative objectives for the reduction of energy use are essential.

- To safeguard political acceptance, the development and implementation of the program needs to be supported by some suitable measures to shape stakeholders' ideas and guarantee their participation and engagement (Kelly et al., 2004).

18.5.3.4 Effective measures to reduce fossil energy use in urban transport

- **Spatial planning.** The creation of compact settlement structures with a sufficient settlement density well above 50 people/ha is essential to offer attractive non-motorized and public transport options. To this end, regulatory measures alone are insufficient; some market-based policy instruments are needed also, such as charging infrastructure development cost to users in areas of lower density.

- **Integrated planning concepts to save energy.** Since no single measure will reduce urban transport energy use, successful programs, including whole-bundle measures, need to be planned at national, regional, and local levels and implemented in a continuous process. Coordination and harmonization of transport policy across all levels is necessary.

- **Internalization of external costs.** In principle, an internalization of external costs is essential for all transport modes to make the polluters pay for the cost they cause. This is an excellent market-based instrument to reduce fossil-fuel use, which can be achieved by fuel surcharges, but also by parking fees and road pricing. The latter policy option is most effective if linked to the distance traveled and the environmental damage caused.

- **Environment-oriented road pricing.** Reduced fees for automobile pools or a variable and dynamic kind of road pricing, depending on utilization rates and congestion status (Supernak, 2005), create additional incentives to save energy. If road tolls are used only in urban areas or certain areas within cities, there is a high risk that undesired side-effects might occur, such as shifting routes to side streets, moving stores and other facilities to the outskirts where no fees are levied, and, in the long run, even a relocation of companies to areas outside cities (Sammer, 2009b), which would lead to undesirable urban sprawl.

- **Parking management schemes.** Measures to limit parking in cities and towns that cover all densely populated areas are highly effective – such measures include parking fees on public streets. These are particularly effective if they are graded depending on environmental friendliness or energy use of automobiles (Graz, 2010). Since there is considerably more private than public parking space in many towns and cities, it is recommended to include large private automobile parks (e.g., of industrial enterprises) within the parking fee scheme and combine this with levies on parking spaces for their operators (Sammer et al., 2007). In areas with a well-developed public transport system, land-use and zoning planning should fix an upper limit for available parking slots instead of (the customary) minimum number of mandated parking spaces (Sammer et al., 2005).

- **Attractive public transport.** The transport user wants a qualitatively high door-to-door mobility service, and does not care which operator is responsible for different parts of the system. Therefore the good cooperation of all public transport operators, an integrated ticketing and timetable system, and some overall

responsibility for the integrated public transport system are essential for an attractive system. There is an obvious need to improve public transport with respect to intermodality, more efficient and rationalized operations, intermodal connections, information, and marketing. To compensate for some disadvantages, public transport should be given priority over motorized private transport by the provision of high-occupancy-vehicle (HOV) lanes and priority treatment at crossings with the help of suitable traffic lights. To make public transport more attractive, good synergy effects can be achieved by linking the system to non-motorized traffic (bike-and-ride, etc.) and by combining the measures already mentioned with restrictions of motorized private transport under a 'push-and-pull' policy strategy.

- **Cost-effectiveness of public transport.** When choosing types of public transport a careful check of costs and effectiveness is needed, since investment and operating costs of various systems differ considerably. In general, buses tend to be considerably cheaper than trams or suburban railways, which require tracks, and underground track-bound systems are more expensive than above-ground systems. Experiences show that Bus Rapid Transit (BRT) systems are very efficient public transport systems that provide a very attractive service at a reasonable cost level for industrialized and developing cities (e.g., Curitiba, Bogota). Renovating existing transport systems is most cost effective, for example by eliminating existing obstructions by automobile traffic or by giving public transport priority over motorized private transport with the help of HOV lanes and traffic lights.

- **Non-motorized traffic (walking and cycling).** Measures to encourage and support non-motorized traffic are a highly efficient way to save energy, particularly if they are combined with support of public transport and restrictions for automobile traffic. Suitable measures are the extension of an area-wide network of walkways and cycling routes and making them more attractive to use, more places (public and private) to leave bicycles, more information, marketing, and measures to shape people's ideas, bicycle renting, permission to transport bicycles in the public transport systems, company bicycles, etc. (Meschik, 2008).

- **Access restrictions for motorized private transport.** Environment-oriented access restrictions for automobiles in city centers are highly effective measures to save fossil fuel, for example the temporally limited or unlimited prohibition of access for certain types of vehicles, as in environmental zones to keep the air clean (Umweltzone Berlin, 2009).

- **Access contingents for automobiles with combustion engines.** This means that egress is restricted by an area-wide traffic light system in such a way that only so many automobiles are allowed to pass so that no congestion will be caused at the next crossing regulated by traffic lights. Outside these areas with such traffic-light management, additional space needs to be provided for automobile traffic, and also HOV lanes and park-and-ride facilities.

- **Extension of road networks.** If the goal is to reduce fossil-fuel use, to extend the existing road infrastructure, as is frequently done in urban areas, cannot be recommended. Every extension of existing capacities induces an increase in motorized private transport, and further substitution away from other, more environmentally friendly transport modes.

- **Highway corridor management.** This concept aims to optimize traffic flow by suitable measures, such as HOV lanes, high occupancy-and-toll lanes by variable pricing, ramp-metering, information about suitable times, etc. Such management systems should help to avoid congestion and time loss because of congestion. It is doubtful that they would help to reduce energy use significantly in the long term. At present, some 'Integrated Corridor Management Projects' (RITA, 2009) are being conducted in the United States; they try to include public transport, for example by using emergency lanes as bus lanes.

- **Mobility management at the enterprise level.** This is a highly efficient tool. It includes many types of incentives to make individuals do without automobiles. Suitable measures are the support of automobile pools by providing incentives for their use (guaranteed home transport if the usual transport is missed, preferential parking slots, financial incentives), 'job tickets' for public transport (employers subsidize season tickets or provide them free of charge), repair and shower facilities for cyclists, etc. The effect can be increased by providing HOV lanes or by making large companies develop mobility-management plans (ICARO, 1999). In-company mobility management leads to a three-way win-win-win situation because employers, employees, and the general public all benefit. For mobility management at the company level to be successful, a permanent management process must be professionally run.

- **Voluntary programs to change travel behavior.** Such programs quite efficiently raise awareness of the impacts of energy-saving traffic behavior. They have the potential to reduce the use of fossil fuels of the target population in urban areas by 5–10%. Suitable ecomobility alternatives must be available for such programs to work. Currently, some attempts are being made to combine such programs with energy-saving measures in private households (Brög and Ker, 2009; DIALOG, 2010).

These generic policy options to reduce urban transport energy use are applicable to cities in industrialized and developing countries alike.

18.5.3.5 Summary and Conclusions for Urban Transport

- **Modal split.** The existing modal split of cities is one of the key determinants of urban transport energy use and also a good

indicator for the progress toward improved sustainability of urban transport systems. A wide range of modal split and thus energy-use patterns can be observed across different urban settings. This variation in urban mobility is not *ex ante* given, but rather results from deliberate choices of individuals and of decision makers.

- **Public acceptance.** The factors that determine urban transport choices can be changed if a strong determination for sustainable traffic policy and a corresponding wide public acceptance of the overall goals of such a policy exists. This wider acceptance of the overarching goals is also the condition to implement some individual measures (e.g., traffic calming, parking fees, etc.) that often face public opposition.

- **Energy and environmental characteristics of transport supply.** An urban transport system has specific characteristics. For noise, emissions, energy use, and economic costs, non-motorized modes of transport are superior to motorized ones, and public transport is significantly superior to private motorized transport, provided a sufficiently high occupancy rate in public transport can be achieved which in turn is contingent on minimum density thresholds.

- **Precondition for attractive public transport:** To make public transport attractive, a dense public transport network and a high service frequency with short intervals is necessary. This can only be guaranteed if the densities of development of residential areas in cities are considerably higher than roughly 100 people/ha and densities of development within the whole urban area are more than 50 people/ha. The large amount of space required for road areas and the low-density housing types (e.g., single-family dwellings) that preordain private automobile uses mean automobile-dependent urban settings typically have population densities far below these critical threshold levels.

- **Strategies for more efficient energy use.** A remarkable number of suitable strategies and measures are known to reduce urban transport energy use. A very effective strategy is the promotion of high urban densities in combination with active promotion of a high-quality supply of non-motorized and public transport options combined with a restrictive automobile policy. Soft measures have generally a very high potential and high cost-effectiveness to reduce energy use, but politically they are the most difficult to sell. Transport fuel use can be reduced most effectively through well-coordinated bundles of policies and measures.

- **Internalization of external cost.** The key measure is the internalization of external costs of motorized private transport combined with the provision of a high-quality alternative offers of public and non-motorized transport. To be able to internalize external costs, political acceptance of this unpopular measure is essential.

18.5.4 Urban Energy Systems Planning, Design, and Implementation

18.5.4.1 Introduction

The energy-system elements and networks of a city reflect myriads of 'local optimizations.' The networks have thus evolved over time, but seldom exploit the opportunities for broader optimizations with other networks or urban form. They are consequently not usually resource efficient when viewed in aggregate. Systems and integration methods are now becoming available with the potential for reductions in direct primary-energy use by 30–50% without other significant physical impacts, except the advantages of reductions in externalities of energy use such as air pollution.

18.5.4.2 Modeling Urban Systems: The SynCity Model

Given the complexity of a city's energy and transport systems, it is not surprising that, to date, detailed holistic analyses of the interplay between urban form, a city's built environment, energy-demand characteristics, and its transport and energy systems have not been attempted. Bottom-up assessments of energy efficiency improvement potentials in different sectors have been developed for many cities to inform policy choices, but interactions, both in terms of potential synergies or trade-offs, cannot be explored by such compartmentalized approaches.

New computational modeling frameworks and access to new data sources promise to overcome these barriers. The relationship between key parameters, such as population density and energy, may be obscured in the real world by differences in other factors, such as wealth and income. To explore these interactions under comparable *ceteris paribus* conditions, this assessment commissioned illustrative model simulations with one such modeling framework (see Box 18.7), the results of which are reported here.[35]

In these examples, the synthetic city (SynCity) is an urban settlement for 20,000 people in a service-orientated local economy, in a moderate climate and with natural gas (and oil) as the primary fuels. Five SynCities were explored with the energy model optimizer. At one extreme, the optimization is constrained as a low-density city, fed from a power grid, with modest building-fabric energy performance. This city is taken as characteristic of one that has evolved in an economy in which resources are relatively inexpensive, such as the United States. The optimizer is left to choose the location of fixed infrastructures to minimize transport costs. The city at the other extreme is optimized with only a constraint on the lower bound to population density. It is comparable with an economy that is resource efficient, such as Japan. The location of housing and commerce, and the choice of whether to use embedded generation of power are left to the optimizer. Three intermediate cases are considered based on an intermediate density and imposed mononuclear layout (e.g., the United Kingdom).

35 Fuller detail is given in a GEA Chapter 18 working paper posted on the GEA website, www.globalenergyassessment.org.

Box 18.7 | SynCity Modeling Tool Kit

SynCity is a software platform for the integrated assessment and optimization of urban energy systems, developed at Imperial College London and supported by funding from BP. The goal of the tool kit is to bring together state-of-the-art optimization and simulation models so that urban energy use at different stages of a city's design can be examined within a single platform.

Three layered models within the system are used here:

- a *layout model*, which determines the optimal configuration of buildings, service provision, and transportation networks;
- an *agent-activity model*, which simulates the activities of heterogeneous agents that act within a specified urban layout to determine temporal and spatial patterns of resource demand; and
- a *resource technology network (RTN) model*, which determines the optimal configuration of energy-conversion technologies and supply networks.

The *layout model* is a mixed-integer linear programming model that seeks to satisfy urban demands for housing and activity provision, while minimizing energy demand from buildings and transport. Users specify average visit rates for each activity type and the model determines the optimal location for housing, commercial buildings and activities, and transport networks.

The *agent-activity model* is a simulation model designed to estimate the resource demands of a population that lives within a particular city layout. Briefly, the model operates as follows. First, it creates a synthetic population of individual agents with random characteristics, such as gender and education. Agents are grouped into household ensembles and assigned to jobs and dwellings. The model then loops over 16 indicative time periods that represent two seasons (summer and winter), two day types (weekday and weekend), and four time intervals during the day. For each interval, a probabilistic four-step transport model is used whereby citizens select an activity, an activity provider, a transport mode, and a travel route. The agents then move around the city and perform their planned activities, which results in spatially and temporally explicit demands for different end-use energy resources, such as electricity or heat.

The *RTN model* is also a mixed-integer linear programming model to determine the optimal configuration of energy-supply technologies to meet a given pattern of demand. The objective is to minimize the total cost of the energy-supply system that comprises the annualized cost of capital equipment (e.g., boilers, turbines, and distribution networks) and the annual cost of imported resources necessary to operate the system (e.g., supplies of gas and electricity). Users specify the full suite of possible technologies at the outset and the model returns the lowest cost system configuration.

Further details on the methodology are given in Keirstead et al., 2009.

The increased density in a compact urban layout means that individual dwellings are smaller and have less external wall area per dwelling, which results in reduced heating demands (and also in a saving of one-third, as for high-standard fabric implemented for all buildings, but at lower densities). So, efficient building design and urban density and form both yield comparable energy-demand reductions in the simulations. This highlights the importance of considering both policy options simultaneously, as to avoid the risk that the efficiency improvements of building structures with better insulation can easily be compensated by a shift toward less-compact settlement patterns.

Conversely, the construction of large houses in a low-density sparse layout increases these heat losses (one-third increase in primary energy) and also substantially increases transport energy use. This 'suburbanization' scenario, a worst-case scenario in the simulations, results in an almost three-fold increase in energy use compared to the optimized solution. That is, building a Passivhaus standard single-family home in a low density (sub)urban area would not lower energy use substantially compared to remaining in a much less-efficient home located in a more compact urban setting (e.g., a 19th century townhouse located close to education, leisure, and shopping facilities) with its corresponding lower individual transport needs. This is clearly shown by the alternative simulated urban layouts of the model runs (Figure 18.30).

The results for each simulated city type are summarized in Table 18.19 and Figure 18.31. Numerical values are indexed to the annual primary energy use of the sparse city design (144 GJ/capita in the simulation). 'Upstream' energy is energy used at power stations to supply grid electricity to the city. 'Delivered' energy is the energy delivered to stationary infrastructure, including CHP plants, and the final end-users (i.e., a combination of final and secondary energy). The total of delivered energy,

Table 18.19 | Primary energy use of five alternative urban designs for a town of 20,000 inhabitants. Results are indexed with sparse city =100.

Type	Building fabric	Density limit	Electrical power	Layout	Transport	Delivered	Upstream	Total
Sparse	Medium	USA	Grid	Optimized	26	57	17	100
Distributed generation	Medium	UK	CHP	Mononuclear	17	52	0	69
Efficient buildings	High	UK	Grid	Mononuclear	17	28	12	57
Compact layout	Medium	Japan	Grid	Optimized	12	28	10	50
Optimized	High	Japan	Optimized	Optimized	12	31	0	43

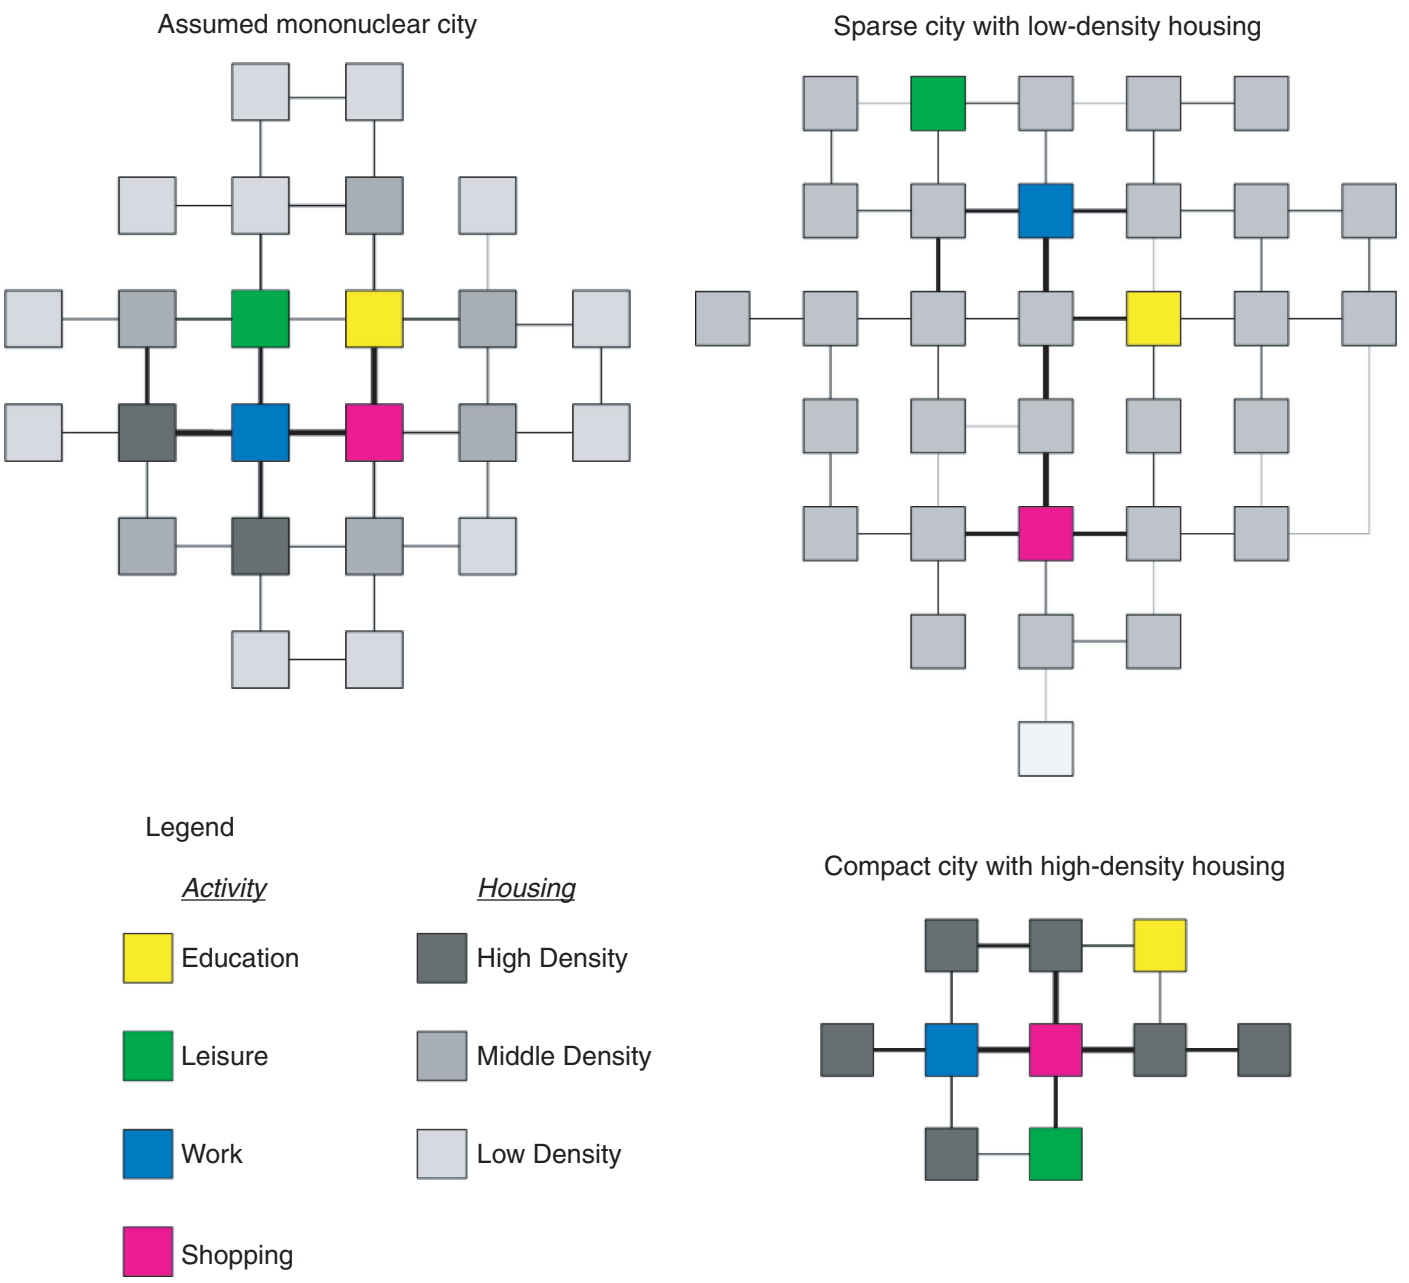

Figure 18.30 | Urban layouts, from left to right: the assumed mononuclear city, a compact city with high-density housing, and a sparse city with low-density housing. In each figure, the colored cells represent activity provision: green for leisure, blue for work, pink for shopping, and yellow for education. The gray cells represent housing at different densities, and the labels indicate the density in dwellings/ha. The black lines that connect the cells indicate road connections and indicative traffic flows.

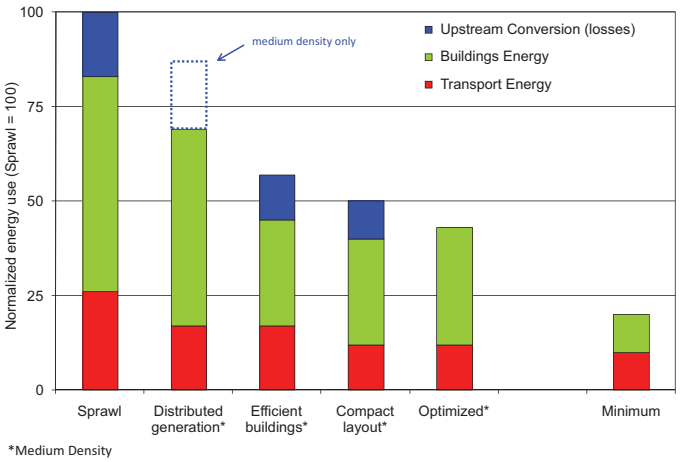

Figure 18.31 | Energy use for five alternative urban designs by major energy level and type. See Table 18.19 for definitions of the five simulations. The "Minimum" urban energy use estimates refers to implementation of the most efficient building designs (see Chapter 10) and transport options (see Chapter 9) available and which could not be considered in the scenario simulations.

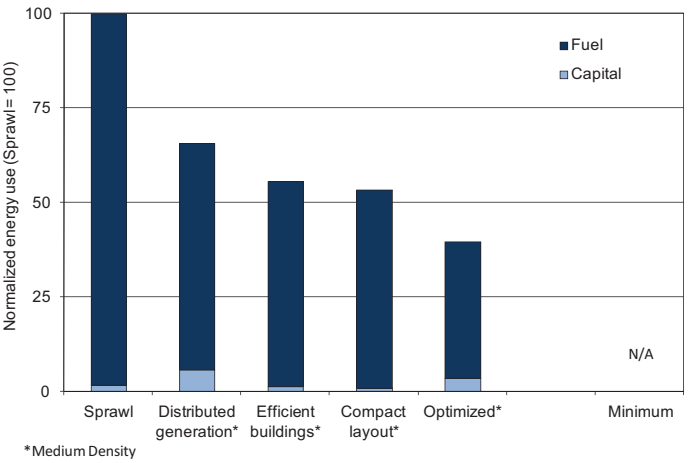

Figure 18.32 | Total lifecycle costs (capital plus fuel) of the five city designs indexed to sprawl city = 100 (see Table 18.19 for definitions of the five simulations).

transport, and 'upstream' energy corresponds to the customary reporting of primary energy use.

The model results generally support the interpretation of comparative city data analyses. First, 'upstream' energy loss in power generation represents 20% of primary energy where the grid is used. To ignore this contribution and focus only on delivered energy misses important upstream implications of energy choices for power. Second, a SynCity with low resource efficiency is likely to consume about twice as much primary energy as one designed for high resource efficiency. Both transport and primary energy for heating and power are reduced by about the same proportion. This, in part, reflects that low-density cities not only require higher speeds of travel over longer distances, but that buildings tend to occupy larger areas with consequently more exposed surface for the same standard of construction. The effects of urban planning and differences in fabric standards are comparable and should be considered together with upstream consequences.

To address these three policy fields simultaneously is also of prime importance for the economic viability of cogeneration and district-heating systems. Energy-efficient, single-family homes located in low-density suburban settings are unlikely to yield the head-load densities required to install capital-intensive cogeneration systems combined with local district-heating grids (not to mention large centralized cogeneration and distribution systems, although these may allow room for other technologies, such as PV or ground-source heat pumps). To test the consequences, these city models were rerun to minimize whole life-cycle costs. The layout model (see Box 18.7) optimizes transport costs, but it is instructive to see what the resource technology model makes of the stationary energy-service costs. The results in terms of total lifecycle costs are summarized in Figure 18.32 using UK electricity and natural gas costs as example. The discount rate used in the simulations was 6% in real terms.

The results encouragingly follow a similar pattern to that of primary-energy minimization, in part because capital costs remain a small part of the annuitized energy costs. However, minimizing only capital cost biases the outcomes away from the minimum energy solution. This emphasizes the importance of proper finance and pricing systems in bringing about optimal solutions for utilities and customers combined.

Summary

This brief analysis analyzed three ways in which cities can improve the efficiency of their energy systems: improving the quality of the built environment, increasing the density of the urban layout, and using integrated, distributed energy systems, such as CHP. A few general conclusions can be drawn from this case study:

- Cutting urban energy use by half is possible through integrated approaches that address the quality of the built environment (buildings efficiency), urban form and density, and urban energy-systems optimization (cogeneration).

- Final energy use is not a sufficient indicator of energy system performance. In cogeneration systems in particular, this metric may show an increase in delivered fuel use that masks upstream conversion and distribution losses. This effect also occurs in bioenergy-based supply systems. Primary energy use should, therefore, be the basis of scenario comparisons.

- Annual energy-system costs (i.e., the costs of energy conversion and distribution), but not demand-side measures, such as increased

building efficiency or urban layout, are dominated by fuel costs. However, these costs are distributed differently between stakeholders in each of the scenarios. In current practice, most of the capital and fuel costs are paid by end consumers, whereas in a distributed energy system much more of the cost is borne by energy utilities. This suggests that to achieve overall system efficiency, policymakers should design markets that help utilities implement distributed energy installations despite their unique capital and fuel-cost structures.

Increased urban density and improved building efficiency deliver primary energy use and carbon-emission savings of about one-third each; distributed energy systems provide approximately 10% primary energy and carbon emissions saving. This indicates the importance of urban planning measures. These decisions – for example, on the building energy-performance standards or on the location of infrastructure – are difficult to change in retrofit and can lead to significant increases in energy use; in the cases studied here, urban sprawl led to a one-third increase in primary energy use. Efficient distributed-energy systems, to a certain extent, can be retrofitted into existing urban forms, but they too can benefit from long-sighted urban planning by encouraging sufficient demand density and by reducing the costs of the network infrastructure.

The above simulations suggest that the effects on energy demand of urban form and density, and that of the energy efficiency characteristics of technologies, processes, and practices (e.g., buildings) are of comparable magnitude, i.e., are comparable size 'mitigation wedges' to paraphrase a concept developed by Pacala and Socolow (2004). Conversely, the impact of narrow energy systems optimization (e.g., through cogeneration of renewables) is much smaller.

18.1.2.1 Urban Energy Systems Planning Design – Review

A holistic view of urban energy systems is multifaceted and relates to the analysis of city lifecycle, technologies, systems modeling, and optimization.

Existing versus planned layouts

The problem of planning improved urban energy systems is very different for existing and for new urban areas. The advantage of new developments (e.g., ecocities and zero-carbon cities planned in places such as China and the Middle East) is that holistic planning tools can be employed to integrate the design of the urban form, the built environment, the transportation infrastructure, and the energy system. Opportunities for resource efficiency – such as optimized transport, material, and energy cascading, demand heterogeneity, and robust network design – can be explored ahead of implementation.

Existing cities, however, are captives to their history and struggle to escape path dependency without massive capital investment. Nevertheless, relatively short turnover times for many technologies provide opportunities to improve in efficiency and integrated design. Large-scale upgrades of the built environment have been demonstrated, for example in Germany, where new technologies at the building and building-cluster level are being employed and new ideas are emerging for new uses of existing infrastructure (e.g., using a natural gas network to transmit bioderived gas in cities, see also Chapter 10).

Energy-related technologies and systems

Demand-side management and reduction

The primary focus of efficiency in most cities is on the built environment (dwellings and commercial properties) and transport. In the built environment, there is considerable inertia and irrational behavior given the relatively low or even negative cost of GHG abatement through refurbishment. This suggests that there is a strong argument for prescription and regulation regarding building standards.

Supply side

The supply side has seen much innovation in resource-efficient network design, where integrated thinking pervades the design of new ecocities – each of which is sympathetic to its hinterland and optimized for its local climate. The integration of water and energy systems is coming to the fore in supply-side planning. In these planning applications there is an important role for systems modeling and Life Cycle Assements (LCA) in support of holistic rather than piecemeal perspectives to avoid burden shifting. Given that all city systems are subject to uncertainty and change, there is also a need for option-based design techniques that allow city growth and technological evolution and that avoid strongly path-dependent solutions.

Role of real-time systems

There is a long history of promising designs related to urban energy systems that have not delivered the expected performance. For new, resource-efficient city designs, enough of the budget and expertise must focus on the postdesign, operational phase. There are fascinating opportunities for ubiquitous sensing and computing to embed sensing and distributed 'intelligent' and autonomous control (inspired by, for example, cybernetic modeling, which indicates how local control rules can result in system solutions close to those optimized centrally). This enables effective management of real-time performance, and perhaps eventually will ensure that resource use is minimized in operation. The interactions between systems and citizens can be augmented through real-time pricing of energy and virtual energy markets, real-time displays of household, large building, neighborhood, city resource-use profiles, and personalized decision-support services.

18.5.5 Urban Air Quality Management

18.5.5.1 Air Pollution Trends

Energy and air pollution are closely linked because urban outdoor[36] air pollution is primarily a result of fuel burning in power generation,

36 Residential energy use, e.g., for cooking, can result in high levels of indoor air pollution and result in health impacts (see Chapters 4 and 19).

industries for domestic production and exports,[37] transport, and commercial and residential sectors. Low-quality fuels, such as coal, biomass, and high-sulfur diesel, emit more air pollutants than cleaner energy sources. From the urban energy-usage perspective, the literature shows that high urban density tends to be associated with lower per capita energy uses (see Section 18.5.2), which reduces air-pollution problems somewhat. However, the trade-off at this density reflects on the issue of air-pollution control. High density makes air-pollution control more urgent and requires better management systems, especially in the rapidly growing dense and large Asian megacities.

Historically, the concentrations of pollutants such as SO_2 and TSPs, which mainly result from industrial production systems were concentrated in cities, have declined in industrialized cities. In the United States, the average national SO_2 level at 147 sites in 2007 was 0.0038 parts per million (ppm), which is 68% lower than 0.0118 ppm in 1980, while the National Ambient Air Quality Standard remains at 0.03 ppm (USEPA, 2009). In Japan, SO_2 average levels have declined from 0.06 ppm in 1967 to 0.017 ppm in 1980, and further by 50% in 1980–2005 alone (MOE, 2005). A key component of industrial air-pollution control mechanism was the development and deployment of end-of-pipe technologies (such as flue-gas desulfurization and particulate removal), and the introduction of cleaner fuels under stringent air-quality legislations. The 'pollute first and clean up later' paradigm had actually worked for many industrial cities, but one generation suffered acute air-pollution problems. Currently, the SO_x and TSP pollutants in industrialized countries are no longer an issue for energy use in cities, because urban energy systems are dominated by electricity or other cleaner fuels, and emissions from large point sources are tightly controlled.

In developing countries, SO_x and TSPs have shown a decreasing trend in recent years (Figure 18.33) for key Asian cities. SO_2 is reasonably within WHO limits in these cities (except Beijing), while TSPs remain far higher than the WHO limits. Today, cities in developing countries can learn from the experiences of the industrialized countries and have access to the technologies developed previously to tackle SO_x and TSP. In contrast to the developed countries, industrial relocation and FDIs constitute a key aspect of air-pollution control in the developing countries, with both positive and negative effects. At the same time, relocation of existing dirty industries of cities from populated areas to less populated area or outside the cities has contributed to reductions in industrial air pollutants. Given that pollution-control technologies are readily available, the industrial air pollution in developing countries today largely results from either an inability to pay for the technology or inherent institutional, policy, and market problems.

37 As discussed in Section 18.6.2, global market integration and economic structural change can result in relocations of industrial activity and hence exercises an additional effect on local pollution.

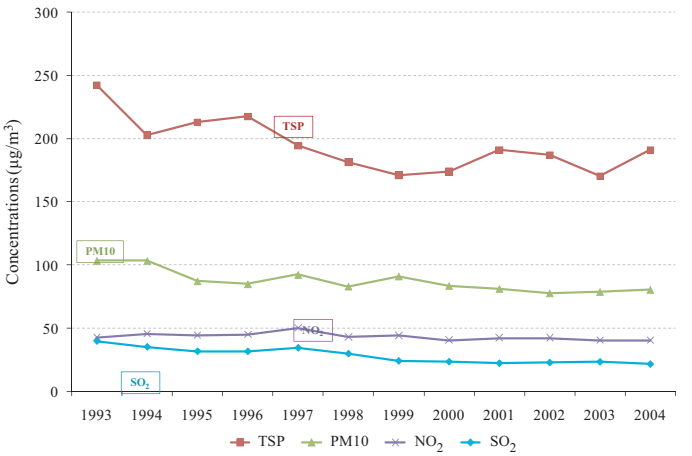

Figure 18.33 | Trends of major criteria air pollutants (1993–2004) for selected Asian cities. Source: Benchmarking Study on Air Quality Management Capability of selected Asian cities. Clean Air Initiatives in cooperation with UNEP and WHP (cf. Schwela et al., 2006). Cities included in the study: Bangkok, Beijing, Busan, Colombo, Dhaka, Delhi, Hanoi, Ho Chi Minh, Hong Kong, Jakarta, Kathmandu, Kolkata, Mumbai, Manila, Seoul, Shanghai, Singapore, Surabaya, Taipei, and Tokyo.

While industrial air pollutants are falling, the challenges to control pollutants from mobile sources, as a result of automobile dependency of cities, in particular for particulate matter (PM), NO_x, and O_3, are increasing. Even in the cities of industrialized nations, to reduce the levels of NO_x, O_3, and fine particles is proving a challenge. In the United States, monitored data show that the average levels of O_3 in 269 sites (0.078 ppm in 2007 – a reduction of 21% from 0.10 in 1980 – eight-hour average) slightly exceed National Air Quality Standards (USEPA, 2009). A recent report by the American Lung Association (ALA, 2009) shows that 125 million people (42%) in the United States live in counties that have unhealthy levels of either O_3 or particle pollution (PM-2.5). In Japan, the compliance rate of monitoring sites for O_3 is extremely low – merely 0.2% in 2004 (MOE, 2005).

PM-10 is one of the key public health issues in the cities of many developing countries, where their levels are many times higher than the WHO or USEPA. Only 160 million people in cities worldwide are breathing clean air, more than one billion need improved urban air quality, and for 740 million urban air quality is above the minimum WHO limits. While Figure 18.33 show that TSP and PM-10 generally have decreased in Asian cities, ambient concentration levels remain, nonetheless, above WHO, USEPA, and EU limits in numerous cities worldwide (Figure 18.34 and Table 18.20; See also Chapter 4).

A city-by-city analysis (Figure 18.35) further shows that PM-10 is lowest in Singapore at 30 µg/m³, which meets 50 µg/m³ standards set by USEPA (Singapore adopts USEPA standards), but fails if compared with the WHO 2005 updated guideline of 20 µg/m³. PM-10 values in all of the 20 Asian cities reviewed fail to meet WHO standards. Of 17 cities that monitor NO_x data, only eight meet the WHO guidelines, which indicates

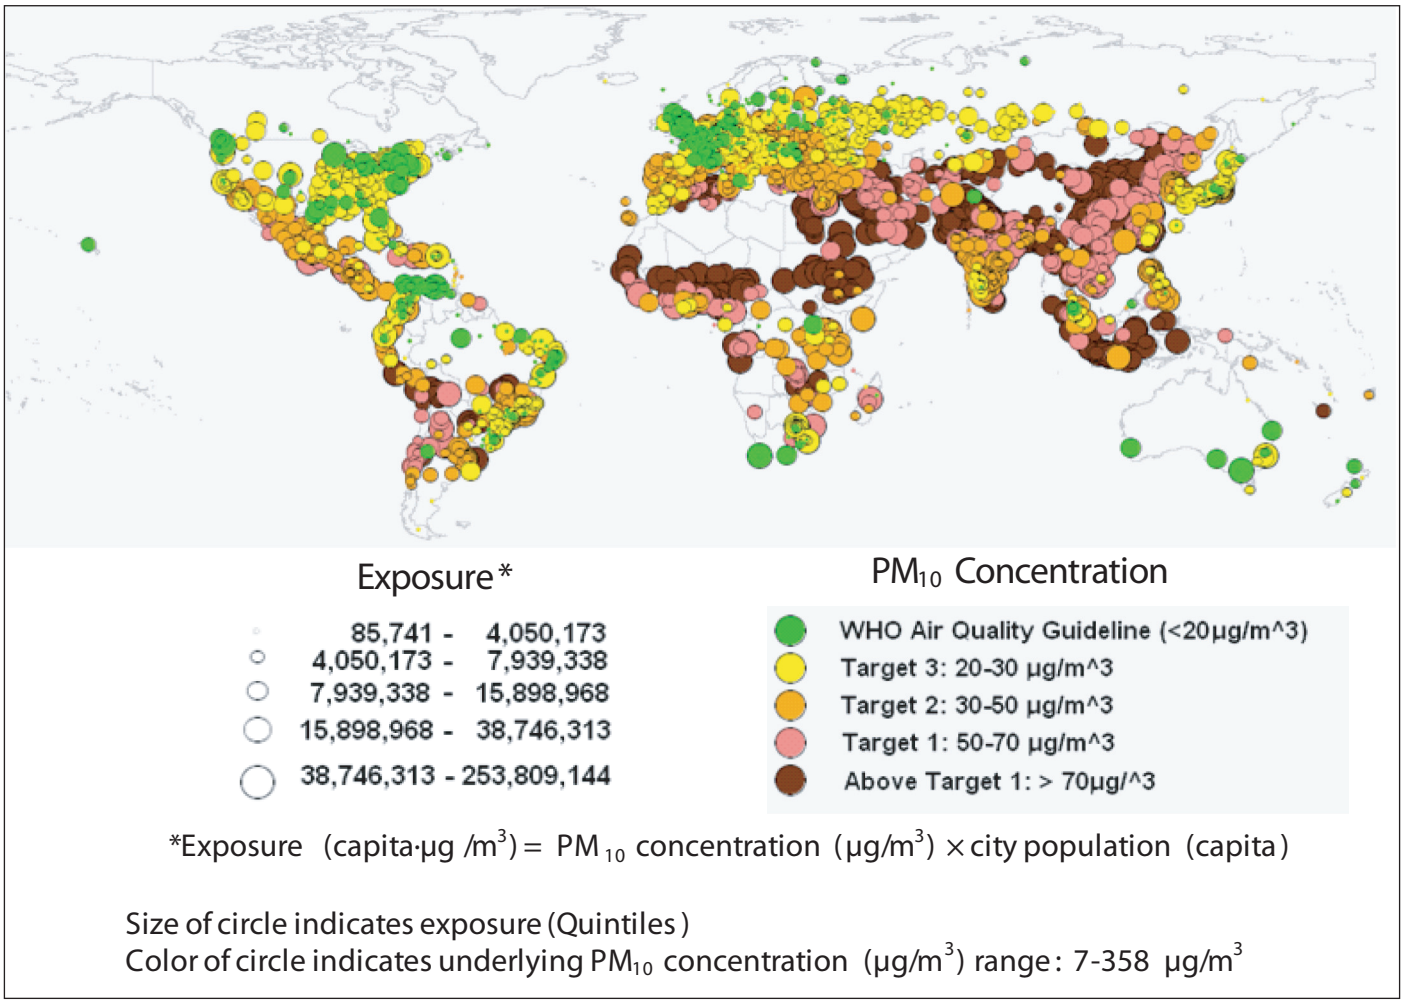

Figure 18.34 | Human risk exposure to PM-10 pollution in 3200 cities worldwide (For a numerical summary see Table 18.20). Source: Doll, 2009; Doll and Pachauri, 2010, based on World Bank data.

that NO_x pollution is of special concern for Asia megacities. The reason is the rising number of private automobiles in cities of the developing world as a result of rising affordability, rising mobility demand, and slow development of public transport infrastructures. Over the years, the fuel efficiencies of new automobiles have improved considerably, the sulfur content of fuels are on a constant decline, and the emission standards have tightened (Figure 18.36), but the high volume of automobile travel demand has far overwhelmed vehicle-efficiency gains and the impacts from cleaner fuels. This confirms that urban air-quality management especially needs to address transport-related emissions from a much more systemic perspective, including transport policies that influence the urban modal split toward a reduced automobile dependence in addition to traditional vehicle efficiency, and exhaust emission and fuel standards measures.

While the majority of air pollution is associated with energy use, in many cases other sources also play an important role. Natural factors, such as dust and fine sand particles, flow across the boundary between the natural and anthropogenic sources, and also contribute to urban air pollution. The role of transboundary air pollution is particularly important for SO_x.

18.5.5.2 Examples of Air Pollution Control Measures and Urban Energy

A wide variety of air-pollution control policies and measures are in place globally. Some are system-wide and comprehensive measures, while others address a specific sector or technology depending on the prevailing sources of the air pollutants. Some of these measures are regulatory, while others are technological, managerial, or a mixture. Here a few representative examples are illustrated that touch a broad range of such measures, namely legislation, market, court rulings, and technology. Each has different implications on urban energy systems.

United Kingdom 'smoke control area' regulation

The United Kingdom started air-pollution control with a strictly source-control approach. It gradually shifted to a complex, but integrated, and risk management effects-based approach (Longhurst et al., 2009). Intense pollution from domestic coal use persisted in the United Kingdom until the 1950s and 1960s. Heightened concerns after London's Great Smog episode of December 1952 led to the introduction of The Clean Air Act of 1956 as an emergency measure. Significantly,

Table 18.20 | Number of cities and residing population categorized by ambient PM-10 WHO air quality standards (ACQ = WHO air quality guidelines met (less than 20 µg/m³), for definition of Target 1 to 3 concentration standards see Figure18.34) for a sample 3200 cities globally and by three regions (ALM = Africa, Middle East, Latin America and the Caribbean).

Global	# of Cities	Population (millions)

some key industrial cities had already taken pre-emptive action, but the politics of a national measure proved more difficult. The Clean Air Act enabled local authorities to control pollution by declaring Smoke Control Areas ('smokeless zones' in which the burning of coal was banned) to whole or part of the district. Various measures were also used to ease compliance with the regulation, such as subsidies for furnace switching. In this regime, each local authority publicized the fuels that could be used and a list of exempt appliances. The Clean Air Act was further extended in 1968 to address the question of unevenness in the implementation, because in wealthier cities it was progressive while in other cities the implementation was less than that desired. The major feature of this regime was to induce a shift from coal to electricity, natural gas, and other cleaner forms of energy and implied a major transformation in energy esnd-use patterns and systems. However, with increasing levels of transport-related pollution in UK cities, NO_x concentration levels can be high and close to the statutory limits. This, in turn, may restrict further expansion of CHP systems in urban areas.

The regional clean air incentives market

The California South Coast Air Quality Management District (SCAQMD) has used a market-based system since January 1994, known as RECLAIM (Regional Clean Air Incentives Market), to reduce system-wide air pollution. SCAQMD covers 27,125 km² (10,473 square miles). At the launching of RECLAIM, it was expected to reduce the cost of achieving the same emissions reduction through a traditional command and control approach by some 40% (Harrison, 2004). Under this system, each facility participating in the RECLAIM program (facilities that emit 4 tonnes/year or more of NO_x and/or SO_x in 1990 or any later years) are allocated RECLAIM trading credits (RTCs) equal to their annual emission limits for SO_x and NO_x. The facilities must meet these allocated emissions limits. If a facility can reduce emissions more than required, they can sell surplus trading credits to the credit market, which can be bought by facilities that could not meet their own emission-reduction targets. The system is designed in such a way that the total allowable emission cap was reduced over time until 2003 after which it remained stable. It requires facilities to cut their emissions by certain amounts each year. By 2003, the program anticipated to reduce the total emission load for NO_x and SO_x in SCAQMD by 70% and 60%, respectively (Anderson and Morgenstern, 2009). In January 2005, RECLAIM decided to reduce cumulatively the emissions further, by 7.7 tonnes/day or about 20% by 2011 (Figure 18.37).[38]

Introduction of compressed natural gas vehicles in New Delhi

To address high concentrations of air pollutants in Delhi, the Supreme Court of India, acting on public interests litigation filed at the behest of civil society, directed the government of the National Capital Territory of Delhi and other authorities in Delhi to act on mitigating air pollution through specific technological interventions. The legal deliberations began as early as 1990, but the key court decisions were made in 1998. The cornerstone was the conversion of all diesel public transportation into compressed natural gas (CNG) vehicles, which began implementation in April 2001. Along with the implementation of these directives, authorities enacted a series of other measures, such as expansion of the scope of CNG coverage, scrapping of older vehicles, improving fuel quality, implementing stringent emission standards for vehicles, and improvements in the infrastructures. The implementation involved a series of policy instruments, such as penalties for noncomplying vehicles, sales-tax exemption, interest subsidy on loans to replace three wheelers, making CNG retrofitting kits available, expansion of CNG fueling stations, and others. The literature shows an ambiguous picture of the impact of CNG conversion on air pollution, but generally agrees that CNG conversion was one of the several key factors and that it triggered other measures that led to improvements in the air pollution of Delhi (Goyal and Sidhartha, 2003; Kathuria, 2004; Jalihal and Reddy, 2006; Ravindra et al., 2006; Kandlikar, 2007; UNEP, 2009).

18.5.5.3 Key Policy Issues

The ways and methods adopted to mitigate urban air-pollution impacts in urban energy systems differ widely. In Delhi, deliberate CNG introduction to reduce air pollution created a new urban energy supply, demand, and infrastructure, largely following a technology strategy. The ban on coal-fired boilers in Chinese cities such as Beijing and Shanghai, led to greater use of electricity and natural gas (Dhakal, 2004). As an example of a regulatory approach to urban air pollution, it largely follows the historical United Kingdom 'smokeless zone' regulatory model. City energy-system decisions in China are influenced by air-pollution mitigation, public transport improvements, and energy-security concerns (Dhakal, 2009). The will to control PM-10 prompted many cities in Asia, America, and Latin America to move progressively toward discouraging diesel. Europe is moving more on the path of dieselization with stricter control of the sulfur content of diesel combined with particulate filters in automobiles.

Despite improvements in both vehicle technology and fuel quality, the high growth rates in private automobile ownership and usage with rising income is proving a challenge to the control PM-10, suspended particulate matter, and NO_x pollutants in cities of developing countries (Dhakal and Schipper, 2005). The key policy challenges for air pollution that have direct bearing on urban energy systems are (adapted from Schwela et al., 2006):

- Comprehensive assessment of the effectiveness of different options is needed in cities, but requires adequate institutional capacity, which remains comparatively weak in many large cities (Table 18.21), not to mention smaller ones. Often problems are addressed on a piecemeal basis without considering the complete system and thus rebound effects are prevalent.

- Development of more reliable inventories of air-pollution emissions is essential. Cities are not regularly updating their inventories

Table 18.21 | Classification of urban air-quality management capacity in Asian cities.

Capability Classification	Cities

and often there are serious ambiguities in emission volume and sources data.

- The need to adopt more stringent vehicle-emission standards is evident. The pace of adopting new emission standards in the face of rapidly rising private transportation is very slow. In addition, a reasonable global harmonization of air-quality and technology standards is needed. Currently, decision makers are torn between the Euro Standards and the USEPA standards, which affects technology choice and fuel regimes differently.

- Introducing cleaner fuel more actively for motor vehicles, industries, and power plants is necessary.

- Transport polices that affect urban mobility choices need to complement vehicle- and fuel-specific policy measures. In their absence, any air-quality improvements are likely to be quickly overwhelmed by continued motorized transport growth.

- Despite good policies on technology and fuel, inadequate emphasis on inspection and maintenance of systems remains one of the key challenges. Much of the existing air-pollution problems can be addressed by simple *implementation and stricter enforcement* of existing legislations, standards, and inspection and monitoring regimes for air quality.

- For transboundary air-pollution issues, such as acid rain and black carbon (emerging as key problems, particularly in Asia), regional approaches and regimes are needed, but such regional coordination emerges only very slowly in many world regions.

- To harmonize many environmental issues within common policy responses, estimation of the co-benefits of air-pollution management with respect to human health, urban energy system improvement, energy security, climate change mitigation, and ecosystems in general is essential. In developing countries such a co-benefit approach can help devise limited resources more efficiently, and also broaden the technology and financial resources available for air-pollution control.

18.6 Summary and Conclusion

18.6.1 An Urbanizing World

The world is already predominantly urban, with the urban environment housing more than 50% of global population and accounting for even larger shares in economic and energy activities. Almost all future population growth of some three billion people to 2050 will be absorbed by urban areas. This urban growth is the combined result of natural increases in urban populations plus migration from rural to urban areas such that the increase in rural population in many developing countries will be overshadowed by population flows to the cities.

In contrast, rural populations globally will peak at around 2020 at a level of 3.5 billion people and decline thereafter. This global result masks heterogeneity in regional trends: whereas rural populations in Asia are projected to decline rapidly after 2020, the African rural population will continue to grow at least to 2040, before also declining.

Patterns of urban population growth have been and will remain heterogeneous. Most of the growth will continue to occur in small- to medium-sized urban centers, which explains the remarkable robustness of the distribution of city-size classes over time and across different regions. Growth in small cities poses serious policy challenges, especially in the developing world. In small cities, data and information to guide policy are largely absent, local resources to tackle development challenges are limited, and governance and institutional capacities are weak. Despite much public attention, the contribution of 'megacities' to global urban-population growth will remain comparatively small.

Shrinking cities in the developed world are an increasing phenomenon in urban dynamics, and could continue as below-replacement fertility levels outstrip increased longevity and so lead to declining populations in almost all high-income countries (and potentially in low-income countries in the long-term). The impacts of population contraction on urbanization remain a major unknown.

Cities of the future will have significantly older populations. Cities in developing countries will approach the age structures already prevalent in some cities of the industrialized world, with more elderly than young residents. This urban aging effect is likely to be mitigated temporarily by continued rural-urban migration as migrants comprise predominantly younger and more enterprising age cohorts, both nationally and internationally. Conversely, this demographic pattern suggests that aging will also be significant for rural settlements in low- and high-income countries alike. 'Graying' rural villages are probably the logical counterpoint of continued urbanization combined with a continued unfolding of the demographic transition worldwide.

18.6.2 Urban Energy Use

The urban share in current world-energy use varies as a function of system boundaries in terms of spatial scales (cities versus agglomerations), energy-systems definition (final commercial, total final, and total primary energy), and the boundary drawn to account for embodied energy in a city's goods and services, both imported and exported. The direct transfer of national energy (or GHG emissions) reporting formats to the urban scale is often referred to as a 'production' approach, and contrasts to a 'consumption' accounting approach that pro-rates associated energy uses (or GHG emissions) per unit of expenditure of urban consumer expenditures, thus accounting for energy uses irrespective of their form (direct or embodied energy) or location (within or outside a city's administrative boundary). Both approaches provide valuable information and should be used as complementary tools to inform urban policy decisions. However, to be useful, urban studies need to adhere to much higher standards in terms of clarity and documentation of the terminology, methodology, and underlying data used. To improve comparability, this assessment recommends specifically that all accounts based on the consumption approach (which are data- and time-intensive to prepare, and so exist only for a very limited set of megacities) be complemented by corresponding production-based energy accounts (which are much simpler and easier to determine). To ensure reproducibility, this assessment also recommends explicitly that no urban GHG-emission inventory be published without the underlying energy data used in the assessment.

Available estimates of current urban energy use based on a production approach (direct final energy use, or primary energy use, i.e., including pro-rated upstream energy sector conversion losses) suggest that urban energy use accounts for between 60% and 80% of global energy use. Total energy use is therefore already predominantly urban. Mirroring the growing importance of urban areas in demographic and economic development, urban energy use will continue to grow further as a fraction of total global energy needs. This implies that energy sustainability challenges need to be addressed and solved primarily by action in urban settings.

There is great heterogeneity in urban energy-use patterns, especially when manufacturing and transport energy uses are included. In many developing countries, urban dwellers use substantially *more* energy than their rural compatriots, which primarily reflects higher urban incomes. Conversely, in many industrialized countries per capita urban final energy use (i.e., based on a production-accounting approach) is often substantially *lower* than the national average, which reflects the effects of compact urban form, settlement types (multi- versus single-family dwellings) and availability and/or practicability of public transport infrastructure systems compared with those in the suburban or rural sprawl. The few available data, however, suggest that urban energy use in high-income countries is not substantially different from national averages using a consumption-based accounting approach that also includes energy embodied in imports. So, the effects of lowered direct final energy use through a more service-oriented urban economy, urban form and density, and resulting lower transport energy use are largely compensated by higher embodied energy use associated with higher urban incomes in high-income countries. For low-income countries, available data are too sparse to allow a similar comparison. However, it is highly likely that, because of the much higher income differential between urban and rural populations in low-income countries, their urban energy use is significantly higher on a per capita basis compared to national averages in a consumption-based accounting framework as well. Levels and structure (access to electricity, clean fuels for households, private motorized transport) of urban energy use in low-income countries are therefore a powerful leading indicator of future developments to come with rising urbanization and income growth in the developing world.

Drivers of urban energy use include geography and climate, resource availability, socioeconomic characteristics, degree of integration into the national and global economy (imports/exports), and urban form and density. Not all of these can be influenced by local governance and decision making. Priorities for urban energy and sustainability policies, therefore, should focus where local decision making and funding also provides the largest leverage effects: urban form and density (which are important macrodeterminants of urban structures, activity patterns, and hence energy use), the quality of the built environment (energy-efficient buildings in particular), urban transport policy (particularly the promotion of energy efficient and 'eco'-friendly public transport and non-motorized mobility options), and improvements in urban energy systems through cogeneration or waste-heat recycling schemes, where feasible. Local action, however, also requires local capacities and responsibilities in addressing urban energy and environmental problems, including a mediating role among the multiple stakeholders characteristic of decentralized urban decision making.

Conversely, the promotion of local solar or wind renewables will, at best, have a marginal impact on the overall energy use of larger cities (typically <1%)[39] because of the significant energy-density mismatch between (high) urban energy use and (low) renewable energy flows per unit land area available in urban areas. Smaller cities, however, could provide more avenues to integrate renewable energy into urban energy systems than large cities. Cities could also play an important role as consumers of renewable energies, creating niche market impulses as well as potentially exerting leverage on the application of sustainable social and ecological production criteria for their renewable energy suppliers.

Nonetheless, urban energy and climate policy should recognize that the most productive local decisions and policies influence the *efficiency* of urban energy use that is the demand side of the energy system, rather than its supply side.

39 Important exceptions include utilization of urban wastes and, where available, geothermal resources, both of which are characterized by a high energy density.

18.6.3 Facing the Challenges

18.6.3.1 Urban Poverty

Several hundred million urban dwellers in low- and middle-income nations lack access to electricity and are unable to afford the cleaner, safer fuels. Most are in low-income nations in southeast Asia and sub-Saharan Africa. In many low-income nations, more than half the urban population still rely on charcoal, fuelwood, straw, dung, or wastes for cooking, with significant adverse consequences for human health and urban air quality. A large part of the poor urban population that lacks clean fuels and electricity not only cannot afford these, but also faces political or institutional obstacles to accessing them.

In many middle-income and all high-income nations, nearly all low-income urban dwellers have legal electricity connections and access to clean fuels. The shift to clean fuels and the availability of a reliable electricity supply bring many advantages in terms of health, convenience, and time saved in accessing and using energy.

The costs of connection to an electricity grid and the use of electricity can be beyond the reach of low-income groups, but innovations have reduced these costs – for instance, rising tariffs with low prices for 'lifeline' electricity use, pay-as-you-use meters, and standard 'boards' that remove the need for individualized household wiring.

The constraints on supporting the shift to clean fuels and providing all urban households with electricity are less to do with energy policy than with authorities' handling of issues of informal settlements. A large part of the population that lack clean energy and electricity live in informal settlements. It is mostly in nations where this antagonistic relationship between local government and the inhabitants of such settlements has changed, through widespread public support to upgrade 'slums' and squatters, that clean energy and electricity reaches urban poor groups.

Housing, infrastructure, energy, and transport services are the key sustainability challenges to accommodate some three billion additional urban dwellers in the decades to come, especially in low-income countries. Informal settlements will be one of the transitional forms of settlement for many of these new urban dwellers and will require a much more proactive, anticipatory policy approach, especially with respect to the location of informal settlements and subsequent infrastructure connections and upgrading programs.

Energy-wise, low-cost and fast implementation options will take precedence over 'grand' new urban designs that require unrealistic capital provision over long periods. In low-income countries access to clean cooking fuels and electricity, as well as pro-poor transport policies, which include safer use of roads by non-motorized modes (walking and bicycling) and making public transport choices available (e.g., through BRT systems) need to receive more attention.

18.6.3.2 Livable Cities: Urban Density and Form

Urban density and form are not only important determinants for the functionality and quality of life in cities, but also for their energy use. Historically, the diversity of activities and ensuing economic and social opportunities that are the major forces of attraction to urban settings were provided by high density and co-location (mixed land-uses) of a diversity of activities that maximize the 'activity zone' of urban dwellers while minimizing transport needs. This urban history contrasts with decades of trends toward lower urban densities, which include widespread urban sprawl, and even 'ex-urban' developments.

It is widely agreed that there is no theoretical or practical argument for defining a universal 'optimal' form or density for a city. In theory (and often also in practice) higher densities increase the *economies of scope* (i.e., of activity variety) in a city. These are the main locational attractions of urban places in terms of potential number of jobs, breadth and variety of specialized trades and economic activities, along with cultural and many other attractions, usually summarized as *positive agglomeration externalities* that also extend to urban infrastructures (e.g., communication and transport networks). Conversely, higher densities can entail negative externalities as well, such as congestion, high land prices that limit the quality of residential living space for urban dwellers, or environmental problems (noise, air pollution).

Nonetheless, empirical data strongly suggest that the *net balance* of these positive and negative agglomeration externalities remained stable for extended periods of time, as illustrated by the remarkable stability of the rank-size distribution of cities (with dominating positive or negative net agglomeration externalities the growth of the *ensemble*[40] of larger cities should be above or below that of smaller cities, which is not the case). The historical evolutionary processes that govern urban growth have played out differently over time and space, which results in *path dependency*. Cities that evolved along alternative pathways have alternative density levels from high-density 'Asian' (e.g., Tokyo, Shanghai, Mumbai) and 'old European' (e.g., London, Madrid, Warsaw) to low density 'new frontier' (e.g., Los Angeles, Brasilia, Melbourne) pathways, each of which have different structural options available to improve energy efficiency and optimize urban energy and transport systems in terms of sustainability criteria.

Despite this diversity, two important generalizations can be drawn. First, the implications of urban density on the requirements of urban energy systems are that they need to be basically *pollution free*, as otherwise even relatively clean energy forms can quickly overwhelm the assimilative capacity of urban environments. This especially applies to the million, decentralized energy end-use devices (stoves, heating systems, vehicles) for which end-of-pipe pollution control is often not an option. Thus, in

40 Evidently, ***individual*** cities can forge ahead or fall behind the overall distributional pattern of aggregate uniform urban growth rates as outlined by the rank-size rule.

the long-term all end-use energy fuels consumed in urban areas need to be of zero-emission quality, as exemplified by electricity or (eventually) hydrogen, with natural gas as the transitional fuel of choice in urban areas. (Evidently, pollution levels also need to be minimized to the maximum technologically feasible at the point of production of these fuels.) This 'zero-emission' requirement for urban energy transcends the customary sustainability divide between fossil and renewable energies, as even 'carbon-neutral' biofuels when used by millions of automobiles in an urban environment will produce unacceptable levels of NO_x or O_3 pollution.

Second, the literature and above discussion repeatedly has identified important size and density thresholds that are useful guides for urban planning. The importance of these urban thresholds extends to specialized urban infrastructures, such as underground (metro) transport networks that are, as a rule, economically (in terms of potential customers and users) not feasible below a threshold population size of less than one million. It also extends to energy (e.g., cogeneration-based district heating and cooling) and public transport networks, whose feasibility (both for highly centralized and decentralized, distributed 'meso'-grids) are framed by a robust gross[41] density threshold between 50 and 150 inhabitants/ha (5000–15,000 people/km^2). Such density levels of 50–150 inhabitants/ha certainly do *not* imply the need for high-rise buildings, as they can be achieved by compact building structures and designs, both traditional and new, including town or terraced houses, while still allowing for open public (parks) or private (courtyard) spaces – but they do preclude unlimited (aboveground parking) spaces for private vehicles. Zoning and parking regulation, combined with public transport policies and policies that promote non-motorized transport modes and walkability thus constitute the essential 'building blocks' of urban energy efficiency and sustainability 'policy packages.'

18.6.3.3 Mobile Cities: Urban Transport

Urban transport is a key policy concern, both for its high visibility (potential opposition to 'top-down' policies) and its crucial importance to the very functionality of cities. Two fundamental observations need to guide urban transport policies.

First, on a sustainability metric there is a clear contradiction between growing private motorized transport and growing energy use and pollution. This contradiction relates not primarily to the technological artifacts *per se* (automobiles or scooters), but rather to the *organizational form* of their *usage* as privately owned vehicles with correspondingly low occupancy rates (and thus high energy/emissions per unit service delivered). Well-designed taxis or automobile-sharing schemes are excellent examples that the (selective) use of automobiles as modes of individual transport when needed (as opposed to their preordained use, despite congestion, simply because of a lack of alternatives) can be reconciled with the prerogatives of an energy-efficient city. Conversely, along the same sustainability metric, non-motorized mobility (walking and bicycling) and public transport schemes that function well and have high occupancy rates are the options of choice for urban mobility and should receive corresponding priority.

Second, the fundamental interrelations between demand and supply often create a 'vicious circle' for urban transport planning: more automobiles lead to congestion, which improved urban road infrastructures aim to alleviate. But more (road infrastructure) supply *induces* yet more demand (individual mobility and land-use changes) in an ever-spiraling 'rat race' of 'supply following demand' growth. A new public policy paradigm for urban transport needs to break this cycle of rebound effects through integrated urban energy transport policies that deal with both demand and supply.

The wide variation in urban transport choices observed in the modal split across cities illustrates that urban mobility patterns are not *ex ante* given, but rather result from deliberate choices of individuals and decision makers. Urban transport choices can be changed, if both a strong determination for sustainable transport policy *and* a corresponding wide public acceptance of the overall goals of such a policy exist. This wider acceptance of the overarching goals is also required to implement some individual measures (e.g., traffic calming, pricing schemes (for roads and parking, etc.)) that often face lobbying opposition. Restrictive measures that limit individual mobility by automobiles need to be complemented by proactive policies that enhance the attractiveness of non-motorized and public transport choices, and 'soft' policy measures (e.g., fees, tariffs) also need to be complemented by 'hard' (i.e., infrastructural investment) measures. The overriding goal is to turn the often automobile-dependent 'vicious' policy cycle into a 'virtuous' cycle that favors non-motorized and public transport choices.

One key measure in this context will be the progressive internalization of external costs of motorized private transport along with the provision of high-quality alternative public and non-motorized transport. Estimates for Europe suggest that these external costs are at least in the order of 6–10 cents per passenger-km (see Table 18.16), which when fully internalized would double private motorized transport costs. Comparable estimates for low-income countries are not available, but given their generally much higher road-accident rates, external costs are likely to be even larger. However, accompanying measures and strong leadership will be needed to increase the political acceptability of this invariably unpopular measure. Recent experiences with the introduction of road prices and congestion charges in cities across a wide political spectrum suggest that such policy approaches are both feasible and have the ability to alter urban transport behavior.

Attractive public transport systems require a dense public transport network and a high service frequency with short intervals, which are only

41 i.e. a minimum density level over the entire settlement area that comprises residential zones of higher density with low density green spaces.

feasible with a minimum threshold of urban density. A rule-of-thumb goal might be to have only urban settlements within easy walking (<500 m) access to a viable public transport service. Investments in public transport systems need to find an appropriate balance between improvements that are less capital intensive and faster to implement, and radical solutions. BRT systems are, therefore, a much more attractive option for many cities in low-income countries than are capital-intensive subway systems, even though, in the long term, the latter offer the possibility of higher passenger fluxes and greater energy efficiency. Often there is no contradiction between incremental versus radical public transport policy options: for instance, BRT can also be considered as a transitional infrastructure strategy to secure public transport 'rights of way,' which offer subsequent possibilities for infrastructure upgrades, for example in putting light rail systems in BRT lanes. Many of the new urban settlements being formed easily meet these density targets. The policy issue is to exploit the advantages before 'lock-in' into private transportation takes hold.

18.6.3.4 Efficient Cities: Doing More with Less Energy

From all the major determinants of urban energy use – climate, integration into the global economy, consumption patterns, quality of built environment, urban form and density (including transport systems), and urban energy systems and their integration – only the final three are amenable to an urban policymaking context and therefore should receive priority.

Systemic characteristics of urban energy use are generally more important determinants of the efficiency of urban energy use than those of individual consumers or of technological artifacts. For instance, the share of high occupancy public and/or non-motorized transport modes in urban mobility is a more important determinant of urban transport energy use than the efficiency of the urban vehicle fleet (be it buses or hybrid automobiles). Denser, multifamily dwellings in compact settlement forms with a corresponding higher share of nonautomobile mobility (even without thermal retrofit) use less *total energy* than low-density, single-family 'Passivhaus'-standard (or even 'active,' net energy generating) homes in dispersed suburbs with two hybrid automobiles parked in the garage and subsequently used for work commutes and daily family chores. Evidently, urban policies need to address both systemic and individual characteristics in urban energy use, but their different long-term leverage effects should structure policy attention and perseverance.

In terms of urban energy-demand management, the quality of the built environment (buildings efficiency) and urban form and density that, to a large degree, structure urban transport energy use are roughly of equal importance. Also, energy-systems integration (cogeneration, heat cascading) can give substantial efficiency gains, but ranks second after buildings efficiency and urban form and density, and associated transport efficiency measures, as shown both by empirical cross-city comparisons and modeling studies reviewed in this chapter.

The potential for energy-efficiency improvements in urban areas remains enormous, as indicated by corresponding urban exergy analyses that suggest urban energy-use efficiency is generally less than 20% of the thermodynamic efficiency frontier; this suggests an improvement potential of more than a factor five. Implementing efficiency improvements (including systemic measures) should therefore receive highest priority. In the built environment, there is considerable inertia and irrational behavior, given the relatively low or even negative cost of GHG abatement through refurbishment of buildings. There is therefore a strong argument for prescription and regulation regarding building standards.

Conversely, the potential of supply-side measures within the immediate spatial and functional confines of urban systems is very limited, especially for renewable energies. *Locally harvested* renewables can, at best, provide 1% of the energy needs of a megacity and a few percentage points in smaller, low-density cities because of the mismatch between (high) urban energy demand and (low) renewable energy supply densities. Without ambitious efficiency gains, the corresponding 'energy footprint' of cities that import large-scale, centralized renewable energies (biofuels for electricity) will be vast and at risk of producing 'collateral' damages caused by large-scale land conversions (e.g., soil carbon perturbations and albedo changes), and competition over food and water. Given that all city systems are subject to uncertainty and change, there is also a need for option-based design techniques that allow for city growth and technological evolution, and that avoid strongly path-dependent solutions and 'lock-in' into urban energy-supply systems based on current- or near-term renewable options that, ultimately, will be superseded by third and fourth generation renewable supply technology systems. Improved urban energy-efficiency leverages supply-side flexibility and resilience, and thus adds further powerful arguments for strategies that focus on urban energy-efficiency improvements.

Finally, *energy security* is a re-emerging issue for many cities because energy security declined over recent decades and security concerns need to be integrated increasingly into urban energy policies and sustainability transition analysis. Better efficiency and improved energy systems integration will also benefit urban energy security, although a further assessment of energy security is beyond the scope of this urbanization chapter (as dealt with in the energy security Chapter 5).

18.6.3.5 Clean Cities: Air Pollution

To a degree, the observed significant improvements in urban air quality caused by the elimination of traditional air pollutants, such as soot, particles, and SO_2, in cities of high-income countries are a powerful illustration that cities act as innovation centers and hubs for environmental improvements that lead to a sustainability transition path.

The first signs of progress in these traditional air pollutants are evident in countries of lower income as well, and are illustrated by the

recent decline in the emissions of some traditional pollutants in Asian megacities. Nonetheless, an exceedingly high fraction of urban dwellers worldwide are still exposed to high levels of urban air pollution, especially TSPs with fine particle emissions (PM-10s) continuing their upward trend.

A wide portfolio of policy options is available, ranging from regulatory instruments such as mandated fuel choice ('smokeless zone' regulations), air-pollution standards, regulation of large point-source emissions and vehicle exhaust standards, to market-based instruments (or hybrid) approaches that incentivize technological change. An important feature of these regulatory or market-based approaches is *dynamic target setting* to reflect changing technology options and to counter the consequences of urban growth and potential consumer 'take-back' effects. The tested experiences in a diversity of settings from the United Kingdom through California to New Delhi provide valuable lessons for policy learning. However, an institutional locus on the exchange of policy lessons and capacity building (including pollution monitoring), particularly in small- and medium-sized cities in low-income countries, remains sorely lacking.

Air pollution is also the area of urban environmental policy making where the most significant co-benefits of policies can be realized: improving access to clean cooking fuels, for example, improves human health and lowers traditional pollutant emissions, and also has (through reduced black carbon emissions) net global warming co-benefits. (See also Chapters 4 and 17 on illustrations of co-benefits). Similarly, improved energy efficiency and public transport options (e.g., New Delhi's transition to CNG buses) can also yield co-benefits on a variety of fronts (lower energy and transport costs for the poor, cleaner air, improved urban functionality) and should therefore be higher on the policy agenda than more single-purpose policy measures (e.g., renewable portfolio standards for urban electricity supply). Examples of the management of urban heat island effects also illustrate well the potential significant co-benefits between mitigation and adaptation measures.

Realization of the significant potential co-benefits, however, requires more holistic policy approaches that integrate urban land-use, transport, and energy policies with the more traditional air-pollution policy frameworks. Cities in low-income countries, where the growth trends of urbanization and air pollutants are the most pronounced (to the extent that they will determine global trends), are also where institutional capacities and information needs are largest. These must be improved to be able to reap the multiple co-benefits of more integrated urban policies. A renewed effort to improve measurement and monitoring as well as planning and modeling of urban environmental quality, with a particular focus on urban energy and urban transport policy, is urgently needed. This needs to be coupled with the development of institutional capacity for the design, implementation, and enforcement of policies and plans.

18.6.4 Policy Leverages, Priorities, and Paradoxes

The highest impacts of urban policy decisions are in the areas where policies can affect local decision making and prevent or unblock spatial irreversibilities or technological 'lock-in,' or to steer away from critical thresholds.

Examples include preventing the further development of low-density, suburban housing and of shopping malls, or promotion of the co-location of high energy supply and demand centers within a city that enable cogeneration and waste-heat recycling for heating and cooling purposes (e.g., in business districts). Buildings energy-performance standards are also a prime example of policy interventions that need to be implemented as early as possible to reap long-term benefits in terms of reduced energy use and improved urban environmental quality. New technologies, like smaller micro- and mesogrids are particularly attractive options that are also suitable for deregulated market environments. The literature on urban energy use, particularly with respect to transport, also identifies a critical 'threshold' of between 50 and 150 inhabitants/ha below which public transport (or energy cogeneration) options become economically infeasible, which thus leads to overproportional increases in energy use (e.g., longer trips using private automobiles). To avoid such critical thresholds being crossed should be a high priority for urban administrations.

Given capital constraints, it is entirely unrealistic to expect 'grand' new urban 'ecodesigns' to play any significant role in integrating some three billion additional urban dwellers to 2050 into the physical, economic, and social fabric of cities. Building cities for these three billion new urban citizens along the Masdar (Abu Dhabi) model would require an investment to the tune of well above US$1000 trillion, or some 20 years of current world GDP![42] The role of such new, daring urban designs is less a template for development, but rather a 'learning laboratory' to develop and test approaches, especially to low-cost options for sustainable urban growth in low-income countries and to retrofit and adapt existing urban structures and systems across the globe.

To address urban energy sustainability challenges will also require a new paradigm for drawing systems or ecosystems boundaries that extend the traditional place-based approach (e.g., based on administrative boundaries or ecosystems such as regional watersheds or air-quality districts). Sustainability criteria need to be defined on the basis of the functional interdependence among different systems, which are not necessarily in geographic proximity to each other.

42 This extreme estimate does not suggest that energy efficient cities are prohibitively expensive. A wide range of measures in building retrofits and low-cost new energy efficient housing as well as in public transport policies can result in significant reductions of energy use at modest investment levels. For estimations of the investment needs of the GEA transition pathways, see Chapter 17.

System analytical and extended LCA methods are increasingly available to address the question of the social, economic, and environmental sustainability of urban energy systems that almost exclusively rely on imports. However, clear methodological guidelines and strategies to overcome the formidable data challenges are needed, a responsibility that resides within the scientific community, but that requires support and a dedicated long-term approach for funding and capacity building.

A common characteristic of sustainable urban energy system options and policies is that they are usually systemic: for example, the integration of land-use and urban transport planning that extends beyond traditional administrative boundaries; the increasing integration of urban resource streams, including water, wastes, and energy, that can further both resource (e.g., heat) recovery and improve environmental performance; or the reconfiguration of urban energy systems toward a higher integration of supply and end-use (e.g., via micro- and mesogrids) that enable step changes in efficiency, for example, through cogeneration and energy cascading. This view of more integrated and more decentralized urban infrastructures also offers possibilities to improve the resilience and security of urban energy systems.

And yet this systemic perspective reveals a new kind of 'governance paradox.' Whereas the largest policy leverages are from systemic approaches and policy integration, these policies are also the most difficult to implement and require that policy fragmentation and uncoordinated, dispersed decision making be overcome. This governance paradox is compounded by weak institutional capacities, especially in small- to medium-sized cities that are the 'backbone' of urban growth, as well as by the legacies of market deregulation and privatization that have made integrated urban planning and energy, transport, and other infrastructural policy approaches more difficult to design and yet more difficult to implement.

However, there are good reasons for (cautionary) optimism. Urban areas will continue to act as innovation centers for experimentation and as diffusion nodes for the introduction of new systems and individual technological options (Bai et al., 2010) by providing critical niche market sizes in the needed transition toward more sustainable urban energy systems. The task ahead is to leverage fully this innovation potential of cities and to scale-up successful experiments into transformative changes in energy systems. Individual and collective learning, transfer of knowledge, and sharing experiences and information across cities and among stakeholders will, as always, be key objectives to which this chapter hopes to contribute.

Executive Summary

Key Challenges

- A quarter of humanity today lives without access to any electricity and almost one-half still depends on solid fuels such as unprocessed biomass, coal, or charcoal for its thermal needs. These people continue to suffer a multitude of impacts detrimental to their welfare. Most live in rural villages and urban slums in developing nations. Access to affordable modern energy carriers is a necessary, but insufficient step toward alleviating poverty and enabling the expansion of local economies.

- Even among populations with physical access to electricity and modern fuels, a lack of affordability and reliable supplies limits the extent to which a transition to using these can occur. Those who can afford the improved energy carriers may still not be able to afford the upfront costs of connections or the conversion technology or equipment that makes that energy useful.

- Beyond the obvious uses of energy for lighting, cooking, heating, and basic home appliances, uses for purposes that might bring economic development to an area are slow to emerge without institutional mechanisms in place that are conducive to fostering entrepreneurial activity and uses of energy for activities that can generate income. Without the expansion of energy uses to activities that generate income, the economic returns to energy providers are likely to remain unattractive in poor and dispersed rural markets.

- Significant success has been achieved with small pilot projects to improve energy access in some rural areas and among poor communities in urban areas. But subsequently, less thought is focused on how to scale-up from these small pilot and demonstration projects to market development and meeting the needs of the larger population.

Key Messages

1. While the scale of the challenge is tremendous, almost universal access to energy, both electricity and clean cooking for all, is achievable by 2030. As estimated in Chapter 17, this will require global investments to the tune of US$36–41 billion annually, a small fraction of the total energy infrastructural investments required by 2030, and may have a negligible or even negative impact on greenhouse gas (GHG) emissions. Immediate benefits from improved health for millions of people will result and the socioeconomic benefits from improved energy access will extend well beyond those to the current generation.

2. Electrification rates have been more rapid and far in excess of population growth rates in many countries and regions such as East Asia (including China) and Latin America. Between 1990 and 2008, almost two billion people got connected to electricity globally. This provides a basis to believe that electrifying the remaining 1.4 billion people without electricity by 2030 is feasible.

3. The progress with providing clean cooking services globally has been rather dismal over the last decades, with the numbers of people dependent on solid fuels rising in the rural regions of most developing countries and the percentage of rural populations dependent on solid fuels virtually unchanged over the last decade. This suggests that transitioning the global population to clean cooking fuels by 2030 will not be feasible and for some populations, a transition to improved stoves will be necessary to improve their cooking experience. This will require significant advances to be made in rapid diffusion of low-cost, high performing and standardized stoves and more sustainable management and practices along the entire biomass value chain.

4. While the challenge is considerable, the experiences and approaches followed in countries that have been successful in achieving improved access provide important lessons that can be applied elsewhere to achieve universal access by 2030. This will require leveraging funding from public and private sources, both for necessary investments at the macro level, and for meeting costs for low-income households at the micro level. Creative financing mechanisms and transparent cost and price structures will be key to achieving the required scale-up and quick roll-out of solutions to improve access.

5. No single solution fits all in improving access to energy for development. Programs aimed at increasing access must be cognizant of local needs, resources, and existing institutional arrangements and capabilities.

6. Supportive policy and institutional frameworks need to be created that encourage private sector participation, as well as replicability and the scale-up and scale-out of successful programs.

7. Diverse sources of energy supply (fossil and renewable), a wide portfolio of technologies, and a variety of institutional and innovative business and energy service delivery models that are adapted to local circumstances and allow for sustainable replication, deliver social benefits, and generate wealth for the community are required to meet the challenge.

8. An enabling environment shaped by sustained government commitment and enhanced capacity building at all levels is paramount to ensuring access targets are met.

9. Complementary development programs and enhancement of market infrastructure are needed to ensure sustained economic growth and steady employment and income generation for the poor, in order to provide them with a means to pay for improved energy services.

Structure and Roadmap of Chapter 19

Chapter 19 builds strongly on the concerns raised in Chapter 2 ("Energy and Society"), Chapter 3 ("Energy and Environment"), and Chapter 4 ("Energy and Health"). The Chapter is structured as follows (see Figure 19.1).
Section 19.1 presents a brief overview of the linkages between energy access, human wellbeing, and the environment. It also lays the foundation for understanding why energy access is essential for poverty reduction and development. Section 19.2 assesses the historical efforts and trends and the current global status of access to electricity, clean cooking/heating fuels and stoves, and modern energy carriers for income generating activities. The following section, 19.3, provides a more differentiated and nuanced analysis of regional efforts and strategies to improve energy access in households and the status of access in each region. Finally, Section 19.4 concludes with lessons learnt and implications for the way forward. The role of policy and institutional issues is also discussed briefly in this chapter; however, a deeper discussion of this is left to Chapter 23, which focuses specifically on policies and measures for expanding energy access.

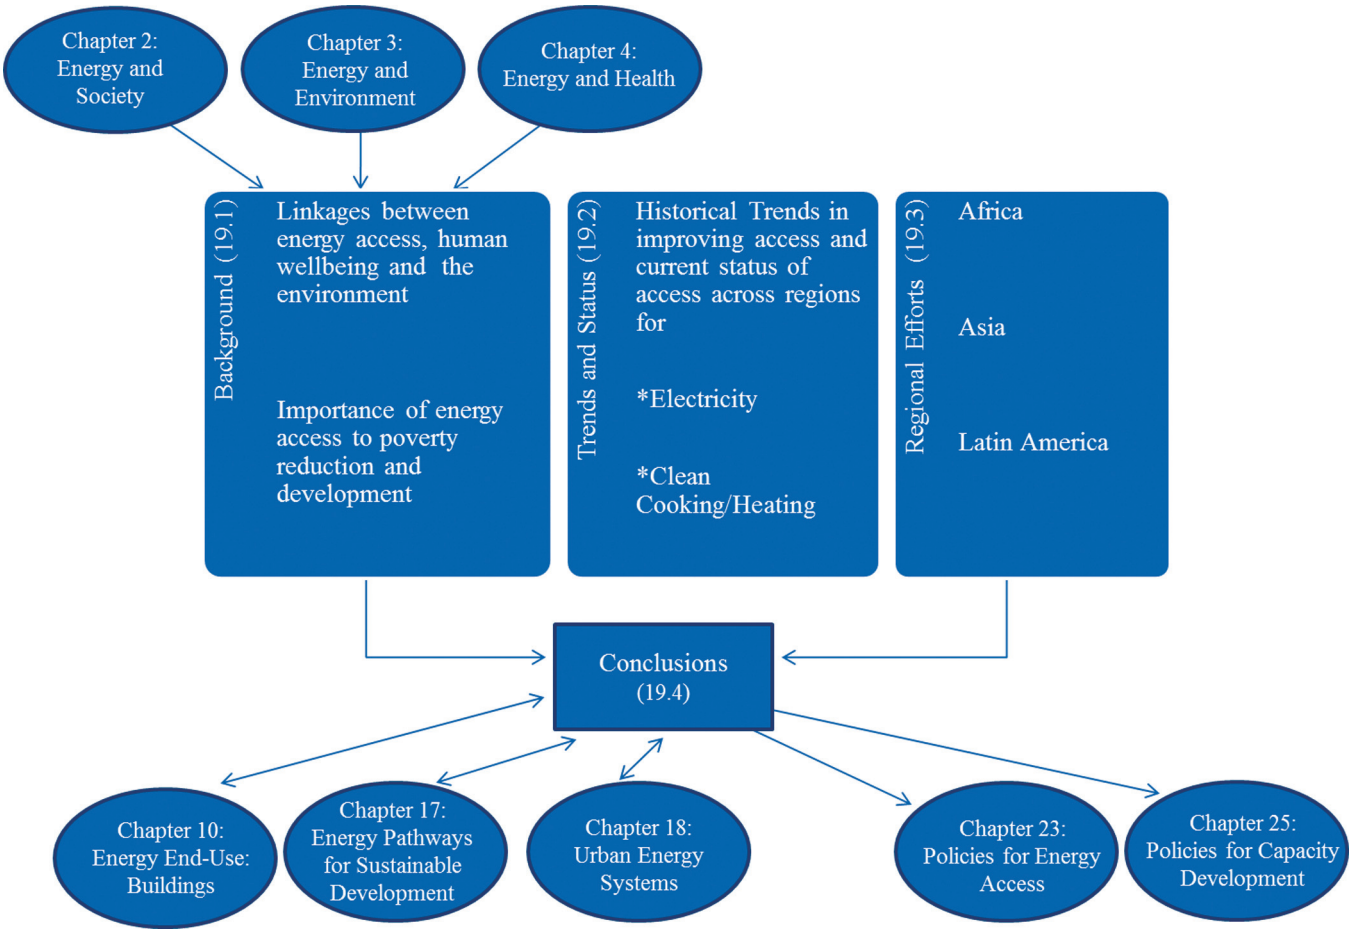

Figure 19.1 | Roadmap of Chapter 19 and its linkages to other chapters.

Box 19.1 | Definitions and Dimensions of Access

The simplest definition of universal access to modern energy is the physical availability of electricity and modern energy carriers and improved end-use devices such as cook stoves at affordable prices for all. A target of energy access for all by 2030, set by the United Nations Secretary-General's Advisory Group on Energy and Climate Change (AGECC, 2010), recommends access to be provided in accordance with this basic definition so as to enhance services such as lighting, cooking, heating, and motive power for populations in developing countries. This is no longer only a moral imperative, but also socially prudent and an economic necessity to enable the almost one and a half billion people living without any electricity and over three billion dependent primarily on solid fuels to lift themselves out of poverty and improve their living conditions. Providing access to improved energy carriers is clearly a necessary, but insufficient condition for overall poverty alleviation and socioeconomic growth. Alleviating poverty, in its totality, clearly also requires improving the earnings of the poor by providing them with more sustainable livelihood opportunities through encouraging the use of energy in activities that can generate income. This requires defining access in a much broader sense and would require making available reliable and adequate qualities and quantities of energy and the associated technologies at affordable costs in a manner that is socially acceptable and environmentally sound so as to meet basic human needs and for activities that are income generating and could empower growth and development.

Such a broader definition of access includes several elements and dimensions, including quality, reliability, adequacy, affordability, acceptability, and environmental soundness. Unfortunately, national level indicators and statistics to measure and monitor these various dimensions of access are extremely scarce, particularly for the least developed countries and regions where the issue is the most pressing.

Within GEA, we abstain from defining any global quantitative thresholds for the minimum amount of energy needed to meet basic needs. This is because basic needs are normative and vary significantly between countries and regions depending on climate, social customs and norms, and other region and society-specific factors. We are, however, mindful of the fact that some national governments have defined basic or lifeline energy entitlements for their poorest citizens. In most cases, these fall within the range of 20–50 kWh of final electricity per household per month to meet basic lighting, communication and entertainment needs, and the equivalent of 6–15 kg of LPG per household per month for cooking. Heating requirements, being seasonal, are often approximated as the equivalent of 15–30 kWh useful energy per square meter of living space, annually. Defining lifeline entitlements in final energy units of course also has the limitation that efficiencies of end-use appliances and equipment are not accounted for.

Clearly, such entitlements fall far below what is required for purposes that can generate income to empower growth and development. Ensuring adequate amounts of energy to achieve this end may require defining some average energy equity thresholds and estimating not only direct energy needs, but indirect or embodied energy requirements as well. This is a much more complex endeavor and would require taking account of national economic and energy system structures and characteristics, as the same amount of energy can provide a wide range of energy services. Previous efforts at quantifying such equity thresholds provide estimates in useful energy terms in the range of 1–2 kW per capita to meet basic needs and much more (Goldemberg et al., 1985; Imboden and Voegelin, 2000).

19.1 Introduction

19.1.1 Background

Energy deeply influences people's lives and is an engine for social development and economic growth. Over the centuries, energy has helped transform societies and has underpinned human development. Energy contributes to fulfilling the most basic human needs, including nutrition, warmth, and light. Furthermore, there is ample evidence that access to reliable, efficient, affordable, and safe energy carriers can directly affect productivity, income, and health, and can enhance gender equity, education, and access to other infrastructure services. However, energy use patterns, in terms of both quality and quantity, are highly inequitably distributed on all sides of the development divide – North and South, rich and poor, men and women, rural and urban. This inequity in energy access and use compromises human welfare and has adverse impacts on the environment. The lack of access to reliable, affordable, and modern energy carriers,[1] particularly in rural areas of developing countries, is a major challenge faced by over one-third of humanity even today. This presents a major impediment to growth and compromises progress toward sustainable development. Providing access to electricity and modern energy carriers and/or devices[2] to all populations is not only a moral obligation, but is also necessary for improving living conditions and may provide economic returns in the long run that far exceed the costs involved.

The world still faces the task of satisfying the demand for energy services of a vast majority of its population to meet basic needs for lighting, cooking, and heating, and for use in activities that can generate income. Recognizing the centrality of improving energy access for the poor, the international community has been increasingly active in discussing the setting of a global energy access target. Several governments and regional bodies have already set national targets to improve access. Building on these, the United Nations Secretary-General's Advisory Group on Energy and Climate Change (AGECC, 2010) recommends ensuring universal energy access by 2030. Meeting such a target requires the provision of affordable[3] electricity and modern fuels and improved end-use devices by 2030 to all who currently lack access. To some, this may appear unattainable, but the technologies and examples of successful policies to achieve this already exist. The challenge to meet such an access target is greater, but can have even more significance for the rural populations of the world. Before the beginning of 2008, rural areas contained more than half the world's population (UN, 2008), with nearly 90% of the rural population, close to three billion, living in developing countries. However, this half of the population still consumes only a small fraction of total global fossil fuels and electricity, and rural energy issues remain largely overlooked in national energy and developmental plans.

The use of unprocessed solid fuels, both commercial and noncommercial, on the other hand, is predominantly concentrated in rural areas of developing countries, and particularly among the poor. This remains the primary source of fuel for cooking and heating for most of the rural population in the developing world and many urban residents as well. Globally, over three billion people rely on solid fuels, largely biomass (wood and residues), charcoal, and coal for cooking and heating (UNDP and WHO, 2009). The use of biomass is both arduous and time consuming in its harvest, transport, and use and is associated with negative environmental consequences. The majority of biomass harvest is carried out by women and children and its negative impacts on them have been discussed in Chapter 2. Negative health impacts from this traditional use of biomass and other solid fuels, discussed in Chapter 3, include those due to household pollution, which accounts for an estimated almost two million deaths/year, with a higher percentage of these being women and children in developing countries (UNDP and WHO, 2009). Furthermore, the burning of wood fuels contributes to climate change through emissions of GHGs, as discussed in Chapter 4. When the biomass burnt is not sustainably harvested, the use of these fuels has the added disadvantage of no longer being CO_2-neutral. As mentioned in Chapter 4, recent evidence also shows that the climate impacts of Black Carbon are larger than previous estimates suggested, particularly for the melting of arctic and glacial ice (Ramanathan and Carmichael, 2008). Black Carbon, or soot, is a byproduct of the combustion of fossil fuel, biofuel, or biomass, including wood waste and agricultural green waste (Grieshop et al., 2009).

Access to cleaner and more efficient end-use devices, processed biomass and/or more efficient fuels can alleviate the public health, welfare, and environmental concerns associated with traditional solid fuel use discussed in the preceding paragraph. In addition, such access can address the home heating needs of those who live in colder climates. In many societies, women and girls bear the disproportionate burden of fuel gathering, home care, and cooking, and hence the provision of more efficient and safer fuels and technologies can also contribute to reducing gender inequities in health and time burdens.[4] The performance of improved biomass cook stoves is wide ranging. However, throughout this assessment, when we refer to advanced stoves we imply stoves that have proven efficiency close to that of LPG stoves and the ability to reduce emissions that are health damaging.

1 Modern energy carriers in this chapter refer to electricity (grid or off-grid, both renewable and fossil-based) and liquid and gaseous fuels such as liquefied petroleum gas (LPG), biogas, ethanol, and natural gas.

2 Modern devices refer to improved cook stoves (ICS) that meet a minimum efficiency and emissions standard and have a performance that matches that of LPG stoves. Access to such ICS are assumed to improve cooking energy service for the poor and are included in the universal clean cooking target discussed in Chapter 2 and analyzed in Chapter 17 on future scenarios for improving access.

3 "Affordable" is evaluated in terms of the current spending on energy services and household purchasing power.

4 Truly enhancing equity for women and children will require significant additional social and cultural change and development. However, a full discussion of these issues is beyond the scope of this assessment.

In addition to lacking access to modern fuels and devices, about a quarter of the world's population also still lacks access to any electricity (UNDP and WHO, 2009). Over 85% of those lacking access live in rural and peri-urban areas (Derdevet and Caubet, 2007). In essence, four out of five people without electricity live in rural areas in developing countries, predominantly in the least developed countries of South Asia and sub-Saharan Africa (UNDP and WHO, 2009). Thus even today, the services that electricity makes possible, from basic lighting and telecommunications with mobile phones to computer-controlled agro-industrial processing, remain outside the reach of many people in the developing world. The communication revolution was first unleashed by radio, television, and computers and has now advanced with mobile telephony and the internet. These tools have become essential for individual empowerment, enterprise development, and the functioning of social infrastructure. Access to such modern media, efficient lighting, and other labor-saving devices are impossible without electricity.

It is widely recognized that improvements in access to more efficient energy carriers, both electricity and fuels, can have huge impacts on the lives of people, particularly the poorest in the developing world (WHO, 2006; Kanagawa and Nakata, 2007; World Bank, 2008a; Hiremath et al., 2009; Khandker et al., 2009). Chapter 2 highlights the multitude of benefits that improvements in energy access can make possible for the poor. In addition to the social benefits, energy is also essential for improving productivity, which is crucial for bringing the rural poor out of subsistence activities. Irrigation pumps, processing capability, storage, and access to markets and market information is not possible without adequate energy services, increasingly enabled through electricity and mechanical power. The growth and facilitation of enterprises is also intimately linked to access to energy. Communal services such as schools and health centers also require energy. In addition, the existing base of technological infrastructure provided by standardized motor fuels is an enabler of lowered transportation costs, which allows the movement of goods and people. Expanding access to better quality energy for the poor and unserved therefore remains a major developmental and environmental challenge for the world, particularly in the case of the Least Developed Countries (LDCs).[5] National energy policies and poverty reduction strategy papers in these countries very often either neglect energy completely or focus solely on electrification. They neither reflect adequately the energy-poverty nexus nor include targets and timelines to meet the energy needs of the poor. Often there is also a misalignment between national priorities and budgetary allocations for rural energy, resulting in a lack of coherence between strategies and plans and program implementation on the ground (UNDP, 2007a).

5 We follow the UNDP classification of Least Developed Countries and Developing Countries. Please refer to UNDP and WHO (2009) for further details of the countries included.

19.1.2 The Poverty-Energy Relationship

Access to electricity and modern energy carriers that help fulfill energy service needs is of key importance in future efforts at poverty reduction and development, both in rural and urban areas. Chapter 2 includes a detailed discussion of the role of energy in achieving the Millennium Development Goals (MDG). In addition, Chapter 18 deals with the challenges and issues surrounding the lack of adequate and affordable energy access in urban centers. This chapter focuses more specifically on assessing the nature of the access challenge both globally and regionally, and reviewing the progress made to date in improving access in developing countries and regions.

We distinguish between rural and urban areas because the issues related to rural poverty are fundamentally distinct from those of urban poverty and the challenges related to providing access to energy for the rural poor differ from those in urban areas (for further discussion on this topic, see also Chapters 2 and 17). About 75% of the developing world's poor currently live in rural areas, with some marked regional differences (Chen and Ravallion, 2007; Ravallion et al., 2007). Analyses for very different countries, like Brazil, Ecuador, Thailand, Malawi, and Viet Nam, show that poverty rates tend to be higher in remote rural areas than in more accessible areas, and poverty is deeper and more severe in remote areas. While the numbers of rural poor are declining globally, poverty rates in rural areas remain very high, particularly in some regions, and the energy problems of the rural poor persist. The numbers of urban poor, on the other hand, have grown during the last few decades. Indeed, it has been argued that urbanization has helped reduce overall poverty, except that this is shown to be true more for rural poverty than for urban poverty (Ravallion et al., 2007; World Bank, 2008b).

Poverty is linked not only to deprivation of income, but also a lack of access to resources and assets, social networks, voice, and power (UNDP, 2010). Poverty, particularly in rural areas, is often accompanied by both a lack of access to electric power services and an extreme dependence on unprocessed biomass, coal, or charcoal for basic uses such as cooking, water and home heating, as well as a lack of adequate and appropriate energy carriers for use in activities that are income generating. There tends to be a two-way causal relationship between the lack of access to adequate, affordable, and appropriate energy forms and poverty. This has often been termed the "energy-poverty nexus" (UNDP, 2006; Masud et al., 2007) or the "vicious cycle of energy poverty" (WHO, 2006). The cycle is considered vicious because households that lack access to appropriate energy are often trapped in a vortex of deprivation. The lack of energy, in addition to insufficient access to other key services and assets, affects productivity, time budgets, opportunities for income generation, and more generally, the ability to improve living conditions. The low productivity and livelihood opportunities, in turn, result in low earnings and no or little surplus cash for these people. This contributes to the poor remaining poor and consequently, also energy poor, since they cannot afford to pay for improved energy services

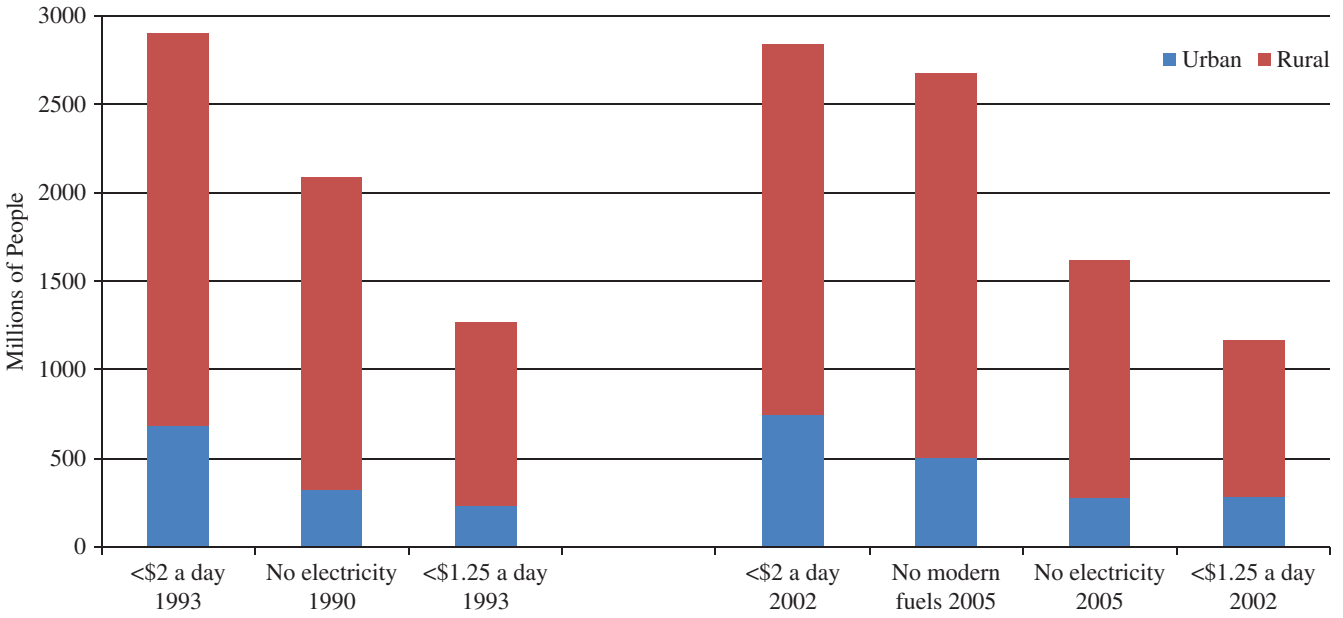

Figure 19.2 | People living in poverty and with lack of access to electricity and modern fuels. Source: data from IEA, 2002; 2007; Ravallion et al., 2007.

(often neither the fuels nor the equipment). Thus the problem of poverty remains closely intertwined with a lack of energy. This is also evident from looking at the data on the incidence of poverty and lack of access to electricity and more efficient liquid or gaseous fuels, termed "modern fuels" (see Figure 19.2).

Paradoxically, the communities that are the poorest in terms of access to energy are also often the most vulnerable and unable to cope with the threats of climate change. This is because these communities are often those most dependent on their local ecosystems for their livelihoods and energy needs. The Intergovernmental Panel on Climate Change described Africa, the world's poorest region, as "the continent most vulnerable to the impacts of projected change because widespread poverty limits adaptation capabilities" (IPCC, 2007). As these ecosystems are increasingly affected by climate change, the communities dependent on them will need other energy options and livelihood opportunities (Johnson and Lambe, 2009). Diversifying the energy sources available to these communities could thus also be an important means of enhancing the adaptive capacity of these regions.

19.1.3 The Role of Energy Access in Poverty Reduction and Rural Development[6]

Energy can reduce poverty and enable development in direct and indirect ways (Cabraal et al., 2005). Chapter 2 provides a detailed discussion of the role energy can play in meeting the MDGs, more specifically in reducing poverty and improving literacy, health, gender equity, and community services, as well as how energy contributes to other positive social and environmental outcomes. All of these improvements in welfare constitute an improvement in social and human capital, which in turn can enhance the potential for higher income generation. Energy can also have a more direct influence on income in a variety of ways, such as making possible labor-saving mechanization, freeing up time, and increasing the length of productive hours in a day. The provision of energy itself is necessary, but insufficient to achieve these positive developmental benefits. To reap the largest positive impact, additional efforts and institutional mechanisms conducive to fostering entrepreneurial activity and uses of energy for activities that can generate income are also required.

Mechanical power provides energy services for productive uses and basic processing in many different rural livelihood activities undertaken in enterprises, farms, mines, workshops, forests, wells, and river crossings, to name a few. These energy services are fundamental to rural livelihoods and to the efficient transformation of natural resources into vital products and services, which results in wealth creation for producers and affordable prices for consumers.

Historically, progress in reducing rural poverty in many countries has gone hand in hand with agricultural development (World Bank, 2008b). While economists have struggled to disentangle the multiplicity of factors that enable agricultural growth, studies from Asia show that irrigation has played a prominent role. In particular, groundwater irrigation can be an important means of securing access to water as it allows farmers greater control over the amount and timing of irrigation. However, groundwater

6 This section draws heavily on Chapter 2 and Chapter 6. Energy access alone is insufficient for development. Several other factors are essential to the development process. A fuller discussion of all these enabling factors is, however, beyond the scope of this assessment.

Box 19.2 | The Role of Energy in Powering Rural Development in India

Literature providing evidence to support the hypothesis that agricultural growth has a strong impact on poverty reduction is well developed in the context of India, a major player in the Green Revolution (Ahluwalia, 1978). In India, groundwater irrigation was predominantly enabled by motorized pumps, either electric pumps energized through highly subsidized grid power or diesel pumps energized through low cost diesel fuel (the diesel is also subsidized). Barnes et al., (2002) report that irrigation led to income gains from 45–80% for farms of varying sizes.

More recent evidence from Gujarat state in India has also demonstrated the importance of access to electricity to rural businesses. A new scheme called *Jyotigram* was implemented in Gujarat to ensure reliable 24/7 metered supply for any nonagricultural use. Initial evidence suggests that this change from an unreliable 12 to 18 hour supply has increased rural prosperity through increased nonfarm activity as well as access to electricity for social infrastructure and communications (Shah and Varma, 2008).

irrigation requires energy to lift water. For growing cereal crops, this is difficult to achieve without mechanized pumps. Access to mechanized water pumps can increase incomes in multiple ways, such as:

- improving yields due to reduced risk from rainfall variability;
- facilitating a switch from single- to multi-cropping and more remunerative cash crops; and
- increasing the willingness of farmers to invest in fertilizer, improved seeds, and other farming technologies which further increase agricultural productivity, as the risk of crop failures is reduced.

The positive impact of irrigation for agricultural development and its contribution to food security, income generation, and poverty reduction has not been uniform across different regions. In general, unless the cost of irrigation is a small fraction of the value of the food produced, the enabling developmental outcomes are unlikely to materialize. Tube well irrigated agriculture in India uses on average close to 1000 kWh of electricity per hectare of irrigated land (Srivastava, 2004). With electricity supply to Indian farmers being highly subsidized, the costs associated with such mechanized irrigation remain low. While this has resulted in a litany of environmental problems associated with the over-pumping of groundwater in certain regions of India, the improvements in irrigation have been critical in creating the surpluses in food production, which in turn have enabled a transition to a more diversified economy, higher incomes, and now, with an increasing emphasis on female education, may also be helping drive a demographic transition.

In many sub-Saharan African countries with poor existing electricity grid infrastructure and very low rural demand densities, the cost associated with providing electric power for mechanized water pumps tends to be much higher. Moreover, with the exception of a few countries such as South Africa, Nigeria, and Tanzania, which have ample coal and/or natural gas resources, mechanized irrigation in the region remains dependent upon diesel pumps or grids that rely on heavy fuel oil-fired generators. In either case, the effective cost of generation (at least at the margin) is often much higher than US¢10/kWh. Indeed it is not unusual for costs of power and equipment to add up to as much as US¢30–40/kWh, thus making the cost of energy prohibitively expensive for higher food production in these regions (Modi, 2010). Reliable and reasonably priced energy is an essential ingredient for many aspects of improved or value-added agricultural and post-harvest processes, and is pivotal to enabling development and lifting millions out of poverty. Enhanced productivity in agro/food processing, artisanal activities, and microenterprises has the potential to boost economic development and improve livelihoods. In areas where electricity grids are unable to reach populations, the availability of decentralized mechanical power is particularly important for increasing the social and economic opportunities of the poor. Ironically, despite the importance of this energy service, there exists little data on mechanical power in developing countries.

Access to mechanical power can help increase efficiencies and effectiveness in production, thus raising income levels, which is an important factor for graduating from subsistence production (Box 19.2). A survey carried out in 2005 by the United Nations Development Programme (UNDP) in the villages of Sikasso and Mopti in Mali, showed that women earn additional revenue averaging US$68/year through access to mechanical power from multifunctional energy platform services. Taking into account their expenses, this translates into an average US$0.32/day, or US$44/year of additional income. The cost-benefit ratio is estimated as at least 1:2.5, given that the intervention cost is between US$80–90 per direct client (i.e., woman user) and that the minimum lifespan of a platform's engine is five years. In a country where the average gap between the dollar-a-day international poverty line and the mean income of the poor is US$0.37/day, the additional income is a significant step towards poverty reduction (UNDP, 2005).

Improvements in energy access, in addition to having a positive impact on agricultural production, processing and marketing, can also

Box 19.3 | "Sol de Vida": Empowering women through Solar Technologies in Costa Rica

Building solar cookers has achieved more than just providing alternative energy sources in the Guanacaste region of Costa Rica. The project has built and emphasized links with women's empowerment by creating new organizations led by women. Empowering women to take actions on their own, particularly regarding environment and livelihood issues, is a central goal of the program. So far, ten such community organizations have been created.

The solar oven promoted by Sol de Vida has been refined over the years to meet the specific needs of Central American families and continues to evolve to work under local conditions. The stove is basically a wooden box set inside another box, surrounded by insulation. The oven is covered by two panes of glass through which sunlight passes to heat the oven to an average temperature of 150°C. The stove can be built with US$100–150 worth of locally obtainable materials.

This project illustrates how a new form of energy use can be fully integrated into the lifestyle of a community. Use of the solar cookers is sustained because women build the stoves themselves. Women who learn how to build these stoves can then teach others to duplicate them at the same low cost.

Casa del Sol also creates locally adapted models of solar-powered stoves, water pumps, water heaters, and crop dryers. Educational programs at the Casa del Sol also help improve knowledge about these technologies, some of which can be reproduced locally. In fact, they have designed a parabolic solar stove which they hope to export.

catalyze a diversification of the rural economy into off-farm activities. Energy access can enable households to engage in a more diverse range of income-generating activities and contribute to the development of home enterprises, rural businesses, and cottage industry. The provision of adequate and affordable thermal, mechanical, and/or electrical energy is crucial for the development of rural entrepreneurship and microenterprises that often provide a significant proportion of off-farm employment opportunities in developing countries. Households are less likely to have a nonfarm enterprise and also have a lower income share from such activities if they live in a location that is more remote, has lower quality roads, lacks access to electricity, and suffers from frequent electricity blackouts. Evidence from rural Indonesia suggests that improvements in village-level infrastructure between 1993 and 2000 were associated with increases in the share of households having nonfarm enterprises (Gibson and Olivia, 2010). Dependable, reasonably priced energy access can contribute to the development and maintenance of small and medium enterprises in several ways. Mechanization and equipment upgrades can transform labor-intensive, low-production enterprises into high value-added operations, increase operating hours, and promote communication. Other benefits of improved access to energy in small enterprises are better efficiency and quality of work, better working environment, and a more attractive and secure environment for customers. In many instances, rural enterprises, especially home-based ones, are run by women. Reaching this segment of the population can serve the dual purpose of improving incomes and gender equity in these communities (Box 19.3). Promoting uses of energy that can enhance income, for both agricultural and off-farm activities, can work directly and effectively in enabling rural economic development. Recent evidence from South Africa suggests that electrification significantly raised female employment within five years. Several pieces of evidence suggest that household electrification raised employment by releasing women from home production and enabling microenterprises in South Africa (Dinkelman, 2010).

19.1.4 The Nature of the Access Challenge

Chapter 17 explores a number of interesting future scenarios for the global energy system to the year 2100. Scenarios have also been developed for household access to electricity and clean cooking until 2030 across key regions of the developing world. As a background to developing these access scenarios, this chapter provides an assessment of the historical progress of improving access. The two key indicators of relevance to this chapter, for which scenarios have been developed in GEA, are as follows:

- "People without access to electricity," which refers to populations that have no access to electricity; and
- "People without access to modern fuels or stoves," which refers to populations relying on traditional inefficient cooking devices (excluding improved solid fuel and clean-burning kerosene stoves) and solid fuels, including unprocessed biomass, charcoal, and coal.

As an input to the GEA scenario development process, a set of projections were generated for the simplest forms of these indicators for which data was available, namely populations with no access to electricity at the household level and populations relying on unprocessed biomass, coal, or charcoal for cooking and heating.

19.1.4.1 Electricity

Globally, less than 68% of the rural population has access to electricity (IEA, 2010b). Two-thirds of the global population lacking electricity access are located in sub-Saharan Africa and South Asia. The region with the lowest electrification level is sub-Saharan Africa, where only 11% of the rural population has access to electricity (UNDP and WHO, 2009). Over 600 million people, more than a third of all those without access to electricity in the world, live in South Asia.

It has been estimated that over 1.2 billion people globally will still lack electricity access in 2030 (IEA, 2010b) without the implementation of any new policies in addition to those already announced in 2010. Electricity for all by 2030 will therefore clearly not be achievable if global events are to unfold in line with current estimated projections (Figure 19.3).

A look at the historical progress with electrification reveals a mixed picture (Figure 19.3). Between 1970 and 1990, the total population without electricity access increased because population growth largely outstripped the pace of electrification in most regions of the world. Between 1990 and 2010, there was a decrease in the global population without electricity as the pace of electrification accelerated in certain countries like China and regions such as Latin America. Scenario analysis carried out in Chapter 17 for the three regions of South and Pacific Asia and sub-Saharan Africa also indicates that between 30–40% of the rural populations in these regions will continue to remain unelectrified in 2030 without additional policies and measures to accelerate access to electricity. In sub-Saharan Africa over 70% of the rural population will remain unelectrified by 2030 without additional new policies. However, if global events were to unfold differently such that a fast track to providing electricity for all by 2030, or not much later into the future, is targeted, various policy interventions would be needed to accelerate the provision of electricity supply to households through a combination of grid and off-grid options over the next twenty years. This would require a steep acceleration in the rate of connecting new households in South Asia and sub-Saharan Africa, at a pace similar to what occurred in East Asia/China in the 1980s and 1990s. In effect, almost 20 million new households would have to be connected every year between 2010 and 2030 in order to meet the global target.

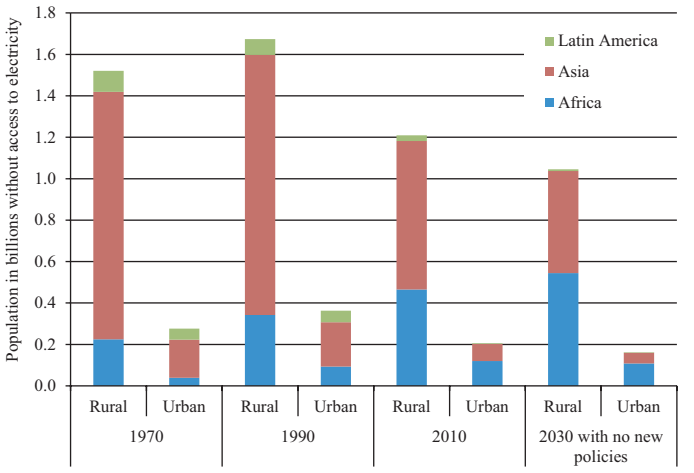

Figure 19.3 | Population without access to electricity in households in developing regions. Source: data from World Bank, 1996; IEA, 2002; UN, 2008; UNDP and WHO, 2009; IEA, 2010b.

19.1.4.2 Solid Fuel Dependence

Current projections on the number of people dependent on solid fuels for cooking and heating differ in some ways from those for electricity. First, there are three developing regions of major concern, including East Asia/China in addition to South Asia/India and sub-Saharan Africa. Second, populations with no access to clean cooking fuels have continued to increase over the last decade, except in the case of China. The monotonic increases in people dependent on solid fuels in sub-Saharan Africa and the rest of Asia (excluding China) are very worrying indeed. It is estimated that almost three billion people will not improve their energy situation for cooking and heating by 2030, if current trends continue (Modi et al., 2006; IEA, 2010b). The GEA scenario analysis presented in Chapter 17 also indicates that the numbers of people dependent on solid fuels is projected to remain almost unchanged until 2030 if no new policies beyond those already in place by 2010 are implemented (Figure 19.4).

Given these trends, encouraging the use of improved stoves might be an additional way of increasing the efficiency and sustainability of the use

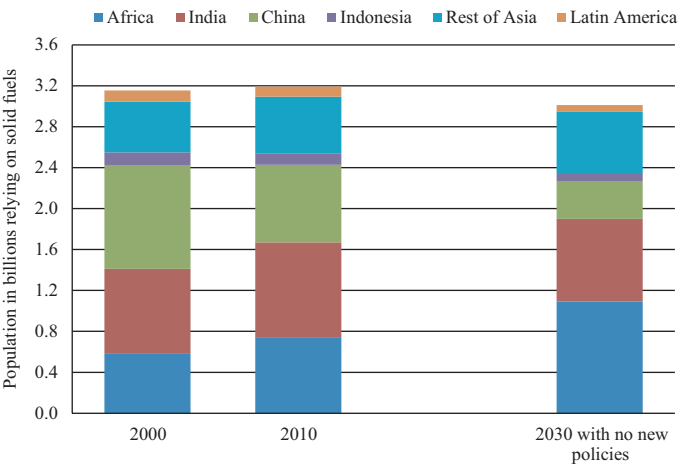

Figure 19.4 | Population dependent on solid fuels in households in developing regions. Sources: IEA, 2002; UN, 2008; UNDP and WHO, 2009; IEA, 2010b.

of biomass. Improved stoves vary widely in terms of performance, efficiency, and emissions. Better quality control and standards are clearly needed to regulate the improved stoves market. However, even relatively simple and inexpensive artisan-produced improved stoves can reduce the amount of fuel needed for cooking by as much as 20–35% (GVEP, 2009). Future scenarios for improving access to the energy services needed for cooking and heating thus consider both shifts and transitions from the use of solid fuels to more efficient liquid or gaseous fuels and the wider dissemination of improved stoves to the poorest households who are likely to continue to depend on biomass fuels in the shorter term.

Given this rather gloomy picture, is there any realistic basis for envisioning a fast track approach to providing universal access by 2030, as far as clean cooking and heating services are concerned? What possible developments at the global, regional, national, and subnational levels, and what possible policy options, could lead to deep cuts in the numbers of people dependent on solid fuels? What would be the constituting elements of such a paradigm shift and what are some of the experiences to date that would point in this direction? The following sections will review the experiences to date and provide answers to some of these key questions. Specific policies needed to achieve such desirable future scenarios will be discussed in Chapter 23, which deals specifically with policies and measures for energy access.

19.2 Past Efforts and Current Status

19.2.1 Access to Electricity

19.2.1.1 Historical Experience and Current Status

Electricity was first commercially supplied to the public in the mid-19th century in the United Kingdom, and thereafter spread quickly throughout Europe and the United States (Smil, 2005). As many nations attained independence in the 20th century, providing electricity access to their population was considered a prerequisite to modernization and progress and therefore accorded priority by the governments of these countries early on in their development. The political and social pressure to expand electrification was high in these nations, but the financial resources for doing so were often limited. As a consequence, electrification was pursued with uneven ambition and success. The historical model of pursuing electrification through a centralized energy system made it possible to benefit from economies of scale and to supply electricity to a mass market in many industrialized nations. However, this very paradigm, emphasizing the extension of a centralized grid network, also hampered a more rapid spread of electricity infrastructure to remote rural and low population density regions in many developing countries where it was not economical. In most countries, industrial and urban customers were the first to be supplied and the electrification of rural areas lagged behind.

The pace at which electrification occurred historically has been very different across nations (Figure 19.5). While Mexico took almost 90 years to electrify most of its population, Thailand achieved this in essentially a period of 20 years. While a number of factors are responsible for the uneven rate at which electrification occurred across different nations, the historical evidence supports the view that, given the commitment, an appropriate level of investments and appropriate institutional mechanisms, fast tracking the provision of electricity access is possible.

The more recent experience with electrification improvements across regions continues to remain very uneven, but provides a basis for hope. Between 1970 and 1990, over a billion people gained access to electricity, more than half of these in China alone. Between 1990 and 2008, almost two billion people gained access to electricity (Figure 19.6). In Latin America, North Africa, the Middle East, and East Asia, the pace of electrification outstripped the rate of growth of the population by a large margin, so that access significantly improved. In South Asia, the progress has been more uneven. However, in the period since 1990, the pace has increased. In sub-Saharan Africa, the rate at which new electricity connections have been provided over the last four decades has been consistently lower than the rate of population growth. This has been particularly true in rural areas.

Unfortunately, the region that faces the lowest rate of electrification today and the greatest challenge in increasing access, particularly among its rural population – sub-Saharan Africa – is also the region where the rural population density in areas without light is among the lowest in the world (Figure 19.7). This has implications for future options for expanding electricity access to these areas. Clearly, a diversity of electrification solutions is needed to increase access and centralized grid electrification alone may not be the optimal choice in all cases.

While access to electricity has been successfully extended to almost two billion people in the past 20 years, the overall picture is more complex. There is a dynamic associated with getting connected, staying connected, and increasing consumption in a situation of constrained supply. Many poor households that are connected face challenges in staying connected and increasing consumption beyond minimum levels due to poor quality, inadequate supply, and unaffordable connection costs and tariffs (PRAYAS, 2010). Per capita levels of consumption in rural areas in developing countries remain extremely low and in the case of some countries, have even declined because the growth in electricity supply to these regions has not been able to keep pace with rate of population increase and growth in demand.

Variations in the level of electricity consumption across nations, across rural and urban residents, and within rural and urban areas across income levels and different segments of the population, are very large. Just providing electricity connections does not ensure adequate access if the reliability and quality of supply remains exceedingly irregular or households just cannot afford sufficient amounts because of their exceedingly

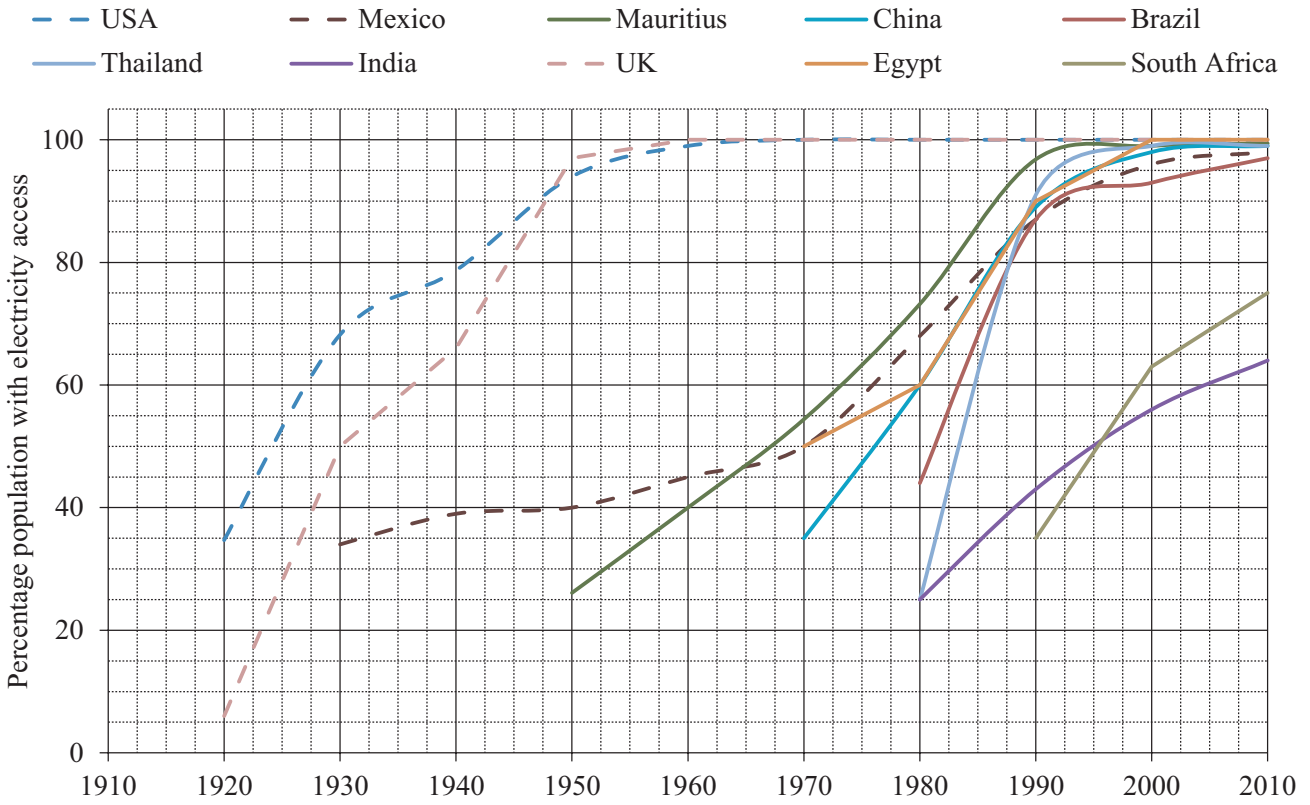

Figure 19.5 | Historical experience with household electrification in select countries. Source: Byatt, 1979; Goldemberg et al., 2004; Shrestha et al., 2004; UNDESA, 2004; Karekezi et al., 2005; Pan et al., 2006; Pachauri, 2007; UNDESA, 2007; Bekker et al., 2008; Collins, 2009.

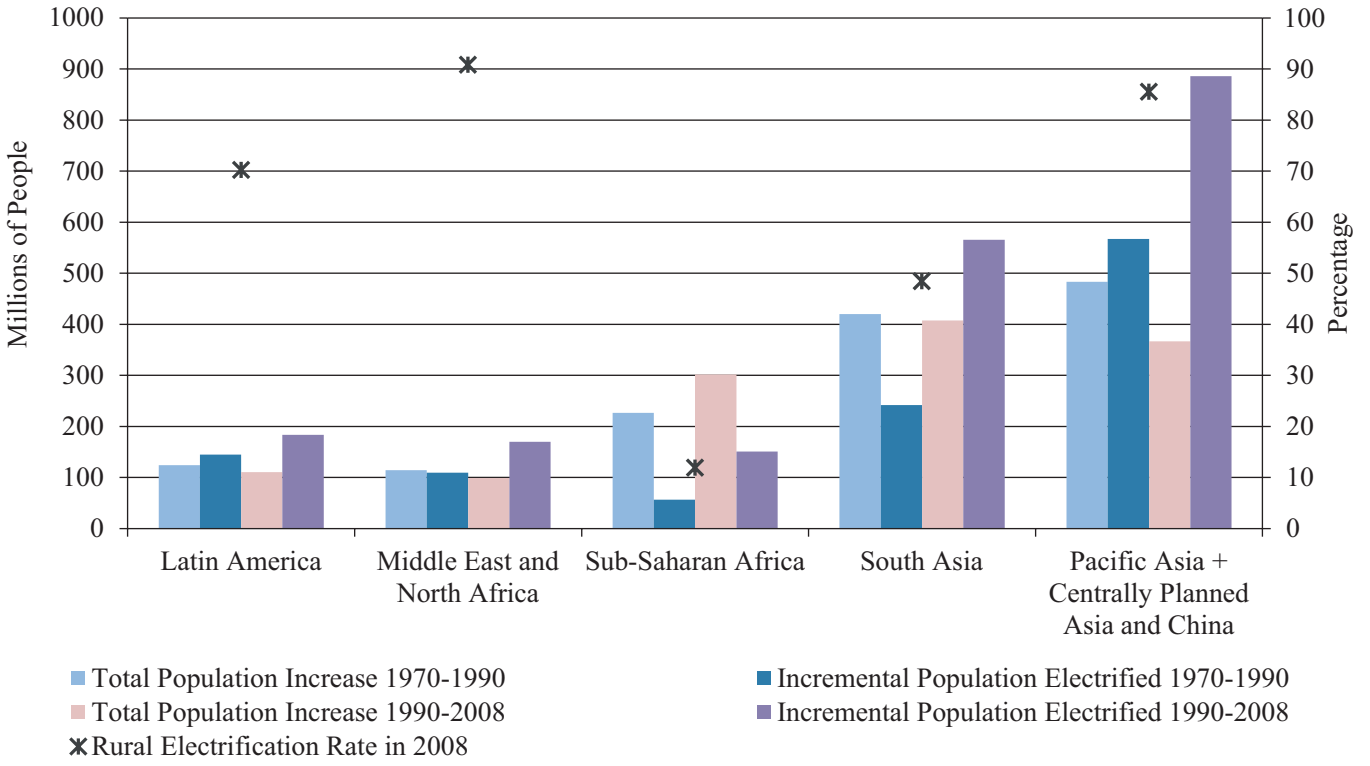

Figure 19.6 | Change in population and electrified population by region between 1970 and 2008. Source: data from World Bank, 1996; IEA, 2002; UNDP and WHO, 2009; IEA, 2010b.

low incomes and purchasing power. Figure 19.8 depicts changes in the mean residential electricity consumption per electrified inhabitant for major regions of the world. The average residential sector electricity consumption per electrified inhabitant is lowest in South Asia, even though a much larger proportion of the population has access to electricity in South Asia than in sub-Saharan Africa. The higher mean residential electricity consumption in sub-Saharan Africa is a consequence of the relatively high electricity consumption in South Africa. Excluding South Africa from sub-Saharan Africa would result in a lower average consumption for that region as a whole. South Africa has been relatively successful in improving access and increasing consumption of electricity even in low-income households through innovative financing and tariff schemes for providing lifeline electricity entitlements to the poorest consumers. However, issues relating to adequate metering and monitoring need to be resolved before such schemes can be implemented on a wider scale (see Box 19.8 for a fuller discussion of South Africa's lifeline electricity entitlement policy).

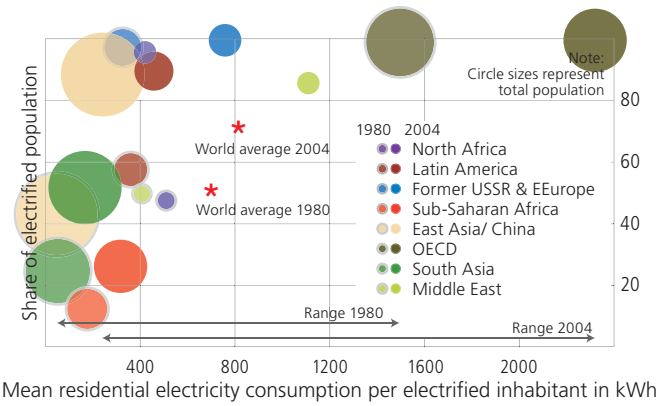

Figure 19.8 | Changes in residential electricity consumption and access. Source: Pachauri, 2007.

19.2.1.2 Social and Efficiency Benefits from Improved Energy Service through Electrification

Immediate applications of electricity in newly electrified households are for lighting and appliances, communications, and entertainment. Among community needs, public/street lighting, refrigeration, health centers and schools, piped water, communication, and the like are often cited. As already mentioned above in Section 19.1.3, electrification also benefits productive enterprises and agricultural activities. Electrification has the potential to be particularly beneficial to women, as their daily drudgery is reduced, their safety is enhanced, and the availability of lighting allows them to spend more time on leisure or productive activities. Electrification can also influence social capital and civil society. Well-lit streets, illuminated buildings, and systems of mass transit all increase mobility, giving citizens the ability to participate in community activities. These and other multiple benefits that are made possible through access to electricity have also already been described in Chapter 2.

Households also benefit from the use of many types of appliances that use electricity. There is a clear progression in terms of the energy services enjoyed by those connected to electricity. The first use is for lighting and entertainment. Thereafter, a wide array of benefits are potentially available – from security, comfort, and convenience to education, health, and

home productivity –made possible by appliances such as electric lamps, radios, televisions, computers, refrigerators, fans, stoves, and electric pumps. In 2008, the Independent Evaluation Group of the World Bank (World Bank, 2008a) confirmed the findings of earlier World Bank work that valued the benefits of household lighting at US$5–16/month and the added benefits of entertainment, time savings, education, and home productivity at US$20–30/month (World Bank, 2002). These amounts are much higher than the US$2–5/month that a household typically pays for electricity service. However, even these low payments are often beyond the reach of cash-stripped, poor households and cannot be afforded despite the large potential benefits and high value attached to these services.

Access to electric lighting can even save households money through efficiency gains. Estimates of the effective cost of electricity for home lighting, computed on the basis of the cost of an equivalent amount of electricity needed to deliver the same amount of lighting as that provided by kerosene, are as high as US$3–4/kWh. Similar high costs are involved when one computes the cost of electricity obtained from batteries that are poorly charged and discharged. Surveys for Millennium Villages in Africa show that nearly half of households surveyed spend about US$5/month on such poor substitutes for electric lighting (Figure 19.9). This is because the substitutes to electricity used for lighting, such as kerosene or candles, are extremely inefficient (Figure 19.10). In addition to being highly inefficient, the use of kerosene and candles for lighting are associated with fire and poisoning hazards. These have been quantified for the case of South Africa in Spalding-Fecher (2005).

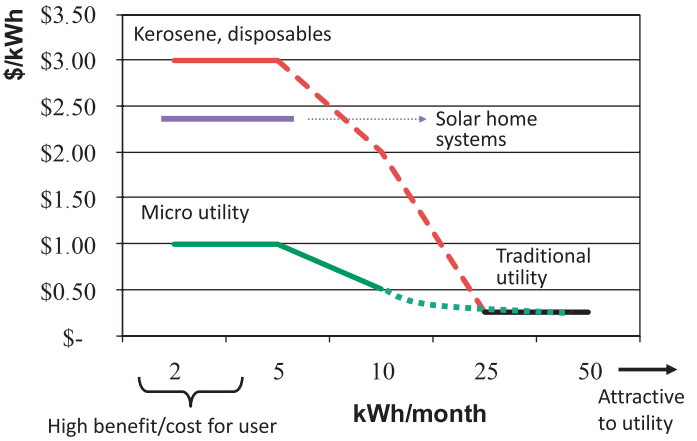

Figure 19.9 | Effective costs for lighting services. Source: Modi, 2010.

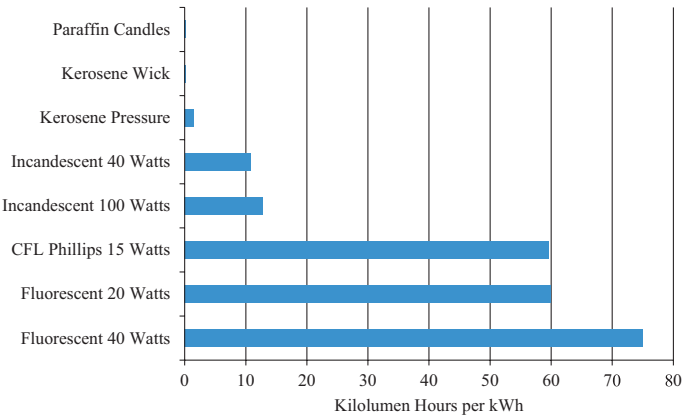

Figure 19.10 | Relative efficiency of different sources of lighting. Source: World Bank, 2010b.

19.2.1.3 A Multitrack Approach for Future Electrification

Traditionally, the centralized model for electrification has been followed in most nations. To improve the status of access in the future, multiple tracks should be explored. Development strategies should consider innovations in the development and deployment of economically accessible distributed energy sources. Many renewable energy strategies look for land and natural resource conditions available in less developed landscapes where rural communities reside. The potential for providing meaningful livelihood options related to distributed energy supply and usage may provide a broader set of development pathways than those currently envisioned. Development of strategies along a more holistic framework that takes account of the socioecological system and incorporates development goals is needed.

While the reasons for continued lack of access to electricity are complex, there are two main reasons why many poor and rural households are still not connected to a source of electricity supply. The first is that a connection is not possible due to distance from a source of supply. The second is that that even though the grid may pass through the community, some households cannot afford the cost of electricity installation. If the connection of low-income households is to be made financially viable to utilities, then special approaches are required to address the problem of low revenue caused by very low levels of consumption, and the highly dispersed and low density of consumers, particularly in rural areas. In addition, the connection and supply costs of providing electricity to low-income households need to be reduced by adopting least-cost options.

Success in the continued expansion of electricity access means adapting programs to local contexts and country environments. The past has witnessed strong advocates for centralized grid approaches to rural electrification, as well as more decentralized off-grid approaches. More recently, countries have adopted strategies that include both grid and off-grid approaches executed by various types of institutions, including public and private companies and large and small nongovernmental or microfinance organizations. Such a multitrack approach is based on the costs of supply, expected electricity demand, and development impacts of the project. The rationale is based on the difference in the cost of supply in areas with different socioeconomic and geographic profiles. Studies have shown how the cost-effectiveness boundary between grid

electricity service and off-grid solar photovoltaic (PV) service changes as load density and village distance from the grid change (Cabraal et al., 1996). The implications of this are that the approach to electricity expansion must match the demand characteristics of population types. In addition, from an equity perspective, people in remote areas for which the cost of grid supply is high should not have to wait to gain access to grid electricity service when less costly alternatives could be made available with appropriate incentive policies.

Main Grid Electrification

The costs of conventional grid-based rural electrification vary greatly, both among and within countries. Local material and labor costs, terrain, and materials and construction standards can all have a major effect on the overall construction and maintenance costs. Typical figures quoted for marginal cost of grid electrification, including generation, transmission, and distribution, are in the range of US$0.10–0.20/kWh (Malik and Al-Zubeidi, 2006; Eberhard et al., 2008), with costs in rural areas typically higher than in urban ones. In many cases, the high initial costs of grid electrification can be held down by using design standards suitable for areas with less demand. Most rural consumers use about 0.5 kWh/day, much less than the minimum electricity connections typical of developing country utilities (Barnes et al., 1997). The high cost of wiring installation by utilities can be lowered by simplifying wiring codes to encourage lower electricity consumption levels. Other cost-cutting strategies include using cheaper utility poles and involving local people in construction and maintenance.

Although their institutional forms vary, as a general rule successful grid-extension programs require financially and technically strong utilities (Barnes, 2007). To ensure sustainability, distribution companies must address the issue of increased technical losses and low revenues in creative ways. The Tunisian Electricity and Gas Company (STEG), for example, reduced the capital costs of rural grid extension by shifting engineering standards and using capital subsidies provided by the government (Cecelski et al., 2007). By adopting a MALT (*mise à la terre*) design, a blend of three-phase backbone and single-phase network distribution, financing costs were reduced 20–30%. Making this technical design decision was not easy for STEG, which faced opposition from many of its own engineers accustomed to serving high-demand urban areas. This case demonstrates how careful and critical analysis of design assumptions and implementation practices reveals the potential for significant cost savings and thus more attractive financing (Cecelski et al., 2007; STEG, 2010).

Extending the grid to rural industries or commercial consumers can also promote economic growth while increasing revenue that can be used to maintain lower prices for residential and other rural consumers (Cabraal et al., 2005). Giving priority to major load centers and productive facilities can also help improve financial viability.

Microgrid Electrification

Off-grid electricity is necessary in some instances because the expansion of grid electricity will require decades to reach remote populations. In the short and medium term, the only way to reach many remote households without electricity may be through single household systems and small electricity providers using both renewable and conventional energy sources. Although these approaches to electricity provision may sound straightforward, in practice they have been difficult to implement. Decentralized, isolated distribution systems have been common in remote population centers for many decades. In most developing countries, they predate the establishment of main grid systems. The marginal costs of such systems are about US¢20–60/kWh. But diesel generators in remote locations can be hard to maintain and expensive to operate because of the high cost of spare parts and fuel. Micro hydropower systems have lower operating costs but involve higher capital costs for the systems and civil works to channel the water. Most other types of microgrids have similar cost levels.

Successful service delivery in remote locations via microgrids often involves specialized government agencies that perform an enabling role in support of private and community-based operators. For example, five years ago the Cambodian government created the Rural Electrification Fund to support small, private-sector operators of grid systems in rural areas. These indigenous operators had developed in rural and market towns, but faced significant investment constraints to expansion. To date, some 140 minigrid operators have been licensed under the new program. The Fund board, which provides overall guidance and policy oversight, comprises both public- and private-sector nominees. The Fund secretariat, which is responsible for operations, includes technical, finance, and administrative units. To ensure safety, quality, and service standards, Fund support is available only to qualified operators that are licensed by the Electricity Authority of Cambodia, the country's regulatory agency, for a minimum five-year period. The Fund has been fully operational since April 2007, and projects involving approximately 23,000 connections have been approved.

Renewable Energy and Household Systems

For countries endowed with the necessary natural resources, solar, wind, and pico and micro hydropower systems offer attractive options. The marginal costs of electricity generated by such systems are about US$0.50–1.00/kWh. Off-grid projects in such countries have taken advantage of private-sector institutions, nongovernmental organizations, and microfinance institutions that operate in rural areas. These programs can provide electricity to people in remote areas where main grid electrification is prohibitively expensive owing to the high capital cost of extending electricity lines.

The best off-grid models typically combine private-sector organizations (e.g., private entrepreneurs in Kenya have sold more than

200,000 PV systems to households that lack access to grid electricity), donor agencies, local communities, and national utilities supported by a strong energy agency whose role is to promote off-grid electrification. For example, Bangladesh's Rural Electrification and Renewable Energy Project combines main grid financing for rural electric cooperatives administered by the Rural Electrification Board and an off-grid component administered by the Infrastructure Development Company Limited, a public financial institution. The project offers participating organizations – nongovernmental and microfinance institutions, including the Grameen Bank, municipalities, and private-sector institutions – both credit and grants with which to cover about 20% of the purchase cost of solar home systems. Each participating organization signs an agreement with the Infrastructure Development Company for this blend of loans and grants, which lowers the cost for customers (Asaduzzaman et al., 2010; IDCOL, 2010). Under this program, more than 150,000 rural off-grid consumers are receiving electricity. Similar programs supported by the World Bank are functioning in more than 30 countries, including China, Sri Lanka, and Bolivia. Under these programs, funds have been committed to support services to 1.3 million consumers (seven million people). Currently, about half of these households receive electricity.

Off-grid household programs in Bangladesh and Sri Lanka demonstrate that it is possible to implement large-scale, off-grid projects that complement strong grid electrification programs. Off-grid projects in both countries have taken advantage of private-sector institutions, nongovernmental organizations, and microfinance institutions that operate in rural areas. However, this has also been backed by strong centralized institutional support.

19.2.1.4 Principles for Success

Countries must discover solutions consistent with their geography and natural resources; demographics; and socioeconomic, cultural, and political realities. Rural electrification is a dynamic, problem-solving process. Problems change as programs evolve, but certain underlying principles guide successful programs (Barnes, 2007). Governments' sustained commitment must be reflected in effective institutional structures that exhibit a high degree of operating autonomy and accountability, strong management, and dynamic leadership with the capacity to motivate and train staff. Successful programs also require effective prioritization and planning. Clear criteria based on market research are required for prioritizing areas to supply. Key factors include capital investment costs, level of local contributions, numbers and density of consumers, institutional capacities, and likely demand. For off-grid systems, reducing construction and operating costs as well as sustained financing is also vital. Sustained financing will require increased and more effective use of both domestic and external funding sources. When cost recovery is pursued, most other program elements fall into place.

Summarizing some of the key lessons and principles for successful electrification as discussed in Krupp (2007) and Barnes (2007), the following are key:

- sustained financing;
- metering and payment for cost recovery;
- local buy-in and training;
- flexible and adequate institutional arrangements;
- independent regulation; and
- lower-cost options for supplying power.

In spite of the many challenges to rural electrification, many countries have been successful in providing electricity to their rural areas. In Thailand, well over 90% of the rural population has electricity access. In Costa Rica, cooperatives and the government power utility provide electricity to nearly 100% of the rural population. In Tunisia, over 90% of rural households are already supplied. Studying countries like these and others there appear to be certain factors critical to the successful implementation of rural electrification. Strong and sustained political commitment, intensive financial support and clear earmarking of funds by the government, along with the establishment of clear planning criteria for rural electrification, are paramount to success (Barnes, 2007).

19.2.2 Access to Modern Fuels and Technologies for Cooking and Heating

Households in developing countries, particularly those in rural areas, largely rely on a range of fuels rather than electricity to meet their cooking and heating needs. Electricity use for cooking remains rare in most developing-country households because of high service and appliance costs associated with the use of electricity, limited availability, and relatively low incomes levels. Hierarchies in household energy services are quite common. Almost always, cooking and heating are the first functions fulfilled, followed by lighting and then entertainment. For the poorest people in developing countries, cooking (and space heating in particularly cold climates) can account for up to 90% of the total volume of energy used (WEC and FAO, 1999). Cooking is an energy service that is often associated with strong and highly specific fuel and appliance preferences. In addition, cooking is often only one of a range of services that are delivered from a stove or a fire. For example, coal and wood stoves serve multiple functions, including cooking, space heating, water heating, lighting, and social focus (van Horen et al., 1993). The multifunctionality of some stoves is one of the key reasons why households are at times averse to substituting their old stoves for newer more efficient and cleaner technologies.

Households use a variety of fuels for cooking and heating purposes, such as wood, dung, crop wastes, charcoal, kerosene, LPG, coal, and electricity, to name the most common. Households use the different

fuels in different combinations, depending on the needs they satisfy, their availabilities, and the socioeconomic circumstances of the households. Fuels are chosen for their cost effectiveness, ease of access, and perceived efficacy in performing specific tasks. Fuel use patterns may differ at different times of the year. Tastes and cultural preferences also play an important role in decisions concerning which fuels are used, particularly in rural households.

The use of more efficient liquid or gaseous fuels and efficient appliances for heating homes and cooking food has significant social and environmental benefits and yet access to these among most of the developing world remains extremely limited (Figure 19.11 and 19.12). In sub-Saharan Africa only 16% of people use modern fuels as their primary cooking fuel. The level of reliance on modern fuels is lower than in any other geographic region, and is comparable to that in the average for all LDCs (10%). Overall, some 41% of people in developing countries have access to different types of modern fuels for cooking. Across all developing countries, almost one-third of people (33%) use gaseous fuels (including natural gas, LPG, and biogas) as their primary cooking fuel (Figure 19.11). Use of gas is much less common in the LDCs and sub-Saharan Africa, where only 7% and 4%, respectively, of the population rely on gas as their main cooking fuel.

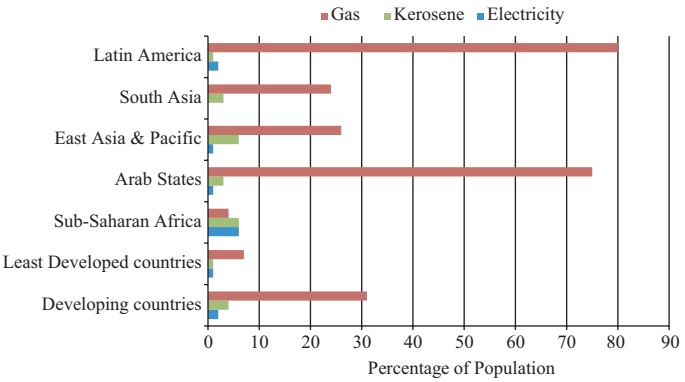

Figure 19.11 | Share of population using non-solid fuels. Source: UNDP and WHO, 2009.

About 75% of people living in rural areas use traditional biomass for cooking, primarily wood, while 65% of those living in urban areas rely on modern fuels, especially gas (UNDP and WHO, 2009). Of those who rely on solid fuels, roughly 800 million people (only 27%) are estimated to use improved cooking stoves, most of which belong to households situated in China and Brazil. There has recently been an increased effort to bridge the gap between the inefficient use of traditional fuels such as wood, straw, and dung by promoting the use of improved stoves. Stove programs around the world have had an uneven history, but there are some recent developments involving more durable efficient biomass stoves that are encouraging for the future.

The environmental consequences of unprocessed biomass, charcoal, and coal use – first put before the international community several decades ago as the "other energy crisis" (Eckholm, 1975) – involve household air pollution and degradation of local and global commons. Cooking and heating with biomass fuels on open fires or traditional stoves results in high levels of health-damaging pollutants and has been associated with numerous respiratory problems, thus contributing to global mortality and morbidity. Fuel collection can lead to a deterioration of the local

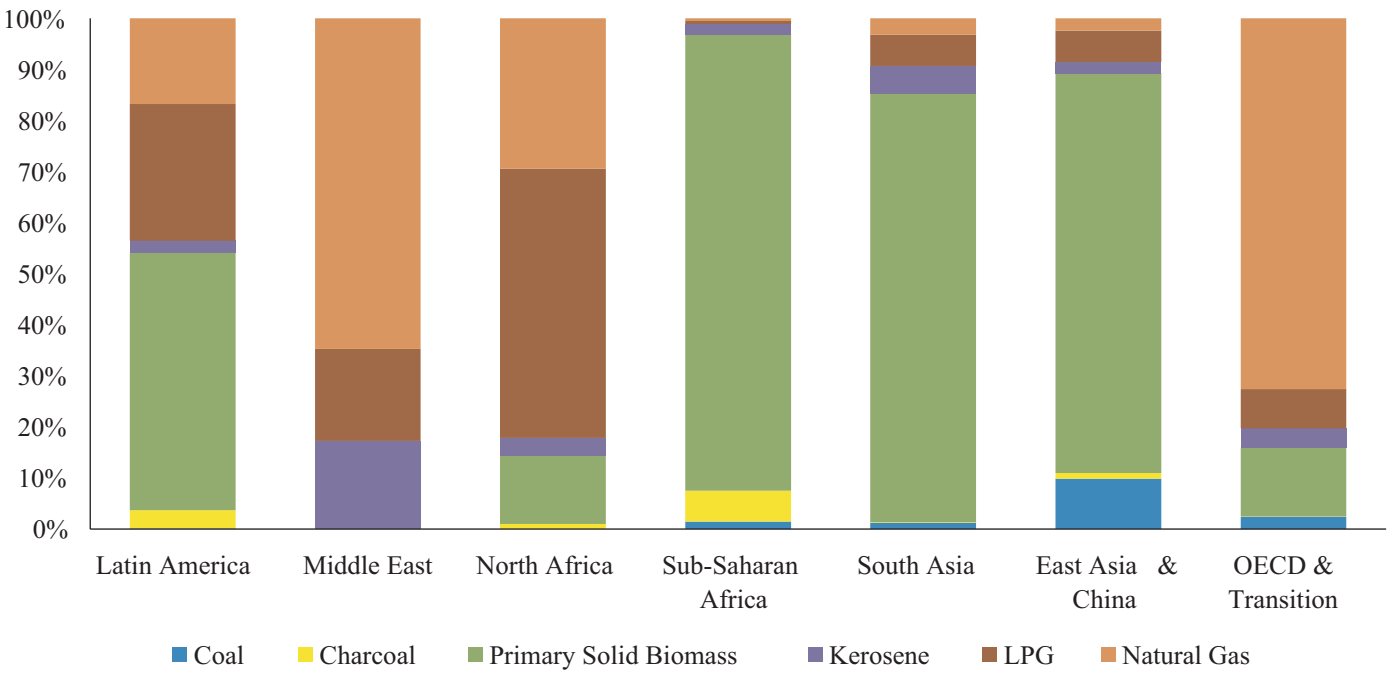

Figure 19.12 | Structure of final residential fuels use across regions in 2006. Source: Based on IEA, 2008a; b.

environment and depletion of biomass, meaning ever-longer walks to collect fuel. In Haiti, for example, the overall decline in forested areas resulting from charcoal production for urban use is well documented (Stevenson, 1989). The production and use of energy for cooking and heating in developing countries contributes to threats to human health and quality of life, affects the local ecological balance and biodiversity as demand for traditional fuels outstrips supply, and alters the climate that we live in through pollutant emissions, such as those of black carbon (Bice et al., 2008).

High dependence on traditional biomass and coal leaves many people in developing countries with few options for improving their lives. In the recent past, the health costs of the continued dependence on traditional solid fuels have been very high, particularly for many developing countries. Current estimates indicates that annually, almost two million worldwide deaths from pneumonia, chronic lung disease, and lung cancer are associated with exposure to household air pollution resulting from cooking with biomass and coal, and 99% of these deaths occur in developing countries (UNDP and WHO, 2009). The poor devote a large portion of another important asset – their time – to cooking and heating energy-related activities; women and young girls can spend in excess of six hours per day (see Figure 19.13) gathering fuelwood and water, cooking, and agro-processing (UNDP, 2007b).

Studies on understanding the factors determining fuel choices and drivers of fuels usage in developing countries are limited (e.g., Heltberg, 2004; Ouedraogo, 2006; Pachauri and Jiang, 2008; Ekholm et al., 2010). Data on fuel choices and consumption and how these factors have changed over time also remains very sparse, particularly for rural areas and in the poorest countries. Progress with expanding access to modern fuels and technologies for cooking and heating in developing countries over the past 25 years has been rather dismal. A recent review of World Bank lending for improving energy access over the period 2000–2008 also shockingly concludes that only about 1% of the total lending was dedicated to promoting a transition to more modern cooking fuels or clean cooking devices (World Bank, 2010a). More efficient and cleaner fuels and improved stoves to meet people's most basic cooking needs are still out of the reach for the majority of populations living in developing countries, especially those in rural areas. The widespread diffusion of improved and clean cooking stoves has also yet to happen even though new designs of clean stoves are being piloted around the world. Much remains to be done on the fuel-stove package to make it available as a clean cooking option. An astounding three billion people in developing countries primarily rely on coal and traditional biomass such as wood, charcoal, and dung for their cooking and heating needs, with little or no access to more efficient, modern forms of energy (UNDP and WHO, 2009). In other words, almost half of humanity still uses traditional biomass or coal, with about 2.7 billion relying on traditional biomass alone (IEA, 2010b). Access to improved cooking stoves is also very limited. The IEA estimates that people will continue to rely on these solid fuels for the next few decades, and those relying on traditional biomass alone will increase to 2.8 billion by 2030 (IEA, 2010b) in the absence of any new policies beyond those already in place in 2010. The majority of these people will remain concentrated in rural areas of the LDCs in sub-Saharan Africa and South Asia. This places a huge burden on the economies of these countries and stifles efforts toward achieving the MDGs and poverty reduction for these populations (Modi et al., 2006).

Data on the use of biomass and other solid fuels, both in terms of the percentage of population dependent on these fuels and the actual consumption levels, remains exceedingly scarce, particularly for those countries that remain the most dependent on these fuels. Internationally comparable statistics over time are hard to find. However, over the last decade, there has been a slight decline in the number of people dependent on biomass alone, largely on account of a significant reduction in the number of people using biomass in China (Figure 19.14). Overall, little change is observed in the dependence on solid fuels, particularly among households in rural areas.

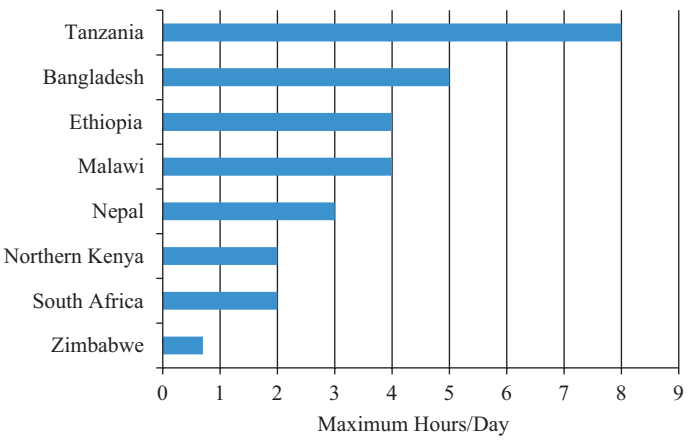

Figure 19.13 | Selected data on time spent in wood collection. Source: Practical Action, 2010.

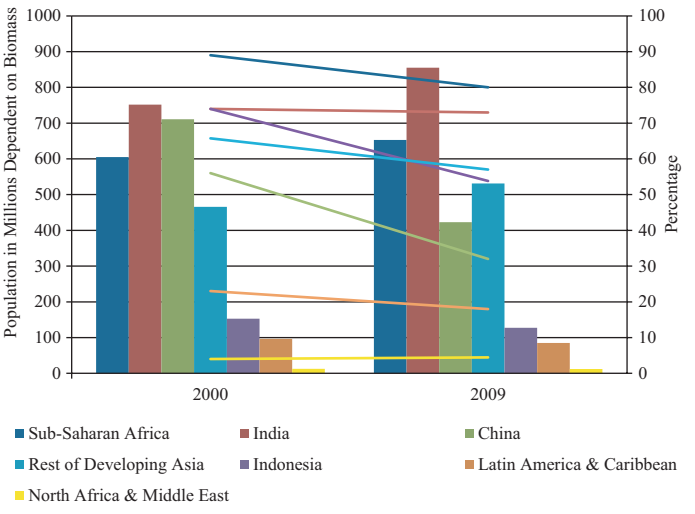

Figure 19.14 | Changes in the number of people relying on biomass. Source: IEA, 2002; 2007; UNDP and WHO, 2009.

Cooking is the major energy end-use among poor families in developing countries. Because most staple foods must be processed, conserved, and/or cooked, and thus require some form of heating before consumption, access to affordable, clean cooking fuels and equipment are among the most basic energy needs of the world's poor.

The importance of gender issues in understanding transitions in the use of cooking fuels and/or stoves cannot be overemphasized. Women tend to have limited control over and access to productive assets and income in many developing countries, especially in the poorest households. They often have little say in how much can be spent on fuels or new stoves. While not all women would embrace new fuels and stoves if given the choice, often a proposed change has to benefit the man of the house to have a chance of being adopted (Lambrou and Piana, 2006). In addition, women are disproportionately burdened by the drudgery and poor health impacts associated with the use of solid fuels. Gender issues related to energy have often been overlooked due to a lack of gender-specific data in the energy sector (Parikh, 1995; ENERGIA, 2010). However, it is well recognized that greater attention to the energy needs and concerns of women in developing countries can improve the effectiveness of energy policies and projects (Clancy, 2000).

The estimates of the numbers of people using improved cook stoves (UNDP and WHO, 2009) suggest that programs to disseminate such stoves have not had much of an impact. This is despite the fact that examples of improved cook stoves abound (see Table A19.1 in the appendix and Chapter 10 for more on improved biomass cook stoves). However, the characteristics of the stoves, the level of efficiency gains, and the level of sophistication and mode of manufacturing all vary enormously. Developing programs aimed at the sustainable dissemination of improved cooking stoves must overcome a number of barriers, including issues that relate to the maintenance and replacement of free-of-charge or self-produced stoves. Recently, there has been a surge of social entrepreneurs entering the energy field and a drive toward market models by implementing institutions and social investors, which may result in larger scale-up (GVEP, 2009). Product developers (e.g., ENVIROFIT), donors, and social investors are shifting the focus for design and diffusion of clean burning, off-the-shelf cook stoves toward a market-based approach. How successful these market approaches will be in reaching the poorest consumers remains to be seen.

Heating and cooking often go hand in hand in developing countries, particularly in cold mountainous areas where household energy is primarily used for space heating. Space heating is also common in tropical countries that have very warm weather during the day and cold temperatures at night. The need for space heating is often higher among the poor because their houses are not necessarily constructed well enough to preserve heat. Space heating is extremely important for improving health and livelihoods, especially for the young and the elderly.

19.2.2.1 Expanding Access to Modern Fuels and Technologies: Status and Implications

Energy for Cooking: There are a number of ways in which those dependent upon biomass can benefit from switching to cleaner burning cooking fuels or stoves. Practical solutions also include smokeless biomass cooking devices fitted with chimneys or hoods and switching fuels from biomass to biogas, kerosene, LPG, ethanol, or electricity. It is important to consider all of these options when evaluating suitable intervention for a specific target population. The availability and access to fuels, ease of handling, and affordability are all important determinants in the selection of a particular intervention in a given context. Contexts may be defined by factors such as urban/rural settings, domestic situation, institutional setting (schools, hospitals, prisons, etc.), poor/rich clients, and biomass-rich or -degraded areas.

Energy for Heating: Charcoal is the most popular biomass fuel for space heating in biomass stoves in peri-urban households because it emits less smoke and the thermal efficiency of charcoal stoves is relatively high. Firewood is widely used in rural homes where cooking and heating are the two major uses of fuel. Coal is widely used in China. Other fuels and energy sources such as electricity, kerosene, and LPG are not widely used in most developing country households because of limitations in affordability, availability, and accessibility.

In colder rural areas of the world (including high altitude areas within the tropics), space heating is often required during the winter months. Vast quantities of energy are used to achieve this. Not all buildings in rural areas of developing countries are designed to conserve heat. Firewood is the main fuel used for space heating in rural areas, followed by charcoal, which is the primary heating fuel for relatively few people. Providing affordable warmth to the peri-urban poor is among the main challenges facing many developing countries. The peri-urban poor often use a mix of fuels depending on availability, accessibility, and affordability. Charcoal is an important fuel for space heating in peri-urban areas; carbon monoxide poisoning is occasionally reported in peri-urban areas during the cold seasons because of use of charcoal in unventilated houses. Firewood is also used in biomass stoves with chimneys but is not a popular source of energy for space heating in peri-urban areas. Where electricity is available, small space electric heaters are used, albeit sparingly and only when extremely necessary, such as when there is a newborn baby or an elderly person in need. One option in addressing the space heating problem is housing policies – including housing finance – that take energy efficiency and improved stoves into account.

19.2.3 Access to Energy for Income-Generating Activities

The poor, especially those living in rural and remote areas of developing countries, face limited or total lack of access to reliable modern

energy for activities that can generate income, commonly referred to as productive end-uses. It should be noted that the distinction between "productive uses" and "consumptive uses" is by no means clear cut. However, we refer to "productive uses" of energy as those that involve the utilization of energy, both electric and non-electric, in the forms of heat or mechanical energy, for activities that enhance income and welfare. The problem of access to energy services for productive end-uses in developing countries is far greater in rural areas than in peri-urban and urban areas (Bates et al., 2009).

To spur sustainable development in rural areas and indeed, nationally, improved rural productivity is needed. Productive end-uses can be enhanced by reducing the problems associated with dependence on solid fuels (traditional biomass and coal) in rural households and expanding access to electricity and other modern energy carriers and technologies and mechanical power. It can be accelerated by scaling up distribution of cleaner energy-conversion devices (e.g., improved stoves, gasifiers, and kilns); cleaner fuels (e.g., biogas, ethanol, and LPG); and decentralized energy options (e.g., wind, biomass micro distilleries, micro hydropower, and solar energy) that have shown some level of success (UNDP, 2006). For it to succeed, massive mainstreaming of energy issues into development planning, mobilization of finance for scaling up of energy for productive end-uses, and extensive building of national and local capacity to deliver modern energy for specific productive end-uses is needed.

To reflect the full extent of the energy access for productive end-uses in developing countries, it is important to highlight the role of mechanical power[7] in improving the lives of the poor in developing countries. Energy for mechanical power is obtained from electricity and nonelectric sources and is used for daily livelihood activities including agroprocessing, artisanal activities, and small and micro enterprises. Over the past century, technological advances have helped reduce the drudgery of human labor through the widespread use of mechanical power. Mechanical power is perhaps second only to cooking when it comes to the sorts of energy services poor people need most. Mechanical power is critical to enhancing the productive end-uses of labor and poverty alleviation.

Challenge one: With respect to access to mechanical power for productive uses, a desk survey by UNDP indicates that mechanical power is not included in most policy debates at the country level. Despite its importance in expanding access to energy services, little data exists on productive end-uses of energy or mechanical power in developing countries. Governments lack vision, time-bound targets, or data concerning the contribution of mechanical power to general human development. Even where there are targets, programs to upscale initiatives are lacking. National decision makers often fail to recognize the significance of productive end-uses through the provision of energy especially by motive power. For example, Table 19.1 shows that although five out of the 50 LDCs have a national target on access to modern fuels, and 22 have targets on access to electricity, none of them has a specific national target on access to motive power.

Table 19.1 | Mechanical power is least documented by LDC countries that provide data on access to modern energy (baseline and target).

		National	Rural	Urban
Fuels for cooking/ heating	Baseline	48 (96%)	17 (34%)	15 (30%)
	Target	5 (10%)	2 (4%)	2 (4%)
Mechanical Power	Baseline	0 (0%)	2 (4%)	0 (0%)
	Target	0 (0%)	2 (4%)	3 (6%)
Electricity	Baseline	48 (96%)	38 (76%)	35 (70%)
	Target	22 (44%)	16 (32%)	9 (18%)

* The 50 LDCs are used in the calculation. (%) indicates the percentage of LDCs that provides data on access to modern energy.
* Source: UNDP and WHO 2009.

The lack of data is a challenge, particularly considering that the majority of developing countries' rural and peri-urban populations depend on mechanical power for activities in households, agriculture, or small and micro enterprises. For instance, small commercial enterprises and agriculture depend on motorized and nonmotorized mechanical power. Devices such as treadle pumps, ram pumps, floating pumps, wind-powered water pumping, hydro-powered carpentry, or agricultural processing enterprises such as corn threshers, are all important mechanical power devices that are commonly used in developing countries. Diesel or electric motors for mechanical power are becoming increasingly important for providing mechanical power in most developing countries. Mechanical power is one of the quickest ways that energy is used for productive end-uses, mainly in agriculture and forestry and at the small enterprise level. In terms of targets for access, national plans are lacking in all areas of energy access, with cooking fuels much more poorly represented than electricity, and mechanical power not even registering. The lack of data in this regard is a serious barrier to setting such targets. What is needed is detailed data on ownership and use of machinery and power availability at the farm level, as well as studies that link this with yields and productivity improvements (Figure 19.15).

Small and microenterprises (SMEs), many belonging to the informal sector, have become integral in many developing country economies. Studies in India have shown that SMEs enable rural households to generate nonfarm income, which can largely contribute to poverty reduction (Lanjouw and Shariff, 2002). In general, SMEs purchase (rather than harvest or collect) their energy, including electricity, LPG, kerosene, firewood, charcoal, etc. This is true even in rural areas. Moreover, despite energy being one of the significant factors for most microenterprises, there is a knowledge gap on how much energy is being used; neither is it systematically documented what role energy

7 Mechanical Power is defined here as the effective outcome of transforming different forms of energy sources (e.g., wind, hydro, fossil fuels, etc.) to kinetic energy (to cause motion).

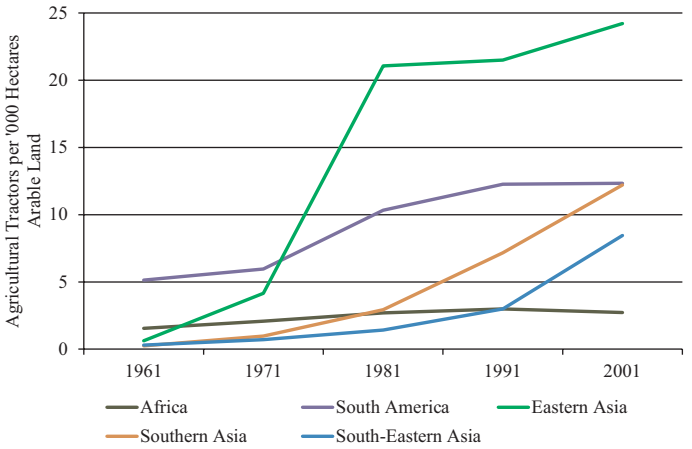

Figure 19.15 | Growth in agricultural mechanization. Source: FAOSTAT, 2010

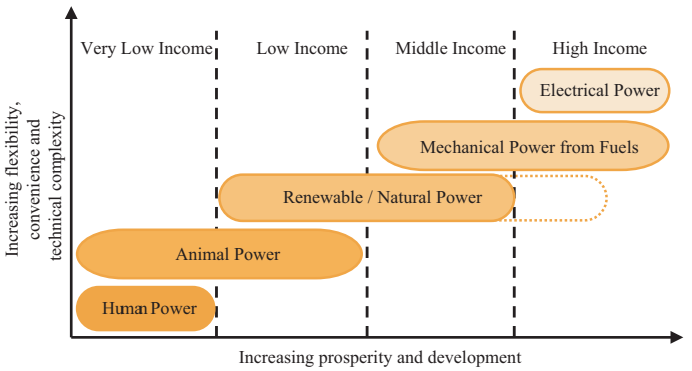

Figure 19.16 | Mechanical power ladder. Source: adapted from WHO, 2006; UNDP, 2009a.

plays in diversifying production and expanding employment opportunities by microenterprises, both in urban and rural areas (Clancy and Dutta, 2005).

Challenge two: The second challenge is the lack of improvement in technology or form of use in impoverished regions of the world today. Since the industrial revolution, access to advanced forms of mechanical power has defined the pace of human development and advancement, and shaped development in various ways in different parts of the world. However, the gap between technologies used for mechanical power in developed countries and in the rural areas of developing countries is increasing. Despite technological improvements, those without access to modern energy still depend on less efficient and effective versions of mechanical power that use human, animal, or unimproved motorized equipments to meet their energy needs, resulting in low efficiencies and limited productivity. The implications for the poor include lower incomes, increased drudgery, and a continued dependence on subsistence production practices. Access to motive power has remained an important driver of livelihood activities in impoverished regions of the world. Figure 19.16 depicts this challenge (UNDP, 2009a).

19.2.4 Institutional Development and Financing Mechanisms for Scale-up of Access

In order to meet the ambitious energy access targets discussed in Chapter 2 and highlighted in Section 19.1.1, new ways to generate additional sources of funding will be needed and funds made available will have to be allocated effectively and efficiently. In the following sections we discuss the need for innovative institutional approaches and financial mechanisms for scale-up of access initiatives and activities.

19.2.4.1 Need for Innovative Institutional Approaches

Massive diffusion of new technologies for meeting thermal energy (e.g., cooking), motive power, and electricity needs is necessary to meet the grand challenges of improving access laid out in previous sections. While electricity grids have expanded and programs have been put in place to spread distributed generation technologies and cleaner cook stoves and fuels, these efforts have often been plagued by numerous problems and the scale of expansion is barely sufficient to keep pace with increasing demand and even population growth, as in the case of many sub-Saharan countries. In many cases, the barrier is in the policies and institutional arrangements. While it may not always be clear what is needed for a given region, what is clear is the need for change to meet these grand challenges. It is also clear that some key lessons can be learned from mistakes of the past.

The circumstances in developing countries militate that energy pathways, especially for rural and peri-urban areas, be dissimilar to those followed by developed countries. This requires innovation and experimentation on both technological and institutional levels. In Ethiopia, for example, the use of inappropriate institutional structures was found to be one of the key factors hindering wide dissemination of modern energy services to rural areas (Habtetsion and Tsighe, 2002). Lack of appreciation of such approaches at a policy level is curtailing progress, as many policymakers tend to follow conventional approaches without taking into account contextual differences. It is critical that policy makers realize that the markets in developing countries are quite different from those that have emerged in the industrialized world. For example, the impetus to rationalize prices and engage in reforms of the electricity sector may actually be stronger in developing countries due to the poor state of utility finances in many of these countries, the lack of easy access to capital for system expansion, and the resulting inability to maintain existing systems or meet latent demand (e.g., the Indian utilities). However, at the same time, electricity reforms[8] could have negative impacts on low-income households that are already facing hardships quite different from those in the industrialized countries.

8 The role and impact of electricity and wider energy sector reforms on the poor is dealt with in greater detail in Chapter 2.

Box 19.4 | Issues with Measuring and Monitoring Access

Identifying progress in providing access and the extent of electrification depends heavily on the official definitions adopted and the measurement units used. Foley, in his 1990 paper, states that the definition of rural electrification, in particular, varies considerably across countries. In one country "rural" may include provincial towns with a population up to 50,000 while in another it may refer to small farming villages and surrounding areas. The unit of measurement also matters. The initial focus of Indian rural electrification was on "village electrification," rather than household electrification, with this being very loosely defined. As a consequence, villages were often deemed "electrified" without a single household having been connected. Changes in the definition of "electrified village" also impacted the measurement of electrification over time (Pachauri and Mueller, 2008).

The source of electricity supply can also matter. In many countries, official electrification rates refer to connections to grid electricity alone. Thus in Cambodia, where the government has not had a strong involvement in rural electrification, official electrification rates (defined only in terms of connections to a central power grid) remain very low (15%). However, according to Zerriffi (2007), the number of households with access to at least a minimal amount of electricity (e.g., enough to power a light bulb and maybe a small television) is extremely high (50% of the households have a television and an estimated 85–90% have a light bulb). Their electricity comes primarily from rural electricity entrepreneurs that run diesel-based microgrids, battery charging stations, or a combination of the two.

Measuring electricity access can also be complicated by the issue of unauthorized or illegal connections and consumption. In some countries, such as in India, transmission and distribution losses in the electricity sector can be as high as 20–30%. A large part of these losses are attributable to electricity thefts or pilferage by poor households who illegally tap electricity lines (Tongia, 2003). Official access numbers often do not account for these people.

Ideally, the quality and reliability of supply should also be a part of any access measure, but often, well-documented data and indicators measuring quality remain lacking. However, in many developing countries, particularly the least developed, the duration, reliability, and quality (measured in variability of voltage) of electricity supply remain highly irregular.

The importance of institutional factors for the implementation and sustainability of access efforts for poor and rural communities has most recently been reiterated in a World Bank review of its own rural electrification projects (World Bank, 2008a). The review of different country experiences supports the view that there is no superior institutional model. Public, private, and cooperative approaches have led to both success and failure. These models are also not necessarily mutually exclusive. What is important is the choice and strengthening of a framework that takes advantage of the country's strengths and considers the nature of their specific challenges (World Bank, 2010b). Learning these lessons has not been easy. Field surveys undertaken in Thailand show that despite flaws in the implementation of heavily subsidized solar home systems (SHS) and PV battery charging systems in rural areas, the inefficient policy continued over a 15-year period at a cost of over US$11 million (1984–2001), and by the time of the analysis, 60% of the systems were no longer operational (Green, 2004). In Viet Nam, a survey undertaken in 2006 found that 80% of SHS in a project in Vientiane Province were not working properly due to technical hitches, in some cases reducing the power available to the households to about 30 minutes a day (World Bank, 2008a). This implies the need for continuous monitoring and strategic corrections to programmatic activities (Box 19.4). However, funding is not always allocated for the necessary monitoring and evaluation activities. Furthermore, path dependencies and institutional inertia can make mid-course corrections difficult to implement (Annecke, 2008).

The lack of infrastructure and access to energy creates further economic problems at both the micro and macro level for countries. In the recent past, many sub-Saharan countries have faced sporadic and critical power shortages forcing them to resort to emergency power access methods. Over 23 countries have experienced crises, including an electricity crisis in the largest power system in the region: South Africa. This obviously undermined the well-publicized success story of rural and peri-urban electrification in South Africa. The general response to the crises has been largely dominated by the installation of high-cost diesel generators that have eroded savings made by governments or imposed additional financial burdens on those forced to install their own private generators. The consequences have included extremely high tariffs and crippled economies. In general, the low quality and reliability of centralized power, as well as issues of accessing centralized power systems, have created significant opportunities for the use of decentralized generation to meet local energy needs. However, significant financial and institutional barriers exist to the effective use of decentralized technologies, particularly for rural electrification (Zerriffi, 2010).

The provision of energy services accessible to all is often considered to be part of the social contract between governments and their people. For example, in the electricity industry, the social contract was an exchange in which the government regulates the industry and guarantees its financial viability while ensuring protection of the poor and the

environment (Heller et al., 2003; Chaurey et al., 2004). However, there have been some fundamental problems with this model. It has generally relied on a combination of centralized organizations, particularly ministries, and heavy subsidies to reduce the costs to the end users. This has not always been financially viable and can exclude options that might better meet social needs. Therefore, new and innovative institutional frameworks are necessary. This may involve a greater role for the private sector, community groups, consumer organizations, and other alternatives to the centralized model of energy service delivery. However, this puts a greater emphasis on the need to rationalize the financing of rural energy efforts. The result will be an increasingly decentralized and heterogeneous approach to rural energy delivery and an emphasis on rationalizing the finances of rural energy efforts (Zerriffi, 2010).

19.2.4.2 New Financing Mechanisms

New financing mechanisms are needed for every scale of energy intervention, from large-scale infrastructure investments by both the public and private sectors to local entrepreneurs and right down to the individual household level. Mobilizing local finance is crucial for sustainability, especially taking into account that Official Development Assistance is decreasing and, in addition, it is mainly driven by donor interests (Hansen and Rand, 2006). For example, in 2006 the Kenyan utility, KenGen, offered 659 million shares to the public at 11.90 K. Shillings (~ US$0.15) with additional shares offered to KenGen employees at the same price. The goal was to raise around US$110 million. By the end of the public offering, it was over-subscribed by US$200 million (UPDEA, 2009). Notably, the investors originated from all walks of life and areas of the country, demonstrating the availability of local money and confidence in the local market.

There are a number of ways to overcome the problems of cost, affordability, and access to financial resources that do not rely entirely upon subsidies. In the case of standalone technologies, the first is to reduce the total amount of capital required by reducing the size of systems (e.g., lower wattage PV systems or smaller LPG canisters) (Cabraal et al., 1998; Barnes and Halpern, 2000; Martinot et al., 2002). Another solution to the capital cost problem for the consumers are rental models or fee-for-service models. This saves the household from having to raise enough capital to purchase the technology outright, and dealers can presumably improve their buying power and access different credit facilities (Barnes and Floor, 1996; Cabraal et al., 1998; Barnes and Halpern, 2000). A third option is to use a fee-for-service model in which the consumer only buys energy and not a technology. In the case of electricity, this would include microgrid systems or battery charging stations. These can be run by a local entrepreneur, the local government, a cooperative, or an NGO. The capital cost problem still remains for the provider of the service, however. This is an area of active institutional experimentation with various approaches for incentivizing existing financial institutions to enter into this market as well as setting up new financial arrangements. This can include revolving capital funds and dedicated loan programs.

For the private sector at the local level, one way to address this deficiency is through what are called Market Facilitation Organizations. These are "public-private entities that support the growth of particular markets through a variety of means" (Martinot et al., 2002), ranging from more intangible benefits – such as access to information and networking – to technical support and financing.

One solution to the rural finance problem that has proven successful in a number of nonenergy areas and is now being applied to energy is the presence of microcredit lending agencies (Martinot et al., 2002; Armendáriz and Morduch, 2005). For example, Grameen Shakti has been successfully providing credit for the purchase of solar home systems in Bangladesh (Biswas et al., 2004; Uddin et al., 2006). The challenge with microcredit is that the sums may be too small for some energy purposes and at the household level, energy purchases may not lead directly to increased income, often a requirement for microlending.

Reforming the way in which energy access activities are financed and sustainably operated has potentially serious social consequences. For example, the implications of subsidy reform are that rural and peri-urban electricity consumers may be served with lower levels of energy service than their urban counterparts and by local actors rather than large government or private utilities. However, this does not absolve centralized governments of their responsibilities nor does it call for a complete removal of the international donor community from solving the problem. Some form of lifeline subsidy is needed at a minimum for low-income households.

There are conditions under which cross-subsidies could be implemented while minimizing the economic damage. Such cross-subsidies, if kept to a modest level, can be effective. Many institutional innovations may be implemented through local-scale actors, making traditional cross-subsidies for energy supply more difficult. If energy subsidies are desired, then new mechanisms may be needed. One option would be to provide subsidies directly to the end-users as an energy subsidy rather than being tied to a particular end-use or technology (Howells et al., 2006). Consumers can then make decisions based upon their energy needs and the availability of different options for meeting those needs. This would remove what is essentially a societal and political decision from affecting the functioning of the energy sector. A second option would be to create transfers among the electricity service providers either directly or via the government. This would depend on the particular institutional arrangements in each country. It could include partnerships between small actors such as NGOs, cooperatives, and small entrepreneurs and the utilities within a regulated concession model.

These new institutional arrangements may require a different role for both higher level government agencies and international donors (both official donor aid and NGO aid). This is necessary in order to maintain

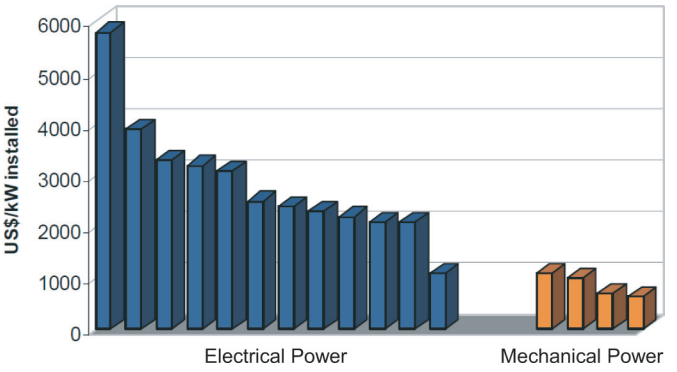

Figure 19.17 | Various costs per kW installed for rural hydro schemes in Africa, Asia, and Latin America. Source: based on UNDP, 2009a.

the social contract that previously existed, though perhaps in a different form. The key is to find a role for nonlocal actors to meet certain societal goals without destroying the market segmentation, local needs-based decision-making and possible contributions to greater rural development that comes with smaller scale solutions. Some principles, such as supporting energy planning, making investment capital available, creating incentives for commercial lending, promotional campaigns, and technical assistance have already been identified for certain markets. Centralized agencies can also aid in coordination, reduce their conflicting mandates and programs, and help create sorely lacking local institutional and organizational capacity (Bird, 1994; Cabraal et al., 1998; Radulovic, 2005; Srivastava and Rehman, 2006).

A number of development agencies are helping to facilitate microcredit schemes or small scale financing options by assisting the private sector and providing the interface between poor communities, energy providers, and private capital (UNDP, 2009b). The financial commitment of communities and entrepreneurs, together with a commercial approach, offers more guarantees for sustainability and poverty alleviation. Cost reduction, though not specific to productive end-uses of energy or mechanical power, is achieved mainly by addressing nonenergy barriers that hinder access to financing (e.g., policies, institutions), community participation, and enabling costs to be reduced by employing a local labor force and/or utilizing other community-owned assets, such as land, as collateral to secure loans. Cost reduction is also achieved by advocating for the incorporation of productive end-uses into national and international energy programs, budget allocations, strategies, and declarations, and finally, by implementing financing initiatives to scale up productive end-uses alongside other energy options in new and existing financing windows.

Financing prospects are linked to the productive end-uses ranging from financing for provision of social services, to income generation activities (commercial), to motive power for value-addition activities in rural areas (Bates et al., 2009).

For *social services*, it is likely that subsidies and grants from governments and international donors, in collaboration with relevant government ministries and NGOs, will remain a key mechanism for funding productive end-uses and mechanical power installations for basic services. For this category of services (e.g., water pumping for drinking water or sanitation), substantial incentives (government grants, support from projects/programs) remain necessary to reach the poorest. Indeed, income generated from social services is generally extremely low and is not sufficient to pay back the up-front investment. Nevertheless, tariffs in line with the beneficiaries' willingness or ability to pay should be set in order to ensure that the maintenance costs (labor force, spare parts) are covered and costs are shared between public funding, community contributions, and, where possible, private finance.

For *income-generating activities* (for instance, grain milling or manufacturing), soft and/or commercial loans, coupled in some instances with small subsidies, are instrumental in creating thriving businesses. The success story of microhydro in Nepal is mainly based on an implicit strategy aimed at prioritizing microhydro for productive end-uses through mechanical power and income-generating activities. Experiences highlighted in Khennas and Barnett (2000), based on case studies from five countries in Latin America, Africa, and Asia, illustrate the relatively low financial barriers to enter the microhydro business aimed at end-uses supplied by mechanical power. Despite interest rates of up to 17%, hundreds of schemes were developed on a sustainable basis in Nepal by small entrepreneurs.

For *enterprise-based productive end-uses* and mechanical power initiatives, there is a range of sources of funding already in existence that are potentially appropriate, based on commercial or semi-commercial loans, including AREED (African Rural Energy Enterprise Development)[9] in Africa. The Government of Senegal, for example, has used the AREED approach to develop its national program delivery in rural areas. For stand-alone productive end-uses and mechanical power systems at the farm or household level, financing and microlending models have been developed, such as that of the Grameen Bank of Bangladesh. This microlending agency has over 1000 branches and two million members and disseminates energy systems through a nonprofit rural energy company, Grameen Shakti. Loans are made after a small down payment and, while the model was initially developed for solar PV systems, it is extending into other sectors that include productive end-uses such as treadle pumps.

A survey of UNDP projects that expands access to modern energy at the local level indicates that the average cost per beneficiary for providing mechanical power by use of multifunctional platforms/equipment attached to stationery engines is US$24. Despite the relatively low cost (see Figure 19.17), there are inherent bottlenecks related to financing access to mechanical power (Bates et al., 2009).

9 AREED offers rural energy entrepreneurs in sub-Saharan Africa a combination of enterprise development services and start-up financing. The program allows entrepreneurs to structure their companies for growth and, by mainstreaming local financial partners, makes eventual investments possible through loans.

For *decentralized productive end-uses* and mechanical power systems, such as community water supply or shared milling resources, additional financing options are considered, drawing from existing experience in revolving funds for microhydro. Loans are given to institutions involving local government and the community, often with the management and operation of schemes headed by trained local enterprises.

The promotion of productive uses of energy with the objective to stimulate economic development should go hand in hand with other activities and instruments to support the establishment and/or development of enterprises. This requires cooperation with many actors and provision of other conditions for entrepreneurship and business (e.g., the availability of easy credit). Energy per se will not lead to the establishment of new enterprises and the alleviation of poverty. It is linked with factors of rural development, market demand and access, infrastructure, and entrepreneurship. Productive-use development must be based on demand-pull rather than technology-push.

19.3 Improvements in Household Access to Modern Energy: Regional Efforts and Status

In the following sections, the issue of household access to electricity and modern cooking/heating is assessed from a regional perspective. The focus is on the regions where the lack of access is most acute, including Africa, Asia, and Latin America. Data and information available for these three regions varies widely. For this reason the three regions are dealt with differently, although the discussion adheres to a common framework as much as possible. The objectives in discussing the following regions in more detail are to understand past trends and efforts, assess the current situation regarding access, and draw lessons from each region that might be applicable for other regions or individual nations. We do not include a deeper discussion of policies for access here, as Chapter 23 provides in-depth coverage of that issue.

19.3.1 Africa

Africa is home to about 15% of the world's population and 22% of its land. It also hosts an adequate share of energy reserves, but these remain largely unused. From 1997 to 2007 African economies grew at a steady average rate of 5.4% (World Bank, 2007) and the percentage of Africans living on US$1.25 a day decreased from 58% in 1996 to 50% in the first quarter of 2009 (World Bank, 2009). Nevertheless, Africa remains the continent with the lowest electrification level, and a third of all people in the world without access to electricity live in this region. Even today, only 11% of the rural population in sub-Saharan Africa has access to electricity and the majority of households cook with wood and charcoal over open fires or on inefficient stoves (UNDP and WHO, 2009). The use of traditional cooking fuels is highest in rural areas (93%), but it is still very significant (about 70%) in urban households (Banerjee et al., 2009).

A detailed account of the energy access situation and efforts in North Africa, West and Central Africa, and Eastern and Southern Africa is presented in the following sections. Compared to Latin America and Asia, there are fewer studies and summaries on energy access in Africa. For this reason, data and case studies from individual countries have been widely used.

19.3.1.1 North Africa

North Africa, unlike sub-Saharan Africa, has made relatively good progress with respect to the provision of modern energy for the majority of people in the subregion.

Access to Electricity

The disparities in access to electricity between North and sub-Saharan Africa cover urban and rural populations. The rural electrification rate is around 98% in North Africa (IEA, 2010b). In urban areas of North Africa, electricity access is almost universal.

Algeria, Libya, and Egypt, the three oil and gas producing countries in North Africa, accelerated their electrification efforts over the last 30 to 40 years and achieved universal electricity access (Figure 19.18). Tunisia and Morocco, the two oil importing countries, pursued ambitious electrification drives that led to universal access in Tunisia and to 97% electricity access in Morocco. Mauritania is the exception in this region with national electrification levels as low as 30% and rural access levels at 2%. Mauritania is more similar to sub-Saharan Africa than other North African countries. Morocco's Global Rural Electrification Programme (PERG) (Box 19.5 and Fig 19.19) shows how political will, supported by technical and financial plans and capacity, lead to a steady increase in rural electrification levels from 18% in 1995 to 95% in 2008.

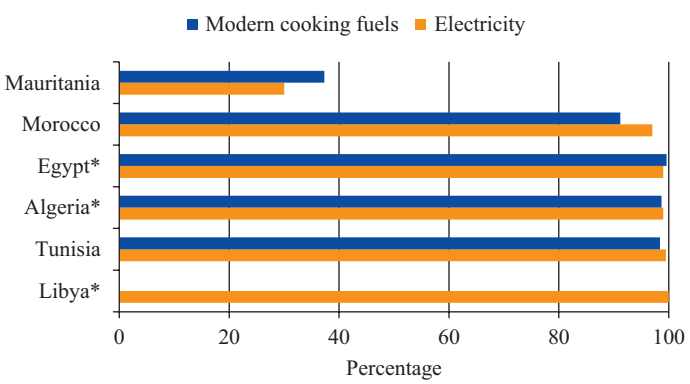

Figure 19.18 | Access to electricity and modern cooking fuels in North Africa. Source: UNDP and WHO, 2009. Note: Countries indicated with * are oil exporting.

Box 19.5 | Rural Electrification in Morocco, PERG Program

The Global Rural Electrification Program (PERG) was launched in 1996 with the aim to achieve complete rural electrification by 2010. This target date was reviewed to achieve the electrification objective in 2007, through the expansion of the electrification pace from 1000 to more than 1500 villages/year. Starting from 18% in 1995, a rural electrification level of 95% was achieved by the end of September 2008 (Figure 19.20), as a consequence of the ambitious PERG and its associated budgetary provision.

The PERG is based on the following three "global" principles:

- Territorial: it aims to provide electricity to all rural households, in all communities;
- Technical: it aims to integrate all the available electrification techniques (grid extension and decentralized power generation) to meet the electricity needs of each household and within feasible technoeconomic conditions;
- Financial: it integrates all financial resources that can be used for the rural electrification nationwide, under the PERG global financial mechanism. This financial mechanism involves three contributing partners, namely the Electricity Utility (ONE), the local authorities, and the end users/beneficiaries. The PERG budget amounted to about 20 billion Moroccan Dirham (US$2 billion).

The ONE contributes 55% of the financial cost through a fund raised from a 2% levy on grid electricity sales (35% of the electrification cost) and its own contribution of 20%. Local authorities co-finance 20% of the program costs: either 2085 MAD (~US$200) per household or 500 MAD (~US$48) per household/year over five years. Households contribute 25% of the electrification cost: either 2500 MAD (~US$240) per household or 40 MAD (~US$ 4) per month over seven years.

Decentralized electrification is being implemented mainly through solar PV installations, targeting 150,000 remote households.

Access to Modern Cooking and Heating Fuels in North Africa

North Africa, including the Saharan desert, is generally a region with low rainfall. Access to traditional biomass and sustainably harvested wood resources for household cooking and heating needs has been a major challenge in the region, particularly in rural areas. North African governments have addressed the problem and successfully replaced traditional biomass with modern fuels by making access to LPG and natural gas a policy priority. Access levels in Egypt, Algeria, and Tunisia range from 98% to almost 100%. Morocco is slightly below that and Mauritania lags behind with only 37% of households having access to LPG (Figure 19.18).

The three oil and gas producing countries – Algeria, Egypt, and Libya – used their own local resources. Morocco and Tunisia import gas from their neighbors. Most of the gas used in households is LPG, but access to natural gas for household uses is also quite well developed in the North African gas-producing countries and is progressing or emerging in the countries where gas pipelines are passing through to feed the European gas markets (Morocco and Tunisia).

In Egypt, natural gas consumption reached 25.39 Mtoe in 2003/2004. 1.7% of the total consumption is used in the residential and commercial sectors. The country has been trying to improve the availability of natural gas for residential customers by allocating service areas to several private companies since the beginning of 1998 (Drück et al., 2007).

In Tunisia, gas pipes pass through the country from the Algerian border to Italy, over an onshore length of more than 320 km. The Electricity and Gas Utility has a natural gas network that presently covers the coastal cities from Gabes to Tunis. There are plans to extend the gas network to include the Djerba and Bizerte areas (MEDREC and GNESD, 2009).

In Morocco, a natural gas market is emerging after the implementation of the Algeria-EU gas pipeline crossing the country. The first applications are for power generation, with the prospect of opening this market to improve household access to modern energy. However, about 30% of the population is still dependent on biomass (Mchirgui and Kanzari, 2006). To improve household access to LPG, some governments, such as Morocco, have been subsidizing gas bottled in small (e.g., 3 kg and 12 kg) canisters.

Access to Domestic Hot Water

Tunisia and Morocco showcase successful experiences of solar thermal applications, especially for solar water heating.

The Tunisian program, PROSOL, is supported by the electricity and gas utility (Box 19.6) and shows the importance of implementing appropriate financial mechanisms to sustain a quality dissemination of solar water heaters (SWH).

In Morocco, the SWH program (PROMASOL), supported by the Global Environment Facility, targets the installation of a capacity of 400,000 m^2 of solar collectors by 2010. According to the Renewable Energy Centre, the objective of one million m^2 of collectors is set for the year 2020. The program is based on awareness-raising and communication, quality equipment, and after sale maintenance, as well as adequate financial mechanisms for households (leasing approach) and the tertiary/services sector.

In Egypt, the introduction of SWH technology to the national market started in 1980 with the import of 1000 home solar water heaters. In the same year, the first private local manufacturing company started and since then, SWH systems are manufactured in the country. In the mid-eighties a law was passed to promote the technology, which made the installation of solar water heaters compulsory for residential buildings in new satellite towns. Unfortunately this law did not have a lasting effect. Major obstacles included a lack of execution by the local authorities and the often poor quality of the SWH heaters, which gave the technology a bad reputation (Drück et al., 2007). More than 500,000 m^2 of solar collectors have been installed (end 2004), particularly in the new cities and tourist villages resorts. About 200,000 families are using SWH systems in Egypt. Tourist resorts and hotels are considered to be the main customers in this market. The distribution of the installed SWH systems shows that 40% of the total capacity is installed in new cities while 14%, 24%, and 14%, respectively, are installed in old cities, tourist villages, and government and public enterprises (Drück et al., 2007).

Box 19.6 | Large-scale Dissemination of Solar Water Heaters in Tunisia: PROSOL Program

Within the framework of its strategy to develop renewable energy, the Tunisian government decided to implement a program of massive dissemination of SWHs in the residential sector. This program, called "PROSOL TUNISIA" (Solar promotion for Tunisia), was launched in February 2005 and targets three types of SWH: 200-, 300-, and 500-liter capacity.

This program benefits from institutional and financial backups to promote the SWH market development. The financial support covers the following main incentives under the PROSOL:

- 20% subsidy of the SWH cost, provided by the government through the National Fund of Energy with a maximum of 100 Tunisian Dinar/m^2 (TD/m^2);
- A complementary subsidy of about 80 TD of the 300 liters SWH cost, supported by the Italian government through MEDREC Funds;
- A loan mechanism to finance the remaining cost of a SWH, granted over a period of five years, and paid through the electricity bill of the utility (STEG);
- The reduction of the interest rate, using UNEP funds during 2005 (MEDREP Program).

Therefore, the end user needs to provide only 10% cash contribution toward the SWH cost.

The installed capacity of SWH decreased to about 8000 m^2 in 2003 from around 18,000 m^2 in 2001. The PROSOL Tunisia Program aimed at reaching 225,000 m^2 SWH over the period 2005–2008; 500,000 m^2 SWH in 2009; and finally, 540,000 m^2 to achieve an installed capacity of 740,000 m^2 in 2011.

Lessons Learnt from North Africa

North African countries have succeeded in providing electricity access ranging from 97% to 100% of their populations. Access to modern cooking fuels is also very high and varies from 91% in Morocco to almost 100% in Egypt. The following lessons from the success of the programs in this region may be useful to other regions, particularly sub-Saharan Africa:

- The political will to implement rural electrification programs is a key driver to improve access to electricity in rural areas.
- The availability of fossil fuels resources in some countries helped in implementing early strategies for improving access to electricity and natural gas.
- The adoption of adequate financial mechanisms, involving cross subsidy, fee-for-service, stimulates large-scale access to electricity.
- Mobilization of decentralized access to electricity through renewable energy resources helps speed up access to electricity in remote villages.
- Subsidies stimulate LPG penetration and improve access to modern cooking fuels, especially when combined with the reinforcement of the LPG filling units and distribution network.
- Household access to natural gas is secured in gas-producing countries and facilitated by the gas pipelines passing through nonproducing countries.
- There is significant potential for South-South cooperation around energy access, between North African and sub-Saharan countries. Morocco and Senegal are cooperating in rural electrification through the implementation of the electrification concession in North Senegal, based on successful experiences in Morocco.

19.3.1.2 West and Central Africa

The energy access situation in West and Central Africa[10] compares poorly to North Africa and is similar to Eastern and Southern Africa (minus South Africa). Biomass energy forms the bulk of energy supply in the two regions, contributing more than 81% of final energy (GNESD, 2007) with related environmental consequences. At a national level, in countries such as Liberia, Chad, and Togo, more than 95% of the population relies on traditional biomass for cooking and heating. Access to modern energy for cooking is very low in most countries. Access to LPG remains low, but there has been encouraging progress made in Senegal and to a lesser extent in Ghana, where a range of government policy and fiscal interventions have helped scale-up access to LPG.

Access to Electricity

According to the West African Power Pool (Diallo, 2009), only 30% of the population in West Africa has access to electricity, with 53% having access in urban areas and 7.5% in rural areas. The recent unprecedented escalation of oil prices has had a devastating effect on the economies in the region. Some countries, such as Ghana, Nigeria, Cameroon, Cote d'Ivoire, and Senegal, have household electricity access levels above 35% (IEA, 2009), with Ghana often regarded as a role model in these two regions with an access level of about 54%. At the bottom end of the scale are countries like Burundi, Chad, and Rwanda, which have access levels of 5% or below. In most rural areas, where the poor are mostly found, household access to electricity is lower than 1%. The low access levels of the poor are due in part to the high level of poverty of local communities and the underdevelopment of the electricity supply infrastructure (Sokona et al., 2004). There is insufficient grid coverage in most of the major load centers. Where available, national electricity grids are bedeviled with intermittent power supply, with frequent blackouts and sometimes power rationing as generating capacities fail to match growing populations and consumption levels (Brew-Hammond and Kemausuor, 2007). Also, the deterioration of distribution infrastructure has led to supply bottlenecks and higher technical losses comparable to other parts of sub-Saharan Africa, where inefficiencies in collection of revenues and distribution losses amount to 1.9% of GDP (Foster and Briceño-Garmendia, 2010). In Ghana, for instance, technical and commercial losses account for about 25% of supplied electricity (Energy Commission Ghana, 2008).

Several plans have been outlined in a number of countries to increase access to electricity. About 54% of the total population of Ghana has access to electricity, achieved largely through the National Electrification Scheme described in Box 19.7. The government is hoping to achieve universal access by 2020. In 2008, only 47% of the Nigerian population had access to electricity, mainly in urban areas (UNDP and WHO, 2009). The Government of Nigeria has committed resources to improve the access situation. There is an increased drive toward regional approaches in addressing the region's developmental challenges. The energy sector is spearheading this initiative, as demonstrated by the ongoing regional projects such as the West African Power Pool (WAPP) and the West African Gas Pipeline (WAGP).

In Central Africa, only 3.5% of Chad's population has access to electricity and only 30% of households in Cameroon have access to electricity (UNDP and WHO, 2009). In 2007, the Cameroon government signed an accord with the European Union worth about US$16.2 million to facilitate access to electricity in some rural areas in the country. The

10 The United Nations' definition of West Africa comprises all countries forming the ECOWAS, namely, Benin, Burkina Faso, Cape Verde, Cote d'Ivoire, Gambia, Ghana, Guinea, Guinea-Bissau, Liberia, Mali, Niger, Nigeria, Senegal, Sierra Leone and Togo. For the purpose of this review, Central Africa comprises all countries forming CEMAC: Cameroon, Central African Republic, Congo, Gabon, Equatorial Guinea and Chad.

Box 19.7 | Electricity Access Scale-up in Ghana

Ghana increased its electrification levels from 23% in 1985 to 54% in 2005. In 1985, only 250 out of about 4202 towns and cities in Ghana, in five of the then nine regions, had access to the national electricity grid. The national electrification drive in Ghana started in 1985 with the preparation of a project by the Volta River Authority to extend the 161 kV National Grid northward to reach all the administrative regions of Ghana under a project captioned the Northern Electrification and System Reinforcement Project (NESRP). The total project cost was estimated at US$150 million.

The Volta River Authority completed the definition of the project and obtained financial support for the first phase from the African Development Bank in 1987. Thereafter, several other multilateral agencies joined in quick succession to provide support for the entire scope of the project.

Implementation of the NESRP project was successful in every respect: financial, technical, and social. Within three years of project commencement, the national grid supplied electricity to all the regional capitals except the Upper West regional capital. The construction, commissioning, and testing of the 600 kilometers of high voltage (161 kV) lines and associated substations had been completed within budget and ahead of schedule.

The impact of the achievement of the NESRP objective by the Volta River Authority spurred the preparation of a plan called the National Electrification Scheme (NES) which was issued in 1990. The goal of the NES was to provide within a 30-year timeframe, electricity access to about 4200 settlements with populations of 500 or more. The NES was pursued through various discrete projects. Prominent among these were the Northern Electrification Project and the Self-Help Electrification Project (SHEP).

The SHEP was a nationwide scheme that was introduced as a policy framework under which communities could advance their electrification projects ahead of the dates indicated in the NES by meeting agreed criteria for community contributions to the project implementation. The SHEP aimed to connect to the national grid ahead of their respective scheduled dates any communities that:

- were within 20 km of an existing 33 kV or 11 kV network;
- had procured low-voltage poles for the network within the community; and
- had a certain minimum number of premises wired and ready to receive power.

The Government's obligation was to provide the conductors, transformers, pole-top, and other materials and assume responsibility for the construction work required to make the connection.

The achievements of the electrification drive (i.e., connecting 2350 communities in just ten years after the launch of the NES plan, reaching 40% of all communities with population exceeding 500 in 2000, and achieving an electrification rate of 54% by the end of 2005) were impressive. The NES was reviewed in 2010. It was estimated that the level of electrification stood at close to 70% at that time and the government has recommitted itself to building on the successes of the last two decades to achieve universal electrification by 2020.

Cameroonian government co-financed 50% of the projects and some 128 villages are expected to benefit.

Access to Fuels

Millions of households in West and Central Africa lack access to modern cooking fuels. For most of these households, energy from biomass (mainly fuelwood, charcoal, bagasse, and animal and agricultural waste) is the main fuel source for cooking, even with its attendant environmental and health hazards. In many countries in these regions, including Liberia, Guinea, Mali, Sierra Leone, Niger, Togo, and Chad, more than 95% of the population relies on traditional biomass for cooking and heating (Figure 19.20). Only in Gabon, Cape Verde, and Senegal does more than 40% of the population have access to modern cooking fuels. In most of these countries, biomass energy accounts for over 80% of

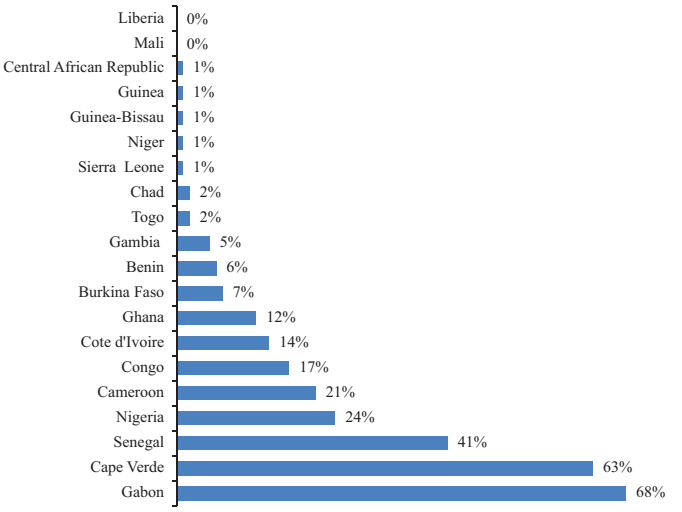

Figure 19.20 | Share of population with access to modern fuels in West and Central Africa. Source: data from UNDP and WHO, 2009.

total energy used (Hagan, 2006). The bulk of modern energy fuels used in these two regions comes from LPG.

The numbers of people relying on traditional biomass for cooking in these regions is projected to increase consistently over the next 20 years (Modi et al., 2006; IEA, 2010b). Bearing in mind the negative effects of these projections, several countries are making efforts to reverse this trend for the better. But while many countries have tried, only Gabon, Cape Verde, Senegal, have succeeded in implementing far-reaching programs to substitute woodfuels for cooking with LPG. Nigeria and Cameroon follow in that order, but the access levels are very low compared to the LPG potentials from the oil and gas industries in these two countries. Interestingly, the same countries that have somewhat higher access to electricity also have higher access to modern fuels for cooking. Ghana, and to a lesser extent Cote d'Ivoire, seem to deviate slightly from this trend. For example, Ghana's electricity access rate of over 54% compares poorly with its 12% access to modern fuels. There has been a recent drive in Ghana to focus attention on modern fuels and an ambitious target of increasing the population using LPG to 50% by 2015 has been set but it remains to be seen how this will materialize given the frequent LPG shortages in the country.

Participation of Regional Economic Communities in Energy Access Scale-up and Lessons Learnt

Following recommendations from the New Partnership for Africa's Development (NEPAD) in 2002 to the Regional Economic Communities, the Economic Community for West African States (ECOWAS) and Communauté Economique et Monétaire de l'Afrique Centrale (CEMAC) proposed some very ambitious targets. The regional organizations have developed strategies or action plans, such as the ECOWAS/UEMOA White Paper on Energy Access (ECOWAS, 2006) and the CEMAC Action Plan for Promotion of Energy Access (CEMAC, 2006) with assistance from UNDP and the EU Energy Initiative Partnership Dialogue Facility. Whereas CEMAC is aiming for 80% access to modern fuels for cooking by 2015, ECOWAS is hoping to achieve 100% access to modern fuels by 2015, with between 50% and 70% being provided through LPG and the rest through improved fuelwood cook stoves (Table 19.2). Judging from progress made so far, it is going to be very difficult to achieve these

Table 19.2 | Specific Energy Access Targets by ECOWAS and CEMAC for 2015.

	ECOWAS	CEMAC
Modern energy for cooking	100%	80%
Modern energy / electricity for basic needs in urban an peri-urban areas	100%	50%
Electricity for rural households	36%	35%
Electricity for schools, clinics and community centers	60%	56%
Mechanical power for productive uses in rural areas	60%	-

Table 19.3 | Barriers for LPG access for households and LPG suppliers.

	Demand Side	Supply side
Accessibility	Rural Household Access to LPG – Local LP Gas supply to households – Smaller cylinders – Full local sales and services – Fast and convenient refills – Plenty of cylinders frequently refilled	LP Gas Supplier Access to Rural Households – Dispersed customers – Long supply chains – Lack of rural supply infrastructure – Need for local agents and sub agents – Higher investment, risk and maintenance cost
Affordability	Low LP Gas Appliance Prices – Ability to pay – Need for credit – Small quantities – Low cost of appliance to switch to LP Gas – Access to credit – Below poverty line households	Higher Margins to Support Higher Rural Supply Cost – Low LP Gas prices – Small margins – Economic viability – Need for subsidies for market entry appliances – Need to reduce overheads – Special third party financial support
Acceptability	Rural Household View of LP Gas – Low or zero cost fuel alternatives such as wood – Higher fuel cost – Safety and proper usage – Cooking major usage – Government friendly household energy policy – Zero rated taxes – Many competing suppliers	Attractiveness of Rural Markets to Suppliers – Added cost of competitive marketing – Low margins – Costly user education – Small volumes of LP Gas – Government policy favoring other fuels such as paraffin/ natural gas – VAT on LP Gas sales – Exclusive supply territories

Source: WLPGA, 2005.

targets and they may need to be revised with greater emphasis placed on developing capacity.

The penetration of LPG, particularly in rural areas, has been very slow and access levels remain very low. The World LPG Association identified several key barriers to the accessibility, affordability, and acceptability of LPG, in particular for rural households and suppliers (Table 19.3). The World LPG Association believes that increasing access to LPG would require a concerted effort by industry and government to address all aspects of the energy puzzle, including developing local resources, financing, building capacity in local energy entrepreneurs, developing joint marketing campaigns, and increasing public awareness, with the right mix of policy changes, dissolution of market barriers, and responsible investment (WLPGA, 2005). Senegal is one country that managed to address all the barriers successfully and LPG access levels are 41% overall, with 74% in urban areas and 12% in rural areas (UNDP and WHO, 2009).[11]

Efforts that succeed in integrating productive uses and income generation activities into energy access initiatives may well turn out to be the deciding factor in improving access to households in this region. So far, private sector participation in energy access scale-up has been abysmal, as policies and tariffs have not been favorable for encouraging the private sector to venture into power production. Countries in the two regions should be learning from the experiences of Senegal – and countries outside the regions, such as Botswana and Brazil – to explore sustainable ways of increasing access to LPG, emerging biofuels, and improved cook stoves. Ultimately, a major shift is needed in the current access trajectory if realistic increases in energy access are to be achieved by 2030, which is the reference date for most forecasts by the Regional Economic Communities, the IEA, and the World Bank.

19.3.1.3 Eastern and Southern Africa

In most countries in Eastern and Southern Africa[12] energy use overall has risen and governments and utilities have made efforts to increase generation, transmission, and distribution capacities, but the progress made has been too slow to keep pace with population growth. The energy supply and use situation is generally similar to West and Central Africa (see above), but national rates of deforestation are much heavier in Eastern Africa, and in many regions, adequate supplies of wood and charcoal fuels are an issue. The cost of these fuels, when purchased, has been rising steadily. In most countries, traditional biomass still plays the major role (up to 80%) in energy supply. Some governments have implemented projects and policies to make modern cooking fuels (LPG and kerosene) more easily available in rural and peri-urban areas (e.g., Botswana, Lesotho, and South Africa) and private companies sell them more widely now. In other countries, deregulation of LPG and kerosene made them more expensive for the end-user, leading to a decline in kerosene use. Many African countries grow sugarcane and there is a rising interest in producing ethanol for the transport sector and as a household cooking fuel. In Eastern and Southern Africa, ethanol gelfuel – ethanol with a gelling agent – was introduced, starting with the Millennium Gelfuel Project, but wider dissemination did not follow. The efficiency of technology using ethanol gelfuel compared with LPG and kerosene was also found to be significantly lower. The retail price of ethanol gel fuel would have to be well below that of kerosene and LPG to make ethanol gelfuel competitive.

Improved cook stoves have received much attention and the Kenyan Ceramic Jiko, an improved charcoal stove, is distributed to over eight million customers across Africa, from Senegal to Ethiopia and South Africa, and has become an African success story (AFREPREN/FWD, 2009). Biogas plants have been introduced on a project basis in the region. The biogas scheme in Rwanda that integrates agriculture and energy appears to be one of the more successful ones.

Access to Electricity

Levels of household access to electricity in Eastern and Southern Africa range from a low of about 6% in Rwanda to 100% in Mauritius. The countries with the highest access are Mauritius (100%) and South Africa (73%). The two countries are the two middle-income economies in the regions. Electricity supply is not always the largest limiting factor to improved access, and barriers sometimes lie in the lack of national infrastructure. The Democratic Republic of Congo (DRC), Lesotho, and Mozambique are exporting electricity through the Southern African Power Pool to other countries in the region, while their national electrification levels are less than 15%.

In Southern Africa, four countries – Botswana, Mauritius, South Africa, and Zimbabwe – have successfully extended electrification to rural areas using different approaches. In Botswana, the utility connects households on a cost-recovery basis and customers can apply for loans for their electricity connection. Monitoring the implementation and impact of the rural electrification policy, the Energy, Environment, Computer and Geophysical Applications Group (EECG, 2004) found that if the upfront payment and monthly repayments are small and extended over longer periods, the uptake of connections increases significantly. South Africa highly subsidises electricity to low-income households. Under the National Electrification Programme, access to electricity is very affordable even for the urban and rural poor. In addition, the Free Basic Electricity allocates 50kWh/month free of charge to poor households (Box 19.8). In Zimbabwe, the Rural Electrification Agency targets rural growth centres where local government infrastructure such as agricultural extension, health services, schools, and police stations are concentrated. Local councils facilitate enterprise development and lease stands to medium and small enterprises that provide services including automotive, electrical, electronic and

11 See Chapter 23 for further discussion on the success of transitioning to LPG as a cooking fuel in Senegal.

12 For this study, Eastern Africa includes Burundi, Djibouti, Eritrea, Ethiopia, Kenya, Rwanda, Tanzania, Somalia, Sudan, and Uganda. Southern Africa includes the 15 countries of the Southern African Development Community (SADC): Angola, Botswana, Democratic Republic of Congo (DRC), Lesotho, Madagascar, Malawi, Mauritius, Mozambique, Namibia, Seychelles, South Africa, Swaziland, Tanzania, Zambia, and Zimbabwe.

Box 19.8 | South African National Electrification Programme and the Free Basic Electricity

Through the government's National Electrification Programme, electricity connections in South Africa grew from 36 % of households in 1995 to over 70% in 2008. Electricity to low-income households is subsidised, making access affordable for the poor. The blanket roll out, in which whole areas are provided with electricity supply so all potential customers are served, not only customers applying and paying, significantly reduces cost. Technological innovations such as prepayment meters further reduce costs.

While the National Electrification Programme facilitated access to electricity, the poor did not automatically benefit from being connected. Often they could not afford to use the electricity and consumption levels among the newly connected households remained low. In 2003, the government introduced the Free Basic Electricity so the poor could benefit from the huge investments in national electrification.

The example of Cape Town illustrates how the subsidised connection works. The municipality of Cape Town charges ZAR 225 (approximately US$29) for a subsidised connection of 40 ampere to recognised areas of informal housing. If the new customer cannot pay the connection fee upfront, the amount is charged to their prepayment account and deducted gradually each time an electricity purchase is made, at the rate of 20% of the purchase. No interest is charged on the advanced connection fee. If customers use less than 450 kWh/month they are eligible for a lifeline tariff divided into three blocks. The first block up to 50 kWh/month is free, the second block from 51–150 kWh at ZAR cents 58.11/kWh, and the third block from 151–450 kWh is charged at ZAR cents 70.47/kWh. This compares to the domestic consumption tariff without subsidy of ZAR cents 93.32/kWh.

Why are some excluded from subsidised access?

Informal houses built on land not approved for electrification (flood plains, road reserves, power-line servitudes, private land, etc) cannot get a metered electricity connection and have to rely on extension cords to neighbouring houses that are metered. This generally costs twice as much as electricity from metered access.

general repairs, welding and spray painting, milling, carpentry, secretarial, and general retail services. In Mauritius, the rural electrification program started well before the country gained its independence in 1968 from the British. Since that time, the Central Electricity Board has been the only electric utility responsible for generating, transmitting, and distributing electricity in Mauritius and it had connected all households by the year 2000.

Over half a million households in Africa use PV systems for lighting and communication (AFREPREN/FWD, 2009). In Kenya, about 150,000 solar systems have been distributed through the market. Other countries, such as South Africa, started subsidised programs in the late 1990s. The number of systems distributed was far below the target figure. Financial and technical barriers and the expectation of the recipients, particularly those who live near the national grid and hoped to get a grid connection, seem to have been the major problems. In Botswana, the distribution of solar systems has been stepped up and is bringing light and communication to remote villages and dispersed cattle posts.

Access to Fuels

Fuelwood is still very widely used in Eastern and Southern Africa and 80% of the population in 13 of the 24 countries use fuelwood for cooking. In six countries, households are almost entirely dependent on woodfuels: Burundi (99.3), Madagascar (99.1%), Malawi (98.6%), Rwanda (98.6%), Somalia (99.1%), and Tanzania (96.6%). Out of these, Burundi, Malawi, and Rwanda are land-locked countries without any fossil fuel resources. In contrast, 80% of the population in four countries have access to modern fuels (electricity, gas, and kerosene). These are Djibouti (86.1%), Mauritius (95.8%), Seychelles (>95%), and South Africa (83.2%). The first three countries in the latter set have small populations below 1.3 million and make up only a small proportion of the sub-Saharan African population. Gas is a major cooking fuel in only three countries: Angola (51.9%), Botswana (45.8%), and Mauritius (91%) (Figure 19.21).

Not only a high proportion of households, but also a significant number of industries in Eastern and Southern Africa depend on fuelwood and charcoal for their energy needs. The poorest use fuelwood and as incomes rise charcoal is the preferred fuel. Charcoal is also the preferred fuel in urban areas. In densely populated areas and particularly around major cities, fuelwood and charcoal are becoming scarce and overharvesting contributes to forest and soil degradation. Woodfuels (fuelwood and charcoal) have become a lucrative trade and are a major source of income for many households. The poor are employed along the entire value chain, from the rural woodcutters and charcoal

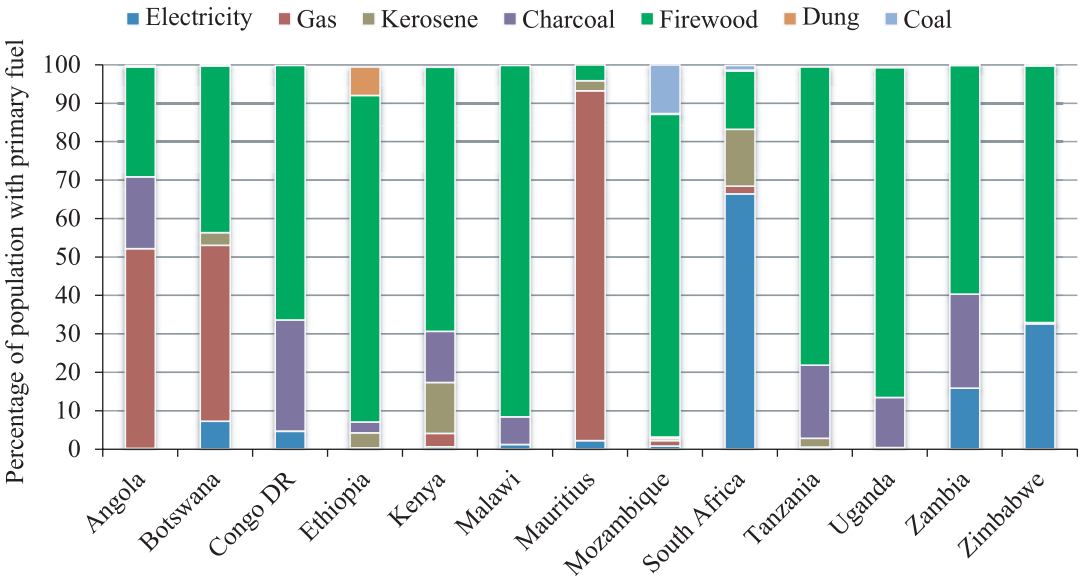

Figure 19.21 | Fuels used for cooking by country in Eastern and Southern Africa. Source: UNDP and WHO, 2009.

producers to the transporters and the urban distributors. The growing wood and charcoal markets are in many cases seen as a threat to forest and woodland resources, but if they are regarded as an opportunity to create employment for the rural poor and provide affordable energy they could provide an important contribution to poverty alleviation. This would require that forest management and the charcoal trade are well and transparently regulated and the implementation of the regulation is in the interest of all stakeholders. It is estimated that the woodfuel trade in Malawi and Rwanda is about 2% of GDP and governments could collect substantial revenues from a regulated woodfuel industry. This income could contribute to making the markets sustainable.

Generally, woodfuel policies and strategies need to be better integrated and address the following objectives: to provide a sustainable woodfuel supply for the majority of sub-Saharan Africans, to protect the environment, and to approach the fuelwood chain as an opportunity for poverty alleviation and job creation.

The traditional three-stone cook stove is still used in many parts of Eastern and Southern Africa. At the same time, improved cook stoves are locally designed and manufactured to reduce heat loss, decrease indoor air pollution, increase combustion efficiency, and improve heat transfer (AFREPREN/FWD, 2009). The best known example is the Kenya Ceramic Jiko, which is disseminated in Kenya and other African countries. The dissemination level for improved woodfuel stoves (Table 19.4) is low in relation to the number of people using woodfuels for cooking. The barriers may be limited local production levels, acceptance, and affordability of the improved cook stoves.

Table 19.4 | Dissemination of improved woodfuel cook stoves in Eastern and Southern Africa.

Country	Number disseminated
Botswana	1500
Eritrea	50,000

19.3.2 Asia and Pacific

With about 60% of the world's population, the Asia and Pacific region comprises the largest of the global regions. A very high level of the population in the region still lives in poverty. Although economic development has resulted in rapid urbanization and changed the composition of the population, about two-thirds of the region's population still lives in rural areas. Furthermore, these rural areas are home to more than three-quarters of the poor in the region, who are distinguished by some of the lowest levels of per capita energy use in the world. Huge variations within Asia are evident in the levels of access to both electricity and modern fuels and more efficient devices. Progress with

electrification has also been extremely uneven across the region in the past. The problem of provision of modern fuels and/or devices for thermal energy needs, however, remains a larger challenge for Asia. For most countries in the region, the majority of the rural population relies on unprocessed biomass or coal for most of their cooking and heating needs. Over half of the total global population relying on biomass lives in China and India alone.

A detailed account of the energy access situation and efforts in the two largest Asian nations, China and India, and that for the other developing Asian countries is presented in the following sections.

19.3.2.1 China

China is an example of a country that has achieved significant success in improving the access to electricity for its rural population and in the dissemination of clean cook stoves. In overall terms, total residential energy demand increased little in China over the last couple of decades, because of a transition from inefficient to efficient fuels. However, significant changes in the pattern of residential energy occurred, largely on account of shifts in the choices of energy used in urban households. Within the rural sector, relatively little change in the patterns of household energy use took place (Figure 19.22 and Table 19.5). What has been significant is the access to modern energy among rural households in the country. However, actual consumption amounts of the modern energy sources remain very low in rural households.

Access to Electricity

China has achieved enormous success in electrifying its population.[13] During the 1980s and 1990s, almost the entire population was electrified, with over 900 million rural inhabitants gaining access to electricity (Peng and Pan, 2006). Currently, it is estimated that only about 1% of the total population remains without access to electricity. Strong government commitment was important to achieving the current status of

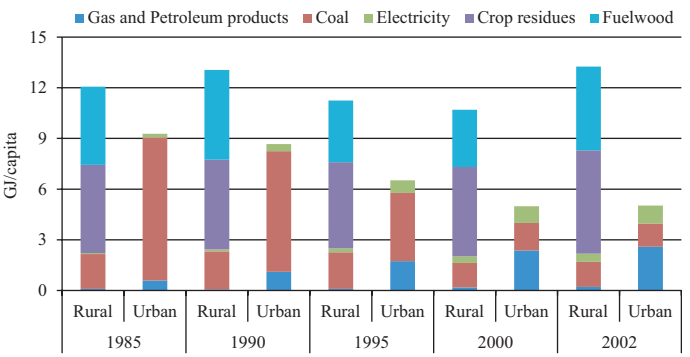

Figure 19.22 | Average household energy demand by energy type in China 1985–2002. Source: Pachauri and Jiang, 2008.

electrification in China. The latest statistics from the National Energy Administration suggest that in 2008, two million rural households still lacked electricity in China, which represents some nine to 10 million people (IEA, 2010a). Through the deployment of decentralized power systems, the government aims to supply about 10 million people with electricity by the end of 2020. The government expects, however, that by 2020 universal access will still not be achieved (the last customer will not be connected). At present, most areas without electricity are located in western regions and islands in the eastern coastal areas, far away from the grid. Most of these areas are rich in renewable energy resources (hydropower, solar, and wind energy), which can practically and economically provide electrification to remote regions. Lessons from the electrification programs in China point to certain key factors that were responsible for its success. These include strong government commitment, technological flexibility, a sense of ownership for the electrification solutions among remote communities not served by the grid, and the inclusion of the private sector in the implementation of electrification programs (IEA, 2010b).

Access to Modern Fuels and Stoves

Biomass and coal continue to be key sources of cooking and heating energy among rural households in China. Today, over 700 million

13 For a more detailed assessment of the policies that led to the success of the electrification efforts in China, refer to Chapter 23.

Table 19.6 | Shifts in the percentage of population using different sources of household energy in India.

	1983		1987–1988		1993–1994		1999–2000		2004–2005	
	Rural	Urban	Rural	Urban	Rural	Urban	Rural	Urban	Rural	Urban
LPG	0	9	1	20	2	33	6	47	12	61
Coal/coke	3	21	3	14	2	8	2	5	2	5

Dung	53	27	56	24	53	18	52	12	46	10

Source: Pachauri and Jiang, 2008.

inhabitants of China continue to rely on solid fuels. Although gas, oil, and electricity consumption in rural areas has increased over the last 25 years, it still remains very low, and much lower than in urban households in aggregate and per capita terms. The total consumption of biomass has remained high in rural areas because of population growth and the relatively slow transition away from the use of this fuel. Urban households in China use a larger share of modern energy. Looking at changes over time among rural households, although per capita biomass use gradually declined during most of the 1990s and coal use was moderately substituted by modern energy, no significant transition in energy use patterns occurred. In urban households, in contrast, a significant shift away from biomass and coal has taken place over the last twenty years. Without any new policies, it is projected that about a quarter of the total population will still rely on solid fuels in 2030.

The Chinese have also made significant efforts in improved dissemination of cook stoves. Between 1982 and 1999, the Chinese National Improved Stoves Program disseminated 180 million improved biomass stoves (Zhang and Smith, 2007). While it is difficult to know how many of these stoves are still in use, the recent UNDP and WHO study (2009) suggests that many still are. The Chinese ICS program, the largest and arguably most successful in the world, relied on rural private stove companies for its success. Main features of the program included:

- stove adopters paying the full cost of material and labor (about US$10);
- government-provided support to producers through designs for stove construction, training, administration, and promotion support; basically there was an indirect subsidy to pay for the costs of stove-making enterprises;
- establishment of local energy offices to provide training, service, installation support, and program monitoring;
- fostering the development of self-sustaining rural energy enterprises that manufactured, installed, and serviced the stoves; and
- an unprecedented scale of rural energy intervention.

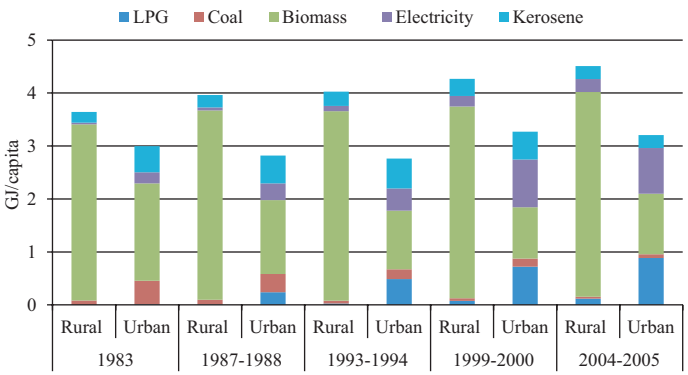

Figure 19.23 | Average household energy use by energy type in India, 1983–2005. Source: Pachauri and Jiang, 2008.

19.3.2.2 India

Even today about 40% of India's rural population lacks access to electricity and almost 80% rely on unprocessed biomass for their cooking and heating needs (Pachauri and Jiang, 2008). Several programs were implemented in the past to improve access; however, the focus was largely on improving access in urban centers and in fertile agricultural belts in rural areas.

Rural households did not witness any striking changes in their patterns of energy use. Biomass use per capita increased in absolute terms, but only slightly between 1983 and 2005. The total amounts and the proportions of commercial energy used in rural households continue to remain very low. In urban households, a much more rapid substitution of biomass by commercial fuels and electricity is evident. Biomass consumption per capita declined, and this decline resulted in a decrease in total per capita household energy demand in urban households between 1983 and 1993–1994 and between 1999–2000 and 2004–2005. However, during the mid-1990s, rise in LPG and electricity consumption among urban households drove up per capita energy use (Table 19.6 and Figure 19.23).

Access to Electricity

India today hosts the world's largest population without access to electricity. Traditionally, village electrification was used as an indicator of the

Box 19.9 | Achievements of the Rajiv Gandhi Grameen Vidyutikaran Yojana

The Rajiv Gandhi Grameen Vidyutikaran Yojana program, with a total estimated budget of over US$5 billion, is one of the most ambitious to date in India. It aims at electrifying all unelectrified villages, electrifying all households in electrified villages, and providing free electricity connections to all below-the-poverty line (BTL) households. In all, the program aims to electrify about 115 thousand unelectrified villages and connect 23.4 million BPL households. Close to 90% of the funds committed have been disbursed and the table below provides an overview of the programs achievements to date.

	Electrification of Unelectrified Villages	Intensive Electrification of Electrified Villages	Connection to BPL Households
Total Numbers (%)	103,402 (87.8%)	248,553 (69.7%)	18,912,729 (76.5%)

Source: India Ministry of Power, 2011

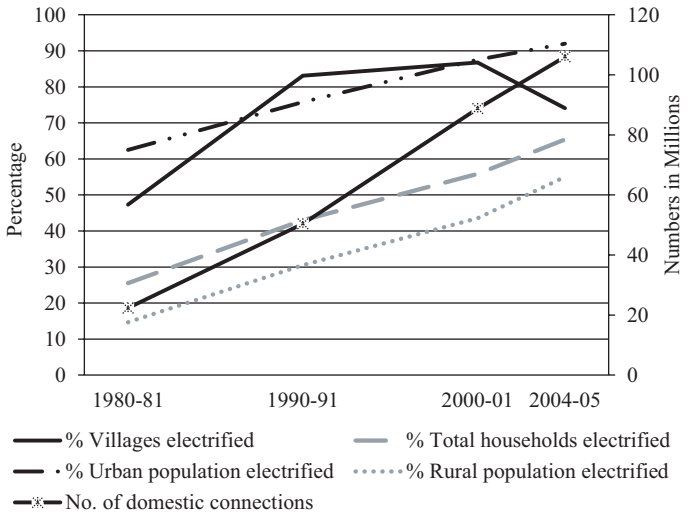

Figure 19.24 | Progress with electrification in India according to different indicators. Source: Pachauri and Mueller, 2008.

extent of rural electrification, but this did not provide an accurate picture of the actual use of electricity among households and also changed over time as a consequence of changes in the definition of "electrified village" (see Figure 19.24). Historical progress on electrification in India when measured in terms of household access has been rather poor, but the status varies significantly across states and regions.

The Indian government has recently redoubled its efforts at initiating policy reforms and new programs for accelerating electrification. The Rural Electrification Policy 2006 aimed at the provision of electricity access to all households by 2009 and a minimum lifeline consumption of one unit per household/day as a merit good by the year 2012. The National Electrification Policy 2005, which preceded this by a year, targeted total village electrification by 2010 and total household electrification by 2012 (India Ministry of Power, 2005). The main program through which universal access objectives of the Electricity Policy are being implemented is the Rajiv Gandhi Grameen Vidyutikaran Yojana, launched in April 2005. A large effort towards grid extension and strengthening of the rural electricity infrastructure has been initiated through the Rajiv Gandhi Grameen Vidyutikaran Yojana. The government's Rural Electrification Policy 2006 also specifies, among other things, guidelines for decentralized distributed generation. The Ministry of New and Renewable Energy has also initiated a new remote village electrification program. Significant progress in providing access has been achieved in certain regions and states of the country. However, in other states, particularly among rural households, large fractions of the population are still in the dark. The ambitious targets for 2009, 2010 have not been met and future target for 2012 will also likely not be met given current trends (Pachauri and Mueller, 2008).

Access to Modern Fuels and Stoves

In 1980–1981, over 90% of energy used by households in India was from biomass sources. While this share declined to just over 80% in 2000–2001, the actual quantity of biomass consumed increased continuously over the entire period (Pachauri and Jiang, 2008). As observed in Table 19.6, major changes are evident in the percentage of persons using different energy types across rural and urban households over this period. The percentage of population using LPG increased from 9% to 61% in urban areas. However, in rural households the uptake of LPG was much slower and even in 2004–2005, only 12% of the rural population used this fuel. Thus, for the majority of the rural population even today, biomass remains the main source of cooking and heating fuel. Over 800 million people – 75% of the rural households and 22% of the urban households – rely on solid fuels in India today. Without any additional new policies, the number of people relying on solid fuels is projected to increase or at best remain unchanged by 2030.

In order to improve the access to improved end-use devices, especially among rural households who are likely to depend on biomass for the foreseeable future, the Ministry of New and Renewable Energy of the Government of India has launched a new initiative on biomass cook stoves, with the primary aim of enhancing the availability of clean and efficient energy for the energy deficient and poorer sections of society.

The new initiative is based on the recognition that cook stove technology has improved considerably in the past few years. But further advances are still possible and, indeed essential. The aim is to achieve the quality of energy services from cook stoves comparable to that from other clean energy sources such as LPG. Under this initiative, a series of pilot-scale projects are envisaged using several existing commercially-available and better cook stoves and different grades of processed biomass fuels. The goal of the program is to sell 150 million stoves in 10 years.

The Indian government is not alone in its effort to expand Indians' access to cleaner biomass cook stoves. International donors such as the Shell Foundation are increasing their support of cook stove programs that show potential for economic sustainability and scalability. Corporations such as Royal Philips Electronics, First Energy (formerly a BP company), and Bosch-Siemens, are developing cleaner cook stoves that can be customized for cooking needs around the world. Companies that can manufacture stoves include Envirofit, StoveTec, First Energy, WorldStove, and HELPS International. The Shell Foundation has invested US$3.5 million in Envirofit to support its program to sell 5–7 million stoves in seven states in India in the next five years and is investing several million dollars in a public awareness campaign. So far most companies are marketing only to consumers who can afford to pay about US$20 for a stove, which excludes the very poor. But Envirofit plans to launch a new model that customers can purchase through monthly payments to a microfinance company. The users will be required to pay about US$1 a month for around a year. Another payment option that stove companies, including Philips, may pursue is to seek carbon credits for cleaner stoves (Adler, 2010).

19.3.2.3 Other Developing Asian Countries

As mentioned above, Asia is a very diverse region. In this section we discuss the state of access in developing nations of Asia other than India and China. It is also one of the world's most dynamic regions, and as such, the region has made relatively rapid progress towards socioeconomic development. Even so, a very high level of the region's population lives in poverty, the highest in the world. As early as the 1970s, countries in the region had already adopted energy development programs that aimed to alleviate poverty. These energy development programs focused mostly on rural electrification because the majority of the poor people in these countries reside in rural areas. The view that rural electrification would be enough to generate rural development and lead to poverty alleviation was widely held when these programs were initiated.

Access to Electricity

About 14% of the total population without electricity globally is living in other developing nations in Asia. In the 1970s, nationwide electrification programs, which were generally based on grid-extension systems, were implemented with uneven success in several developing countries in the region, such as Bangladesh, Indonesia, Malaysia, Philippines, and Thailand. While some of these countries have been fairly successful in providing access to electricity to their rural populations, most of the rural population

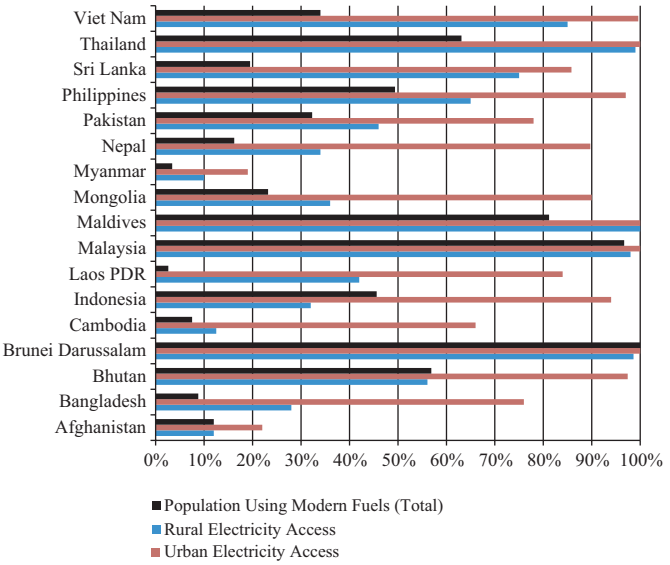

Figure 19.25 | Status of electrification and dependence on solid fuels in the Rest of Developing Asia. Source: UNDP and WHO, 2009.

in South Asia, other than in Sri Lanka and about 70 million Indonesians, are estimated to be unconnected to electricity (Figure 19.25).

More recently, Viet Nam and Laos have been extremely successful in improving the access to electricity for their populations. The World Bank and the Asian Development Bank have been particularly instrumental in improving access in these two countries.

Recent initiatives in the region have also focused on off-grid solutions to electrification and promoting renewable energy technologies. For instance, The Grameen Shakti Solar Home Systems Program in Bangladesh sells SHSs on credit. It is implemented in several districts of the country and initially targeted the installation of 8000 systems in three years. Since the systems are expensive, Grameen Shakti, part of the microfinancing institution Grameen Bank, has introduced soft-financing systems for the customer. Grameen Shakti encourages PV users to venture into income generating activities using their PV systems such as charging cellular phones; provision of light to post-harvest processing facilities, small enterprises, household-based livelihood activities and clinics so these can extend operations to early evening hours (thus increasing daily income); and power for radio/television repair shops (Shakti, 2010).

Access to Modern Fuels and Stoves

The problem of provision of modern energy for thermal energy needs remains a larger challenge for Asia. For most countries in the region, the majority of the rural population relies on unprocessed biomass or coal for most of its cooking and heating needs. Bringing about shifts in the energy-related behaviors of millions of households requires strong policies and large investments. Though complex, the problem of solid fuel use is not insoluble. Programs to reduce solid fuel use have been successful, most visibly the Chinese National Improved Stove Program mentioned above. Within other countries in the region, relatively little change in the dependence of rural populations on traditional solid fuels has taken place.

Box 19.10 | Enterprise Approach to Improved Cook Stove Programs in Asia

The Sri Lankan Anagi stove was promoted by encouraging artisans to enter business as mass producers of stoves that they market through normal market mechanisms. Village potters were trained to manufacture the models made of clay within strict standards. General distributors (wholesale buyers) visit the production centers to buy the stoves in bulk. Producers thus have their regular buyers. Stoves purchased are distributed to retail shops spread over a radius of about 200 km. Small producers living in isolated areas sell their products directly in the village. Today, about 300,000 stoves are annually produced by 120 rural potters trained by an NGO (IDEA) scattered in 14 districts of the country. The Anagi ICS has become one of the most widespread pottery items in village grocery stores.

In Cambodia, the Cambodia Fuelwood Saving Project provides technical and business development training to stove entrepreneurs to produce improved cook stoves. For each ICS, the producers invest an average of US$0.50 more than for a traditional stove. The Cambodia Fuelwood Saving Project has also created the Improved Cook Stove Producers and Distributors Association of Cambodia, which facilitates sectoral development, quality assurance, and the long-term sustainability of ICS dissemination.

In the Nepal program, capacity building inputs are provided by the government agency Alternative Energy Promotion Centre, which supported the participation of the informal private sector in cooperation with the Center for Rural Technology and other NGOs. Stove artisans (many of them women) have been trained and are now paid for their services constructing and maintaining stoves in their villages. The constructions of the improved stoves are exclusively carried out by these trained, predominantly women, masons. In 2005, there were about 1700 such trained technicians.

A UNDP survey of poor communities in the Asia Pacific region clearly indicates that rising oil prices left the poor with few choices other than to cut back on their consumption of oil products or, for uses that cannot be avoided, to bear the higher prices and look elsewhere in their household budgets to find the additional money (UNDP, 2007c). Since the urban poor rely more on oil products like kerosene and LPG, they are worse off than their rural counterparts, who are either biomass users or have the biomass option to fall back upon. The rural poor, however, are more vulnerable to higher lighting fuel prices, especially in unelectrified villages but also in electrified villages subject to frequent supply disruptions. Improved cook stove initiatives have been seen to be an important complement to improve cooking energy services for the poor and militate against rising oil prices.

19.3.3 Latin America and the Caribbean

The levels of access to electricity and clean cooking services in Latin America and the Caribbean (LAC), as shown in Section 1 of this chapter, are much higher than those in the other developing regions. Close to 90% of the region's population have access to electricity, compared to 62% for South Asia and around 28.5% for sub-Saharan Africa. (World Bank, 2010a). Access levels for clean cooking (and heating) services follow a similar pattern, with Latin America leading the way followed by Asia and then sub-Saharan Africa. Nevertheless, in Latin America and the Caribbean, approximately 200 million people currently live under the poverty line, and approximately 133 million live in urban areas and 67 million in rural areas. Seventy-two million are in absolute poverty (50% in urban areas and 50% in rural areas).

Table 19.7 shows that approximately 21.5 million people are estimated to have no access to electricity in the sample of the 14 most populated countries in the region (excluding Mexico). The largest numbers of people without access to electricity are concentrated in Peru and Brazil (over 7 million each); Bolivia, Guatemala, and Honduras (over two million each); and Nicaragua (over 1.5 million). Table 19.7 also highlights that in most countries, over 70% of the people without access to electric service are poor.

19.3.3.1 South America

The lowest energy use rates for modern energies are invariably in nations with the lowest Human Development Index (HDI) rankings. The correlation between access to modern energies, per capita energy demand, and HDI rankings are not exclusive to this region and similar correlations are observed worldwide (Fig 19.26).

In general, in all LAC countries the poor use less energy than the other social strata but they spend a higher proportion of their income on energy than the non-poor. Additionally, lower energy use by the poor is reflected in the differences in the level of access to equipment between income quintiles.

However, illegal connections, especially to electricity, could reflect very high consumption levels for services like cooking or heating. Energy access policies should be combined with efficient use of energy programs in closer coordination with public utilities.

Table 19.7 | Estimates of population without access to electricity in a sample of Latin American countries.

Country	Poor population without electric service (thousand)	Non poor population without electric service (thousand)	Total population without electric service (thousand)	% poor in total population without electric service	Country share % in total population without electric service
Argentina	57	91	148	38%	0.5%
Bolivia	2904	708	3611	80%	12.2%
Brazil	5123	2753	7875	65%	26.7%
Chile	62	168	231	27%	0.8%
Colombia	420	956	1376	31%	4.7%
Costa Rica	34	18	52	66%	0.2%
Ecuador	51	15	66	77%	0.2%
El Salvador	751	191	942	80%	3.2%
Guatemala	2569	687	3256	79%	11.0%
Honduras	2272	210	2482	92%	8.4%
Nicaragua	1377	219	1596	86%	5.4%
Paraguay	510	75	585	87%	2.0%
Peru	5264	1982	7245	73%	24.6%
Venezuela	16	19	35	46%	0.1%
Total estimate	21,410	8092	29,501	73%	100.0%

Access to Electricity

The process of rapid urbanization in South America and domestic migration from rural to urban areas has been accompanied by an increasing need for energy, but has also made it easier to provide electricity access. In effect, a high density concentration of potential consumers has meant lower costs to expand distribution systems. Greater access to employment for the new inhabitants of the cities has been accompanied by higher payment capacity from an important share of urban consumers. The combination of these different issues has provided an important opportunity for cross subsidies to facilitate access for the poor population.

The information at the national-average level conceals large differences between urban and rural areas (Figure 19.27). For instance, countries with a relatively higher development level have problems of extreme poverty more serious than those of relatively lower development.

Even in countries with significant electricity access, poor households generally lack basic electrical equipment to benefit from energy services and have very limited access to communication and information technologies in comparison with the upper income groups within the same country. As shown in Figure 19.28 below, the percentage of upper income population (q5) with access to electric and communication equipment, relative to the percentage of lower income (q1) with access to the same type of equipment, can be 10 to 40 times as large in countries like Brazil, Uruguay, and Paraguay, which already have more than 90% electrical coverage. These data highlight the fundamental role of providing equipment in order to achieve effective access to energy services as coverage is extended to the poor sectors of the population.

Access to Fuels

The consumption of firewood in households drastically reduced from the 1970s to mid-1990s. Since then, firewood consumption has remained stable or even grown in some cases as shown in Figure 19.29. This

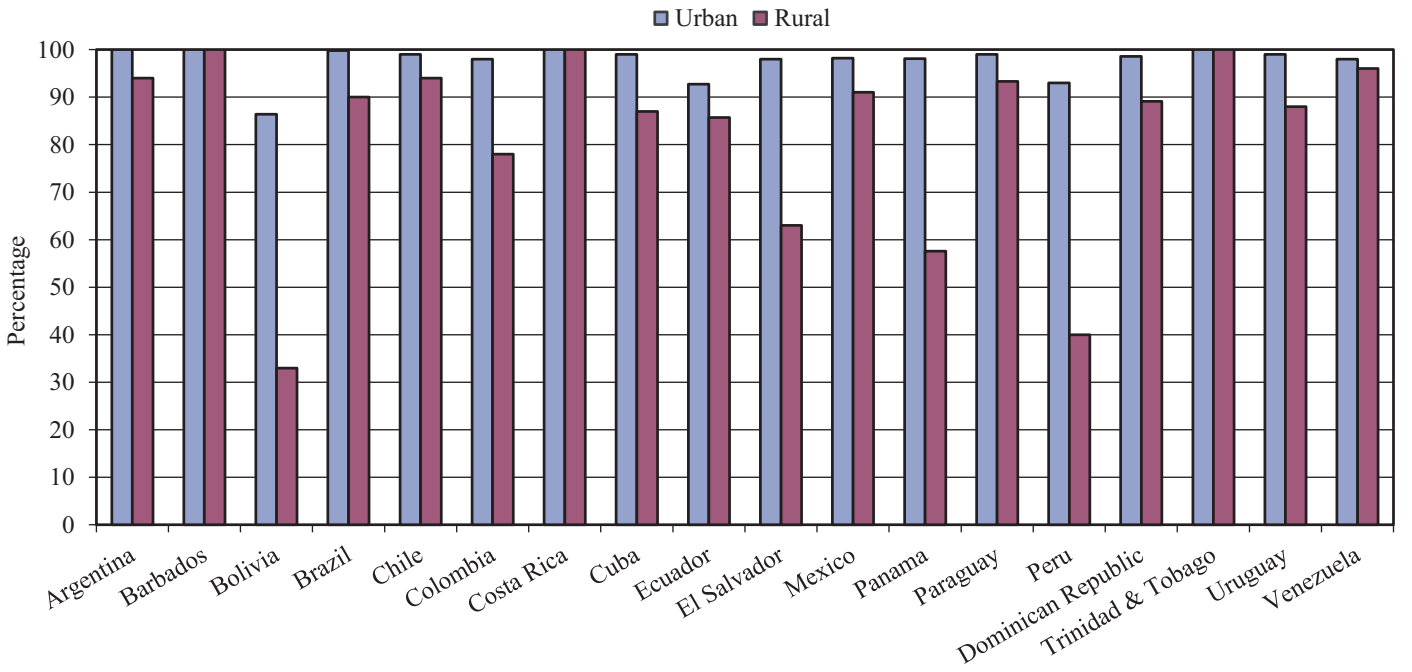

Figure 19.27 | Access to electricity in urban and rural areas of Latin America. Source: OLADE, 2008.

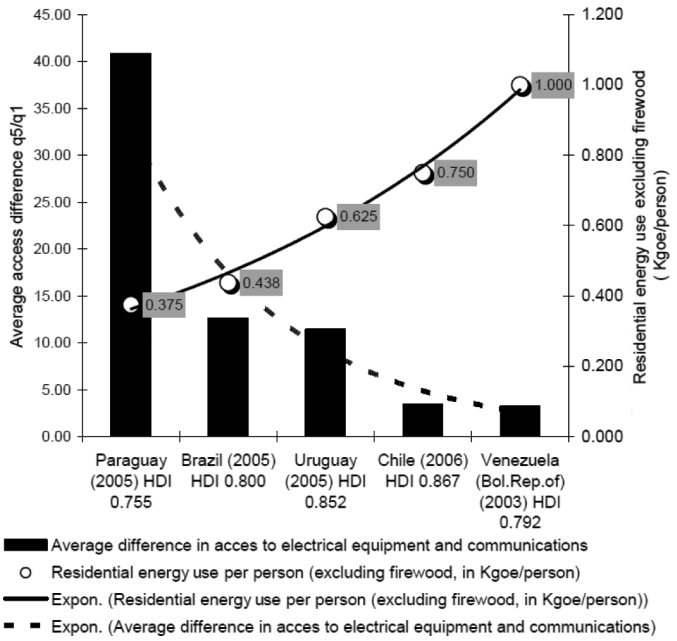

Figure 19.28 | Differences in access and use across income quintiles in select countries of Latin America. Source: ECLAC et al., 2010.

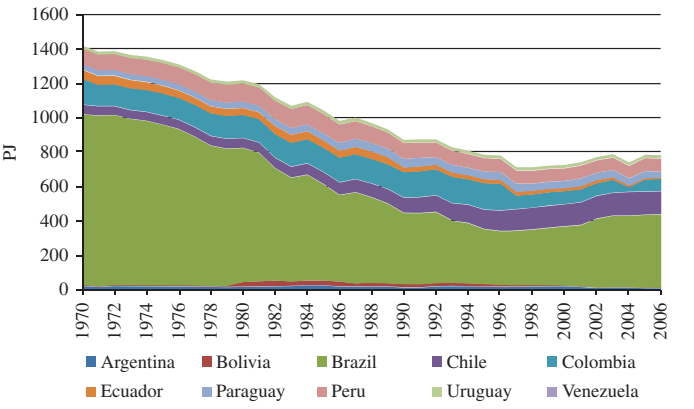

Figure 19.29 | Evolution of firewood consumption in the South American household sector. Source: based on estimates with data from OLADE, 2008.

phenomenon has been the result of rural-urban migration processes more than the introduction of end-use technologies for firewood savings. For instance, the diffusion of improved fuelwood stoves in South America is low compared to other developing regions like China and India.

In some countries, like Brazil, Chile, and Uruguay, the daily consumption of firewood per inhabitant has been growing systematically. Therefore, despite the rural-urban migration processes and the resulting reduction of the rural population, the total consumption per inhabitant has increased. This situation represents many simultaneous realities, as in the case of Brazil where, in spite of a decreasing trend in the per capita consumption, the energy balances have shown a significant growth in firewood consumption since 1996. In the case of Chile, the consumption of firewood per rural inhabitant has also grown systematically. This may be the result of both the introduction of sustainable-use firewood programs and the impact of better living conditions of the rural population vis-à-vis the lack of commercial energy products that compete with firewood.

Use of LPG or natural gas is a clear indicator of increasing income levels and appears to be most preferred fuel among the rich, as shown for

Table 19.8 | Energy sources used for cooking according to income quintiles.

Argentina	Q1	Q2	Q3	Q4	Q5
Natural Gas	56.6%	57.8%	66.9%	76.4%	89.7%
LPG	40.2%	40.0%	32.3%	23.4%	10.3%
Brazil	**Q1**	**Q2**	**Q3**	**Q4**	**Q5**
LPG	43.5%	52.4%	58.9%	62.9%	72.2%
Firewood	47.5%	40.3%	37.6%	33.3%	26.2%
Charcoal	8.7%	7.0%	3.0%	3.3%	1.2%

Source: based on ECLAC et al., 2010 and OLADE, 2008.

Box 19.11 | The Brazilian Experience with LPG

In Brazil, 98% of households (including 93% of rural households) have access to LPG – a situation attributable to a government policy that has promoted the development of an LPG delivery infrastructure in all regions, including rural area, and subsidies to LPG users (Jannuzzi and Sanga, 2004; Lucon et al., 2004). Until the late 1990s, the rise in LPG use was accompanied by a sharp decline in residential wood consumption.

During the period 1973–2001, retail LPG prices were set at the same level in all regions and the average level of the subsidy amounted to 18% of the retail price. In May 2001, end-user prices were liberalized, as part of a process of deregulating the petroleum sector. At the same time, the government introduced an Auxílio-Gás ("gas assistance") program to enable qualifying low-income households to purchase LPG. Qualifying families were those with incomes less than half the minimum wage (an average daily per capita income of US$0.34/day in 2003). The total program cost in 2002 was about half that of the LPG price subsidization. This program now forms part of the Bolsa Família, by far the largest conditional cash transfer program in the developing world. Recent LPG price increases, however, appear to have led to a reversal of the trend toward lower residential biomass consumption.

Source: IEA, 2006

Brazil and Argentina in Table 19.8. In the case of Argentina, the availability of natural gas has resulted in the replacement of LPG. The lack of availability of natural gas in Brazil has meant that LPG is the preferred fuel for the rich.

19.3.3.2 Central America

The population growth of Central America has been accompanied by rural-urban migration processes, which are generally the consequence of poverty and scarce work opportunities in the rural areas. In 2005, the number of urban inhabitants reached 27.8 million people (57% of the total population) and rural inhabitants were at 21.2 million (43%).

At the beginning of the 1990s, 60% of the total population in Central America lived below the poverty line and 73.7% of the poor lived in rural areas. By 2001, the percentage of the population living below the poverty line had decreased to 50.8%, with 33.6% of the poor living in urban areas and 67.9% in rural areas. Despite this percentage reduction, the absolute number of poor people increased due to the high population growth of the region. The countries with less inequality in income distribution are Costa Rica and El Salvador, while Honduras and Nicaragua are the poorest and least developed countries of Central America.

Access to Electricity

The poorest populations in Central America generally have low access to electricity, as shown in Figure 19.30 for different income levels and various countries in the subregion. Honduras and Nicaragua show the highest levels of population without access to electric power, with 80% of the rural population in these two countries falling into the first quintile.

Even though significant progress may be noted in the level of electrification for every country in Central America, there are still approximately eight million people that do not have access to electricity, most of them in Nicaragua, Honduras, and Guatemala, and poor families in rural areas are generally not connected to the electricity grid (Serebrisky, 2007). Also, electricity accounts for close to, or more than, 10% of household expenditures for the poorest populations.

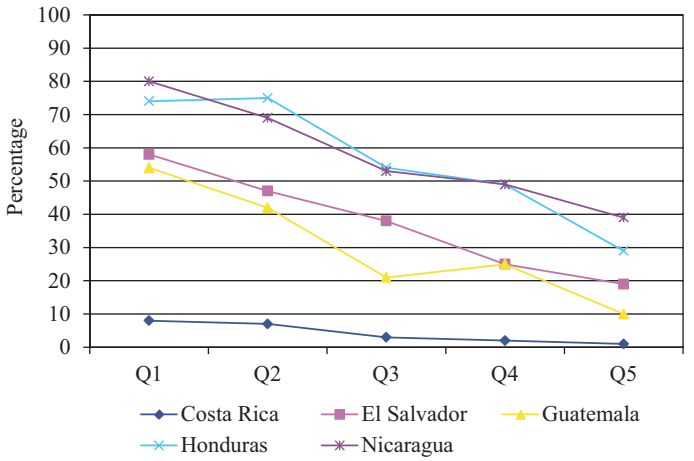

Figure 19.30 | Population without access to electricity in rural areas of Central America, by income level. CEPAL, 2011.

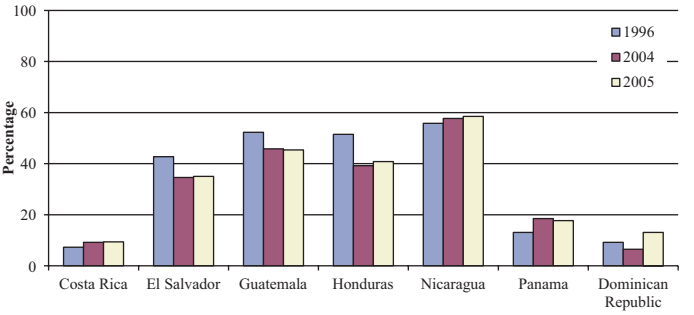

Figure 19.31 | Share of firewood in final energy demand (1996, 2004, and 2005). Source: based on OLADE, 2008.

Access to Fuels

Several LAC countries have implemented subsidies on LPG, considered the fuel of the poor. The following countries, in particular, have LPG subsidies: Argentina, Bolivia, Brazil, Colombia, Cuba, Ecuador, El Salvador, Haiti, Dominican Republic, and Venezuela (OLADE, 2008).

The poorest populations in Central America as a whole also largely depend on biomass (mainly in the form of firewood), which in 2006 represented 83% of the energy used to meet cooking and heating needs. Energy sources for cooking are mainly firewood, electric power, and LPG. Modern energy sources like LPG for cooking and heating have increased, but firewood is still the most widely used in terms of percentages.

There are significant differences in the types of energy for cooking across the subregion, as shown in Figure 19.31, with the following key features:

- electric power (high percentage both in urban and rural areas) – Costa Rica;
- LPG (most widely used) – Dominican Republic;
- LPG and firewood (both widely used) – El Salvador; and
- firewood (highly used) – Nicaragua, Honduras, and Guatemala.

Firewood thus plays an important role in final energy demand in Guatemala, Nicaragua, Honduras, and El Salvador, while the importance of firewood is relatively low in Costa Rica, Dominican Republic, and Panama. In general, LPG (or electricity) does not fully replace firewood in rural areas, but the different fuels are used complementarily; in some cases, firewood is used for cooking and LPG is used for water heating or precooked meal heating (Díaz, 2008).

For the whole subregion, firewood consumption accounted for 37% of the total energy supply and 83% of household energy supply in 2005. In terms of per capita consumption, Nicaragua and Guatemala are

Box 19.12 | The Justa Stove, Guatemala

A fuel-efficient stove called the Justa stove has been developed by Trees, Water and People (a charity working in Central America), the Aprovecho Research Center, the Honduran Association for Development, and Doña Justa Nuñez, a Honduran woman who helped design her namesake stove. The stove uses up to 70% less fuel than the open wood fires and because the design and materials used are simple, it can be made locally, using local materials, and adapted to meet local needs. Because it uses less fuel, the Justa stove decreases deforestation.

The Justa stove is relatively simple in design and can be made easily by local people in a day or less using locally available materials. The new owners of the stove have to contribute materials to the building of the stove. This gives them a personal investment in the stove, making them more likely to take good care of it.

Each stove saves 7.5 tonnes of CO_2 over a 7.5 year period. Each stove saves an average of 1 tonne of CO_2 emissions/year and 78 cubic meters of firewood over a 7.5 year period.

Table 19.9 | Electricity demand profile for the Caribbean region, selected countries.

Selected countries	Installed Power Capacity (MW)	Access to electricity (Total)	Access to electricity (Rural)	Per capita consumption (kWh)
Barbados	210	98%	n/d	1941
Cuba	5430	95%	87%	2321
Dominican Republic	5518	96%	89%	168
Grenada	32	82%	n/d	53
Guyana	308	82%	n/d	1220
Haiti	244	34%	n/d	341
Jamaica	854	95%	n/d	4769
Suriname	389	97%	n/d	1941
Trinidad & Tobago	1425	92%	n/d	2321

the countries with the highest firewood consumption; Honduras, El Salvador, and Panama are at an intermediate level, while Costa Rica and Dominican Republic show the lowest per capita consumption levels. The highest consumption is by lower income families in rural areas. Firewood consumption per capita in Costa Rica, Nicaragua, and Panama has tended to increase.

Sustainable energy for cooking has been pursued by means of different approaches: the adoption of new technologies like improved stoves, the introduction of modern fuels in rural areas to substitute for or complement the use of firewood, and access to electric power through energization programs in these rural areas.

19.3.3.3 The Caribbean

The Caribbean subregion faces huge challenges arising from modern globalization, declining competitiveness, trade liberalization and eroding preferences, the rising cost of imported fuel, the revolution in information technology, and very high vulnerability to natural disasters. Additionally, very high debt has placed seven Caribbean countries among the 10 most indebted countries in the world. The region is also heavily dependent on fossil fuel combustion, with petroleum products accounting for an estimated 93% of commercial energy use. The islands of the Caribbean are predominantly net energy importers, with the exception of Trinidad and Tobago.

Access to Electricity

With the exception of Cuba, Haiti, Dominican Republic, and Jamaica, the Caribbean countries are generally very small island states with populations of around one million or less and with a very important share of rural population. As shown in Table 19.9, yearly electricity consumption for these countries is well below 5000 kWh. However, data on access levels are difficult to find.

19.4 Conclusions for the Way Forward

Access to affordable modern forms of energy for populations currently without is a necessary albeit insufficient step toward poverty alleviation and the achievement of the MDGs. Providing universal access to electricity and modern fuels is not just a moral imperative. A growing body of knowledge shows that it also fosters significant social benefits and environmental improvements. It can also bring significant economic returns, particularly if policies and programs encourage the productive uses of energy to create new employment and income-generating activities through more conducive institutional mechanisms. A greater focus on scaling up pilot and demonstration projects to larger populations is also needed. The assessment of past policies and programs to improve access across different regions of the world carried out in this chapter point to the need for a paradigm shift in the approach to energy planning to meet the energy needs of the poor. An explicit focus is required on energy services. This should include a comprehensive demand-side analysis of the energy needs of poor people to support their livelihood functions, taking into account their particular constraints and opportunities. Current supply-side approaches that simply take as their starting point the provision of modern energy carriers such as electricity, petroleum, or gas, or equipment of a particular type (solar technology, improved cook stoves, biogas) are not sufficient to reap the full potential of social and economic improvements that follow from improved energy access.

A first step to achieving the paradigm shift needed in energy planning for the poor is establishing effective data collection systems based on accepted definitions and indicators of access to measure progress towards energy access targets or goals. The review included in this chapter points to significant data gaps regarding the existing energy access and use patterns in the poorest regions and for the poorest communities. Indicators that adequately assess the energy needs and describe the living conditions of such communities are required Consistent measurement frameworks and regular data collection systems on assessing

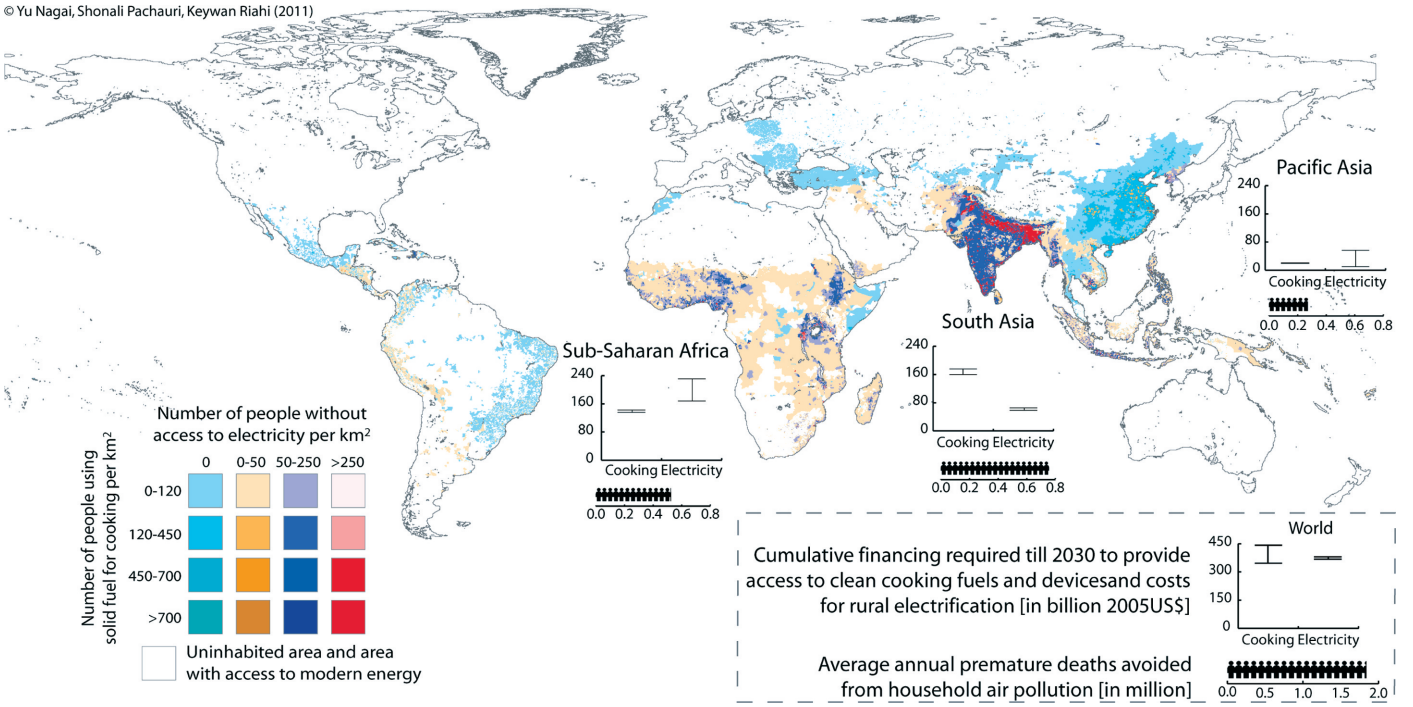

Figure 19.32 | Density of population lacking access to modern energy in 2005 and costs and health benefits of achieving a universal clean cooking and electrification goal by 2030. Colored areas show densities of people per km² without access to electricity and those that use solid fuels for cooking, e.g., dark blue and brown areas are where people do not have access to electricity and cook predominately by solid fuels. Cumulative investment requirements between 2010 and 2030 are shown for three GEA world regions and for the globe as a whole in billion 2005 US$. Also shown is the estimated population that would die prematurely from household air pollution if universal access is not achieved by 2030 (in million).

the energy situation of the poor are still lacking in many nations. In addition, the evaluation of many energy access programs and projects often fail to provide a comprehensive assessment of the impacts. An increase in the evidence base of the positive and significant impacts of such policies and projects can be instrumental in increasing efforts to enhance access activities globally.

Experience to date has resulted in a number of lessons that we must keep in mind when designing policies and programs to improve energy access in the future. Access programs and efforts are more likely to succeed if communities have an adequate understanding rather than act as passive recipients. Those designing and implementing programs need to understand that encouraging uses of energy for income generation, if built into the design of the access programs, is likely to improve sustainability. Programs that have built-in components for community training on operation and maintenance, as well as follow up with providers also have a higher likelihood of success. The extent of government commitment in creating an enabling environment is also paramount to the success of all policies. Improved access to capital that can help secure adequate financial resources, and market development that puts the customer at the center, are important for the successful scale-up of activities. Chapter 23 provides a more in-depth assessment of the full range of policies that are needed to achieve the ambitious energy access targets discussed in this chapter.

The GEA access scenarios[14] explore global strategies toward universal access to affordable and modern sources of energy by 2030. Specifically, the target calls for the provision of electricity and clean cooking fuels, including distribution of improved end-use devices to all those who currently lack access. Achieving the access goals creates multiple benefits for broader development goals, including increased productivity and decreased household air pollution and land degradation. The GEA scenarios indicate that such ambitious targets are feasible as long as financial support for dedicated access policies is provided. With respect to policies for energy access to clean cooking, the assessment suggests that fuel subsidies alone would be neither sufficient nor cost-effective in terms of achieving ambitious energy access objectives. Financial mechanisms, such as microcredit or capital grants, will need to complement subsidies to make critical end-use devices such as clean cooking stoves and connection costs affordable to the poor. The GEA scenarios estimate that the total costs for providing clean cooking services are between US$17–22 billion/year until 2030, with the difference of about US$4.7 billion/year an estimate of the capital cost associated with stove purchases that could be either met through public grants or microfinance options. While the subsidy component of this cost is substantial, it represents less than 5% of present day global fossil fuel subsidies.

14 Please refer to Chapter 17 for a detailed description of the GEA access scenario results.

Scenarios regarding future electrification across world regions vary tremendously, as the base level of electrification across regions is already significantly different and costs for providing grid access, which is dependent on population density, also vary enormously. The GEA electricity access scenarios, described in greater detail in Chapter 17, suggest that the investments required for additional electricity generation, operation and maintenance of plants, and rural grid expansion to reach the almost universal access target by 2030 would be between US$18.4–19 billion/year.

This suggests that the total cost for providing almost universal access to electricity and clean cooking by 2030 is between US$36–41 billion/year. There are two underlying reasons for the large range in the cost estimates derived from the GEA access scenarios. First, in the case of the estimates for providing clean cooking, the range in the estimates reflects whether the costs of new LPG stoves are assumed to be included or not. If these costs are assumed to be met through microfinance institutions, they are not included in the total cost estimate. However, if the cost of stoves is met from public grants, they are included in the estimate. The range in the cost estimates for electrification stems from differences in the modeling approaches used. A large range of estimates for the costs of providing access is also evident from a review of the literature. Typically, the global estimates range between US$30–40 billion/year (see Bazilian et al., 2010 for a recent review), though much higher estimates also exist specially for electrification. The wide range in global estimates parallel the wide range in the costs of providing access across different regions. The investment gap varies tremendously by region (see Figure 19.32). Chapter 23 provides a more in-depth and detailed discussion of the sources of funding that will need to be tapped to meet this investment gap and the kind of regional policies that will be needed for enhancing energy access. Spending on policies and measures to achieve access goals by 2030 will improve the welfare of those benefiting in several ways. Health impacts from improved household air quality have been quantified in Chapter 17. Access policies will result in averting between 0.6 and 1.8 million premature deaths, on average, every year until 2030 and saving about 24 million Disability Adjusted Life Years annually. Additional benefits that are likely to be substantial include time savings for women and children and the potential for improved livelihood opportunities.

Executive Summary

Sustainably managing limited resources, such as productive land areas and available freshwater, will be one of the world's most pressing challenges in the coming years. Population increases and economic growth will significantly influence humanity's future demand for land and water for different uses. In particular, changes in food and energy use will have substantial environmental impacts. They will also influence each other in many ways. At the same time, the production of food and energy, and the water resources they require, will be affected by global climate change. Sustainability issues arising from competition and synergies between future production of bioenergy and food, and related water use, are highly important in this context.

Population growth is one of the factors contributing to increased demand for land and water. While the world's population has approximately doubled since the 1960s, global economic activity has increased approximately 40 fold. Since growth in incomes is strongly correlated with increased consumption of animal-derived food (meat, milk, eggs), the combination of population increases and economic growth will likely result in increased feed and food production. This will drive up pressures on land and water resources if not counteracted by innovations that reduce land and water use. Social inequities are increasing as well, with both very rich and very poor populations often practicing 'inefficient' methods of using land and water.

Considering the importance of these issues, in particular the need to achieve the Millennium Development Goals (MDGs) and beyond (see Chapter 2), the objective of this chapter is to assess and discuss major trade-offs related to the different uses of land and water, in particular related to future energy systems, and to discuss the corresponding sustainability issues.

With respect to land use, this chapter aims to evaluate land availability, including land for bioenergy production. It discusses competition for land from different uses (food, fuel, timber, etc.), environmental impacts, and implications for natural resources (e.g., biodiversity, atmosphere, water), as well as social factors such as food security, health, and incomes.

With respect to water use, the chapter discusses water demand for different kinds of uses, with a special emphasis on water for bioenergy crops in potential competition with water needed for food production. The multiple uses of water considered include human consumption, hydro and thermal power generation, manufacturing, agriculture, water supply security, and bioenergy. Environmental, social and strategic factors, and potential trade-offs, are examined. Competition between food and energy crops may not always be over 'the same water.' Depending on the type of feedstock, it is possible to cultivate energy crops in areas where conventional food production is not feasible due to water constraints.

This chapter confirms major studies suggesting that global land and water resources will be sufficient to adequately nourish a world population of 9–10 billion people in 2050. However, the potential to additionally produce crops for bioenergy will depend on future changes in food systems (including diets), population growth, and agricultural technologies to improve crop yields and livestock feeding efficiencies, institutional arrangements, climate conditions and area demand for biodiversity conservation. Recent studies suggest that the technical potential for bioenergy production is uncertain due to these factors, which are difficult to predict. Studies mentioned in IPCC (2011) indicate that the technical bioenergy potential may reach up to 500 EJ/yr, while others found much lower potentials. This chapter only discusses the potential of dedicated energy crops.[1] Considering sustainability constraints related to possible competing land demands (food, feed and fiber production, biodiversity conservation, etc.), problems posed by possible

1 Dedicated (bio)energy crops are "[f]ast growing species whose biomass yields are dedicated to the production of more immediately usable energy forms, such as liquid fuels or electricity" (Sartori et al., 2006). Dedicated energy crops refer to any crop that is grown for the primary purpose to obtain bioenergy, e.g., sugarcane, switchgrass, or Salix. These crops may, of course, also be grown for other purposes. See also SECO, 2008.

deforestation, and water availability, three studies analyzed in this chapter (van Vuuren et al., 2009; Erb et al., 2009; and WBGU, 2009) found global bioenergy crop potentials of 44–133 EJ/yr in 2050. Another study, Dornburg et al. (2010), concludes that for energy crops (dedicated energy crops) they are 120 EJ/yr. So the range considered in this chapter is 44–133 EJ/yr for 2050.

For a full evaluation of all other bioenergy potentials except dedicated bioenergy crops, see Chapter 7. Chapters 11 and 12 discuss technologies and utilization pathways, including biofuels and power generation from biomass.

Reaching the stated technical bioenergy potential depends on many important factors (land and water availability, feedbacks between food, livestock and energy systems, climate change, etc.). Land allocation for different purposes will have to be monitored and managed carefully through adequate policies to minimize competition between food, bioenergy and fiber markets. Adequate policies to introduce bioenergy plantations to avoid adverse social, economic and ecological effects are also needed, since best-practice examples suggest that such plantations could be sustainable if based on sound strategies. Monitoring, managing and enforcement are required to ensure sustainability of bioenergy production. Policies for sustainable land (and water) use must include agro-economic-environmental zoning and planning, in order to consider specific environmental conditions of each region, like those already existing, for example, in Brazil.

The impact of increased biofuel use on food prices has been debated widely and is also covered here. Adequate food production for the world's growing population strongly depends on future dietary choices as well as the development of agricultural technologies that increase agricultural yields and livestock feeding efficiency through enhancements in crop management and/or genetic modifications, as well as institutional changes. The impacts of biofuel production on agricultural markets and food systems will be minimized if adequate policies for biofuels are in place to ensure sustainable production, prioritize the diversification of technologies and fuels, and identify different options for the future, based on adequate environmental zoning and sustainable policies. This must occur through public intergovernmental policies that govern and regulate markets and stimulate the adoption of efficient technologies. These policies include biofuel sustainability schemes based on certification schemes. Integrated optimization of food and bioenergy production – for example, through the use of by-products and residues, or through optimization of land allocation (zoning) – can help to mitigate possible adverse effects.

Climate change can have a substantial effect on land-use systems, but its impacts are still imperfectly understood. In subtropical and tropical regions, changes in climate and rainfall may change the agricultural suitability of a region significantly. Temperature increases may lead to a shift of some crops and agricultural areas to regions with more temperate climates, or with higher levels of soil moisture and rainfall. In general, crop productivity in the tropics may decline even with a slight increase in local temperatures (1–2°C). An increase in vulnerability of food production due to climate change may also increase the risk of hunger to a large number of people in the world, mainly in poor countries, which are most vulnerable to the effects of global warming and the least prepared to deal with its impacts (IPAM, 2002).

The chapter's main conclusion on water trade-offs is that the increasing stress on freshwater resources brought about by ever-rising demand, due mainly to population growth, is of serious concern. As population increases and development requires additional allocations of groundwater and surface water for the domestic, agriculture, energy and industrial sectors, the pressure on water resources will continue to intensify, leading to further tensions and conflicts among users, and degradation and pollution of the environment. Contamination of rivers, depletion of aquifers and increased utilization for multiple purposes are challenges commonly found in regions where demand exceeds supply and where water management is poorly conducted. Indicators such as water footprints are important to understand these important issues.

Water scarcity leads to competition between different uses, with competing demands from: cities and rural areas; rich and poor people; arid lands and wetlands; public and private sectors; infrastructure and natural environments; mainstream and marginal groups; and local stakeholders and centralized authorities. Water conflicts can arise in water-stressed areas among local communities, and countries, because sharing a very limited and essential resource is extremely difficult.

The lack of adequate legal instruments exacerbates already difficult conditions. In the absence of clear and well-established rules and regulations, severe tensions tend to dominate, and political and economic power can play an excessive role, leading to inequitable allocation of water. A well-developed system of Integrated Water Resources Management, including adequate institutional set-up and a good governance system, is needed in river basins or confined regions where demand exceeds existing supply.

Climate change is expected to account for about 20% of the global increase in physical water scarcity – and countries that already suffer from water shortages will be hit the hardest. This would include African countries, where water is a limiting factor for agricultural food production and also essential for income generation.

20.1 Introduction

World population growth, changing diets and increasing urbanization result in a surging demand for products and services that require land and water as significant inputs. In connection with these changes, increased consumption of fibers (including wood) and bioenergy are likely to lead to a considerable growth in humanity's need for biomass from agriculture and forestry. How this will affect global land and water systems will depend on innovations in agricultural technology as well as future changes in social, economic, political and legal factors that affect land use, such as land tenure, property rights, subsidies, and markets for land and agricultural products, water access and bioenergy (Global Land Project, 2005; Turner et al., 2007).

Moreover, demand for water is likely to be driven up by changes in infrastructure (households, buildings, schools, hospitals, etc.), increased requirements for basic sanitation and drinking water, energy sector uses (e.g., for hydroelectricity or cooling water) and other factors. With increasing purchasing power, consumer preferences and behavior will affect the dynamic interplay between production, demand and consumption, and the efficiency of the whole system. Consumers continue to intervene in the impacts on the water cycle through their preferences for, and use of, various goods and services.

In order to address this complex and intertwined set of challenges, a separate chapter was proposed for a comprehensive discussion of the trade-offs and synergies involved in the use of land and water, particularly as they might affect future energy systems. In presenting this discussion, Chapter 20 addresses critical issues related to environmental and social sustainability, and their policy implications. This chapter discusses only regional and global potentials for primary bioenergy from dedicated energy crops in the year 2050, taking into account sustainability constraints and interactions with other sectors such as food supply and agriculture. Chapter 7 discusses the main concepts and potentials related to all types of primary energy resources, including all types of bioenergy (residues, animal manures, municipal solid wastes, and forestry residues) except energy crops (these potentials are taken from this chapter). Chapters 11 and 12 discuss technologies and utilization pathways, including biofuels and power generation from biomass.

The term 'bioenergy' here denotes all kinds of biomass feedstocks that can be used to produce energy carriers or heat from biomass (excluding nutritional energy for humans and livestock). This ranges from combustion of any solid biomass, including municipal and rural solid waste for heat and/or electricity production to recently introduced technologies such as production of liquid or gaseous fuels for use in vehicles from sugarcane, corn, wheat or oil crops (rape, oil palm, etc.) or other biomass. This chapter only discusses primary biomass potentials (i.e., it estimates the total amount of plant biomass (feedstock) that might become available for energy conversion processes) from energy crops; issues of total biomass energy potential (including residues and biomass from forestry) are evaluated in Chapter 7.

There are concerns related to limited availability of suitable land and/or water resources for bioenergy production. This chapter addresses this controversy and discusses recent studies estimating land areas that will be available for bioenergy as well as their productivity potential. It suggests that despite several possible constraints, significant energy crop potentials could be realized if appropriate policies are implemented (IPCC, 2000; Goldemberg et al., 2008; WBGU, 2008; Erb et al., 2009; van Vuuren et al., 2009; Haberl et al., 2010; 2011).

With respect to land, the main aim of this chapter is to discuss issues of land availability for all uses and land suitability for bioenergy production. This discussion is based on the 'food first' principle, i.e., the assumption that the provision of adequate food supplies must be guaranteed when evaluating bioenergy production options (e.g., Sims et al., 2007).

Limits to freshwater availability are also highly relevant in the context of biomass production and demand, as water is a critical input affecting the primary production of terrestrial ecosystems, including agro-ecosystems. In addition, water availability is critical for many other aspects of energy systems, including hydropower, cooling water, etc. Countries have mainly controlled water by the supply-side management approach, balancing supply and demand in an increasingly precarious way, since exploitation and water consumption indices do not take into account either ecological water demand or the spatial and temporal variability of supply and demand (EC and IPTS, undated).

The following considerations are important when discussing trade-offs and synergies related to land availability:

- The productivity of land areas depends on climate and soil conditions, nutrient inputs (e.g., fertilizers), water availability (including for irrigation when needed), and many other natural and socio-economic factors. Net primary production (NPP, i.e., biomass production per unit area and year) and the production of usable plant parts (e.g., grain in the case of cereals) depend on natural conditions and management alike. Even assuming that there is enough land available for all end uses (Berndes et al., 2003; Goldemberg, 2009), the area available for bioenergy crops, as well as for food, feed and fiber, depends on agricultural yield levels.

- Sustainability of land use in agriculture and forestry is a critical issue. While increases in yields achieved through agricultural innovation can help to save land and thereby to reduce environmental problems (Burney et al., 2010), agricultural intensification has also created a host of social and environmental problems such as nutrient leaching, soil degradation, toxic effects of pesticides, and many more (IAASTD, 2009). Therefore, it is necessary to mitigate any negative environmental effects of the agricultural intensification intended to produce yield growth. When used appropriately, land can generate more than one type of product (such as food, feed, energy, or materials) or service (including protection of the soil, wastewater treatment, recreation, or nature protection) – an observation usually denoted

as 'multifunctionality' or multiple use (Börjesson, 1999; Londo, 2002; Lewandowski et al., 2003; McCarney et al., 2008). Appropriate land management can reduce trade-offs or even turn them into synergies and enhance biomass production, in a win-win situation.

- Integrated optimization of biomass utilization chains – for example, the use of harvest residues or by-products of production processes, a strategy sometimes referred to as "cascade utilization of biomass" (Haberl and Geissler, 2000; WBGU, 2008) or 'integrated food energy systems" (IFES) (Bogdanski et al., 2010) – together with adequate policies, as discussed in this chapter, can help avoid or at least mitigate trade-offs between food and production of energy carriers. It can sometimes even create synergies (e.g., if agricultural by-products can be used for energy provision). This strategy can produce substantial amounts of biomass feedstock at low costs. Constraints to implementing "cascade" or IFES systems, and possible ways to overcome these, are discussed in Bogdanski et al. (2010).

The competition between production of food, biomass for energy, biomass for other uses and use of land for non-production functions (e.g., settlements, nature protection) can influence the amounts of different crops produced, their production costs, their prices, and their environmental impacts. How this competition plays out, however, depends on policy frameworks and the crops used. For example, production of biomass from perennial lignocellulosic crops (second-generation bioenergy crops) can involve the use of land not suitable for cultivation of food crops – for example, degraded and marginal land – and might provide the possibility of combining biomass production with food production or nature protection. On the other hand, some of these areas are currently used by herders for livestock rearing, often in subsistence systems – and this might create new, different trade-offs. Technical innovation in agriculture and biomass conversion can greatly influence trade-offs and synergies between different land uses. Socioeconomic development processes, such as transitions from subsistence to market-based production can play a similarly important role, including the benefits related to the creation of rural jobs through the production of bioenergy in developing countries. Adequate policies are required to achieve synergies where possible and to minimize potential conflicts and adverse affects.

Moreover, population density plays an important role: in regions with low population density, such as many areas in, for example, Africa and South America, bioenergy production with first-generation technologies (such as sugarcane in Brazil) may result in little, if any, competition with food and other end uses if based on well-designed policies (Goldemberg et al., 2008). In other regions conflicts may arise, also through indirect effects from increasing the total demands on land for biomass products. This could become a serious issue with bioenergy and agricultural production at much higher levels than today.

Central to the debate on water issues and water scarcity are water demands and end-use patterns. Water for meeting basic needs, drinking and general household use, though comparatively small in terms of volume, needs to be readily available. The inexorable growth of cities, concentrating large numbers of people in small areas, exacerbates this challenge locally.

River ecosystems, and the fish and other species living in them, of course need continued running water. However, large dams used mainly for hydropower can destroy both river and terrestrial ecosystems due to impounding, flow regulation, and fragmentation of landscapes. Water is also used to produce energy in medium and small hydropower installations, and for cooling thermal power stations. Distribution of water to different sectors, including for energy purposes and for industry, is to be decided by a water management scheme.

An important use of water is for food production. As the world population continues to increase, a growing number of people will require water for cultivation of food, fiber and industrial crops, and for livestock and fish. It is estimated that crop production to feed the growing population will need to nearly double during the next 50 years. The two main factors driving food demand are population growth and dietary change, which is strongly dependent on economic growth. With rising incomes and continuing urbanization, diets move towards consumption of more animal products, fats and sugar, as well as to a greater variety of foods. Shifts in consumption are expected between different cereal crops, and away from cereals towards livestock, fish products and high-value crops that consume more water (UN-Water/FAO, 2007).

In this context, the objectives of this chapter are to assess and to discuss major trade-offs related to the different uses of land and water, in particular related to future energy systems, land availability, and land for bioenergy. It also examines competition for land from different uses (food, fuel, timber, etc.), environmental impacts, and implications for natural resources (e.g., biodiversity, atmosphere, water), as well as social factors such as food security, health, and incomes. With respect to water use, the chapter discusses water demand for different kinds of uses, with a special emphasis on the increasing need for water for bioenergy crops in competition with the increasing need for water for food production.

In relation to water use, the chapter evaluates the multiple uses of water (human consumption, hydro and thermal power generation, manufacturing, agriculture, water security, bioenergy, etc.), as well as environmental, social and strategic issues, and potential trade-offs. Competition between food and energy crops may not always be over 'the same water.' Depending on the type of feedstock, it is possible to cultivate energy crops in areas where conventional food production is not feasible due to water constraints, i.e., the 'water footprints' are of a different character (Lundqvist et al., 2008).

20.2 Trade-offs in Land Use

This section discusses the different uses of land and the trade-offs related to availability of suitable land areas, and derives conclusions for

adequate policies. The discussion of trade-offs starts with an evaluation of current land use, as a basis for analyzing perspectives for future land availability for bioenergy crops, which depends on future cropland areas and yields, livestock, and critical demand components such as food. Sustainability issues related to environmental, social and economic aspects are critical to this discussion.

20.2.1 Current Land Use and Land Availability

The global land-use dataset on a five minute grid (approximately 10x10 km at the equator) summarized in Table 20.1 has the following features:

- Reproduction of national land-use statistics (as reported by the United Nations Food and Agriculture Organization (FAO)) for cropland and forestry at the country level.
- Five land-use classes covering the Earth's total terrestrial area in the form of percent-per-grid cell layers for urban and infrastructure land, cropland, grazing land, forestry, and areas without land use (free of double-counting).
- Spatial patterns derived from thematic GIS maps based on remote sensing.
- Extensive statistical and cross-checks against other, independent datasets such as MODIS, CORINE and others (see Erb et al., 2007).
- Consistency with a geographically explicit database on net primary production (NPP) and its human use (Haberl et al., 2007) as well as with national-level biomass balances and feed balances (Krausmann et al., 2008). This consistency allows analysis of the impacts of allocating additional land for bioenergy production on all other socio-economic biomass flows, above all feed, fiber and food supply.

Most assessments are based on a "land balance" approach: total cultivable area is identified, and then areas already being cultivated are subtracted. Young (1999) argues that this approach has several inherent shortcomings, such as: (1) overestimation of cultivable land (e.g., failure to adequately account for uncultivable land such as hills, rock, outcrops, minor water bodies, etc.); (2) underestimation of land already cultivated (up to 50% in some assessments, in particular in sub-Saharan Africa); and (3) inadequate accounting of land demand for purposes other than cultivation (e.g., grazing or settlements), conservation and ecological services, and urban development. Erb et al. (2009) suggest that it is not realistic to assume that mowing and livestock grazing are confined to "permanent pastures," as reported in FAO statistics. According to Table 20.1, about 76% of the world's land surface is used more or less intensively, with around 15 million km^2 being cropland.

Currently unused areas (24%) include: almost completely unproductive land (aboveground biomass productivity below 0.04 kg/m^2/yr), currently unused grasslands and scrublands (mostly remote and with low productivity), and the world's last remaining pristine forests. Except for pristine forests, currently unused lands are unlikely to be suitable for providing significant additional areas for cultivation in the future. With regard to use of forests, however, there are studies showing that converting pristine forests to bioenergy production would have long carbon payback times and would, therefore, not contribute to the mitigation of climate change over the next decades (WBGU, 2008; Searchinger et al., 2008). Negative environmental impacts from deforestation can be avoided by the introduction of adequate policies and enforcement measures, as discussed in Goldemberg et al. (2008). For production of bioenergy without deforestation, the areas available are those classified in Table 20.1 as cropland and grazing land.

In the case of cropland, it is possible to plant bioenergy crops on land currently lying fallow, or on cropland that becomes available if yield increases surpass the growth in demand for food, feed and fiber, thereby freeing up area for energy crops. Much larger land potentials can be mobilized on land classified as "grazing area" in Table 20.1. This category is a "remainder" category, i.e., it comprises all land not classified as infrastructure, cropland, forestry, or unused land. Land classified as "grazing land" in Table 20.1 includes a large variety of land, ranging from highly productive grasslands intensively used for grazing or mowing to barely productive, very extensively used land dominated by shrubs, more or less bare areas, and other vegetation. This category also includes degraded lands (except degraded cropland or forests), abandoned farmland, and other very extensively used lands.

Up to a certain point (which depends on the respective regional roughage demands of livestock), the use of the land in this category could be used to grow bioenergy crops. This would allow the production of bioenergy without deforestation and with few, if any, repercussions on the livestock sector (see Goldemberg, 2009; Goldemberg et al., 2008; Goldemberg and Guardabassi, 2009; Macedo et al., 2008; Nassar, 2009). In many cases, especially in degraded areas, use of such land for bioenergy production could have a favorable greenhouse gas (GHG) balance due to carbon sequestration in the soil, as discussed in Soares et al. (2009).

Urban areas and infrastructure are bound to grow due to population growth and increasing wealth, taking up sizeable areas of high-quality land, some of which is currently used as cropland. Expanding the amount of cropland available would almost exclusively mean bringing land into cultivation that is currently used for grazing or forestry. Expanding into land classified in Table 20.1 as "grazing land" is possible where this land is used extensively, i.e., where livestock density can be increased without causing degradation. This is possible in many regions where livestock densities are sufficiently low (see Erb et al., 2009). A comparison of the grazing land areas of quality classes 1 and 2 in Table 20.3 with livestock densities estimated by FAO (2006) suggests that much, but by far not all, of the available high-quality grazing land is used for intensive livestock rearing.

It is a difficult task to assess the area and spatial distribution of land that could be suitable as cropland but is at present not used for crops.

Source: Erb et al., 2007.

The following factors need to be taken into account when calculating area potentials for agriculture and energy crops:

- Data on settlements and related infrastructure land (and projections out to 2050) should consider rural infrastructure areas required to support cropland existing now or assumed to exist in 2050 (Table 20.2, Erb et al., 2007; Erb et al., 2009).

- Land under forestry and currently unused land (wilderness, including unused forests) are increasingly accounted separately (see, e.g., Table 20.1), which enables the exclusion of forest areas from the assessment of agriculture and bioenergy crop potentials – a plausible procedure because clearing forests for agriculture and bioenergy production results in large GHG emissions (WBGU, 2008).

- Biomass balances of feed supply and livestock production allow an evaluation of whether or not grazing land remaining after conversion to grow bioenergy crops can support the required livestock feed demand (Erb et al., 2009). An assessment of grazing land quality (Erb et al., 2007) helps to identify grazing areas suitable for bioenergy crops (Erb et al., 2009), as well as for agricultural crops.

Table 20.2 compares current infrastructure and cropland areas with estimates of quality classes of grazing lands based on (a) the assessment of global land use in Table 20.1; (b) an assessment of cropland suitability (Ramankutty et al., 2002); and (c) assessments of cropland suitability from the Global Agro-Ecological Zoning (GAEZ) maps (FAO and IIASA, 2000). The classification of grazing land quality was based on its NPP as well as on land cover information. For example, bare areas and shrub lands were assumed to be less suitable for grazing than areas with herbaceous vegetation (Erb et al., 2007).

The GAEZ study (FAO and IIASA, 2000; Fischer et al., 2002) combined soil, terrain and climate characteristics with crop production requirements. It estimates suitability for crop production at three input levels (low, medium, and high). About 30% of the earth's land surface, except for Antarctica and Greenland (a bit more than 40 million km²), was found to be at least moderately suitable for rain-fed crop production (Bruinsma, 2009).

Bold numbers indicate land potentials, i.e., in regions in which more land of a certain class is available or suitable according to the respective criterion than was used for cropland and infrastructure in 2000.

"Gross availability" of land is impressive, but it is important to bear in mind that not all of that land is really available (Young, 1999). Much of this land is either already used for other purposes (e.g., infrastructure or grazing), protected for reasons of nature/biodiversity conservation, or under forests (Bruinsma, 2009). Nachtergaele and George (2009) estimate that protected areas may cover some 2 million km^2, and forests some 8 million km^2 of that land. Further qualifications must also be made. Land suitability can only be assessed in a meaningful way for a particular crop. Land identified as potentially suitable may be prone to physical or economic constraints, such as ecological fragility, low fertility, toxic compounds in the soil, high incidence of disease, or lack of infrastructure. These factors reduce productivity and profitability (Bruinsma, 2009) and must be taken into account in the elaboration of agro-economic-environmental zoning, following the example of Brazil (see Box 20.5).

Land availability is very unevenly distributed among regions. A large percentage of the suitable land in developing countries, for any agricultural crops, including bioenergy, is located in Latin America and sub-Saharan Africa. South Asia and the Near East/North Africa have lower spare land capacity (Bruinsma, 2009).

Global infrastructure and cropland covered 16.6 million km^2 in 2000 – an area almost equivalent to the estimated cropland with a suitability index higher than 0.7 (Ramankutty et al., 2002). Ramankutty's cropland suitability index is calculated using climate indicators (growing degree days and water availability) and soil indicators (basically, soil pH and carbon) to estimate the probability that a grid cell possesses the physical characteristics for rain-fed cultivation.

In some regions, cropland expansion may face challenges and require costly investments, e.g., in irrigation technologies or other measures of land improvement. In other regions, considerable areas with a cropland suitability index higher than 0.7 are not yet used as cropland or infrastructure. In these regions, cropland expansion can be assumed to be less costly. Globally, only about 57% of the land with a cropland suitability index over 0.5 is already used for infrastructure and cropland. Table 20.2 shows, however, that for two regions, MEE and OSA, current infrastructure and cropland areas already exceed the land with a suitability index higher than 0.5. In these regions, quite poor land is currently used as cropland.

The GAEZ assessment of climate, soil, terrain and slope constraints suggests that the global area of land with no, very few and few constraints is smaller than the area already used for cropland plus infrastructure. However, including land classified as "partly with constraints" results in an additional area which is around the same as the area of land already used for cropland and infrastructure. Cropland expansion potentials seem to prevail in some regions, most notably in sub-Saharan Africa and Latin America and the Caribbean, where agricultural yields could also be improved significantly (Somerville et al., 2010). Moreover, changes in human diets towards less consumption of animal products would allow a reduction in cropped areas compared to a business-as-usual scenario (Aiking et al., 2006; Erb et al., 2009; Dornburg et al., 2010).

GAEZ also provides suitability estimates for rain-fed agriculture with improved technology that differentiate between potentials on currently forested land and potentials restricted to non-forested land. Here the assessment that excludes forests is most relevant (see Table 20.2). Some analyses raise the question of how well suited land potentials labeled "suitable" in this assessment really are for large-scale, intensive cultivation – in particular in tropical regions where land degradation resulting from inappropriate agricultural practices would be a widespread problem (Stocking, 2003). However, other studies (such as Somerville et al., 2010) suggest that there may be a significant potential to improve crop yields in these regions (as also discussed in FAO (2010a) for Tanzania).

Some authors (including, e.g., Showers, 2006) consider that assessments from Ramankutty et al. (2002) and the GAEZ are based on limited sets of data that were extrapolated and applied to large areas. It is recommended that in-depth regional studies should be carried out to avoid overestimating the cropland expansion potential in regions such as sub-Saharan Africa, where transfer of European cultivation techniques has caused large-scale soil erosion, and European agricultural practices often have been unsuccessful.

Much of the cultivable land in sub-Saharan Africa and Latin America is under valuable forests or in protected areas, and these regions are also those where the largest potentials for arable land are found. Ramankutty et al. (2002) argue that tropical soils could potentially lose fertility rapidly if taken into cultivation, and are highly vulnerable to climate-change impacts. IAASTD (2009) estimates that only 7% of the cultivable areas in sub-Saharan Africa, and only 12% of those in Latin America and the Caribbean, are devoid of more or less severe soil constraints that limit sustainable and profitable production. In fact, agricultural yields mainly in Africa are very low, half of those in the United States (Somerville et al., 2010), and some studies suggest large potentials to increase these yields, and also to make more area available (UNCTAD, 2009; UNF, 2008).

A comparison of area potentials from Ramankutty et al. (2002) and GAEZ with the area listed under "grazing classes 1 and 2" (last two columns of Table 20.2) shows that regions with much land in the grazing land class 1 (best-suited grazing area) are mostly also those in which there are large potentials for cropland expansion. These results are found by both Ramankutty and the GAEZ, whereas those regions with little cropland expansion potential also have small areas of high-quality grazing land. Because the assessment of grazing land quality by Erb et al. (2007) is consistent with data on grazing intensity (Haberl et al., 2007), it can be used to calculate potentials to intensify grazing in order to make land available for the additional cultivation of crops, including bioenergy crops.

The studies mentioned in this review indicate that the availability of land for cultivation of agriculture and bioenergy crops depends mostly on the following factors:

- The most important factor is the intensity with which this land is used today for other purposes, in particular grazing. Calculating livestock feed balances based on national-level livestock data from the FAO (e.g., Wirsenius 2003a; 2003b; Haberl et al., 2007; Krausmann et al., 2008) allows us to approximate the intensity with which grazing areas are currently used for feed production (e.g., Erb et al., 2009). Together with other studies mentioned above, the analysis has shown that grazing areas are used with very different intensities across the globe, suggesting that increased feed production through improved management of grazing areas could make considerable areas available for bioenergy production.
- Other important constraints include: the need to set aside valuable areas for biodiversity/nature conservation; limited water availability; and lack of infrastructure such as roads (i.e., limited accessibility). In some regions with poor soil quality, high levels of investment might be needed to allow cultivation. More important, however, is how the availability of land will change in the future due to changes in demand for products from land, and impacts of climate change.

20.2.2 Competing Future Demands for Land

Basically, land is used by humans for at least three core functions (Dunlap and Catton, 2002):

- resource supply, i.e., the provision of raw materials or energy needed for production and consumption processes, including non-renewable resources such as fossil fuels, minerals and other materials extracted from geological deposits, and renewable ones such as biomass or water diverted from current biogeochemical cycles, ultimately driven by an influx of solar energy;
- waste absorption, as well as buffering and regulating capacities of ecosystems; and
- space occupied for human infrastructures, including housing, gardening and recreational areas, as well as industrial and transport facilities.

Most human uses of land are dependent upon the land's biological productivity, i.e., its NPP per unit area and year. Many land uses involve harvesting parts of the actual or accumulated NPP in the form of biomass derived through agricultural or forestry activities (Haberl et al., 2004). At the same time, human land use often alters the land's productivity (Haberl et al., 2007). In some regions, especially sub-Saharan Africa, current land-use practices result in low yields. Implementation of adequate technologies could help to raise agricultural yields considerably (Somerville et al., 2010; FAO, 2010a; Dornburg et al., 2010).

Table 20.3 | Global average per capita supply and demand of primary biomass.

	Per capita flows of dry-matter biomass (kg/cap/yr)	Percentage of total(%)
Supply		
Harvest of primary crops	473	24%
Harvest of fodder crops	94	5%
Harvest by-products (residues)	485	24%
Grazed biomass (from grazing land)	634	32%
Wood harvest (excluding residues)	321	16%
Total supply	2007	100%
Total Supply	**2007**	**100%**
Food	248	12%
Market feed	152	8%
Seed	15	1%
Other uses	233	12%
Non-market feed, including grazing	1004	50%
Firewood	197	10%
Industrial wood	125	6%
Wastes, losses	33	2%
Total Demand	**2007**	**100%**

Source: Krausmann et al., 2008.

As shown in Table 20.1, biomass production through agriculture and forestry takes up by far the largest area. Many buffering and/or regulating services of ecosystems are to some extent compatible with productive functions (see discussion of "multifunctional land use" in the Introduction). Global biomass balances (Krausmann et al., 2008) show that most of the biomass is used for food and feed, fiber, and other uses, whereas the amount of biomass directly used for bioenergy production (as firewood) is relatively small.

Firewood reported in Table 20.3 amounted to about 22 EJ/yr globally in 2000. More than half of global biomass supply is used as feed for livestock (see Table 20.3).[2] Reuse and recycling of biomass (i.e., "cascade" or IFES utilization) already plays an important role; agricultural residues and by-products are used as feed inputs and for bioenergy production (e.g., sawdust, bark, residues from paper production, etc.). These "cascadic flows" and some underreported flows (e.g., collection of firewood on non-forested land not reported in FAO data and, therefore, also missing from Table 20.3) contributed approximately half of global bioenergy production (45±10 EJ/yr) in the year 2000. Because conversion of forests to bioenergy and agricultural crop plantations would result in a large carbon debt and poor GHG emission performance (and bioenergy options in forestry are discussed in Chapter 7), we here focus on farmland, i.e., cropland and grazing areas.

2 It is worth noting that, in fact, a significant part of industrial wood is used as energy (for instance, black liquor is about 50% of wood consumed in the cellulosic pulping industry).

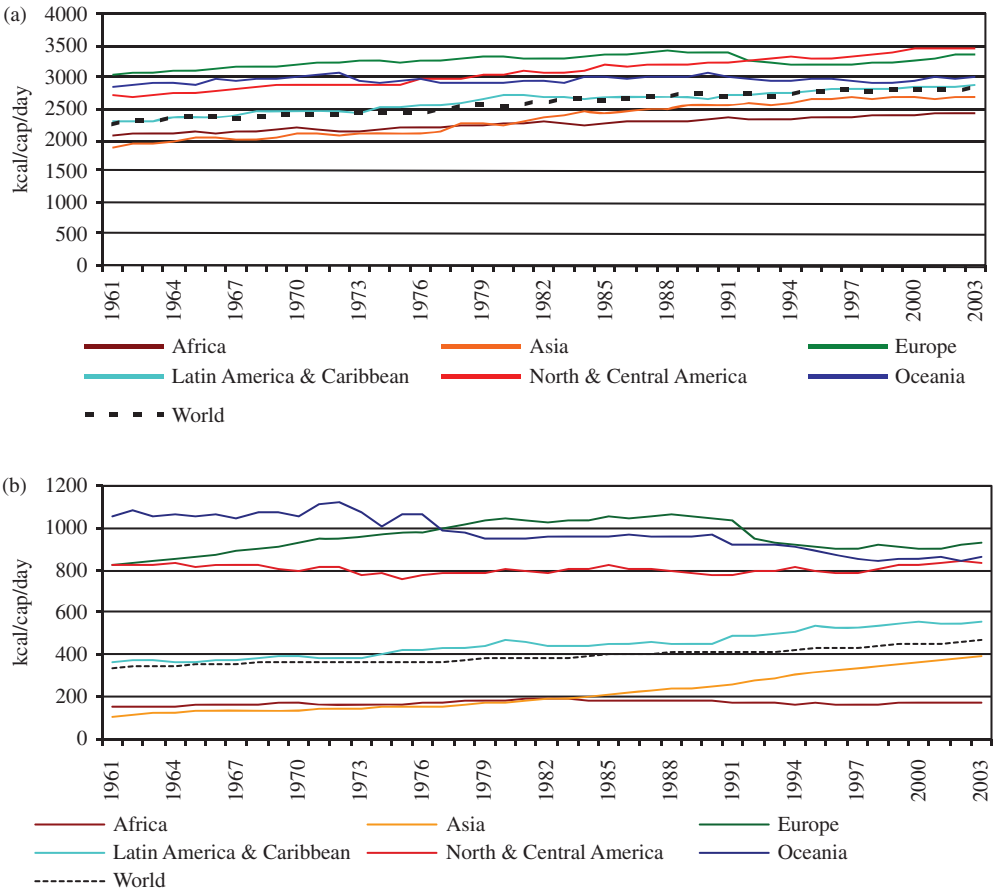

Figure 20.1 | Total food consumption (a) and consumption of animal products (b) 1961–2003. Source: based on data from FAO, 2009a.

As shown in Table 20.3, the food system accounts for a significant amount of the biomass used, as well as the area needed for producing that biomass. Three sets of factors will dominate in shaping the future trajectory of the area required globally for food production:

- The volume and composition of global food demand, which in turn depend on population growth and changes in diets: There is a strong correlation between income levels and the volume and composition of food consumed: food consumption rises with income. The proportions of animal products, sugars and fats rise with income, while consumption of cereals, pulses and roots drops with income (Erb et al., 2009). Figure 20.1 shows global trajectories of per capita food consumption 1961–2003.

- Yield levels on agricultural areas (cropland and grazing land): The total volume of crops, forage and by-products produced is the product of the area used times the yield per unit area and year. Yields are highly variable both between regions and across time (see Figure 20.2).

- Feeding efficiencies in the livestock sector: The relationship between feed input and product output (e.g., meat, milk, eggs) is highly variable between different livestock rearing systems. Cross-country analyses as well as longitudinal data indicate how large these differences are (see Figure 20.3).

Figure 20.1 shows that the total amount of food calories consumed per capita and year is rising continuously in almost all regions. The only exceptions are Europe and Oceania after 1990, where food intake has more or less stabilized at a high level after 1990. The consumption of animal products seems to have stabilized in Europe, North and Central America and Oceania at between 800 and 1000 kilocalories per capita and day (kcal/cap/day); it is rising throughout the developing world, with the exception of Africa, where it has remained almost constant at a low level of 200 kcal/cap/day.

Improvements in agricultural technology have helped to increase yield levels across the globe considerably, while sometimes also resulting in undesired environmental consequences such as soil degradation, water pollution, and others (IAASTD, 2009), when increases in yields are based on intensive high-input monocultures. As Figure 20.2 shows, average global cereals yields grew from 1.35 metric tonnes per hectare and year (t/ha/yr) in 1961 to 3.54 t/ha/yr in 2008. However, yield growth has progressed at varying rates, and has led to considerably different yield levels across the globe. In the lowest-yielding region, yields have remained almost constant,

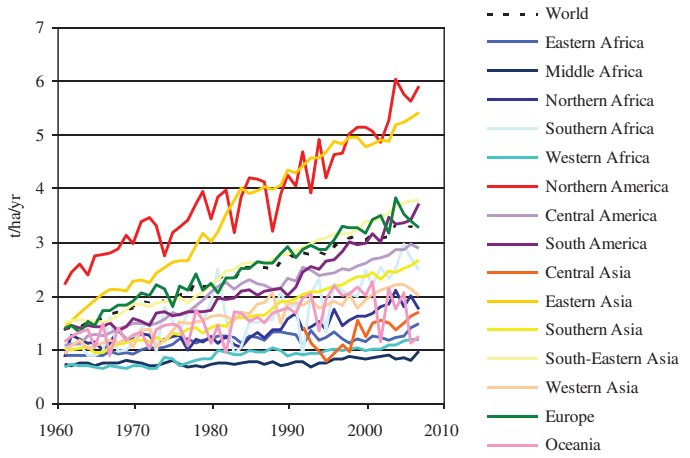

Figure 20.2 | Cereals yields in the world. Source: based on FAO, 2009a.

below 1 t/ha/yr, whereas yields have reached more than six times that level in the highest-yielding region, North America. In some regions where yields are currently low, especially sub-Saharan Africa, implementation of adequate technologies could help to raise agricultural yields considerably (Somerville et al., 2010; FAO, 2010a; Dornburg et al., 2010).

Feeding efficiencies in the livestock sector are also highly variable across time and space (Figure 20.3). The differences are particularly strong for grazers (cattle, buffalo, sheep, goats); less so for pigs and poultry. The amount of biomass required per unit of output and, therefore, also the area needed per unit of output depend strongly on the respective livestock rearing systems.

One main reason for the large differences in feeding efficiencies is that livestock is used in a multifunctional manner in subsistence systems. Besides producing animal-based food, livestock plays a big role as a work force (draught animals), is important for the nutrient cycle (through use of dung as fertilizer), and has important social functions, e.g., in rituals, as status symbols, as buffers for times of poor food supply, etc. (Harris, 1987; Krausmann, 2004; Wildenberg, 2005).

Market-oriented systems can be relatively "inefficient" in terms of their feed balance if area is abundant and other inputs (e.g., labor) are more costly and hence more important optimization criteria (Erb et al., 2009). Considering ecological objectives, animal welfare and product quality criteria in livestock rearing may also reduce feeding efficiencies compared to intensive, indoor-housed rearing systems, although this effect should not be over-emphasized. Compared to subsistence livestock raising, and even some existing market-oriented but feed-inefficient systems, modern, optimized organic and humane livestock systems offer large gains in terms of feeding efficiency (Erb et al., 2009).

Using less land area in livestock production by increasing grazing intensities is possible. For example, in São Paulo State, Brazil (Goldemberg, 2009), cattle density heightened in the last decade, thereby increasing area for food/bioenergy crops. Soares et al. (2009) show that the overall balance on GHG emissions is positive, despite the increases in intensive animal husbandry and the corresponding replacement of cattle areas by sugarcane crops.

Table 20.4 | Changes in cattle numbers and area dedicated to cattle in São Paulo State, 2001–2008.

	2001	2002	2003	2004	2005	2006	2007	2008
Number of cattle (million)	13.15	13.46	13.76	13.77	14.07	13.75	12.20	11.95
Pasture area (1000 km²)	102.9	101.0	101.1	101.2	100.1	97.1	91.2	76.4
Density (number/km²)	128	133	136	136	141	142	134	156

Source: Coelho et al., 2008.

The most important uses of biomass for other uses than food, feed or bioenergy materials are pulp and paper, construction materials and chemicals, most of which come from the forestry sector, as discussed in Chapter 7. In different regions, other products – for example, cut flowers – can be important. The chemical industry could boost its use of biomass in the future, as bulk chemicals from biomass have a large potential to be substituted for fossil-fuel-based feedstocks. At present, the amounts of biomass (and related land) used for this purpose are low, and future projections still indicate a limited demand for land for that purpose. However, estimating land demands for future chemical production must also take into account the production of chemicals in bio-refineries where transport fuel and electricity can be co-generated from biomass.

Furthermore, some bio-based bulk chemicals (i.e., plastics) are often used for waste-to-energy generation in industrialized countries (see Figure 20.4).

FAO estimates that global agricultural production would have to be increased by 70% to feed the global world population expected in 2050, meeting a food supply target of 3130 kcal per capita and day (Bruinsma, 2009). This considerably exceeds global average food supply for 2000, which was 2790 kcal/cap/day (FAO, 2005), but might still leave approximately 4% of developing-country populations chronically undernourished if current patterns of inequality of food distribution persist. On the other hand, the International Food Policy Research Institute (IFPRI, 2009) indicates that daily per capita calorie availability in developing countries in 2000 was 2694 kcal, and that scenarios in these countries for 2050 could reach 2896 kcal/cap/day, if there were no climate change effects, with the largest increase (13.8%) in East Asia and the Pacific. However, there are gains for the average consumers in all countries – 3.7% in Latin America, 5.9% in sub-Saharan Africa, and 9.7% in South Asia. Taking into account climate change, calorie availability in 2050 is lower than those numbers; it actually declines relative to 2000 levels throughout the world (IFPRI, 2009).

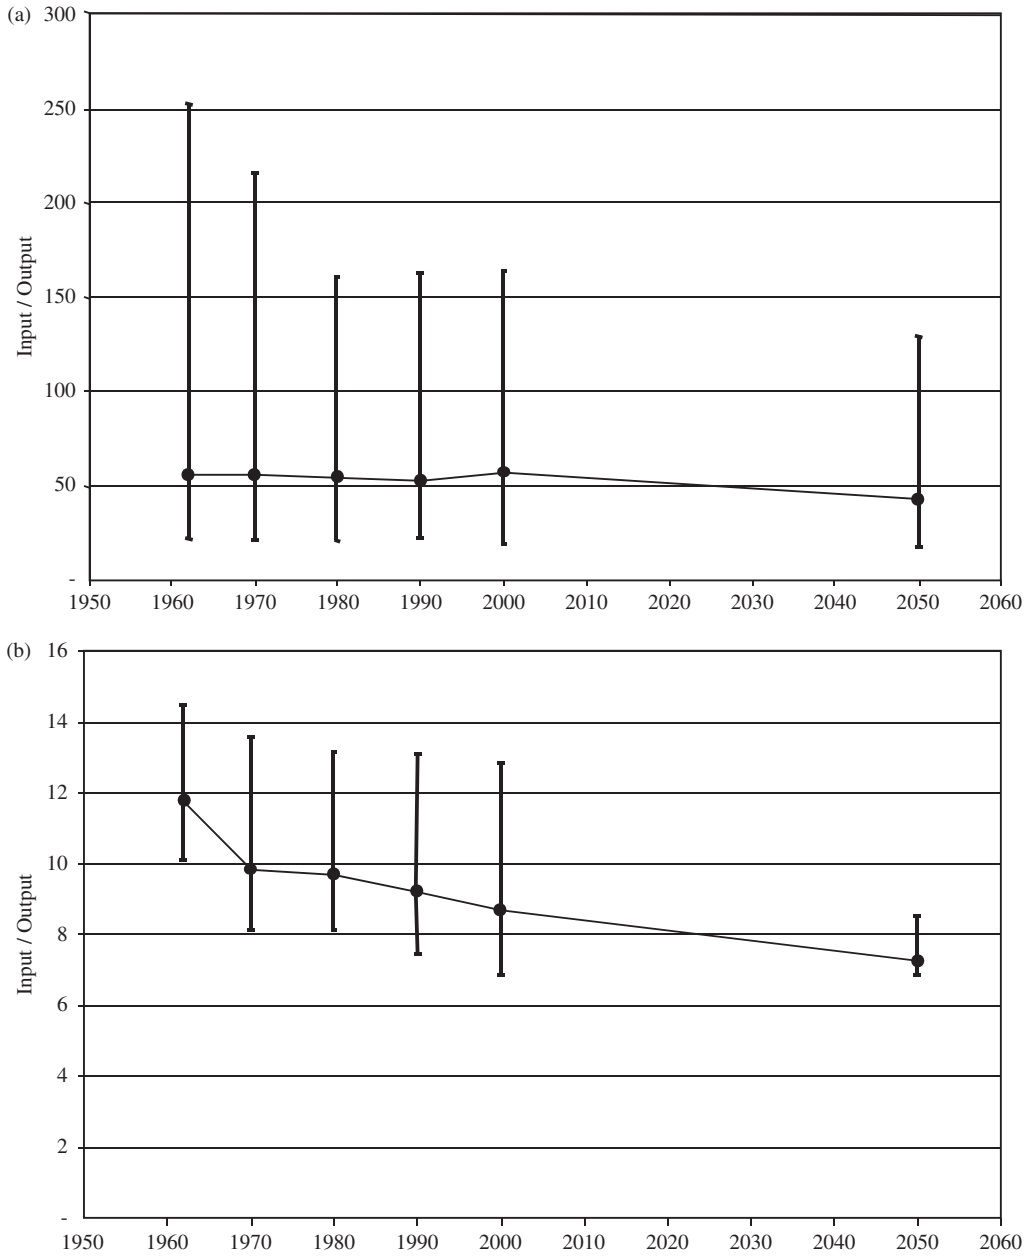

Figure 20.3 | Global feed efficiencies (feed input per unit of animal product output, both measured as dry-matter biomass): (a) Grazers (cattle and buffalo, sheep, goats); (b) Non-grazers (pigs, poultry), 1961–2000. Source: Haberl et al., 2011. Dots represent the weighted global average, whiskers the variability between the 11 regions covered in that study.

The share of animal products in people's diet would strongly affect the amount of primary biomass and area required to meet global food demand. If diets shift towards less protein from animal products, the global demand for cropland and grazing lands can be much lower than in a business-as-usual scenario (e.g., see Erb et al., 2009; Dornburg et al., 2010).

According to the "Trend" (business-as-usual) scenario of Erb et al. (2009) – based on FAO (2006) – higher yields and increased cropping intensity are expected to contribute 90% of the growth in crop production by 2050 (80% in developing countries), with the remainder coming from land expansion. Arable land would expand by around 9% compared to 2000 in the global total. Cropland expansion would be largest in sub-Saharan Africa, Latin America and the Caribbean, and Oceania/Australia. Global cropland area would reach 16.6 million km^2 in 2050 in such a scenario.

In this scenario (Erb et al., 2009), growth of cropland areas in developing countries was assumed to be 12% (1.2 million km^2), almost all in Africa and Latin America, which is partly offset by a decline of some

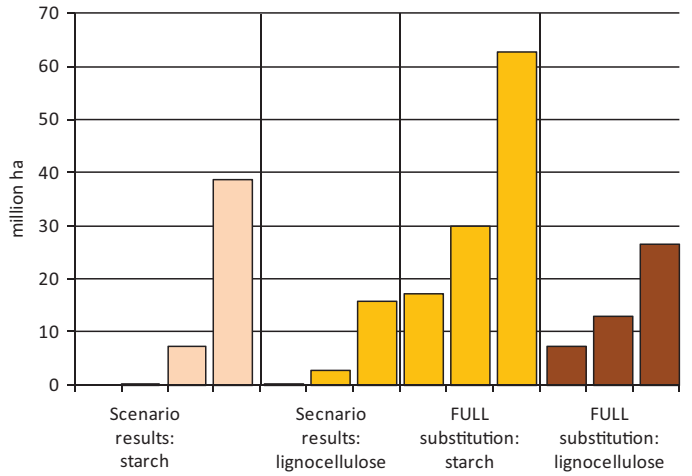

Figure 20.4 | Total land used by 2050 for the selected organic chemicals according to the three scenarios (low, medium and high) and for full substitution of selected chemicals, i.e., 100% bio-based chemical production. Source: Dornburg et al., 2008.

0.5 million km^2 (8%) in developed countries. Land equipped for irrigation would increase by 0.32 million km^2 (11 %), which is assumed to take place almost exclusively in developing countries. Water withdrawals for irrigation are forecast to increase by 11% between 2006 and 2050. It is forecast that crop yields would rise at a slower pace than in the past. Annual growth rates would halve to 0.8% per year compared to historical growth rates.

According to Cassman (1999) and Peng et al. (2000), many options to achieve yield gains have already been discovered, and further increases seem unlikely in some areas due to physiological limits. For example, these authors argue that further improvements in harvest indices that seek to increase the share of the desired product (e.g., grain) at the expense of supporting tissues such as leaves and stems (straw) seem unlikely for many cultivars because of physiological limits. Harvest indices of the most advanced rice cultivars are already around 0.50–0.55. It would seem unlikely that this can be increased substantially.

Tilman et al. (2002) argue that a continuation of past yield increases seems unlikely, because most of the best-quality farmland is already being used. According to these authors, rates of yield increases are already declining (e.g., rice in Southeast Asia), and yields have leveled off (e.g., rice in Japan, Korea, and China) as they approach limits set by soil and climate. Cassman (1999) argues that soil degradation and depletion of nutrient stocks in soils is an additional challenge. Also, a more widespread adoption of less intensive agricultural technologies (e.g., organic farming) could result in lower rates of yield growth or even declines in yields in regions where intensive conventional cultivation methods are common (Erb et al., 2009). On the other hand, Somerville et al. (2010) suggests that high investments can benefit developing countries, mainly in Africa, where countries present the lowest agricultural rates worldwide.

Improvement of management practices could help to maintain growth in yields, mostly due to improved stress tolerance, avoidance of nutrient and water shortages, improvements in pest control, etc. Some scenarios even foresee higher yield increases than the FAO (e.g., IAASTD, 2009). For example, the "Global Orchestration" scenario analyzed in the Millennium Ecosystem Assessment (2005) assumes that yields in 2050 could be, on average, 9% higher than those forecast by the FAO (2006), if world agriculture is pushed towards strong intensification.

Dornburg et al. (2010) mention other studies (Evans, 1998; Smil, 2000) suggesting that sufficient food – even for around 10 billion people – could be produced, provided that crop yields can be further improved by enhanced crop management and/or genetic modifications. It is also stressed that the large variability in regional climate and hydrology necessitates a detailed analysis of the biophysical possibilities for crop production. In any case, substantial investments will be indispensable for maintaining growth in crop yields (Khan et al., 2009), and additional ones are needed to avoid economic constraints that would prevent the realization of such technical yield potentials (Koning and van Ittersum, 2009; Somerville et al., 2010).

In many developing countries, especially in semi-arid and arid regions, yields are often far below those obtained in industrialized economies (IAASTD, 2009; IFPRI, 2009). In many regions, average increases in productivity in recent years have been only moderate, especially in Africa (FAO, 2009a; Somerville et al., 2010). Adoption, implementation and enforcement of adequate policies to foster environmentally, socially and economically sustainable yield increases could, therefore, offer large benefits (IAASTD, 2009). Recent studies call for more research efforts dedicated to "sustainable intensification," i.e., management practices and technologies that allow further yield increases but minimize adverse environmental, social or economic effects (Godfray et al., 2010).

World food systems may be affected by changes in temperature and precipitation (mean values and variability) and the atmospheric carbon dioxide (CO_2) concentration. All three factors could have substantial effects on agricultural yields. At present, however, there are substantial knowledge gaps with respect to underlying processes (e.g., downscaling of global climate scenarios to regional or local levels) and also how they will affect crop growth in the field, under real-life conditions. This depends on factors that are difficult to predict, including responses from farmers.

IFPRI (2009) analyzed climate change effects on crop production and CO_2 fertilization effects and predicted negative impacts, mainly in sub-Saharan Africa and South Asia. In fact, some regions were expected to be adversely affected by climate change, in particular in tropical regions (Cerri et al., 2007; IFPRI, 2009), but regional differentiation of climate change effects is important (IFPRI, 2009). Beyond 2050, climate change implications on crop yields and production were forecast to be severe on the global scale, with or without the CO_2 fertilization effect (IFPRI, 2009).

A recent study (Müller et al., 2010) showed that the effect of climate change on agricultural yields is highly uncertain and strongly depends on the CO_2 fertilization effect, which is poorly understood and could interact with management decisions of farmers. The study was based on simulations using the dynamic global vegetation model LPJmL. It considered three different emission scenarios implemented in five different Global Circulation Models. LPJmL was run with the CO_2 fertilization effect switched on and off, to reflect scientific uncertainty. The study found that crop yields could decrease by 13% or rise by 22% in 2050, compared to the levels forecast to prevail without climate change, depending on scenario assumptions. Using these results, Erb et al. (2009) and Haberl et al. (2011) showed that climate change impacts on agricultural crop yields would, at any given level of global food demand, result in considerable changes in the area available for the cultivation of energy crops; adverse impacts would reduce, and positive impacts would increase, the area available for bioenergy crops.

Case studies show that continuous investments in the improvement of productive technologies (i.e., Brazilian sugar cane) can mitigate or even offset adverse impacts of climate (change) on yields (von Braun, 2007). IFPRI (2009) concludes that even without climate change, greater investments in agricultural knowledge (for all different end uses) are needed to meet the demands of the future world population in 2050, mainly in developing countries, and argues that improved agricultural productivity can be an important mechanism for alleviating poverty indirectly by creating jobs and lowering food prices.

This discussion leads to the conclusion that the availability of productive areas for the cultivation of bioenergy crops in the future will strongly depend on:

- Total future food demand, which is in turn influenced by population numbers, per capita food calorie intake and the fraction of animal-based products consumed: all of this depends on future income levels and a host of other socioeconomic, political and cultural factors.
- Yield levels on farmland, in particular cropland yields: most studies agree that yield increases will be able to meet a substantial fraction of future global food demand so that the growth of cropland area required could be low, perhaps only 5–10%. But significant social, economic, environmental and technological issues related to future yield growth remain to be solved through appropriate research and technology development. Climate change could have significant impacts on yields, which could positively or negatively influence the availability of area for energy crop cultivation.
- Feeding efficiencies and many other critical issues related to the livestock sector: technological and other changes in livestock rearing are likely to contribute to increases in the output of animal-based food per unit of feed intake, but the extent of this efficiency growth, as well as its possible costs in terms of environmental impacts, product quality, and animal welfare, is at present imperfectly understood. Comparison of livestock densities across world regions suggest that livestock densities could be increased, in some regions by large margins, thereby making substantial areas available for bioenergy crops. Appropriate management will be crucial to avoid adverse environmental and socioeconomic effects, in particular where subsistence economies might be affected.
- Area required for other purposes, including infrastructure, biodiversity conservation, and production of biogenic materials for various purposes, most notably feedstocks for the chemical industry, which seems to be of limited quantitative importance but could become more important in the future for integrated multipurpose use of biomass ("bio-refinery").

Note that conversion of forests to bioenergy crops was excluded from that discussion due to the fact that this would entail a large carbon debt, i.e., very unfavorable GHG emissions per unit of energy produced over many years if not decades. Bioenergy potentials from forestry, residues, manures and wastes are discussed separately in Chapter 7.

20.2.3 Area and energy potentials from dedicated bioenergy crops in 2050

The global potential availability of biomass for energy has been assessed in various studies. Many of these studies primarily or exclusively focus on energy crops, and the potentials estimated vary significantly. Dornburg et al. (2010), Hoogwijk et al. (2003) and Berndes et al. (2003) identify methodological differences, critical parameter assumptions and varying system boundaries that are chiefly responsible for the differences in the estimated potentials. Important parameter assumptions determining the technical potential for energy crops are:

- restrictions on land available for energy crops;
- relevant factors for future development of land use, such as population growth, diets, international food trade and technology changes, in particular with regard to crop yields, and feeding efficiencies in animal husbandry;
- future productivity of energy crops;
- agricultural commodities markets; and
- sustainability restrictions on the growth of biomass.

Table 20.5 summarizes the main features of recent studies estimating the energy potentials from energy crops. The considerable differences in the estimates result from the following factors:

- all studies use aggregate modeling approaches regarding future developments of yield and land use;

- only a few studies account for possible future land-use changes and associated uncertainty by using an scenario approach analyzing different futures (Smeets et al., 2007; Hoogwijk, 2004; van Vuuren et al., 2009; WBGU, 2009; Erb et al., 2009; Dornburg et al., 2010); and

- only a few studies explicitly consider restrictions arising from environmental and social impacts of bioenergy production (e.g., land degradation, loss of biodiversity, competition with food, and water limitations) or present spatially explicit data on land-use and bioenergy potentials (WBGU, 2009; van Vuuren et al., 2009; Erb et al., 2009; Goldemberg and Guardabassi, 2009; Dornburg et al., 2010).

According to the present review, a general tendency appears to emerge that the more recent studies show lower estimated bioenergy potentials than earlier ones. The reasons for this include the following: newer studies consider environmental constraints (e.g., carbon payback time and biodiversity conservation in WBGU, 2008); constraints on the suitability of areas for bioenergy production have become more apparent (e.g., WBGU, 2008; Dornburg et al., 2010); many areas assumed to be available for bioenergy production are already used for grazing (Erb et al., 2009); and new research has demonstrated that previous studies overestimated yields of bioenergy crops, often by 100% or more (Johnston et al., 2009).

Recently, one study (Smeets et al., 2007) suggested a very high bioenergy potential from energy crops, with an upper range that even exceeds the theoretical potential for bioenergy production discussed in Chapter 7. This very high potential resulted from a large land area (36 million km^2, i.e., 28% of the earth's land surface excluding Greenland and Antarctica) multiplied by a high productivity estimate (34 $MJ/m^2/yr$). For comparison, the current global average aboveground NPP is 9.5 $MJ/m^2/yr$.

Based on this review, four studies (Erb et al., 2009; van Vuuren et al., 2009; WBGU, 2009; Dornburg et al., 2010) were selected as the basis for this assessment. They were selected because they generally reflect essential environmental constraints such as biodiversity conservation, water scarcity, land quality/suitability, land degradation, and food supply (i.e., future cropland needs and interrelations with feed demand of livestock), although with different methods (see Table 20.5). Moreover, sufficient data allowing calculation of bioenergy potentials on the level of the 18 GEA regions were only available for three of these studies. The results derived from these three studies are then discussed in the light of a larger body of literature (including Dornburg et al., 2010).

As can be seen in the table above, the assessment of the area that would be available for dedicated energy crops varies between different studies. This survey summarized in Table 20.5 shows that yield expectations of bioenergy plantations also differ widely, approximately 1–21 $kg/m^2/yr$. Differences in yields of bioenergy plantations largely result from assumptions on land suitability, choice of bioenergy crop (yields of lignocellulosic crops and perennial grasses are higher than those of food crops), and management (e.g., fertilizer input) (Harberl et al., 2010).

Table 20.6 reports the energy crop areas for three studies, and Table 20.7 the bioenergy potentials found in the four recent studies selected. These potential estimates were derived as follows:

- Van Vuuren et al. (2009) used the integrated modeling framework IMAGE and the energy model TIMER (which is a part of the IMAGE framework) to calculate available area for energy crops and related bioenergy potentials in 2050. Only abandoned agricultural land (according to an approach by Hoogwijk et al. (2005)) and natural grasslands were assumed to be available for bioenergy production, thereby assuming global accessibility factors of 75% (abandoned farmland) and 50% (natural grassland). IMAGE sub-models on land use were used to simulate land required for food production, driven by demand for food and timber, and climate change. Calculations proceeded at the level of grid cells (0.5x0.5°). Water scarcity, land degradation (based on the International Soil Reference and Information Centre's (ISRIC, 1991) *Global Assessment of Human-induced Soil Degradation* – GLASOD) and biodiversity/nature reserve areas were considered in various scenario calculations ranging from "no restrictions" to "strict criteria."

- Erb et al. (2009) followed a "food-first" approach. Assumptions on future diets (four assumptions), cropland yields (three assumptions: FAO, fully organic, intermediate), cropland expansion (+9%, +19%) and livestock feeding efficiencies (conventional, humane, organic) were derived from FAO and other studies and databases. A biomass-balance model was used to identify combinations of factors ("scenarios") that were "feasible," i.e., provided sufficient food. The model closes the balance between biomass supply (harvest of primary crops and grazing) and biomass demand (food and fiber). For scenarios classified as "feasible," the area available for bioenergy crops was calculated by assuming that grazing intensity would be maximized and, if existent, all cropland area not required for food or fiber production could be used for bioenergy. The model calculates bioenergy potentials at three levels: primary bioenergy crops on cropland not needed for food supply, primary bioenergy crop potentials on grazing areas of the highest-quality class (which is assumed to be intensified to its limits), and residue potentials. As the latter are discussed separately (see Chapter 7), Table 20.7 shows only the potentials for primary bioenergy crops. This study considered growth in infrastructure areas and assumed that there would be no deforestation for bioenergy. The MIN scenario assumes the richest diet (which is only feasible with the most intensive technology and highest yield levels), whereas the MAX scenario combines the lowest food demand with the highest possible agricultural yields and livestock feed efficiencies. The "FAO world" scenario was based on FAO (2006).

Table 20.5 | Overview of recent studies on technical potentials of biomass from energy crops

Reference	Type of potential	Regions	Time frame	(Sustainability) constraints	Land use types	Land area used [mio. Km^2]	Productivity [tonnes dry matter/ha/yr]	Potential of energy crops [EJ/yr]
van Vuuren et al., 2009	Technical	Global	2050	Biodiversity, Food security, Soil degradation, Water scarcity	Abandoned agricultural land (75%) Grassland (25%)	13	Depending on land suitability and climate factors 1.0–3.2 kg dry matter/m^2/yr	120–300 EJ/yr (unconstrained) 65–115 EJ/yr (constrained)
WBGU, 2008	Technical	Global	2050	Biodiversity, C balance, Deforestation, Degraded land, Food security, Water scarcity	Land suitable for bioenergy cultivation according to the crop functional types in the model, considering sustainability	2.4–5.0	7.5–12.6 t/ha/yr	34–120 EJ/yr
Campbell et al., 2008	Technical	Global	2000 (not clearly mentioned)	Agricultural lands, Ecosystems, Food security, Releasing carbon stored in forests, Water scarcity	Abandoned agricultural land (100%)	3.9–4.7	4.3 t/ha/y (AGB)	32–41 EJ/yr (AGB)
Field et al., 2008	Technical	Global	2050	Biodiversity, Food security, Ecosystems, Deforestation	Abandoned agricultural land (100%)	3.9	3.2 tC/ha/yr	27 EJ/yr (AGB)
Dornburg et al., 2010	Technical	Global	2050	Land for food excluded Various assumptions on (non-) exclusion of degraded and protected land	Not explicitly specified	Not specified	Not specified	Energy crops: 120 EJ/yr
Smeets et al., 2007	Technical	11 World regions	2050	Biodiversity, Deforestation, Food security	Surplus agricultural land (100%)	7.3–35.9	16–21 odt(oven dry tonnes)/ha/yr	215–1272 EJ/yr

Erb et al., 2009	Technical	11 World regions	2050	Excluded: Land for food and feed, forestry and unproductive land	Cropland not needed for food and fiber supply Intensification of grazing land	2.3–9.9 depending on food and feed demand (44 scenarios)	Equal to potential (cropland) or actual (grazing land) NPP	Bioenergy crops: 28–128 EJ/yr Residues: 21–36 EJ/yr

- The German Advisory Council for Global Environmental Change (WBGU, 2009) considered two assumptions on future land requirements for food production, one in which the current cropland area was held constant, and one in which an additional demand for cropland area of 1.2 million km^2 was assumed. The other constraint was area requirements for nature protection (biodiversity hotspots, nature conservation areas, and wetlands) and exclusion of areas with carbon payback times exceeding 10 years. The study considered the impact of future climate change, including changes in CO_2 levels. Calculations were performed using the LPJmL dynamic global vegetation model that is able to simulate natural and agricultural vegetation (Bondeau et al., 2007). The MIN scenario assumes the highest area requirement for food and nature conservation, the MAX scenario the lowest. "Intermed" is the arithmetic mean of all other combinations.

- Dornburg et al. (2010) developed a sensitivity analysis, using existing modeling tools, to quantify key uncertainties regarding biomass potentials and demand. For the sensitivity analysis, the integrated assessment model (IMAGE) was applied, using the reference scenario of the Organisation for Economic Co-operation and Development (OECD) Environmental Outlook as a baseline (OECD, 2008a). This baseline is a "medium-development" scenario in terms of changes in population, economic development, and agricultural productivity. According to the study, to assess the potential impact of water scarcity on bioenergy potentials, the maps of biomass potentials were overlaid with those of water stress as calculated by the Water Gap model. The Water Gap model uses an index in which a value of 0.2 and higher is defined as moderate water scarcity, while values above 0.4 are defined as severe water scarcity. For all the calculations, rain-fed production conditions were assumed. In order to estimate the impact of degraded land use on biomass potentials, data from the GLASOD database that classified land worldwide in terms of soil degradation was used.

Table 20.6 shows that the area that could be available for bioenergy crops in 2050 ranges from 1.3–9.9 million km², which is about 1–8% of the earth's total land surface excluding Antarctica and Greenland. Erb et al. (2009) found the highest land area availability of all three studies (up to 9.9 million km²), because this study did not exclude areas for nature/biodiversity conservation. The study by van Vuuren et al. (2009) found the lowest land potentials (1.3–2.5 million km²), while those of WBGU are intermediate.

Maps of bioenergy crop areas found to be available in the first three studies are shown in Figure 20.5. These three studies agree that large areas might become available in sub-Saharan Africa and South America, and that areas in cold climates will not contribute significantly to global bioenergy production. Nevertheless, significant discrepancies with regard to extent and spatial patterns prevail in other regions of the world. For example, van Vuuren et al. (2009) and WBGU (2008) find substantial areas in Northern Australia not included in the dataset by Erb et al. (2009). In contrast to van Vuuren et al. (2009), WBGU (2008) and Erb et al. (2009) identify significant potentials in eastern China, India and Southeast Asia. In the United States and Eurasia, patterns differ due to the different assumptions of each of the studies. Erb et al. (2009) and WBGU (2008), for instance, assume that areas for energy crops might be available in the US Corn Belt, whereas van Vuuren et al. (2009) identified suitable areas in western parts of the United States. For Europe, Erb et al. (2009) and WBGU (2008) assume substantial area potentials in Eastern Europe, whereas van Vuuren et al. (2009) identified largest potentials in Northern Germany, the United Kingdom, and Ireland. In conclusion, further work on spatial patterns of possible areas for energy crops would be helpful to identify more robust estimates of suitable areas for energy crops. A refinement of the WBGU (2008) work – which basically confirmed the results of the WBGU study – was recently published (Beringer et al., 2011).

The results displayed in Table 20.6 are in line with a recent study by the IEA (2010) which suggested that 2.5–8 million km² could be available globally for bioenergy crops if constraints such as exclusion of forested land, valuable or protected habitats, etc. are properly accounted for (see also FAO, 2008a). The figures presented in Table 20.6 are a downward revision of earlier estimates that suggested area availabilities of 12.8 million km² (IPCC, 2007) or even as much as 37 million km² (WMO, 2006). The main reason is that new studies consider constraints stemming from livestock farming, nature protection and GHG emissions (carbon payback time) that have previously not sufficiently been considered.

The estimates of the global technical potential of primary bioenergy production (i.e., dedicated bioenergy plants) presented in Table 20.7 were derived from data reported in the same three studies. Table 20.7 summarizes the findings of the three studies and gives ranges for the

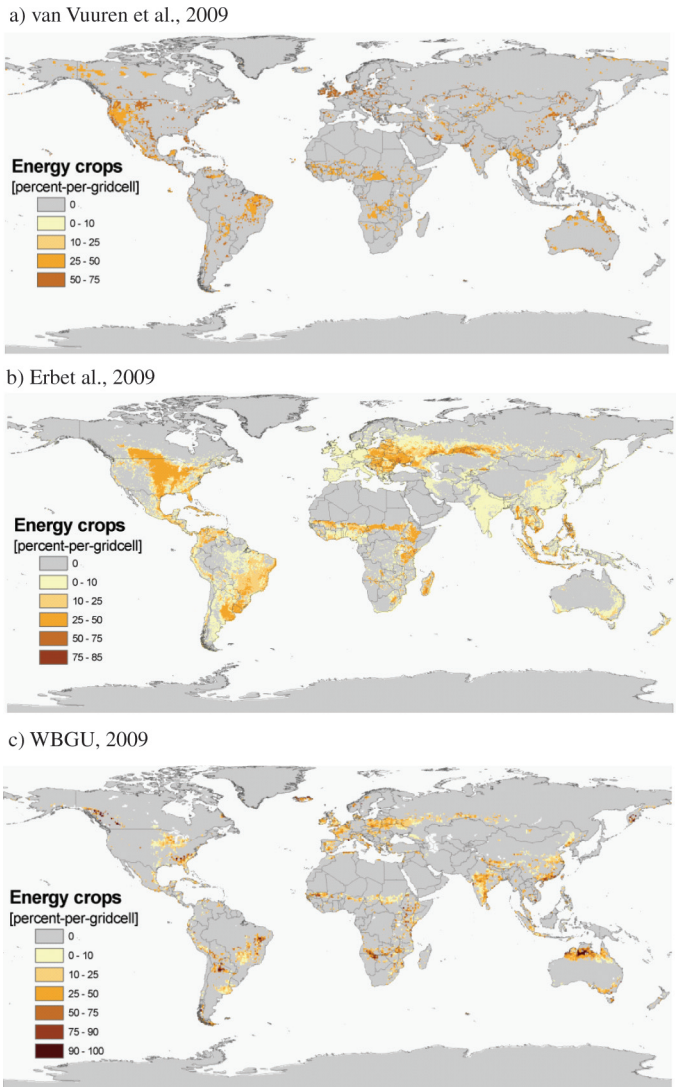

Figure 20.5 | Maps of the areas found to be available in the first three studies used in this assessment: (a) constrained scenario of van Vuuren et al., 2009; (b) TREND scenario based on Erb et al., 2009; and (c) scenario 2 (cropland high, conservation area low) based on WBGU, 2009.

bioenergy potential from primary bioenergy crops in 2050. These potentials were calculated as primary biomass supply potentials, i.e., more or less as the entire amount of aboveground biomass produced by bioenergy plants, multiplied by the gross calorific value of the biomass (18.5 MJ/kg in the study of Erb et al. (2009) and 19.0 MJ/kg in the study by WBGU (2008)). The comparison of these three studies leads to the following conclusions:

- A likely range of future primary bioenergy crop potentials in such studies for 2050 is 44–133 EJ/yr. Factors that would reduce the potential are high food demand (in terms of quantity and share of animal products), low agricultural yields in food production, low feeding efficiencies, large area requirements for nature conservation, and low energy crop yields. Factors that could help to increase the potential are low food demand and diets using fewer animal products, high yields and feeding efficiencies, and low area requirements for nature conservation. Climate change could also affect this potential both directly and indirectly, i.e., by influencing yields of energy crops and by influencing yield (and, therefore, area requirements) of other crops. Moreover, these findings suggest that there may be trade-offs between different environmental considerations such as conserving ecosystems and biodiversity, reducing agricultural pressures of agriculture, animal welfare and water issues, as well as the production of renewable energy from biomass. While there has been progress in better understanding these feedbacks, some of them are at present incompletely understood.

- The studies agree that the largest bioenergy crop potentials are located in Latin America and the Caribbean (LAC) and in Western and Central Africa (WCA). Substantial potentials were also found in the United States, the Former Soviet Union (FSU), and Australia, New Zealand and other Oceania (OCN). There are, however, some differences in the regional distribution of total potentials that result from the differences in methodology. Regional patterns should, therefore, not be over-interpreted.

- Despite the differences in energy crop areas, the results are similar. Van Vuuren et al. (2009) assumed the highest yields and the lowest area availability, whereas Erb et al. (2009) found larger area availability but assumed the lowest energy crop yields. WBGU (2009) used one of the most advanced process-based plant growth models (LPJmL) that incorporated plant functional traits of woody and herbaceous (C4 grass) bioenergy plants, which suggested yield potentials between the two other studies.

Considering sustainability constraints related to possible competing land demands (food, feed and fiber production, biodiversity conservation, etc.), problems posed by possible deforestation, and water availability, the first three studies analyzed in this chapter (van Vuuren et al., 2009; Erb et al., 2009; and WBGU, 2009) found global bioenergy crop potentials of 44–133 EJ/yr in 2050. The fourth one, Dornburg et al. (2010), concluded that for bioenergy crops (dedicated energy crops) they are 120 EJ/yr. Thus the range considered in this chapter is 44–133 EJ/yr for 2050.

20.2.4 Bioenergy scenarios for 2050: diets, agricultural technology and climate change

Previous sections of this chapter suggest that there are strong links between diets, agricultural technology and yield changes of food and bioenergy crops resulting from climate change. Three of the studies discussed (Erb et al., 2009; van Vuuren et al., 2009; and Dornburg et al., 2010) also analyzed possible feedbacks between diets, agricultural technology, and climate change (see Section 20.2.3. above). The model used by Erb et al. (2009) calculates primary bioenergy supply potentials

Table 20.7 | Bioenergy potentials by region from dedicated bioenergy crops from the first three studies.

in 2050 depending on assumptions on diets, cropland yields, cropland expansion, and feeding efficiencies of livestock (see Figure 20.6). The model was calibrated with a comprehensive global NPP, land-use and biomass-use database (Erb et al., 2007; Haberl et al., 2007; Krausmann et al., 2008) for 2000. The FAO report *World Agriculture: towards 2030/2050* and the "best guess" UN population forecast (Bruinsma, 2003; FAO, 2006) were used as baseline ("Trend" scenario). Assumptions for changes in diets, livestock feeding efficiency, cropland yields and cropland expansion were exogenously fed into the model based on literature reviews documented in Erb et al. (2009). The impact of climate change on cropland yields was evaluated using LPJmL runs (Müller et al., 2010).

Figure 20.6 shows how changes in diets and cropland yields may affect the global bioenergy potential of energy crops in 2050. According to Erb et al. (2009), the main assumptions underlying these calculations were:

- **Diets:** The "Trend" diet was derived for each world region by assuming that all countries in each of the 11 regions distinguished in that study would attain a level of calorie supply and animal product consumption similar to the richest country in the region. Results were similar to those derived by the FAO with a completely different methodology. The "Rich" diet assumed a global convergence to current US and European diet patterns, but did not assume that all regions would actually reach those high levels until 2050. The "Moderate" diet assumed the same per capita level of calorie supply as the "Trend" diet but a lower share of animal products. The "Frugal" diet assumed that the global per capita level of calorie supply would remain constant around the 2000 values and only

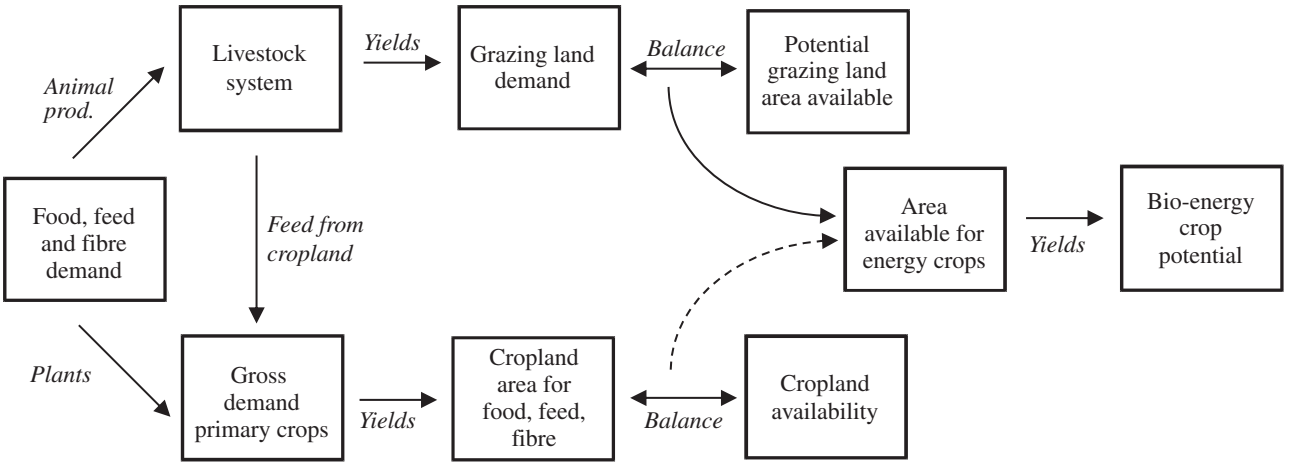

Figure 20.6 | Model structure of the land-use/biomass-balance model. Source: based on Erb et al., 2009.

20% of calories would be from animal products globally. While such a diet is nutritionally sufficient on an average basis, it would result in widespread malnutrition if current patterns of inequality of food supply persist.

- **Cropland yields:** The "Trend" assumption reproduces cropland yields as forecast by the FAO (2007a). The "Organic" yields were derived by assuming that all cropland would be cultivated according to IFOAM standards of organic agriculture. While this would imply substantial yield reductions compared to intensive conventional farming practices, it would also allow significant growth of yields in regions currently dominated by traditional low-input agriculture. The "Intermediate" yields are the mean between "Organic" and "Trend" yields, reflecting a trajectory where yield growth is constrained by environmental considerations. The "High" yields assumption was not part of the original Erb et al. (2009) study. In this case, the highest yield growth trajectory ("Global Orchestration") of the Millennium Ecosystem Assessment (2005) was adopted; yields were on average 9% higher than those forecast by the FAO (2007a).

- **Feeding efficiency:** The study contrasted conventional intensive indoor-housed feeding efficiencies with feeding efficiencies achieved if animal welfare standards or the even stricter standards of organic agriculture are adopted (here only the latter are reported; the "humane" assumptions were between conventional and organic efficiencies).

- **Cropland expansion:** The "Trend" assumption was taken from the FAO's *World Agriculture: towards 2030/2050* and assumed that global cropland area would grow by 9% between 2000 and 2050 (FAO, 2006). This was contrasted with a "Massive expansion" assumption, where growth of cropland areas between 2000 and 2050 was 19% – double the growth assumed by the FAO. Note that the assumption on cropland expansion had little influence on the bioenergy crop potential, because the study calculated the additional area that could be designated to grow bioenergy crops if sufficient grazing area were available to meet the projected level of roughage demand (see Figure 20.6 above).

The results reported in Figure 20.7 show that diet has a strong effect on bioenergy crop potentials. The "Rich" diet leaves little space for bioenergy plantations, while the "Frugal" diet (which could only be adopted without widespread malnutrition if food distribution were egalitarian) allows for large bioenergy crop potentials. As one moves to the poorer diets, the range between the lowest and highest potential also increases. This is because the "Frugal" diet can be easily provided if the most intensive technologies (cropland yields, feeding efficiency) are adopted. However, such a combination might seem particularly unlikely. It is interesting that in the case of the "Frugal" diet, substantial energy crop potentials exist even if "Organic" yields and feeding efficiencies are assumed.

Changes in the assumptions on food crop yields also have a substantial effect on the bioenergy crop potential, as higher yield levels obviously leave more space for bioenergy plantations, assuming all other factors remain the same.

However, note the perhaps unexpected result that the lowest bioenergy potential estimate found in any of the scenarios assumes "High" yields. The reason for this is that the "Rich" diet can only be provided if "High" or at least "Trend" yields are assumed, and this diet leaves very little space available for bioenergy plantations due to the high roughage demand, irrespective of yield levels of food crops. The Erb et al. (2009) study also analyzed the possible effect of climate change on the bioenergy potential. It found that the energy crop potential under "Trend" assumptions on all parameters would be 77 EJ/yr (see Table 20.7) if no changes in yield levels due to climate change are assumed. If the CO_2 fertilization were switched off in LPJmL, however, yields were lower and the energy crop potential dropped by 18% to 63 EJ/yr, while it rose to 120 EJ/yr (+56%) if the CO_2 fertilization effect were switched on. This

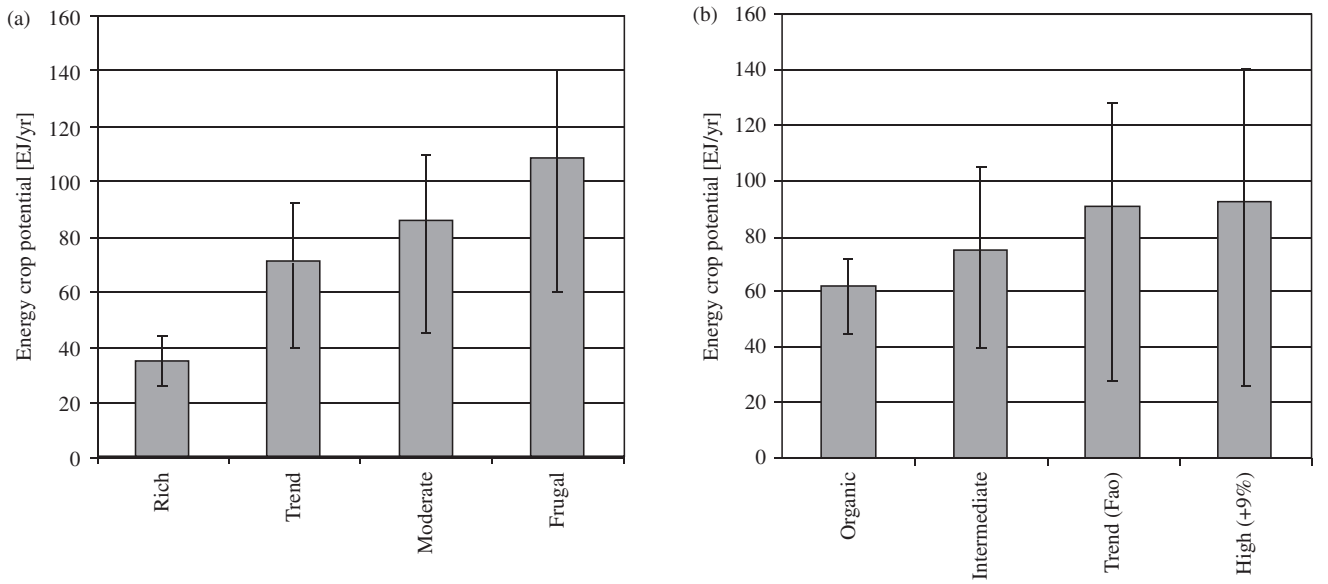

Figure 20.7 | Dependency of the global energy crop potential in 2050 on (a) changes in diets and (b) yields of food crops. Grey bars show the mean of all "feasible" scenarios (i.e., all scenarios that would deliver enough food for the respective diets), whiskers the range between the lowest and the highest scenario. Source: Erb et al., 2009 and additional calculations – see text.

suggests that the possible effect of climate change on yields introduces considerable uncertainty in estimates of global bioenergy potentials, in particular due to the indirect effect on food crops.

Van Vuuren et al. (2009) and Dornburg et al. (2010) also analyzed feedbacks between food demand, agricultural technology, and bioenergy crop potentials. In quantitative terms, comparing their results to those of the Erb et al. (2009) study, they found higher bioenergy crop potentials, mostly due to higher yields (see above), but they found the same basic dependencies of the bioenergy potential on diets and agricultural technology. It can be concluded that future bioenergy crop potentials strongly depend on diets and agricultural technology. Beyond trade-offs between food and energy, trade-offs between environmental quality goals and bioenergy potentials are also relevant. If, however, growth in yields could be reconciled with environmental quality goals (e.g., in terms of soil degradation, water pollution, biodiversity impacts, etc.) through sustainable high-yield practices or technologies, this would result in a major breakthrough in terms of food and energy supply (IAASTD, 2009; Godfray et al., 2010).

In conclusion, it can be stressed that bioenergy potential worldwide can be significant, even considering environmental restrictions to protect fragile ecosystems. However, strong investments are needed (IFPRI, 2009), mainly in capacity-building (to allow the implementation of efficient agricultural/industrial technologies, adequate policies and enforcement related to the environmental and social factors) and also to increase agricultural yields, which is fundamental to allow the implementation of the higher bioenergy potentials.

20.2.5 Bioenergy and land-use change: lessons from regional case studies

The notion of land use refers to a set of human actions – for example, arrangements, activities, and inputs – aimed at using land areas for human purposes. Land use usually results in changes in land cover, ranging from subtle effects to far-reaching alterations, including change from one land-cover type, e.g., forest, to another, such as cropland or grazing land (Lambin and Geist, 2006). The term "land use" also encompasses the social and economic purposes for which land is managed (e.g., grazing, timber extraction, or conservation). Human and natural factors in terrestrial systems are strongly linked, as captured in the recently coined notion of "land systems," conceptualized as coupled human-environment (or socio-ecological) systems in which socio-economic and natural factors are inextricably intertwined (Global Land Project, 2005; Turner et al., 2007).

Land-use change can influence surface albedo, evapotranspiration, sources and sinks of GHGs, or other properties of the climate system, and may thus have a radiative forcing effect and/or other impacts on climate, locally or globally (Baede, 2007). These environmental effects are discussed below in Section 20.4 on sustainability. At the same time, land use and land-use change are socioeconomic processes that are influenced by a host of cultural, political, legal, economic and social factors and can have substantial repercussions on humans. This subsection draws from a selection of case studies that are intended to exemplify how these drivers and feedbacks can interact in cases related to bioenergy and land-use change.

When discussing the issue of land-use change relating to agricultural and bioenergy crops, it is important to consider not only direct effects, i.e., effects caused by establishing plantations, but also indirect effects that could result from an expansion of agricultural and bioenergy crops, e.g., displacement effects between different crops. Indirect effects – indirect land-use change (ILUC) – can be more challenging than direct effects in terms of availability of evidence and the possibility of clearly establishing causal relations. For example, deforestation could result from an expansion of land under feedstock crops and the displacement of food crops from higher-value lands (Cotula et al., 2008). On the other hand, other studies (Nassar, 2009) concluded that there is no significant evidence for ILUC from bioenergy crops.

With regard to supporting rural development, new and profitable land-use systems can provide better opportunities and long-term security for farmers and employees, plus – if processing facilities are near to farms – value-addition possibilities for profits in rural areas (Cotula et al., 2008). For countries with favorable endowments of land, labor and trade conditions, biofuels and bioenergy offer an opportunity to develop new export markets and improve the trade balance (Cotula et al., 2008). However, the FAO (2008a) provides a list of 22 developing countries that are especially vulnerable to the negative effects of bioenergy production due to a combination of high levels of chronic hunger (more than 30% undernourishment) while being highly dependent on imports of petroleum products (100% in most countries) and, in many cases, on imports of major grains (rice, wheat, and maize) for domestic consumption. Countries such as Eritrea, Niger, Comoros, Botswana, Haiti, and Liberia are especially vulnerable due to a very high level of all three risk factors (FAO, 2008a).

Almost all developing countries show strong interest in implementing bioenergy production, both liquid biofuels for transportation and solid biomass/biogas for power production (GNESD, 2010). In Africa, the preliminary conclusions from the Cogen for Africa project (AFREPREN/FWD, 2009), being developed under the coordination of AFREPREN, funded by the Global Environmental Facility/United Nations Environment Programme (GEF/UNEP) and the African Development Bank (AfDB) and aiming to implement efficient biomass-based cogeneration technologies in sub-Saharan countries, show strong interest from these countries to increase sugarcane plantations in the region, not only to produce sugar but also ethanol from molasses (a by-product from sugar production). There is also a high interest in improving agricultural productivity in the region, showing that food production can be increased together with biofuel and bioenergy production. It is important also to notice the main objective of the project – electricity production from biomass (sugarcane bagasse) to increase energy access in the region in a sustainable way.[3]

Also for Latin American countries, biofuels appear an interesting option from the experience in Brazil, without competing with other end uses (GNESD, 2010). Many studies suggest that land potentials for agricultural crops and bioenergy in Latin America are substantial. However, competing demands for land may exist, mainly for agriculture, livestock production, and forestry. The production of agricultural and bioenergy crops has recently emerged as a contentious issue in some countries, either due to the potential direct competition between bioenergy and food crops, such as the use of maize for ethanol production in Mexico, or through direct or indirect expansion of the agriculture frontier over forests, such as soybean expansion in the Amazon (mainly to produce animal feed to export) and the Chaco Region in South America. On the other hand, there are several studies (Goldemberg, Coelho and Guardabassi, 2008; Goldemberg, 2008; Goldemberg and Guardabassi, 2009) showing positive results for Brazil and also presenting the benefits for developing countries when sustainable bioenergy production occurs, such as job generation in rural areas and local investments allowing significant development in developing countries. This could continue. The current liquid biofuel production in Latin America could be doubled sustainably based on first-generation feedstocks (Arias Chalico et al., 2009). Using second-generation feedstocks could further increase the potential. Improving productivity was found to be highly important (Pistonesi et al., 2008; Dornburg et al., 2010).

Sparovek et al. (2009) collected evidence suggesting that expansion of ethanol in Brazil from 1996 to 2006 did not contribute to direct deforestation in the traditional agricultural regions where most of the expansion took place. Their results show that sugarcane expansion did result in shrinking pasture areas and cattle head counts in these areas, as well as stronger economic growth. They could not exclude the possibility that the cattle migrated elsewhere, possibly resulting in deforestation in the Amazon. However, as mentioned above, more recent experience of sugarcane expansion in the State of São Paulo occurred without such impact, and other studies (Nassar et al., 2009) concluded that there is no evidence for such ILUC in the Brazilian sugarcane sector.

In another paper, Sparovek et al. (2007) showed that, if based on sound strategic plans, sugarcane ethanol production in Brazil could be extended in a manner that adequately considers social and environmental concerns. In their view, it would be necessary to integrate sugarcane production areas with existing land-use systems. They concluded that their development model could guarantee substantial expansion of production without resulting in displacement of extensive livestock production to remote areas, i.e., into tropical rainforests. The recent agro-environmental zoning for sugarcane both in São Paulo State and in Brazil (see Box 20.5) contributed to the achievement of these goals.

In Africa, biofuel production projects in low-income countries are often motivated by the seemingly large availability of land to grow feedstock crops. Somerville et al. (2010) claims that this would be the continent with the Earth's largest under-utilized land resources suitable to grow bioenergy crops.

On the other hand, the beginning of a biofuel boom in these countries has also raised concerns about potential environmental and/or

3 Coelho, S. T. Personal information by UNEP in field visits.

socioeconomic pressures. Much of Africa's land resources are characterized by soils and climate that might limit crop production, either due to low general suitability for energy crops or due to decreased potential as a result of land degradation. Bekunda et al. (2009) estimate that only 6–11% of the soils in Africa are devoid of serious constraints to effective management, with about 34% presenting medium or low potential, i.e., at least one major constraint to agriculture, and 55% altogether unsuitable for agriculture (Bekunda et al., 2009).

Food crops may be produced on lands that are less fertile but still suitable for farming, with current users having to relocate to other lands. This shift of farmers from food or cash crops to feedstocks may be voluntary in some situations, e.g., if bioenergy crop plantations offer favorable economic opportunities to farmers. For example, small-scale jatropha projects implemented in Mali have involved a shift from cotton to jatropha; this has been attributed to falling cotton prices and increases in the perceived (monetary and non-monetary) values of jatropha (Cotula et al., 2008). On the other hand, the opposite may occur. In 2011, sugarcane ethanol producers in Brazil decided to produce more sugar than ethanol, considering the high prices of sugar in the international market.[4]

There are concerns about indirect effects associated with large-scale cultivation of biofuel crops, which may include significant negative impacts on land access by local groups. For example, a multimillion dollar jatropha project in the Kisarawe district of Tanzania has been reported to involve the acquisition of 90 km^2 of land and the clearing of 11 villages, which, according to the 2002 population census, are home to 11,277 people. Approximately, US$632,400 was set aside to compensate 2840 households (African Press Agency, 2007).

However, the FAO (2010a) Bioenergy and Food Security (BEFS)[5] study for Tanzania shows that such problems can be avoided when adequate planning and agro-ecological zoning are in place. The study concludes that biofuel developments could provide an important vehicle through which to revitalize agriculture by bringing a variety of investments to increase productivity. The report shows that there are areas potentially suitable for bioenergy production, excluding those that are environmentally protected or under alternative uses. The technically viable and most competitive smallholder-integrated production chains were considered. This analysis has shown that "the dividends from investing in biofuels can have positive impacts on poverty reduction and growth." This case study is the first of several focusing on African countries in the context of the BEFS project, which has the aim of strengthening developing countries' technical understanding of how best to mitigate the impact of bioenergy development on food security.

In Asian countries such as India, some authors have argued that substantial land areas are available for biofuel production. However, several critical issues that needed to be addressed were identified, including the costs of inputs to grow the biofuels on "wastelands," the growing demand for food production, and the social implications of converting areas currently allocated to food production into bioenergy crop plantations. Bekunda et al. (2009) recently analyzed a scenario in which one quarter of the total area of "wastelands" assumed to exist in India (i.e., 104,000 km^2) would be converted to jatropha plantations with an average yield of 1.5 t/ha/yr of oil. They suggest that the lands would require significant inputs of nutrients and the adoption of soil and water conservation measures to realize such yield levels.

On the other hand, a recent report from The Energy and Resources Institute (TERI, 2010) discusses the potential for bioenergy in India, mainly using agricultural wastes and dedicated energy plantations (in degraded lands and wastelands) and indicates that there are 496,000 km^2 of available area categorized under "wasteland," as estimated by the Department of Land Resources. Out of this total, almost 66% falls into the classification of "wasteland suitable for land conversion," with almost 40% (129,600 km^2) of this land in the categories of underutilized/degraded forest land, degraded pastures and degraded land under plantation crops. The report concludes that these offer the highest potential for being converted into land for dedicated energy plantations. It also mentions that there is a large amount of available biomass in rural areas, and its usage in traditional forms causes negative social and economic impacts on rural households. In the proposed scenario, putting the available biomass to productive use would be a good strategy for the sustainable development of rural areas. Finally, the report concludes that bioenergy can contribute to rural development and poverty alleviation.

Some countries have witnessed protests against large-scale land transfers for biofuel production, indicating public concern over the implications of biofuels for land use (Cotula et al., 2008). For example, for Uganda, Cotula et al. (2008) report that there was strong public opposition to a planned allocation of national forest reserves in Bugala and Mabira to foreign plantation companies to establish oil palm and sugarcane plantations. However, conclusions from the recent Cogen for Africa project show that there is now environmental legislation in place (not only in Uganda but also in other sub-Saharan countries) to avoid such problems. Even the financial support of the AfDB is assured only when adequate Environmental Impact Assessments are developed.[6]

There are doubts about the concept of "idle" or "abandoned" land (Dufey et al., 2007; Cotula et al., 2008). In most situations, lands perceived to be

4 See www.conab.gov.br.

5 The BEFS project is funded by the United Nations FAO and the Government of Germany. Under the project, the FAO has developed a quantitative and qualitative framework to analyze the interplay between bioenergy and food security. The BEFS Analytical Framework provides tools that permit policymakers to make informed decisions with respect to bioenergy.

6 Coelho, S. T. Personal information by AfDB in field visits, invited by UNEP.

"idle," "under-utilized," "marginal," or "abandoned" by governments and large private operators provide a vital basis for the livelihoods of poorer and vulnerable groups, through crop farming, herding, and gathering of wild products. Further, seemingly "abandoned" land often provides important subsistence functions in times of stress to vulnerable households. Hence, the promotion of biomass production on degraded lands must avoid competition with these other land uses. These studies also claimed that other issues may cause or increase land-use conflicts, including poor enforcement of laws on land-use planning, particularly when large profits are at stake, as in the case of the expansion of oil palm plantations on native forests or even forest reserves.

Competing demands for land in Africa are primarily for agriculture and forestry, with the production of biomass for energy an emerging issue. Recent efforts have increasingly been aimed at identifying land areas for feedstock production that reduce competition with production of food and other biomass-based products. Policy suggestions have included the planting of biofuel crops on "marginal" and "idle" lands rather than prime agricultural land. Rural development and poverty alleviation from the implementation of bioenergy programs in developing countries have also been extensively discussed.

Some calculations indicate that apparent land availability differs from region to region. This implies the need for detailed regional and national assessments of the amount of land available, the quality of land for producing biofuels, potential conflicts with (or displacement of) land for food production, and the potential to increase food insecurity (Bekunda et al., 2009). Other studies (Martínez-Alier, 2002; Vanwey, 2009) also argue that subsistence agriculture is often strongly influenced by cultural or other social values that cannot be expressed in monetary terms, and that their benefits cannot be estimated using conventional methods such as cost-benefit analysis.

The European Union (EU) biofuels directive (discussed later in this chapter) is further providing incentives for the use of "degraded" lands for feedstock production. The assumption is that biofuel production will not compete with agricultural production on prime lands. Some governments have already taken steps to identify "idle" land and to allocate it for commercial biofuel production. Some governments have claimed that significant land areas are under-utilized and available for biofuel production. For instance, the Government of Mozambique has stated that only 9% of the country's 360,000 km^2 of arable land is currently in use, and that there is the possibility of bringing into production an additional 412,000 km^2 of marginal land currently not being used (Namburete, 2006, cited in Cotula et al., 2008). In fact it has expressed a strong interest in the production of biofuels in the country in a sustainable way.[7]

Another recent study (Müller et al., 2007) also suggested that sub-Saharan Africa could have substantial resources in terms of suitable land and exploitable water to expand areas for agricultural production, including bioenergy production. This conclusion is confirmed by the results of the Cogen for Africa project.

Another important issue is related to women's land rights; some studies argue that they risk being eroded by large-scale biofuel expansion, due to existing gender inequalities. In Kenya, for example, despite providing 70% of agricultural labor, women only own 1% of the land they farm (DFID, 2007). This is replicated across the developing world, with only 5% of women farmers owning their land (IUCN, 2007; Cotula et al., 2008). However, it must be noted that this is a problem for the agricultural sector as a whole and not only for biofuels.

The complexities of women's involvement are recognized in Mali, for instance, where small-scale jatropha cultivation to meet local energy needs has been promoted by both government authorities and development agencies. The Ministry of Mines, Energy and Water is implementing a US$1.6 million Programme National de Valorisation Energétique de la Plante Pourghère to promote the use of jatropha for rural electrification, conversion of vehicles to biofuels, and poverty reduction amongst rural women (Cotula et al., 2008).

The implementation of adequate social policies and enforcement can contribute to reducing these problems. For example, sugarcane plantations in Brazil, mainly in Ribeirao Preto, São Paulo State, allow significant improvements on gender and social issues.[8] Existing statistics from Uniao da Industria de Cana de Açúcar (ÚNICA, 2010) show that in this region inequalities in gender are smaller and social aspects such as strict labor legislation are very much taken into consideration.

Bioenergy produced on currently grazed lands can have large-scale impacts on livestock-rearing subsistence farmers. These may be positive or negative, depending on the implementation strategy. Large-scale bioenergy plantations owned and operated by international, vertically integrated cooperatives tend not to benefit the local farming communities where the biomass is produced, as most of the revenue is generated in the production stage that involves sophisticated biochemical conversion technologies (Sagar and Kartha, 2007). On the other hand, small-scale, locally owned and operated plants, together with sustainability certification systems, might help ensure that benefits accrue to the local farming communities (Lewandowski and Faaij, 2006).

Soyka et al. (2007), focusing on Indonesia, raised the question of whether it was possible to increase tropical biofuel production without increasing tropical deforestation. However, Wicke et al. (2011) argued that palm oil crops are not the main reason for deforestation in Malaysia and Indonesia, and that there are several other factors involved, as discussed in Section 20.4. Figure 20.8 illustrates this discussion.

7 Coelho, S. T. Personal information from field visit to Mozambique invited by UNCTAD, 2010.

8 Ribeirao Preto, the most developed region in the rural areas of the country, has a local economy based almost exclusively on sugarcane crops.

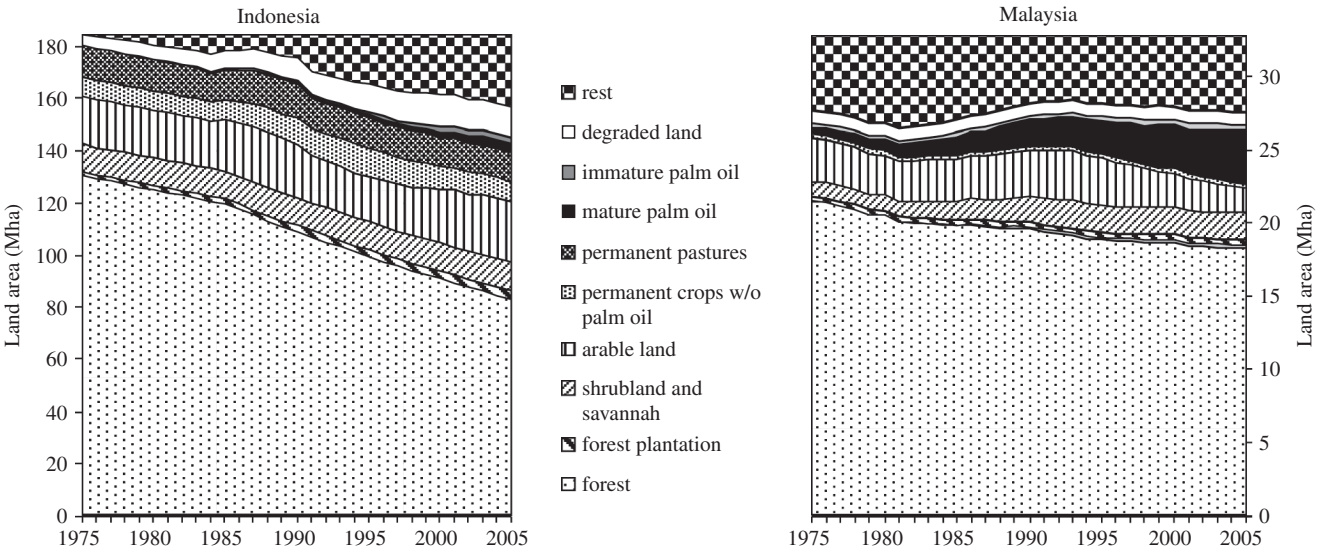

Figure 20.8 | Land-use change in Indonesia (left) and in Malaysia (right). Source: Wicke et al., 2011.

In fact, according to Wicke et al. (2011), it was found for Indonesia that "there are many, interrelated causes and underlying drivers that are responsible for this land-use change (…). Palm oil alone cannot explain the large loss in forest cover but rather a web of interrelated direct causes (including oil palm production expansion) and underlying drivers are responsible. Important direct causes were logging, palm oil expansion and other agricultural production and forest fires, while underlying drivers were found to be population growth, agriculture and forestry prices, economic growth and policy and institutional factors."

For Malaysia, Wicke et al. (2011) show that "the most important causes of land use change vary per region: In Sabah and Sarawak the most important causes have been timber extraction and shifting cultivation, while in Peninsular Malaysia, and in recent years increasingly in Sabah, forest cover has been affected most by conversion to agriculture, mainly oil palm production." The study also concludes that "additional forested land and peat land are not necessarily required for most projections of oil palm production expansion to be feasible. This is because yield improvements can largely reduce land requirements while also large amounts of degraded land exist in Indonesia. (…). As in Indonesia, yield improvements are also an important component of allowing potentially sustainable expansion. In Malaysia, yield improvements in the short term in both countries are mainly possible by applying fertilizer and other inputs more appropriately (and) practicing good harvesting standards (…)."

Moreover, according to the Malaysian Palm Oil Board, protected areas were defined in the country to preserve biodiversity and native forests.

Considering all these issues, Wicke et al. (2011) conclude that adequate policies and enforcement can minimize land-use conflicts due to the implementation of bioenergy crops, especially in regions where motivations of small farmers ("smallholders") include strong components not usually considered in classical agro-economic toolboxes and dominant development models.

The FAO (2010a) also argues that "biofuel developments could play a pivotal role in promoting rural development through increased local employment and energy supply. Implementing bioenergy production can result in improvements or a worsening in the food security conditions depending on the bioenergy pathway chosen."

In conclusion, these case studies suggest that land allocation to different uses, including agricultural and bioenergy crop production, involves sensitive socioeconomic issues related to food security, land tenure, land-use rights, subsistence versus market economy, cultural values, etc. Careful consideration of these issues, and implementation of sensible policies and legal frameworks, will, therefore, be key for the public acceptance of bioenergy crop plantation projects and will have an important impact on whether they will be perceived as beneficial development opportunities or as "land grab" (Friis and Reenberg, 2010).

20.2.6 Economic Effects of Land Use Competition

The discussion of fuel versus food is a long one and quite controversial. In this chapter some recent studies are presented to contribute to the discussion. A number of studies have looked at the linkages between the growth of biofuel production and the dynamics of food prices – both within the 2007–2008 time period and in the follow-up to the 2009–2010 financial market crisis and recovery period. A number of papers that emerged in the immediate wake of the 2007–2008 food price spike were strongly of the opinion that growth in biofuel production was the major contributor to food

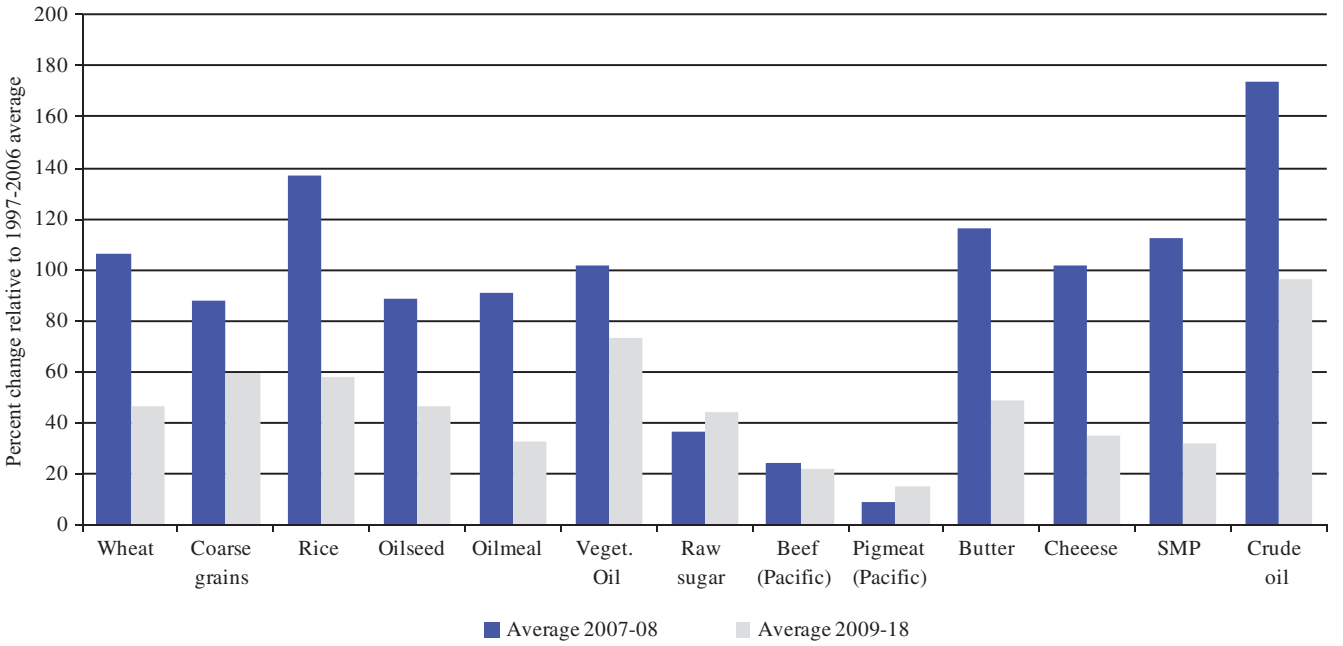

Figure 20.9 | Nominal commodity prices projected 15–60% higher than 1997–2006 but substantially lower than in the 2007–2008 peak. Source: OECD/FAO, 2009 (p19).

price increases (Runge and Senauer, 2007; OECD, 2008b; Mitchell, 2008; von Braun, 2007). In contrast, other authors were more cautious about the estimated impact of biofuels, and placed more weight on the macroeconomic factors such as exchange rates, grain storage policies and possible market speculation that could have played a role in the food market price dynamics during that period (Trostle, 2008; Abbot et al., 2008). Besides food price impacts, some authors also critiqued the economic efficiency of biofuel policies in terms of the distortions they place on markets, as in the case of the US corn ethanol program, where mandates, blending targets and import tariffs, combine in a way that both raises commodity prices and may even encourage the consumption of fossil fuel under certain circumstances (de Gorter and Just, 2007).

In the past, according to the FAO food price indices, nominal prices of agricultural commodities fluctuated but in a medium-term perspective were mostly stable or declining from 1990–2007 (see Figure 20.9). Deflated values suggest that food prices were fluctuating around a continuous long-term downwards trajectory in real terms in the last decades, at least until 2007.

Starting in 2007, many agricultural prices increased substantially and remained high throughout most of 2008, falling sharply afterwards, most probably due to a reduction in oil prices (Faaij, 2009; Goldemberg, 2009) and reduced demand for many commodities resulting from the global financial crisis. Sugar seemed to be an exception; its price peaked in 2006 and then again in 2010 but was low during the period of high agricultural prices in 2007/2008.

These events triggered a debate on the question whether this was just another, only a bit stronger, price fluctuation that would not change the long-term price trajectory, or whether it signaled a structural break, i.e., a long-term change in the trajectory of agricultural prices in an upward direction (FAO, 2009a; 2009b; OECD/FAO, 2009).

More recently, the OECD and FAO (OECD/FAO, 2009) showed that "despite the significant impact of the global financial crisis and economic downturn on all sectors of the economy, agriculture is expected to be relatively better off, as a result of the recent period of relatively high incomes and a relatively income-inelastic demand for food." The report also concludes that biofuels can influence agricultural prices but in general because "energy and agricultural prices have become much more interdependent with industrialized farming (…). Crude oil prices are highly volatile (…). The crude oil price (…) assumed for the baseline is about 60% higher than the 1997–2006 average in real terms, moderately increasing to US$70 per barrel by the end of projection period. If crude oil prices increased to the US$90 to US$100 per barrel level used in last year's (report), agricultural prices would be significantly higher; with the largest impact on crops, driven mainly by reduced crop production with higher input costs, but also increased feedstock demand for biofuels."

Figure 20.10c illustrates projections for the period 2009–2018. The study adjusted the prices for inflation, which are, in real terms, expected on average to be much below 2007–2008 average peak levels. Results show that "the crops expected to undergo the largest fall in real prices, compared to their 2007–08 average, are: rice, wheat, butter, cheese and skim milk powder. However, over the outlook period, real prices of products other than beef and pig meat are expected to be above their average 1997–2006 levels. In real terms, the average crude oil price assumption for the next decade is substantially below its 2007–08 peak, and remains well above, by around 60%, the 1997–2006 average level."

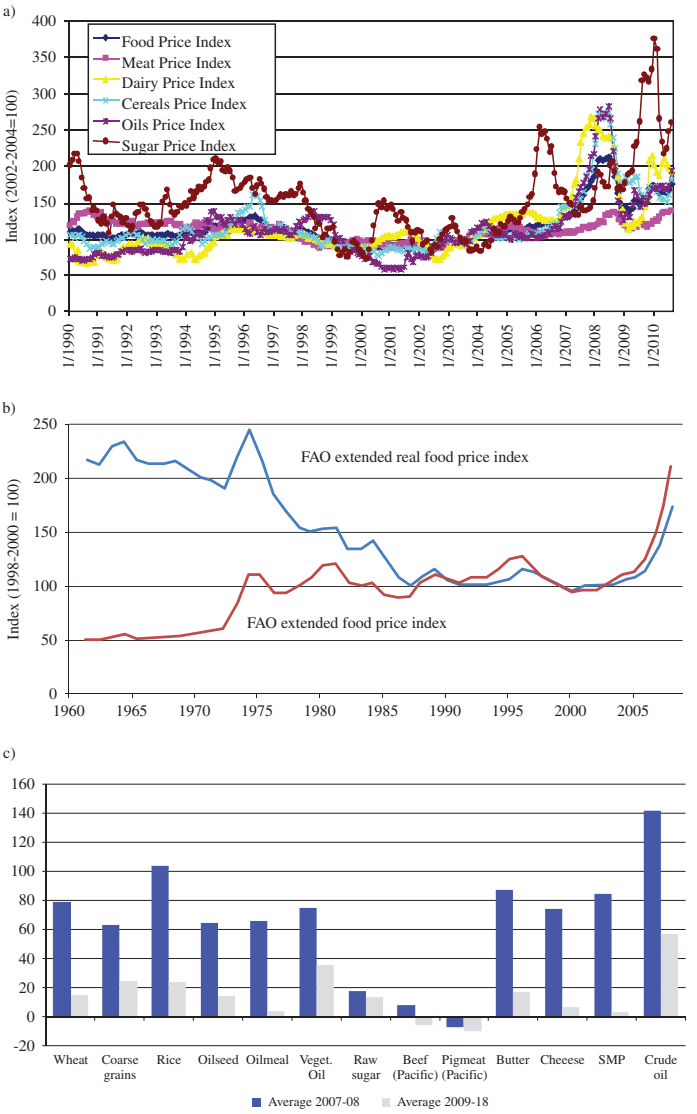

Figure 20.10 | (a) FAO food price index (nominal; monthly values, indexed to 2002/2004 = 100) for the period 01/1990–08/2010. Source: FAO, 2009c. (b) Nominal (yellow) and real FAO food price index 1961–2008. Source: FAO, 2009c. (c) Real crop prices to fall from peaks but to remain above 1997–2006 average. Source: OECD/FAO, 2009 (p19).

The list of potential explanations for the price rally in 2007 and 2008 is long and includes: low yields due to unfavorable weather (droughts); strong policies promoting biofuel production in the United States and Europe; high oil prices;[9] increasing food demand arising from strong economic growth in developing countries, in particular China and India; inflows of speculative funds; and low stocks of many agricultural commodities (OECD/FAO, 2007; 2009; FAO, 2009b; Trostle, 2008). In addition, depreciation of the value of the US dollar compared to other currencies seems to have been one of the reasons leading to the strong increases in prices. The price hikes were less dramatic when expressed in other currencies. However, for the United States and all other countries whose local currencies are pegged to or weaker than the US dollar, the depreciation of the dollar did in fact increase the costs of procuring food (FAO, 2009b; OECD/FAO, 2009).

Estimates of the effects of the growing production of biofuels on food prices vary, depending on the time period considered and the food price indicator chosen. The effect of increased biofuels production on the price of commodities was much larger for those commodities that are used for both food and fuel production such as maize (for food and for corn ethanol in the United States) than the impact on food price indices that consider a broader range of commodities and processed foods.

In its *World Development Report* 2008, the World Bank (2008) argued that rapid expansion of biofuels had strongly contributed to the price hike. For example, the World Bank claimed that the massive use of maize for ethanol production in the United States had reduced maize stocks and had largely caused the surge in maize prices in 2006 and 2007. While a different report by the World Bank (Mitchell, 2008) concluded that US and European biofuel policies were responsible for most of the food price increase, a later study also published by the World Bank concluded that the effect of biofuel policies had been over-estimated in that earlier study (Baffes and Haniotis, 2010).

The OECD (2008b) concludes that while biofuel policies did contribute to the increases in food prices in 2007 and 2008, they would result in rather limited price increases in the medium term, i.e., for the period from 2013 to 2017. For example, the OECD calculated that current EU and US policies would drive up prices of coarse grains by about 5% compared to the baseline. Vegetable oils would be more strongly affected; their prices were forecast by the OECD (2008b) to increase by 15%.

The FAO (2009b) and OECD/FAO (2009) discuss the 2007–2008 price hikes and distinguished short-term effects and long-term trends. With respect to short-term fluctuations in 2007–2008, the FAO concluded that growing consumption in India and China is unlikely to have contributed to the price hike, because, in those years, their growth rates were below that of the aggregate of all other countries and their trade patterns did not show sudden changes. (However, it was argued that changes in their consumption patterns could be relevant over the medium to long term.) This FAO study also concluded that the rapid growth in the use of maize for ethanol in the United States and oil crops for biodiesel in the EU, caused by the introduction of respective blending targets and subsidies, played a major role in influencing prices. In 2007, 12% of the global maize production and 25% of the global rapeseed production were used as feedstock for biofuels, and these shares had been growing rapidly. This coincided with bad harvests in 2005 and 2006 and hence record-low stocks.

With respect to speculation, the FAO mentioned that it was not clear whether speculation was driving prices, or whether it was attracted by prices that were increasing anyway. Speculation might have resulted in

9 The oil price affects the prices of agricultural commodities because of the energy needed in agricultural production, both directly (e.g., tractors) and indirectly (e.g., fertilizer production).

increased volatility, according to the FAO study. In conclusion, the FAO argued that no factor in isolation could explain the price hikes, only their combination and coincidence. With respect to possible structural effects that would change price trajectories in the coming decades, the FAO concluded that biofuels, and indeed any energy technology requiring significant amounts of highly fertile lands and, therefore, competing with food production for land resources, would influence food markets.

The FAO also reckoned that biofuels are at present not competitive with fossil fuels, with the exception of ethanol from Brazilian sugarcane. Therefore, their impact on agricultural markets would remain limited to the extent to which they were subsidized, i.e., their impact on agricultural markets would remain limited except under extraordinary circumstances, such as a rapid introduction through policy interventions in response to weather or other effects. As soon as oil prices climb to a level where biofuels become economically competitive, however, agricultural and energy markets would become linked in a new way: "[a]s energy markets are huge relative to agricultural markets, demand from the biofuel sector could *in principle* absorb any additional production in crops usable as feed stocks so the energy market would effectively set a floor price for agricultural products. It would also set a ceiling on agricultural prices at the point where they have risen so much that biofuel production is no longer competitive. It would be energy demands rather than food demands that would set agricultural product prices and agricultural product prices would be tied to *energy* prices. Clearly, this would be a major departure from how agricultural product prices have been determined in the past" (FAO, 2009c).

Other authors have drawn similar conclusions. For example, Müller et al. (2007) concluded that competition for land would increase and prices of essentially all crops would rise if a growing range of crops became competitive as feedstock for biofuel production. Moreover, other agricultural products that could be used as substitutes for other, non-renewable resources would in this case become increasingly competitive, thereby giving farmers greater flexibility to switch between different crops, e.g., between food and energy crops.

On the other hand, the OECD/FAO (2009) stressed that after the (2007–2008) high-price crisis there has again been evidence of the rapid responsiveness of global agriculture. High international commodity prices have transmitted signals to farmers to allocate more resources and increase agricultural production. However, not all farmers responded similarly, as high world prices are not transmitted to local producers in many instances. A decomposition of the response of farmers by economic region reveals that output expansion in developed countries amounted to over 13%, but developing countries together could only muster a 2% increase in their cereal production. This lack of response from a large part of the world shows the need for policy reform and additional investment in productive agriculture, particularly in many developing countries. Structural problems are likely to persist, especially for the Least Developed Countries, limiting their capacity to produce. Other studies (Goldemberg, 2009; Faaij, 2009) also concluded that the increase in food prices was mainly caused by the rising oil price and poor food distribution in developing countries.

Also, more recent FAO estimates, derived from simulations with the OECD/FAO Aglink-Cosimo model, suggest that keeping biofuel production at 2007 levels would reduce the price of maize in 2017 by 12% and that of vegetable oil by 15% compared to the respective baseline projections (FAO, 2009c).

In brief, as raised by Dornburg et al. (2010), "it is claimed that biofuels will lead to famine, deplete water resources and destroy biodiversity and soils. (…) Biofuels are often regarded as the cause of the dramatic increases in food prices that have occurred over the past few years." In fact, "[b]iofuel developments have local, national, regional and global impacts across interlinked social, environmental and economic domains" (FAO, 2010a).

The recent increase in food prices exacerbated such criticism. However, the report from OECD/FAO (2009) mentioned above showed that agricultural markets saw a reduction in commodity prices in 2009 after their rapid rise during 2006–2008, and perspectives for future prices are not so negative. "Looking forward, real commodity prices over the 2009–2018 period are projected to remain at, or above, the 1997–2006 average. An expected economic recovery, renewed food demand growth from developing countries and the emerging biofuel markets are the key drivers underpinning agricultural commodity prices and markets over the medium term."

As more data became available in the aftermath of the 2007–2008 food price spike, and more analysis was able to be carried out on emerging market-level price, production and consumption data, other authors began to contribute additional insight into the role that biofuels could have played in driving global and regional food prices. The analysis of Heady and Fan (2010) maintained that the influence of biofuels was still strong for markets such as maize, whereas the dynamics for other grain markets such as rice were related to trade policies and national commodity prices in individual countries. Gilbert (2010) is among those authors who argued against the premise that biofuels played a major part in the food price spikes of 2007–2008, and that speculation in agricultural commodity futures had a much stronger role. Baffes and Haniotis (2010) – following on the earlier analysis of food price impacts by Ivanic and Martin (2008) – took a more middle-of-the-road position and argue that even though the role of biofuels may not have been as strong as was suggested in the earlier literature, there does exist a strong link between energy and food prices. They, like other authors, also point to the fact that agricultural commodities are becoming a large part of financial investment portfolios, and point to trends of variability in historic prices of commodities.

Zhang et al. (2010) analyzed time-series prices on fuels and agricultural commodities, and results indicate no direct long-term price relations between fuel and agricultural commodity prices. In fact rising sugar

prices appear to be the leading cause of price inflation in other agricultural commodities; however, the study concludes that, with decentralized competitive agricultural markets, this sugar price impact is transitory.

The estimation of the impact of increased biofuel production on food prices has mostly been done with the help of country- or global-level economic multi-market equilibrium models that are either partial or fully comprehensive in terms of the economy-wide linkages that connect the supply and demand of agricultural commodities to important economic sectors. The nature of the particular model determines how closely the supply and demand dynamics of the agricultural food commodities themselves are linked to important input markets such as fertilizer, labor, and energy – especially biofuels and their interactions with crude oil prices. The particular structure and underlying assumptions of these models, by themselves, can have a considerable effect on the estimates of increased biofuel production on price impacts. A comprehensive meta-analysis of the differences in modeling the impacts of biofuels on land-use change (Edwards et al., 2010) showed evidence of systematic differences across types of modeling approaches, especially when moving from "partial-equilibrium" models that focus mostly on agricultural markets towards those "computable general-equilibrium" (CGE) models that consider the deeper complexities of linkages across many sectors of the economy.

These types of global CGE models have been used to demonstrate both the environmental as well as the price impact of increased biofuel production in more recent studies. The study carried out by al-Riffai et al. (2010) to evaluate the environmental implications of the EU Renewable Fuels Directive, for example, used a global CGE model with linkages to land availability to illustrate the implications of increased OECD biofuel production on GHG emissions.

Besides showing the relative "superiority" (in terms of environmental impacts and GHG emissions) of Brazilian sugarcane over US-based maize ethanol, the authors also show that liberalizing world (and especially US) trade policy to reduce tariff barriers against biofuel imports has the effect of reducing grain prices for both food use and livestock feed.

A recent study by the World Bank (Timilsina et al., 2010) illustrates the effect of increased biofuel production on land use, food prices, and poverty, and argues that moving from a scenario where OECD blending mandates and biofuel production targets are announced at current levels and are further enhanced by scaling up production capacity and doubling blending targets and biofuel production results in a near doubling of modest impacts on food prices. They also show some impacts on the supply of livestock products, sugar, and grains, as a result of the expansion of biofuels production – although the overall effect on the supply of food is relatively small (on the order of 0.2% lower than the baseline case). Even though they argue that their results are similar to those of al-Riffai et al. (2010) and others, this further illustrates the influence that model structure has on the simulated impacts of increased biofuel production.

The additional flexibility that these models have built into their structure, to capture the land-use dynamics and competition between crop, livestock and forestry cover, may understate the price impacts through their tendency to freely adjust land supply in response to relative price changes across commodities. This points to trade-offs that are inherent to different modeling approaches that try to either capture the environmental impacts of biofuels or the commodity market interactions (Nassar et al., 2011).

20.2.7 Bioenergy and Food Security

Food security (see Box 20.1) must be addressed in line with the world's commitment to eradicate extreme poverty and hunger as part of the Millennium Development Goals (MDGs) (UN, 2000). In fact, some food

Box 20.1 | Food Security

"Food security exists when all people, at all times, have physical, social and economic access to sufficient amounts of safe and nutritious food that meets their dietary needs and food preferences for an active and healthy life. There are four dimensions to food security: availability, access, stability and utilization. Availability of adequate food supplies refers to the capacity of an agro-ecological system to meet overall demand for food (including animal products, livelihoods and how producers respond to markets). Access to food refers to the ability of households to economically access food (or livelihoods), defined in terms of enough purchasing power or access to sufficient resources (entitlements). Stability refers to the time dimension of food security. Stability of food supplies refers to those situations in which populations are vulnerable to either temporarily or permanently losing access to resources, factor inputs, social capital or livelihoods due to extreme weather events, economic or market failure, civil conflict or environmental degradation, and increasingly, conflict over natural resources. Utilization of food refers to peoples' ability to absorb nutrients and is closely linked to health and nutrition factors, such as access to clean water, sanitation and medical services."

Source: Faaij, 2008.

price fluctuations will always occur. Therefore, to protect poor people, and food security generally, adequate policies have to be implemented, such as adequate agro-environmental zoning together with economic and environmental legislation.

The linkages between bioenergy and food security are complex. Food availability can be threatened if land, water and other resources are diverted from food to biofuel production (Dornburg et al., 2010). Competition for resources is reduced if biofuels are produced from non-edible crops and if the biofuel crops are cultivated on land that would not be utilized for food production in the foreseeable future. Crop selection, farming practices and yield growth patterns can have significant implications for potential impacts of biofuel growth on food availability. Food access is determined by the prices of food and the income levels of the poorest segments of society depending upon food purchases to meet their dietary needs. A significant number of people produce less food than they consume and in some cases may face an immediate negative impact in response to rising commodity prices (FAO, 2008c; 2009b; 2009d; OECD/FAO, 2009).

As mentioned by Dornburg et al. (2010), biofuel production is considered by some as the reason for rises in food prices, mainly grain prices. Poorer households spend a greater percentage of their income on food, particularly on staples, than richer ones, and are thus disproportionately affected by rising food prices. However, this question is much more complex (see discussion in Section 20.2.6.)

There are also opportunities for biofuels to contribute to greater food security. Poor farmers could benefit financially from selling commodities at higher prices. At the national level, high prices offer development opportunities for countries with significant agricultural resources and potential, such as Tanzania (Müller et al., 2007; FAO, 2010a). Greater demand for biofuels can boost incomes by revitalizing agriculture, providing new employment opportunities, and increasing access to modern energy, which can increase household welfare and contribute to rural development (FAO, 2008a; OECD/FAO, 2009).

Higher prices can also provide incentives for intensification, leading to increased food production, and improved livelihoods as long as production methods are sustainable (FAO, 2008a). Establishment of large-scale biofuel production systems could also provide benefits in the form of employment – mainly jobs in rural areas, skills development, and secondary industry (Cotula et al., 2008).

Attention must be given to developing and Least Developed Countries, since the FAO (2009d) warned that high prices for consumers do not necessarily mean high prices for poor producers in developing countries and have so far not triggered a positive supply response by smallholders there. The FAO study reported that access to means of production and assets such as land is critical for small farmers to be able to harness positive effects of price increases – if this cannot be guaranteed, large landholders are likely to benefit most from high food prices. However, the recent study from the OECD/FAO (2009) showed perspectives for agricultural commodity production increasingly shifting away from developed countries towards developing regions.

The impacts of bioenergy developments on food security depend on many factors that are country- and case-specific. Examples of these factors include the type of biomass used, the type of energy carrier produced, the type of land used for biomass production, and developments in agricultural management and in the global food markets (Box 20.2).

Box 20.2 | Preliminary insights from FAO's Bioenergy and Food Security project[10]

"Bioenergy, and particularly liquid biofuels, have been promoted as a means to enhance energy independence, promote rural development and reduce greenhouse-gas emissions. In principle there are many benefits offered by bioenergy developments but these need to be balanced against the impacts on food security and the environment. While there has been a rush by many governments to develop bioenergy alternatives to fossil fuels this has often been done in the absence of a wider understanding of the full costs and benefits of bioenergy."

Preliminary results from three countries (Peru, Tanzania, and Thailand) participating in FAO's Bioenergy and Food Security (BEFS) project suggest that bioenergy developments, if managed correctly and sustainably, can serve as an opportunity to reduce poverty and increase energy access in a number of developing countries.

The success of bioenergy developments depends most importantly on the management strategy of the investments. Biofuel developments that safeguard food security are possible, if a gradual expansion process is adopted that assesses and manages possible

10 The Bioenergy and Food Security (BEFS) project has been developed by the Food and Agricultural Organization of the United Nations (FAO) with funding from the German Federal Ministry of Food, Agriculture and Consumer Protection (BMELV). It was set up to assess how bioenergy developments could be implemented without hindering food security. Available at www.fao.org/bioenergy/.

negative impacts on the most vulnerable people and on the natural resource base. Land – especially large tracts of land – is analyzed to be allocated in line with transparent procedures, assessing land availability and considering projected food production needs, suitability for proposed feed stocks, and competing claims on the land. Particular attention must be paid to vulnerable groups that depend on the land for their livelihoods.

The BFES report for Peru (FAO, 2010b) shows that this country "has witnessed strong agricultural growth which has reduced rural poverty but at a much slower rate than urban poverty. Consequently, urban-rural inequalities have widened."

Overall, according to the conclusions from the project, poor people in both urban and rural areas must be directly involved in the bioenergy production chain. Rural households can benefit from price increases for crops used for both food and energy. The analysis in the case of Peru for the main food staples shows that, for example, increases in the price of maize are detrimental to the urban poor but can increase the welfare of the rural poor.

The report also stresses that "bioenergy and especially biofuel developments, in principal, hold much promise for improving agricultural growth for the benefit of the poor. However, while a mandate has been already set in Peru, feedstock production for liquid biofuel can have serious consequences on food production because they compete for the same resources. Thus, an important question is whether the mandate can be met without compromising the food security status of Peru." It concludes that the three most important policies for Peru are: to increase the knowledge base on bioenergy; to improve strategies and actions on bioenergy; and to enhance decision-making and dissemination.

Preliminary results from Tanzania indicate that countries should look beyond the most established bioenergy production chains and carefully consider feedstock and technology selection to suit the natural resource endowments, biophysical conditions, domestic capacity (including human skills), infrastructure, and economic set-up of the country. Opportunities to improve the economic viability for biofuels are closely linked to developments in the agricultural sector.

More specifically, the assessment suggests that ethanol production from cassava is a more attractive option for Tanzania than other crops, such as sugarcane. The biophysical conditions suitable for growing cassava are more widely present within the country when compared to the limited areas suitable for other crops. Additionally, cassava represents the least-cost feedstock for ethanol production in Tanzania, as it is already widely produced in all areas of Tanzania, and local farmers are familiar with the crop. Cassava ethanol production can be competitive if out-grower schemes are adopted in connection with a core plantation that can guarantee the continued optimal supplies of feedstock required by the processing plant. To ensure a viable and sustainable domestic ethanol industry based on cassava, productivity must be improved, so that the energy balance is lower; adoption of appropriate sustainable management practices, such as conservation agriculture, could considerably increase productivity. Moreover, given poor transport infrastructure and to overcome rapid post-harvest deterioration of the cassava – i.e., starch reduction – it is recommended that the cassava is sun dried into chips at the farm to extend the shelf life. The sun-dried cassava chips can then be collected in centralized sites near the area of production, and the less bulky material can be transported to an ethanol processing plant.

Analysis of the impact of rising cassava prices on the welfare of the poorest quintiles shows differences between regions and household types; while some vulnerable households may be affected negatively, there may be benefits to most people

In general, developing the biofuel industry in Tanzania will require infrastructure development, including efficient and reliable transportation networks to support the connection of the various production components along the supply chain and to facilitate processing, which requires provision of potable and industrial water (agro-processing and biofuel plants) and electrification. Biofuel processing can also be enhanced by producing value-added co-products from by-products to benefit the economies of production and to generate added-value inputs to meet local needs, i.e., biofertilizers, electricity. A sustainable biofuels industry that provides longer-term prospects for economic growth and poverty reduction can be created if the choice of technology is suited to the technical capacity available in the country.

Source: FAO, 2010a; 2010b.

Risks to food security indeed need to be considered at the local level. Large-scale allocation of land for biofuel production without adequate policies may lead to the eviction of vulnerable people, and poor people may also lose access to land, water, and other resources. In a review of large-scale land deals in sub-Saharan Africa, Cotula et al. (2009) observed that whereas there are important opportunities related to large-scale investments in land that can create employment and rural development, many countries do not have sufficient mechanisms to protect local rights and take account of local interests, livelihoods, and welfare. Insecure local land rights, inaccessible registration procedures, vaguely defined productive use requirements and insufficiently developed implementation clauses for social commitments in land contracts, as well as legislative gaps, often undermine the position of vulnerable local people. The review calls for: a careful assessment of local land uses and claims; securing land rights for rural communities; involving local people in negotiations; and proceeding with land acquisition only after their free, prior and informed consent.

On the other hand, driven by technological progress and investments in agricultural research, the rapid output growth in developing countries is particularly remarkable. Nearly 70% of incremental production came from higher yields, approximately 10% from higher cropping intensities, and only about 20% from increasing the area of land used (Müller et al., 2007).

Müller et al. (2007) also claim that, in regions where crops do not benefit from technical progress, farmers remained poor and little progress was achieved in reducing undernourishment, but in general, growth in agricultural production helped to reduce hunger and poverty. In fact, it is noted that the food production situation in developing countries has been promising; the data indicate that over the past 30 years production of food has nearly tripled. Food supply per person has increased by more than 50% in developing countries. However, this increase in gross production could result in a further increase in food consumption, but difficulties mainly related to food transportation and distribution among poor people did not allow hunger to be reduced significantly. This is mainly due to the fact that that these problems do not allow poor people to have access to food, even with the increase in food production.

A recent review on integrated food-energy systems discusses possibilities for, and constraints regarding, large-scale implementation of biofuels versus food (Bogdanski et al., 2010). If policies that integrate bioenergy farming with food and feed farming are implemented, there is a potential to decrease local food shortages and increase the incomes of the world's poorest people (Müller et al., 2007; Sparovek et al., 2007).

20.3 Water Use

Water is a natural resource necessary for human survival and important for economic activities. It is used mainly for household purposes (drinking water, sanitation), industrial purposes (e.g., food processing, mining), energy generation (in hydropower systems and for cooling towers in nuclear and thermoelectric power plants) and, most important, agriculture (food production, feed, bioenergy crops). The increasing stress on freshwater resources brought about by ever-rising demand, mainly resulting from population growth, is of serious concern (see Figure 20.11).

As the world population increases, and development requires increased allocations of groundwater and surface water for the domestic, agriculture, energy and industrial sectors, the pressure on water resources intensifies, leading to tensions and conflicts among users, and degradation and pollution of the environment. Contamination of rivers, depletion of aquifers and increased utilization for multiple purposes are challenges commonly found in regions where demand exceeds supply and where water management is poorly conducted. Indicators such as water footprints are important to understand these important issues.

Increased competition among different water uses due to growing demand is already happening. Water scarcity induces competition for water between users, between economic sectors, and between countries and regions sharing a common resource, as is the case for international rivers. Many different interests are at stake, and equitable solutions must be found regarding the competing demands between: cities and rural areas; rich and poor people; arid lands and wetlands; public and private sectors; infrastructure and natural environments; mainstream and marginal groups; and local stakeholders and centralized authorities.

Water conflicts can arise in water-stressed areas among local communities and between countries because sharing a very limited and essential resource is extremely difficult. The lack of adequate legal instruments exacerbates already difficult conditions. In the absence of clear and well-established rules and regulations, severe tensions tend to dominate, and power can play an excessive role, leading to an inequitable allocation of water. A greater focus is needed on the peaceful sharing and management of water at both international and local levels (UN-Water/FAO, 2007). A well-developed system of Integrated Water Resources Management, including adequate institutional set-up and a good governance system, is needed in river basins or confined regions where demand exceeds existing supply.

Climate change is expected to account for about 20% of the global increase in physical water scarcity – and countries that already suffer from water shortages will be hit the hardest (UN-Water/FAO, 2007). This would include African countries, where water is a limiting factor for agriculture food production and also essential for income generation. Examples of export cultures in water-stressed regions are flower farms in Kenya, Zambia, and Uganda, which are extremely dependent on continued access to water in critical basins and trying to limit costs by using innovative rainwater harvesting techniques (FAO, 2005; Belwal and Chala, 2008; Orr and Chapagain, 2007; Asea and Kaija, 2000).

20.3.1 Water Withdrawal

In 2000, around 3800 km³ of freshwater were withdrawn from all over the world, twice the volume withdrawn 50 years earlier (WCD, 2000). Two thirds of the freshwater on Earth is frozen in glaciers and polar ice, and most of the remaining freshwater is groundwater (WCD, 2000). If all the freshwater resources on the planet were equally shared among the world's population, there would be 5000–6000 m³ of water per capita per year. However, the world's freshwater resources are distributed very unevenly, as is the world's population, and a large number of people in the low latitudes are experiencing water scarcity (see Figure 20.12).

The most dramatic water scarcity conditions are in parts of Asia and Africa. The emerging economies of India and China have regions where the climate is sub-humid or arid. Some areas depend on unsustainable pumping of groundwater aquifers and diversion of water flows for irrigation and human consumption, which can cause conflicts between communities. Unsustainable water use also occurs in developed countries, such as the mid-western parts of the United States, where the High Plains (Ogallala) aquifer has declined more than 100 feet (~30 m), and over 150 feet (~45 m) in some places. This resource underlies parts of eight states – Colorado, Kansas, Nebraska, New Mexico, Oklahoma, South Dakota, Texas, and Wyoming. The area overlying the High Plains aquifer is one of the major agricultural regions in the world. Water-level declines began in parts of the High Plains aquifer soon after the beginning of extensive groundwater irrigation (McGuire, 2007a; 2007b).

The areas of most severe water scarcity are those where high population densities converge with low availability of freshwater. Here, people not only experience a physical water scarcity, where evapotranspiration exceeds precipitation, but also a social water scarcity, where the accessible amount of water per person has decreased below 1000 m³/person/yr. Many countries are already well below the threshold value. Jordan is an extreme case, with less than 200 m³/person/yr (FAO, 2007b).

Growing scarcity and competition for water represent major threats to future advances in poverty alleviation, especially in rural areas. In semi-arid regions, increasing numbers of the rural poor are coming to see entitlement and access to water for food production, livestock and domestic purposes as more critical than access to primary health care and education. For poor people, an economic inability to cope with increased competition for water (being unable to afford rising prices) may result in economic water scarcity. Economic scarcity is caused by a lack of investment in water, or a lack of human capacity to meet the demand for water. Much of the scarcity is due to how institutions function – for example, favoring one group over another and not hearing the voices of various groups, especially women. Symptoms of economic water scarcity include scant infrastructure development, either small- or large-scale, so that people have trouble getting enough water for agriculture or drinking. Yet, even where infrastructure exists, the distribution of water may be inequitable, reflecting social distortions among different extracts of the population. Much of sub-Saharan Africa is characterized

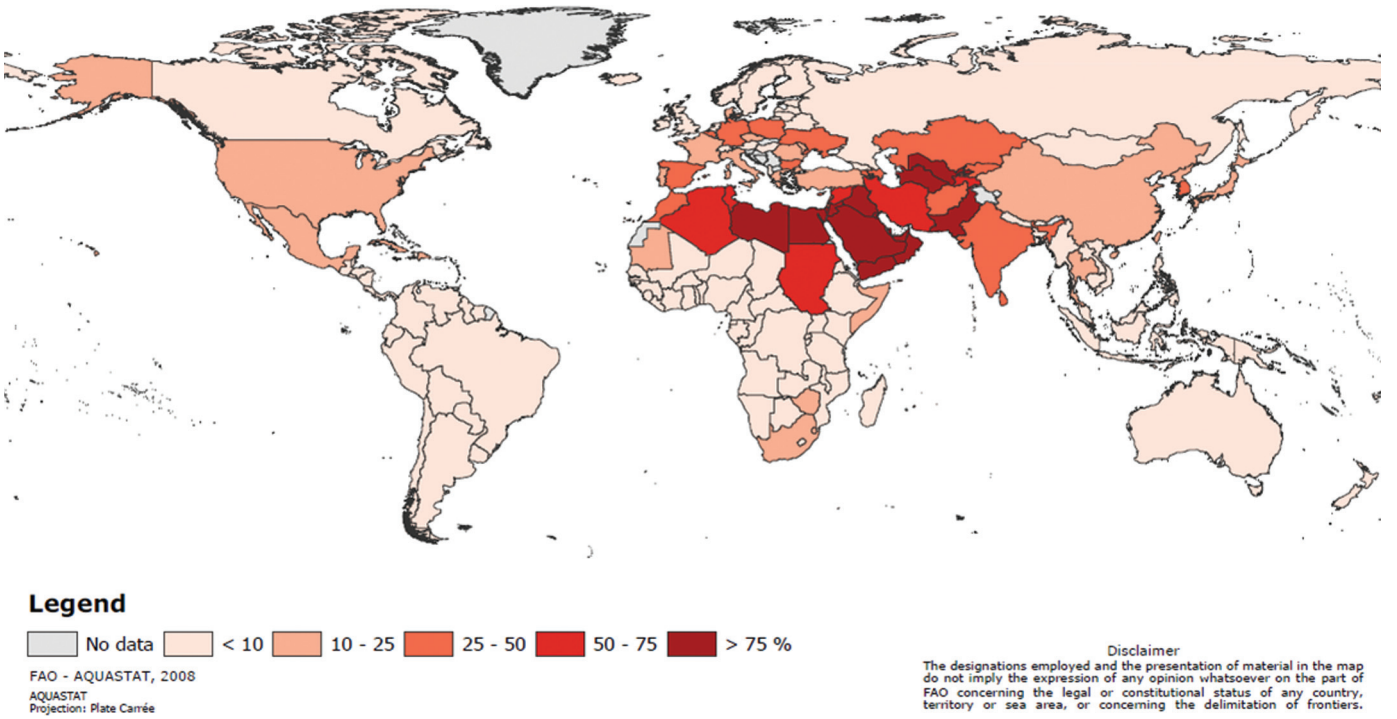

Figure 20.12 | Water resources withdrawn as a share of renewable water resources[11]. Source: FAO-AQUASTAT, 2008.

by economic scarcity, so further water development could do much to reduce poverty.

Physical scarcity occurs when there is not enough water to meet all demands, including environmental flows. Arid regions are most often associated with physical water scarcity, but water scarcity also appears where water is apparently abundant, when water resources are over-committed to various users due to overdevelopment of hydraulic infrastructure, most often for irrigation. In such cases, there simply is not enough water to meet both human demands and natural flow needs to supply the local environment. Symptoms of physical water scarcity are severe environmental degradation, declining groundwater, and water allocations that favor some groups over others (IWMI, 2007a).

20.3.2 Urbanization

In 2000, 75% of the total annual withdrawal of water (3532 km^3) was used for agriculture, but this proportion could decrease to 58% in 2050 (IWMI, 2007a). Growing urbanization may result in tensions and conflicts for water, as large cities need to look for water supply from increasingly distant sources. One example is the city of Johannesburg, South Africa, which is largely supported by water transferred from the Orange-Senqu River basin. Farmers, who have been accustomed to liberal supplies with virtually no fees, now have to face reduced supplies and must often pay for water services (Lundqvist et al., 2007).

In some countries, governments can decide on the allocation of water from one sector to another, depending on how the water rights are defined. In other countries, where land and water rights are private, urban water service providers can buy water from the surrounding landowners, compensating them for reduced irrigation withdrawals or for giving up farming altogether. These examples are so far primarily from developed countries such as North America and Australia. Over-appropriation of ground- and surface water will continue to increase, due to increased food production and increased use of water by industry and cities, with the consequence that freshwater ecosystems will deteriorate. Cities and industries may secure their water supply at the expense of other sectors, such as agriculture and other rural uses, since water brings much higher economic returns for industrial and urban use (Lundqvist et al., 2008).

Urbanization is an important factor that influences agricultural markets. It is expected that the current rural population will remain more or less stable until 2030 and that population growth will be confined to urban

11 Renewable water resources refer to the long-term average annual flow of rivers (surface water) and recharge of aquifers (groundwater) generated from precipitation; they are computed on the basis of the water cycle. Non-renewable water resources refer to groundwater bodies (deep aquifers) that have a negligible rate of recharge on the human time-scale and thus can be considered as non-renewable. While renewable water resources are expressed in flows, non-renewable water resources have to be expressed in quantity (stock) (FAO-AQUASTAT, 2008).

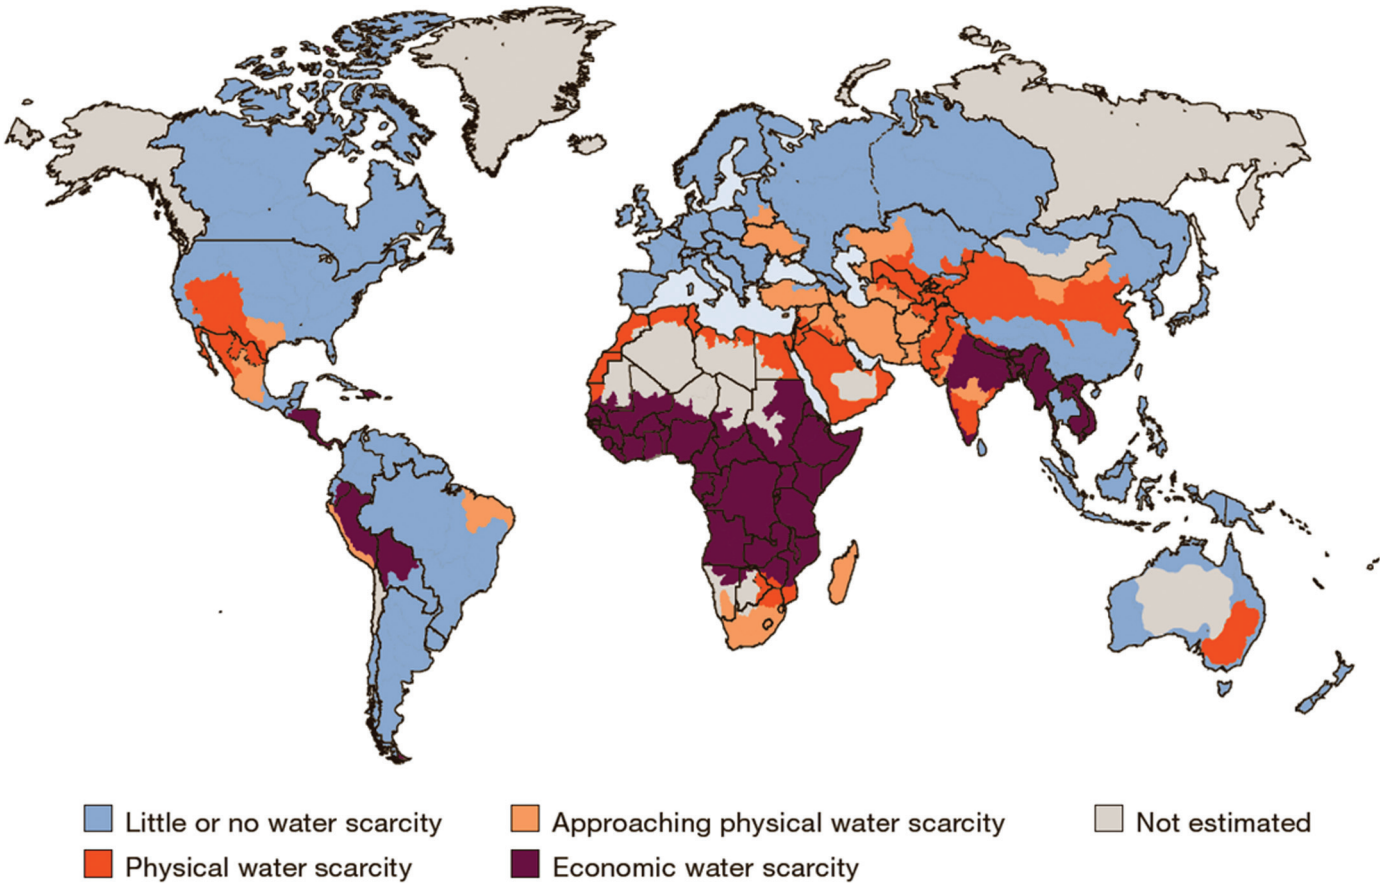

Figure 20.13 | Map of global water scarcity. Source: IWMI, 2007a.

areas. Urbanization has major impacts on markets due to high population density and infrastructure growth. Consumers become closely integrated into the international food markets, resulting in more food trade and changes in diets, with a shift from traditional vegetable foods to a greater demand for meat, which requires more water (Müller et al., 2007; Dufey et al., 2007, cited in Cotula et al., 2008).

In water-scarce regions the increasing reuse of wastewater after treatment processes such as deep-well pumping and large-scale desalination, would increase energy use in the water sector, thus generating more GHG emissions, unless "clean energy" options are used to generate the necessary energy input.

Possible conflicts between climate change adaptation and mitigation measures might arise with regard to water resources, such as biofuel crops that replace fossil fuels but require more water inputs, or water for cooling bioelectricity thermal plants. This indicates the importance of integrated land and water management strategies for river basins, to ensure the optimal allocation of scarce natural resources, including water. Also, both mitigation and adaptation have to be evaluated at the same time, with explicit trade-offs, to optimize economic investments while fostering sustainable development. Adaptation to changing hydrological regimes and water availability will also require continuous additional energy input (Bates et al., 2008).

20.3.3 Water Use in Agriculture

Agriculture accounts for more than 70% of the world's total water use. Its share drops in countries that import food and have a developed and diverse economy, but rises in some countries where agriculture is the primary economic activity (see Figure 20.14). Countries with water scarcity can be said to "import" virtual water when they import crops that have high water requirements.

Production of biomass for energy purposes can, in some cases, expand into areas where conventional food production is not feasible due to water constraints. This is the case with jatropha and sweat sorghum in India, where about 13 million hectares of "wasteland" are being earmarked for cultivation (FAO, 2008c).

Hydropower may offer positive environmental impacts related to water: about 75% of water reservoirs in the world were built for irrigation, flood control, and urban water supply schemes. Many could have small hydropower generation retrofits added without additional

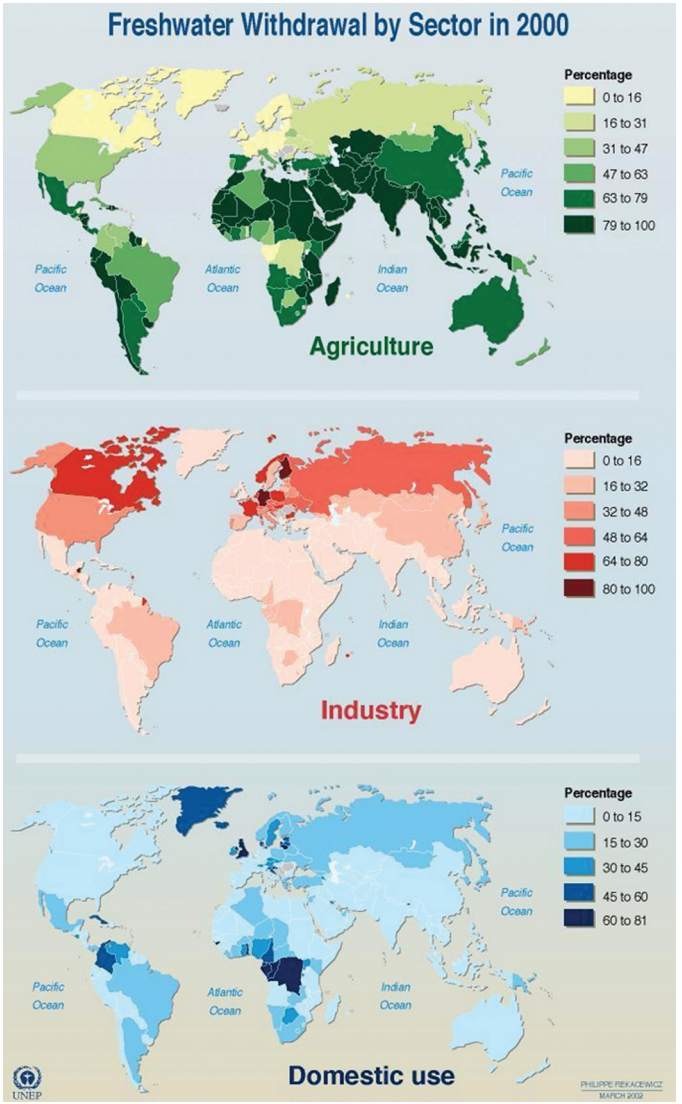

Figure 20.14 | Global freshwater withdrawal: agricultural, industrial and domestic use. Source: UNEP/GRID-Arendal, 2002.

environmental impacts. The many benefits of hydroelectricity, including irrigation and water supply resource creation, rapid response to grid demand fluctuations due to peaks or intermittent renewables, recreational lakes, and food control, as well as the negative aspects, need to be evaluated for any given development. About 18% of the world's croplands now receive supplementary water through irrigation. Expanding this area (where water reserves allow), or using more effective irrigation measures, can enhance carbon storage in soils through enhanced yields and residue returns. However, some of these gains may be offset by CO_2 from energy used to deliver the water (Bates et al, 2008).

Irrigated agriculture provides a direct source of income generation and secure livelihoods for hundreds of millions of the rural poor in developing countries because of the food, income options and indirect benefits it generates. However, widespread irrigation practices may result in pronounced water scarcity. The growth of modern "conventional" irrigation since 1900 has been characterized by large water projects that harnessed rivers through the construction of diversion structures and canal systems. Since 1950, the spread of such technology has accelerated through state-sponsored, large-scale irrigation schemes, including large dams for water storage and regulation (sometimes including hydropower generation). Irrigated areas increased from 40 million hectares in 1900 to 100 million hectares by 1950 and to 271 million by 1998. Water from dams supports 30–40% of this area, with the remainder supplied by direct river abstraction, groundwater and traditional water harvesting systems.

In some areas, improved conditions for increased agricultural yields and better economic growth have resulted from subsidized infrastructure (less than full cost recovery), better agricultural practices, and increased access to electricity for pumping. Irrigated agriculture has contributed to growth in agricultural production worldwide, although inefficient use of water, inadequate maintenance of physical systems, and institutional and other problems have often led to poor performance and return. Emphasis on large-scale irrigation schemes facilitated consolidation of land and brought prosperity for farmers with access to irrigation facilities and economic markets. There are major multiplier effects produced by successful large irrigation schemes. However, economic support to rain-fed agriculture has been limited, even though such systems supported more than 80% of farmers in developing countries, particularly in Africa. As a result, there has been a widening income gap between farmers in irrigated and rain-fed areas. Even within large-scale irrigation systems, there are inequities that lead to the marginalization of smallholders. The regional economic and development context for agriculture differs notably between industrial and developing countries. In the former, agriculture tends to be capital-intensive, with large, highly mechanized holdings requiring minimal labor. In contrast, agriculture in developing countries, particularly in Africa, supports hundreds of millions of smallholder cultivators who depend on the land for subsistence, livelihoods, and food security. These farmers generally do not have access to support mechanisms or economic resources to risk growing high-value crops in volatile market conditions. The low productivity of land and labor of many subsistence cultivators is also symptomatic of the absence of support and widespread neglect of their agriculture and irrigation systems. The extent of irrigated area in Africa is currently high on the political agenda for some countries. With less than one-third of the continent's potential under irrigation, opportunities exist for investing further in water for agriculture. This depends on access to land as well as water, and possibilities of compensating for the high rate of evapotranspiration (WCD, 2000).

Markets, commodity selection, ownership, land tenure, water storage for reliable supply, and international agreements on water allocations within river basins are all key factors in unlocking this potential. Many see the importance of reducing the food import bill borne by some African countries. Many also see the potential for boosting household incomes by creating labor opportunities. However, others recognize that, even in an optimistic scenario in which every hectare created two new

jobs, the significant uplifting of 60 million households would be insufficient to make major inroads into the extreme poverty that pervades the continent. A dual approach is gaining ground, one in which improvements in rain-fed food production for the very many vulnerable African farmers take place alongside the pursuit of viable irrigation opportunities (UN-Water/FAO, 2007).

Increasing water's productivity is an effective means of intensifying agricultural production and reducing environmental degradation. However, water productivity (efficiency) gains may be difficult to realize, and there are misperceptions about the actual scope for increasing physical water productivity. Much of the potential gain in physical water productivity has already been met in high-productivity regions. In addition, the amount of waste in irrigation is less than commonly perceived, especially because of reuse of water locally or downstream – farmers thirsty for water do not let it flow easily down the drain. Meanwhile, major gains and breakthroughs in agriculture that would reduce water requirements, such as those in the past from breeding and biotechnology, are much less likely to continue occurring at the same rate. Finally, a water productivity gain by one user may cause a loss or other damage to another user – an upstream gain may be offset by a loss in fisheries, or the gain may put more agrochemicals into the environment. Increasing economic water productivity would allow users to get more value per unit of water, either through switching to higher-value agricultural uses or by reducing the costs of production. Integrated approaches are important for increasing the value of water, and the number of jobs per drop (e.g., by better integrating crops and livestock in irrigated and rain-fed systems, or using irrigation water for household uses and small industries as well as agriculture). Higher physical water productivity and economic water productivity reduce poverty in two ways. First, targeted interventions enable poor people or marginal producers to gain access to water or to use water more productively for nutrition and income generation. Second, the multiplier effects on food security, employment, and incomes can benefit poor people. To reduce hunger and poverty, such programs must, however, ensure that the gains reach poor people, especially poor rural women, and are not captured by wealthier or more powerful users (IWMI, 2007a).

20.3.4 Water for Industry

Industry is also a water-demanding sector. Industrial use of water increases with country income, going from 10% of a country's total water use for low- and middle-income countries to 59% for high-income countries, where higher industrialization rates raise demand for water even though many processes are in themselves becoming less water-demanding. World water withdrawals for industry represent 22% of total water use. Pollution of freshwater supplies by industry is also a factor to consider in water management practices and policies. This is the case of both organic pollution (including from the food industry) and the inorganic one (e.g., chemicals, metal processing, and others). In developing countries, 70% of industrial wastes are dumped untreated into waters, where they pollute the usable water supply. The current use of clean water for the dilution and transport of wastes is not sustainable. However, the total rate of water withdrawn (and returned) by industry worldwide is slowing, although water consumption for industry is still increasing. Aquatic ecosystems and species are deteriorating rapidly in many areas, and this is having an immediate impact on the livelihoods of some of the world's most vulnerable human communities by reducing protein sources for food, availability of clean water, and potential for income generation (UNESCO, 2003; 2009).

20.3.5 Energy Production, Biofuels and Water Use

Energy sources utilize water in different ways: for cooling towers in thermoelectric plants, for reservoirs in hydroelectricity production, and for irrigated biofuel crops. Despite the limited literature, an effort to assess the impacts of energy technologies on water resources from a life cycle perspective was conducted by the recent *IPCC Special Report on Renewable Energy* (Sathaye et al., 2011). Thermal power plants, hydropower and bioenergy are vulnerable to water scarcity, exhibiting risks of increased competition. Operational water consumption for different technologies in the US electricity sector is summarized in Figure 20.15.

Problems with cooling water availability (because of reduced quantity or higher water temperature) could disrupt energy supplies by adversely affecting electricity generation in thermal and nuclear power plants (Bates et al., 2008). Figures 20.16 and 20.17 compare water withdrawal across fuel cycles of electricity-generation options based on US data, except for the wind cycle, which uses information from Denmark. For thermoelectric fuel cycles, the life-cycle water withdrawal ties closely to the operational cooling type: on-site cooling water use dominates the life-cycle water withdrawal, while the dry cooling method, more expensive and energy-intensive, is an exception to the overall rule.

As conventional oil supplies become scarce and extraction costs increase, production of unconventional oil will become more economically attractive (although with higher water use and environmental costs). Mining and upgrading of oil shale and oil sands require the availability of abundant water. Technologies for recovering tar sands include open cast (surface) mining, where the deposits are shallow enough, or injection of steam into wells in situ to reduce the viscosity of the oil prior to extraction. The mining process uses about four liters of water to produce one liter of oil but produces a refinable product. Mining of oil sands leaves behind large quantities of pollutants and areas of disturbed land (Bates et al., 2008).

Most renewable energy technologies require little or no water for cooling. However, hydropower plants use water directly to generate power, diverting water from rivers through turbines, via an intake at the dam. In some cases, water is diverted outside the stream for up to several

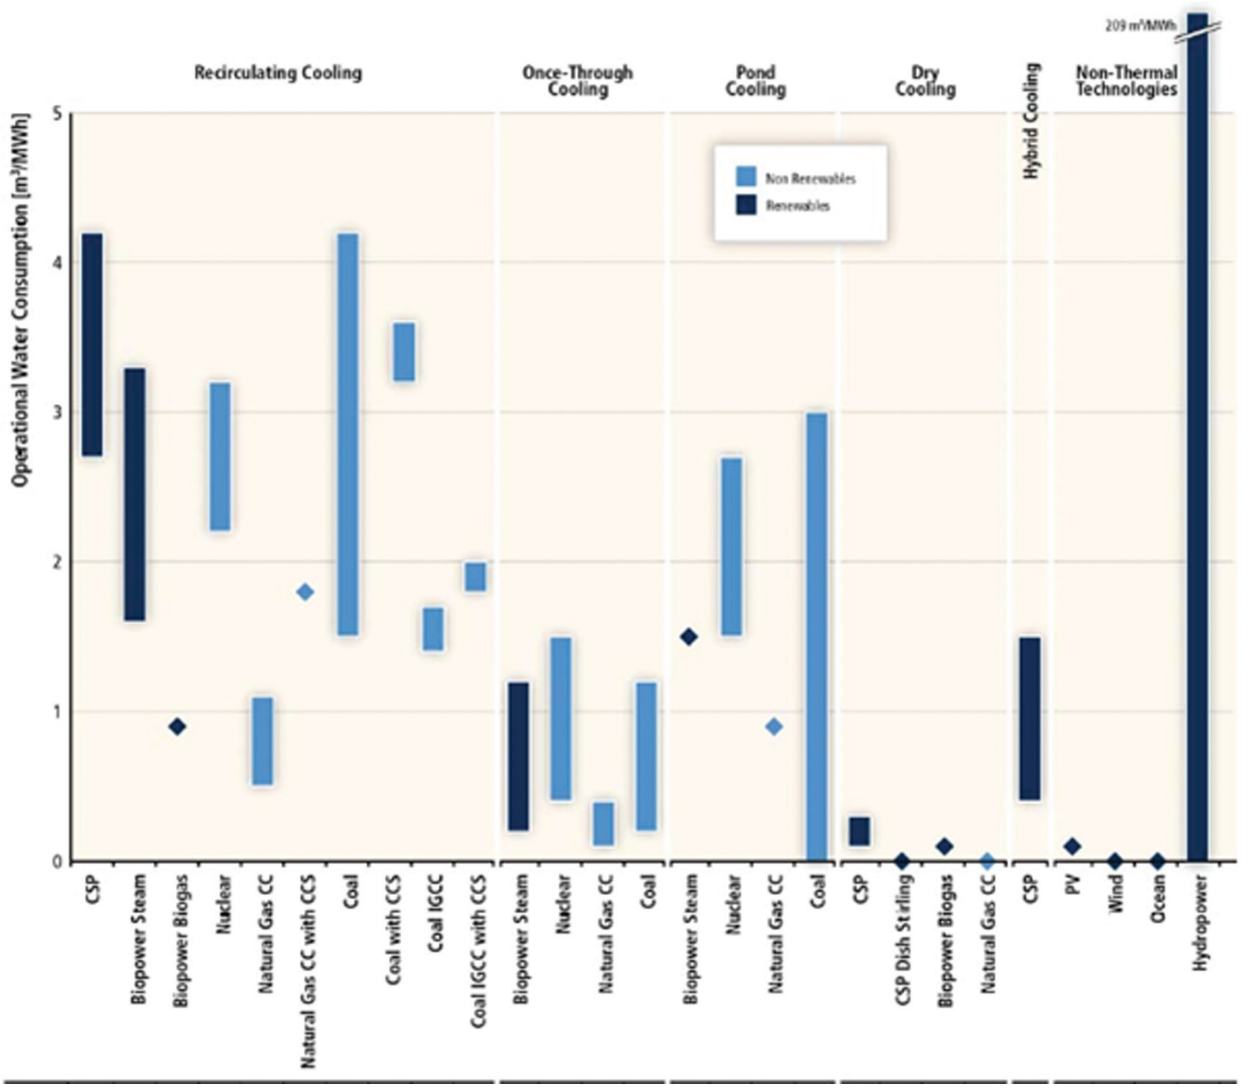

Figure 20.15 | Rates of operational water consumption by thermal and non-thermal electricity-generating technologies in the US (m^3/MWh). Source: Sathaye et al., 2011.

Bars represent absolute ranges from available literature, diamonds single estimates; n represents the number of estimates reported in the sources. Upper values for hydropower result from few studies measuring gross evaporation values, and may not be representative. Notes: CSP: concentrating solar power; CCS: carbon capture and storage; IGCC: integrated gasification combined cycle; CC: combined cycle; PV: photovoltaic.

miles before being returned. Human intervention – through interbasin transfers, dams, and water withdrawals for irrigation – has fragmented 60% of the world's rivers. Since 98% of the water used in hydropower plants is returned to its source, distinctions are made between use (when water is ultimately discharged back into the original water body, although in some cases with chemical or physical alteration) and consumption (where water is lost, typically through evaporation).

The use of water to generate power at hydropower facilities imposes unique, and by no means insignificant, ecological impacts, including:

- impacts on terrestrial ecosystems and biodiversity;
- associated GHG emissions;
- altered downstream flows affecting aquatic ecosystems and biodiversity;
- altered natural flood cycles affecting downstream floodplains;
- impacts of dams on fisheries in the upstream, reservoir and downstream areas;
- enhancement of ecosystems through reservoir creation and other means; and

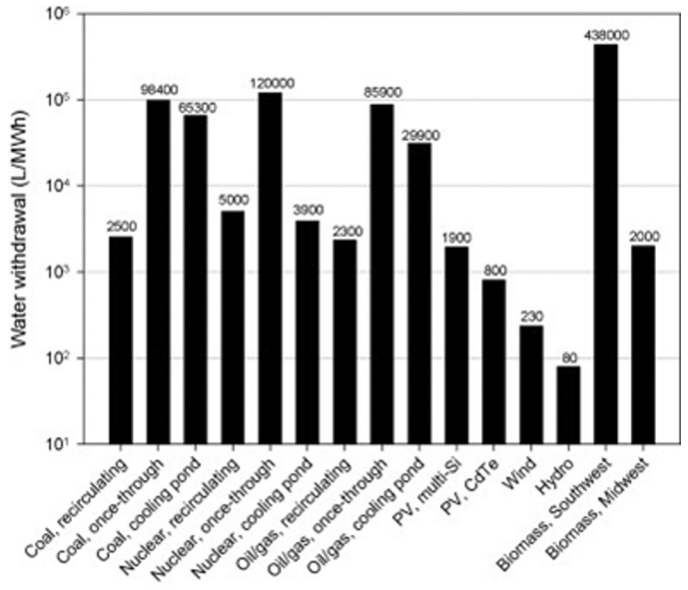

Figure 20.16 | Comparison of water withdrawal across fuel cycles, using US data, except for a Danish case for wind cycle. Source: Fthenakis and Kim, 2010.

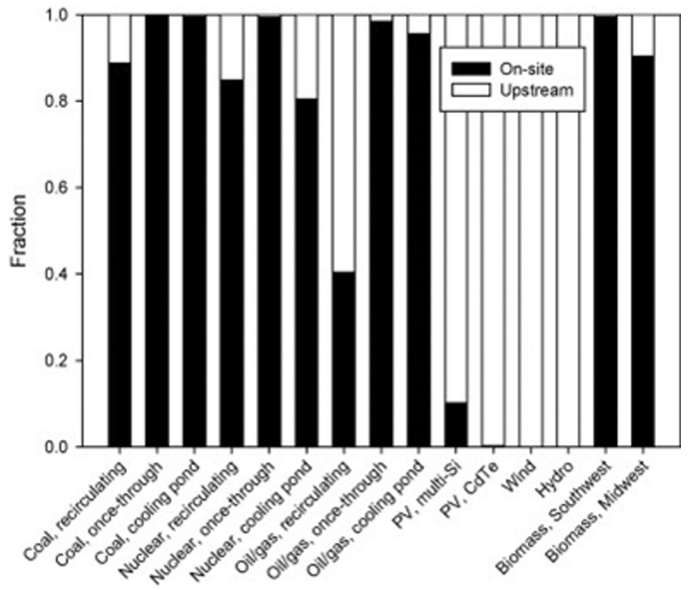

Figure 20.17 | Breakdown of water withdrawals based on the water-use stage. Source: Fthenakis and Kim, 2010.

- cumulative impacts of a series of dams on a river system (WCD, 2000).[12]

Solutions to these problems lie both in more environmentally friendly energy resources, and in more efficient energy end uses (Power Scorecard, 2000). Although there are large regional differences in the extent of hydropower development, hydrological changes will directly affect the potential output of hydroelectric facilities – both those currently existing and possible future projects. A reduction in hydroelectric power is anticipated where and when river flows are expected to decline (Bates et al., 2008).

Geothermal fields of natural steam are rare; most produce a mixture of steam and hot water, requiring systems to separate out the hot water. Sustainability concerns relating to land subsidence, heat extraction rates exceeding natural replenishment, chemical pollution of waterways (e.g., with arsenic), and associated CO_2 emissions have resulted in some geothermal power plant permits being declined. These problems could be partly overcome by re-injection techniques and deeper drilling technology. However, expanding geothermal exploration means in the end a claim on available water resources (Bates et al., 2008).

Although bioenergy can produce climate change mitigation benefits by replacing fossil fuel use, large-scale agricultural production of biofuels could, in some cases, intensify water use, thereby reducing stream flow or groundwater reserves.

High-productivity, evergreen, deep-rooted bioenergy plantations generally have a higher water use than the land cover they replace. Some practices may also affect water quality through enhanced leaching of pesticides and nutrients. Land management practices implemented for climate change mitigation may also have different impacts on water resources.

Many of the practices advocated for soil carbon conservation – reduced tillage, more vegetative cover, greater use of perennial crops – also prevent erosion, yielding possible benefits for improved water and air quality. These practices may also have other potential adverse effects, at least in some regions or conditions. Possible effects include enhanced contamination of groundwater with nutrients or pesticides via leaching when reduced tillage practices are used. However, these possible negative effects have not been widely confirmed or quantified, and the extent to which they may offset the environmental benefits of carbon sequestration is uncertain. The group of practices known as agriculture intensification has environmental benefits that include erosion control, water conservation, improved water quality, and reduced siltation of reservoirs and waterways (Bates et al., 2008).

Total water demand for bioenergy production (prospective of about 150 EJ/year) from plantations in 2050 ranges between 4000–12,000 km^3/year, depending on how much energy can be derived per unit of transpired water. Even if reduction of losses and improvements in agricultural and water productivity are accounted for, meeting the future food demand will most likely require the addition of new cropland (–20–45% of real expansion from today's 1.5 billion ha, depending on the degree of improvements in land area productivity). The annual cropland expansion needed is estimated to be 0.48% on average between 2010–2045 (IWMI, 2007b). While the benefits of bioenergy range from

12 The European Water Framework Directive utilizes a similar classification of impacts (European Commission Environment, 2011).

reduced GHG emissions to renewability and energy independence, increased biofuel production can lead to trade-offs across other ecosystem services if not well addressed, including those derived from water. Besides decreased food supply, other trade-offs include poor water quality associated with increases in aggregate fertilizer use, nutrient runoff, and erosion (Bennett, 2008). The growing of crops for biofuel in semi-arid areas on marginal or degraded lands may require some irrigation, particularly during hot and dry seasons. Further, the processing of feedstocks into biofuels can use large quantities of water, mainly for washing plants and seeds and for cooling.

Globally, irrigation is not likely to be a major water source for biofuel production, although locally there can be water constraints in some areas where food and other non-food crops compete for the scarce available resources. In some cases, irrigated production of biofuel feedstocks has a considerable impact on local water resource balances: the Awash, Limpopo, Maputo, Nile and São Francisco river basins are cases in point. While the potential for expansion of irrigated areas may appear high in some regions on the basis of water resources and land, water quality as well as quantity may be affected. Converting pastures or woodlands into maize fields, for example, may exacerbate problems such as soil erosion, sedimentation and excess nutrient (nitrogen and phosphorous) runoff into surface waters, and infiltration into groundwater from increased use of fertilizer (FAO, 2008c).

Table 20.8 summarizes the main energy and food crops in the world today. With adequate land use management, there are enough rain-fed areas for these crops to coexist. Sugarcane ethanol is a special case, due to its significant potential to provide energy throughout large parts of the world utilizing rain-fed land (see Figure 20.18). Water use for industrial sugarcane ethanol production has improved from 5 to 1.9 m^3/t of cane (1 tonne of cane crushed produces 80–100 liters of ethanol) in the period 1997–2004. Vinasse, the distillery water sludge, is used as a fertilizer, returning part of the water used back to the soil (Elia Neto, 2005).

In terms of water use, studies in other parts of the world have shown that production of energy crops for biofuel production can have substantial impacts on water demand, especially if irrigation is used for their production (Jumbe et al., 2007). The bulk of sub-Saharan Africa's agricultural production occurs under rain-fed conditions, posing substantial risks to farmers and investors because of erratic rainfall patterns and temporal and spatial variability.

Frequent short dry spells during the growing season reduce yields and, in addition, have an indirect impact, as farmers are less likely to invest in inputs and land management. Biofuel production could be affected by these existing conditions, as unreliable rainfall and highly variable yields would also pose challenges for biofuel feedstock production.

On the other hand, new market opportunities through bioenergy production may trigger additional investments in water for agriculture to raise yields and reduce these fluctuations. The water situation in sub-Saharan Africa is also affected by the transboundary nature of most river basins, which flow through several countries. The negotiation and enforcement of water rights and international water treaties is a difficult process requiring a strong institutional infrastructure. Feedstock production requires substantial amounts of water; to produce the biomass for one liter of biofuel, crops evaporate an average 2500–3500 liters of water. Much of this water can be obtained from rainfall, where rainfall is abundant and reliable.

Compared to other regions in the world, the level of water resources development for irrigation in sub-Saharan Africa is low. Only 4% of agricultural production originates from irrigated areas, and only one-sixth of the irrigation potential in sub-Saharan Africa has been realized. In many areas of this region, water scarcity for crop production is caused by the lack of infrastructure to tap into water resources rather than an actual physical shortage (IWMI, 2007b). Development costs for irrigation are high, averaging US$6000/ha in sub-Saharan Africa compared to US$1500/ha in South Asia. It is unlikely that farmers and governments will be able to afford large investments in irrigation for biofuel feedstock, unless significant returns are obtained. Water use by other feedstock crops needs to be studied more systematically across the agro-climatic zones, especially when such crops are to be established in large-scale plantations (Benkunda et al., 2009).

20.3.6 Water Security

Although concepts of food security, energy security and access to natural resources have been widely discussed, it is only recently that the relationship between the environment and water security is becoming more widely acknowledged, mainly due to its political dimensions. It was on the agenda in the process leading up to the UN Conference on Environment and Development, held in Rio de Janeiro, Brazil, in 1992, and is reflected in the Rio Principles. Sharing water resources is an issue that particularly reflects a link between environmental degradation and resource competition resulting in conflicts. Freshwater scarcity is not just a direct cause of insecurity; it is also an indirect security threat, through its potential for causing conflicts.

A key spark for water-related tensions is a mismatch between population levels and the freshwater available for different purposes. This can produce water conflicts at a local level, such as between tribes over grazing rights or the property rights over wells, as has happened in Ethiopia. Tensions can also arise due to construction of a dam or canal which impacts water availability for riparian states, as was experienced during the 1990s by Turkey, Syria and Iraq over Turkey's Greater Anatolia Project on the Euphrates-Tigris River Basin (Coskun, 2007).

Global conflicts over water threaten geopolitical stability. An example is the Baglihar 450 MW dam, near the politically fragile Pakistan-India border along Kashmir's Chenab River. The plant will supply hydroelectric

Table 20.8 | Crops and their requirements.

Crop type	Soil requirements	Water requirements	Nutrient Requirements	Efficiency	Climate	Others
Cereals (wheat, rye, barley, oat, triticale)	less disruptive; very constant yield; straw removal affects humus balance; wheat in a wide range of soils but medium textures	wheat is the cereal with the highest water demand (450–650 mm depending on climate and length of growing period)	medium; wheat has higher fertilizer demand but good uptake	wheat on good soils and rye on poor soils for food; triticale for energy purposes	wheat: moderate climate, tropics away from the equator (winter crop)	highly developed crops; knowledge widespread among farmers
Jatropha	undemanding	both irrigated and rain-fed, wide range (200–1200 mm/yr)	adapted to low-fertility sites and alkaline soils; better yields with fertilizers	grows on marginal land, restores eroded areas, improves soil	tropical and subtropical	very resistant against pests and pathogens; toxic seeds after oil extraction
Maize	low requirements (soils well aerated and well drained); susceptible to water logging.	water demanding (500–800 mm/yr)	fertility demands for grain maize are relatively high	high water efficiency, but often irrigated (water deficits cause losses)	from temperate to tropic, mean daily temperatures above 15°C and frost-free	increased erosion risk; monoculture negative on humus balance (requires crop rotation); high pesticide use
Miscanthus (woody, perennial grass)	good water supply, not saturated brown soils with humus	crucial during main growing seasons	relatively low	high growth rates, cheap	warmer climates, fairly cold-tolerant	risk of invasive species; difficult to rehabilitate land for other uses due to deep root structure
Oil Palm	many soil types (flat, rich, deep), good drainage (tolerate floods)	demanding in excess of 2000mm, even distributed throughout the year	relatively low	highest-yielding vegetable oil crop per hectare in the world	tropical and subtropical; humid 5h/day minimum sunlight; temperature 22–32°C, basically low altitude (< 400m)	fire for land clearing, tropical forest conversion with loss of biodiversity and conflicts of land ownership with local communities, pollution by improper use of agrochemicals (little control), oil mill effluent dumping, soil erosion from land clearing
Poplar	deep, moist (highly flood tolerant)	high; irrigation might be needed	high, with good uptake	high establishing costs, not easily propagated from cuttings; short rotation crop (fast growing tree)	arctic to temperate	resistant to pests and diseases
Potato	deep, moist, well-drained and friable	500–700 mm, depending on climate; irrigation required for climatic negative balances	relatively high (under moderate demand there are late growth and soil erosion risks)	very productive	18–20°C mean; sensitive to changes; cool crop but grows well in warm conditions if water is sufficient	rotation crop (with maize, beans and alfalfa); pesticide-intensive
Rapeseed	mild, deep loamy, well-drained	600 mm/yr minimum	similar to wheat	rotation crop, poor productivity but most grown energy crop in Europe (well-known to farmers and policy supported)	very temperature-sensitive, best 15–20°C.	very intensive culture; high input of pesticides and herbicides
Rice	not demanding (permeable layer and good drainage)	very high, flooded fields	high input of fertilizers	very labor-intensive, different farming systems (rain-fed lowland, upland or dry land, irrigated, deepwater or flood-prone)	high, constant temperatures (13°C–40°C; optimum around 30°C).	high level of landscape alteration for surface infrastructure needed to move water about; anaerobic conditions in underlying soils; has unique impacts on carbon and nutrient cycling

Table 20.8 | (*contd*.)

Crop type	Soil requirements	Water requirements	Nutrient Requirements	Efficiency	Climate	Others
Sorghum	Deep, medium-textured, well-aerated and well-drained soils; tolerant to short periods of waterlogging, moderately tolerant to soil salinity	drought-resistant; high water supply flexibility (water holding capacity of soil very important, needs progressively less water as roots reach deeper)	high in nitrogen, low in phosphorus and potassium requirements	tropical origin, adapted to southern Europe with irrigation, high yields (less than maize), machinery can be used	over 25°C; some varieties adapted to lower temperatures; needs a lot of sunlight	numerous diseases; not competitive at the beginning
Soybean	wide range of soils, optimum growth in moist alluvial with a good organic content; best on high water capacity, good structure, loose soil	relatively high (450–700 mm/ season)	atmospheric nitrogen-fixing crop		warm conditions in tropics, subtropics and temperate climates; relatively resistant to low and very high temperatures	increased risk of erosion compared to corn
Sugar beet	wide range of soils with medium- to slightly heavy- textured, well-drained preferred; tolerant to salinity	550–750 mm/growing period; tolerant to water deficits	high demand		different climates, high sugar yields with night temperatures 15–20°C and day temperatures 20–25°C during the latter part of growing period	heavy machinery and harvested mass lead to soil compaction; can provide nesting habitat and shelter in autumn; soil erosion risks; various pesticide treatments to eliminate weeds
Sugarcane	deep soils, well-aerated, groundwater table more than 1.5 to 2.0 m below the surface	1500–1800 mm/yr, high water requirement, evenly distributed through the growing season	high nitrogen and potassium needs, low phosphate requirements; at maturity nitrogen content of soil must be as low as possible for a good sugar recovery	very high efficiency in conversion of solar energy into biomass	tropical or subtropical climate; germination 32–38°C; active growth at 20°C; for ripening lower temperatures are desirable for enrichment of sucrose	pest management very important
Sunflower	wide range of soils, deep with good water holding capacity; row crop, leaves bare soil until late spring	600–1000 mm, depending on climate and length of total growing period; water-efficient crop but often irrigated as better growth	moderate demand; good fertilizer uptake	intermediate crop for maize plantations	from arid under irrigation to temperate under rain-fed conditions; susceptible to frost; needs full sun	various pesticide treatments to combat pests
Switch grass	diverse growing conditions, from prairies to arid or marsh; conserve soil and improve its quality	tolerant to floods or drought; irrigation only necessary in very hot or very dry climates; because of deep roots, groundwater abstraction is possible	little nutrient requirements	machinery can be used; high yields in marginal or erosive land	warm season plant, good resistance to dry summer months	very little pesticide use
Willow	permanent crop, good soil cover, deep rooting and leafy canopy reduces soil erosion and prevents saturation of the land during heavy rainfall; can grow on land that is too wet for other crops	substantial quantities of water (600 mm rainfall), suffers reduced growth in dry conditions or dry years	significant nutrient uptake but good uptake also	short rotation coppice; easy and relatively inexpensive to plant	can tolerate very low temperatures in winter, but frost in late spring or early autumn will damage the top shoots	level of pest and pathogen unacceptable for food crops can be accepted here; already used in commercial or near-commercial applications; can take up heavy metals (phytoremediation); weed competition is critical; riparian buffer strips; depletion of soil nutrients from frequent and repeated harvesting; rust is an important disease; very competitive, hence no or little pesticides applications necessary

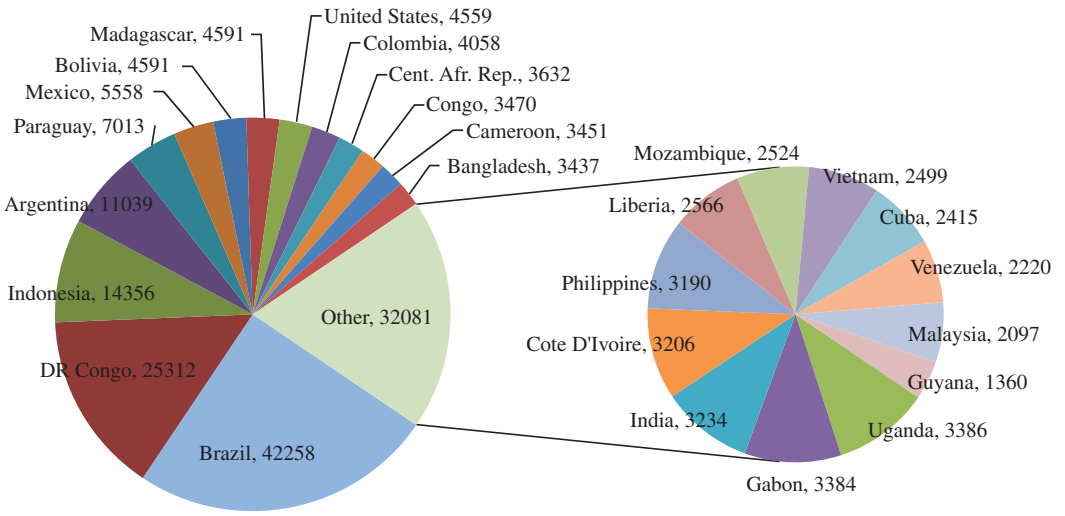

Figure 20.18 | Very suitable and suitable potential land area for sugarcane crops in major 26 countries producers, considering high-, medium- and low-input efforts, with forest area excluded, by country (units in thousand hectares). Total area in these 26 countries is 169 million hectares. Total area in all producers is 191 million hectares, equivalent to 1.46% of all land area. Source: based on data from FAO, 2009a.

power to northern India, but as the dam reaches full capacity, Pakistan is seeking compensation for what it views as a "gross violation" of an international treaty as a result of "stolen" water (Pope, 2008). Around 40% of the world's population lives in watersheds shared between nations, with more than 260 shared river basins of social and economic importance.

Basins with potential for political stresses in the coming years include: the Ganges-Brahmaputra, Han, Incomati, Kunene, Kura-Araks, Lake Chad, La Plata, Lempa, Limpopo, Mekong, Ob (Ertis), Okavango, Orange, Salween, Senegal, Tumen, and Zambezi (Wolf et al., 2003). There are complex linkages among energy, water, agriculture, and environmental degradation issues. Also linked are water-related matters affecting humanitarianism, human health, poverty reduction, economic development, environmental protection and conservation, stability, and geopolitical security. Management of water resources can be a catalyst for cross-border cooperation or a trigger for socioeconomic instability. An instrument establishing agreements over a shared water source among different stakeholders is thus an important, anticipatory structure (Peterson and Pozner, 2008).

The FAO (2008c) outlines some conditions to ensure institutional development to promote water security, as follows:

- Set conditions for more flexible and responsive service-oriented water management.
- Develop tools for water-related conflict resolution and prevention at local and district levels.
- Develop and implement economic and financial trade instruments to remove distortions in water allocation.
- Document and quantify current patterns of water use and water entitlements.
- Develop transparent water allocation mechanisms to protect water use rights while providing greater flexibility to respond to scarcity under anticipated patterns of climate change.
- Develop innovative insurance products.

Further suggestions involve better integration of water resources management, agriculture and food security databases, with much closer monitoring of irrigated and rain-fed production and clearer distinctions between the sources of supply (rainfall, surface water, and groundwater). This effort should consider specific food staples, notably rice and wheat, as well as the productivity of water-dependent aquatic environments (FAO, 2008c).

When using a wider definition of water security, such as the one used by the United Nations Educational, Scientific and Cultural Organization (UNESCO) and several other UN agencies within UN-Water, a broader approach needs to be applied to ensure this: "Water security involves protection of vulnerable water systems, protection against water related hazards such as floods and droughts, sustainable development of water resources and safeguarding access to water functions and services."

20.4 Sustainability Factors

20.4.1 Sustainable development: policies and measures

The concept of sustainable development – a significant one – aims to reconcile environmental, economic and social goals, which became more

important after the World Commission on Environment and Development (1987). It recognizes the multiple challenges resulting from a declining quality of the environment, increasing resource needs of mankind, and the need to reduce malnourishment, poor hygiene, insufficient water supply and other problems related to extreme poverty, without destruction of the natural resources that are the basis for life.

The influential report *Our Common Future* (the "Brundtland Report") defined sustainable development as that which "meets the needs of the present without compromising the ability of future generations to meet their own needs" (World Commission on Environment and Development, 1987), i.e., as a universal, intra- and intergenerational human rights concept.

The 1992 United Nations Conference on Environment and Development (UNCED or Rio 92) in Rio de Janeiro, Brazil, was a major milestone in the international discussion on sustainable development. At the conference, the United Nations Framework Convention on Climate Change (UNFCCC), the Convention on Biological Diversity and Agenda 21 were proposed, and the two treaties were also opened for signatures. It was also decided to initiate negotiation of what became the UN Convention to Combat Desertification. The Climate Conference at Kyoto, Japan, in 1997 resulted in the Kyoto Protocol, a multilateral environmental agreement to curb GHG emissions worldwide. By 2000, the MDGs aimed at reducing global poverty and eliminating social exclusion by 2015. Two years later, energy (both energy efficiency and renewable energy) became a central point at the World Summit on Sustainable Development (WSSD or Rio+10) in Johannesburg.

A fairer and cleaner energy future includes the need to reduce negative social and environmental impacts. Sustainable energy also includes the goal to establish security of supply, which means both guaranteeing access in the short term and preserving resources for the long term. These concepts are closely related to geopolitics, trade liberalization and protectionism, land and water usage, and, not rarely, to military concerns.

Most policies that aim at a more sustainable energy supply rest upon four main pillars (although some of them may be more or less emphasized): more efficient use of energy, especially at the point of end use; increased utilization of renewable energy as a substitute for non-renewable energy resources; accelerated development and deployment of new energy technologies – particularly next-generation fossil fuel technologies that produce near-zero harmful emissions and open up opportunities for CO_2 sequestration; and biosequestration of carbon in terrestrial ecosystems, including soils and biota (see Box 20.4).

Achieving energy equity is another important task, providing access to modern energy to the 2 billion people that still live with only traditional solid fuels (Johansson and Turkenburg, 2004).

Sustainable development is thus a basic principle to be pursued in key policy areas directly or indirectly related to energy: technology research, development and transfer; information exchange; capacity-building; adequate financing; ambitious environmental protection goals; removal of harmful subsidies; and shifting away from business-as-usual patterns of production and consumption.

20.4.2 Sustainable Water Use

This chapter focuses on the following aspects of sustainable water use:

- environmental issues resulting from erosion; excess use of fertilizers and agrochemicals; inadequate management of water resources; inadequate wastewater treatment and disposal; and the need for increased biodiversity protection, solid and hazardous wastes management, and protection against contamination of soils;
- resource base maintenance (freshwater protection, allocation, and sustainable use);
- social concerns (including issues related to employment and access to water, particularly for women and vulnerable groups); and
- economic issues (including weighing present versus future uses).

Table 20.9 summarizes impacts from energy on water systems.

The consumptive use of water (i.e., evapotranspiration) in energy crop production changes according to different bioenergy systems. A large variation in evapotranspiration is attributed to: varying water productivity among energy crops, related to crop type, soil, and climate, and agronomic practice, including water productivity modification options such as changing sowing date and plant density, supplemental irrigation, and microclimate manipulation; variations in the share of the aboveground biomass that is usable as feedstock in electricity/fuels production; and different conversion efficiencies of technology options available for electricity/fuels production.

Irrigation is assumed to be around 15% of the energy crop's water use calculated. If the average efficiency in irrigation water supply is 50%, then about 1175–3525 km^3 of additional water would have to be withdrawn in 2050. Compared to the present withdrawal for irrigation, estimated at roughly 2600 km^3/yr, clearly such additional blue water demand for energy crop irrigation implies tough challenges. Rain-fed energy crop production could potentially lead to similar impacts, by redirecting runoff water to evapotranspiration and thereby affecting downstream blue water availability and quality. Establishment of bioenergy plantations can also lead to increased evapotranspiration, especially if tree crops replace shallow-rooted grasses, herbs, or food crops. It is not possible to make general statements about the impact in terms of water depletion of expanding energy crop production, since the net change of evapotranspiration is uncertain and depends on site-specific circumstances, including the current land use that it aims to replace (Box 20.3; Figure 20.19) (Lundqvist et al., 2007).

Table 20.9 | Positive (+) and negative (-) impacts of energy on water (Lucon, 2010, own elaboration). Water indicative footprints (WF) of different energy sources (from Gerbens et al., 2008 and 2009).

Energy Source	Bioenergy	Solar	Geothermal Energy	Hydro Power	Marine Energy	Wind	Oil	Gas	Coal	Nuclear
Water usage and/or pollution	WF 24–143m^3/GJ. Potentially high water demand, especially in irrigated crops. Specific water stress for cooling towers (-).	WF 0.3m^3/GJ for solar thermal panels. Some toxic wastes from PV. Specific water stress for concentrated solar plant cooling towers. (-)	WF n.a. Risks of water contamination. Specific water stress for plant cooling towers.	WF 22 m^3/GJ according to source, but extremely variable. High impacts in water bodies and regimes (-/+)	WF n.a.	WF ~0.0 m^3/GJ.	WF 1.1 m^3/GJ. Risks of severe, large scale water contamination (-)	WF 0.1 m^3/GJ. Specific water stress for plant cooling towers.	WF 0.2 m^3/GJ. Risks of water contamination, leaching and acid rain effects. Specific water stress for plant cooling towers. (-)	WF 0.1 m^3/GJ. But potential highly toxic contamination in case of nuclear accidents, weapon proliferation tests etc. Specific water stress for plant cooling towers. (-)

Box 20.3 | Water Pressures and Increases in Food and Bioenergy Demand. Implications of Economic Growth and Options for Decoupling

Long-term models out to 2045, as developed by Lundqvist et al. (2007), present scenarios on potential water demand, given that diets may change substantially as countries attain a higher income, and that the use of bioenergy is likely to increase. With current global levels of productivity and efficiency, the consumptive use of water to cater for growth in food demand is estimated to increase by some 50% in the period 2000–2045, from about 7000 km^3/yr to about 10,600 km^3/yr. Estimating the water requirements for the production of energy crops is more difficult, but crop expansion is a reasonable measure to adopt. Higher demands for food, energy and other goods and services are inevitable, but it is possible to achieve a decoupling effect, i.e., more income without a corresponding increase in the pressure on resources. While water productivity improvements on the order of 25% are considered feasible and realistic, reductions in losses and wastage in the food chain can be halved from the present 30%.

By adopting these decoupling measures, it is possible and desirable to meet expected future food requirements in 2045 with about the same water requirement as in 2005. In the search for decoupling opportunities between GDP growth and pressure on water and land resources, it is logical to pay attention to both production and consumption dynamics. Consumption is a critical driver, considering increasing purchasing power, preferences, and behavior. There are major challenges in balancing finite freshwater resources, including competition for different uses in the near future, and the need to stimulate improvements in efficiency. Improvements in yields and water productivity, as well as expanding the agricultural area, cannot by themselves solve the problem. Blue water sources (rivers, lakes, and groundwater) will not be enough to meet the increasing demands for food and biofuel. Recommended strategies include: better utilization of a larger fraction of the rainfall (i.e., a green water strategy); improved yields and water productivity, as well as expanding the agricultural area; and reduced consumption through changes in consumer preferences and behavior, and by achieving a more efficient food chain, primarily in terms of reduced losses and wastage "from field to table." These changes will require planning and systematic implementation over decades.

Source: Lundqvist et al., 2007.

Water use for the growth of bioenergy crops may cause environmental and social problems. Global water demand has been growing by 10% per decade, adding to water stress in many regions. Agriculture accounted in 2008 for close to 70% of all freshwater use (UNEP, 2009), of which 2% was used for bioethanol production (WBGU, 2008).

Bioenergy production may need 70–400 times as much water per unit of energy as other primary energy carriers, excluding hydropower, and ranges from 24–143 m^3/GJ (Gerbens-Leenes et al., 2009). The amount of water per unit of energy is highly dependent on the crops used, the efficiency of the cropping system, and the local hydrological and soil

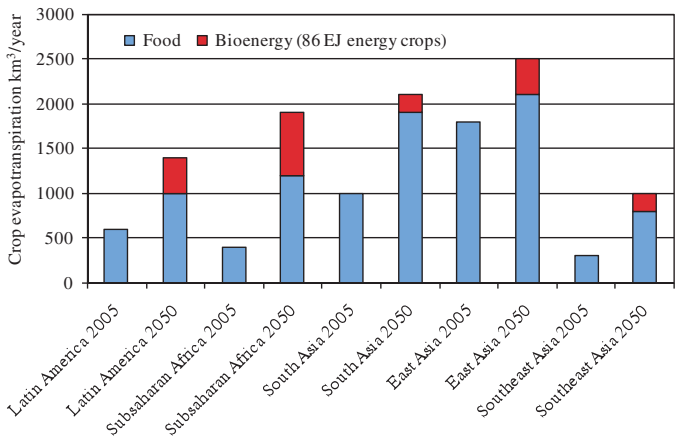

Figure 20.19 | Estimated water requirements for food today and hypothetical water requirements for food and bioenergy around year 2050 with lignocellulosic crops, plant breeding and improved agronomic practices, assuming in the model that lignocellulosic crops will mainly be used for with average water use efficiency of 2.5 kg biomass per m^3 of evapotranspiration. Source: adapted from SIWI, 2008.

conditions. Bioenergy crop plantations in marginal areas may, however, alleviate or reduce other water-related problems such as water-related erosion (Berndes, 2008).

Beyond matching supply and demand for human uses, it has become clear that management approaches need to consider also the ecological water demand and the spatial and temporal variability of supply and demand (EC and IPTS, undated).

20.4.3 Land-related sustainability issues

Energy provision almost always requires land area, at least for infrastructure, except perhaps for energy derived from the ocean (e.g., wave energy). Table 20.10 compiles indicative estimates of the area required for a yearly energy flow of one PJ for different primary energy sources. It shows that the land area required for fossil fuels and nuclear power is small compared to that needed for some renewable energies, particularly bioenergy and hydropower. In most cases, land is needed more or less exclusively to host the infrastructure needed; in the case of coal additional area is required for open-cast mining.

Land areas required for hydropower plants are often small, especially for run-of-river plants, but may be substantial in the case of storage power stations or in regions with flat topography. If poorly designed, hydropower plants can produce substantial negative environmental and social effects including impacts on riverine ecosystems and biodiversity, on hydrological resources, on fisheries, and on local livelihoods, particularly if dam construction requires resettlement of local populations (Goldsmith and Hildyard, 1984; Trussell et al., 1992; WCD, 2000). Plans to build large dams have, therefore, sometimes encountered strong public opposition. Hydropower plants can also have positive environmental or socioeconomic effects, including irrigation or flood control, and are indeed sometimes constructed primarily for such purposes. These issues are discussed in detail in the World Commission on Dams (2010).

Table 20.10 | Indicative area requirements of different primary energy sources.

	Indicative area requirement (km^2/PJ/yr)	Potential sustainability issues
Bioenergy crops	50–500	Impacts on C balance, ecosystems, soils and food systems can be positive or negative, depending on management
Bioenergy residues	Almost no additional area	No or little additional area required if residues or wastes can be used; possible impacts of removal of residues on soil fertility and the soil C balance need to be considered
Solar energy	1–6	Land needed for infrastructure; excess heat can be used for grain drying
Geothermal energy	≈10	Land required for infrastructure and transmission
Hydropower	<1–100	Impacts are highly site-specific and include positive (e.g., irrigation, flood control) as well as negative aspects (e.g., biodiversity and ecosystems, resettlement during construction)
Wind power	1–32	Land for wind power plants plus transmission, affects landscapes; rotors may kill birds
Oil	<1	Land required for infrastructure and transport
Natural gas	<1	Land required for infrastructure and transport
Coal	≈1	Land required for infrastructure and transport, soil contamination
Nuclear energy	<1	Land for infrastructure and transmission; potentially much larger land areas contaminated in case of an accident

Source: calculated based on Tampier (2002), except bioenergy.

Bioenergy requires by far the largest land area per unit of energy and year; as a result, concerns about competition for land, and land-use related sustainability issues involving energy, have received most attention with regard to bioenergy. The remainder of this subsection, therefore, focuses on bioenergy. Bioenergy is produced either by planting dedicated bioenergy crops or using by-products, residues and wastes from agriculture, forestry, food processing, and other economic activities (see Chapter 7). The environmental effects of these pathways are, however, fundamentally different (Cherubini et al., 2009) and are, therefore, discussed separately.

20.4.3.1 Environmental effects of bioenergy crop plantations

Creating and maintaining energy crop plantations can have positive and/or negative environmental, social and economic impacts, depending on the respective regional conditions, the specific crop or technology, and the implementation and management of bioenergy projects (Goldemberg at al., 2008; Dewulf and Langenhove, 2006). For example, growing energy crops can increase the demand for agricultural products, create income and jobs in the agricultural sector, and provide

clean, renewable energy. It can also have unintended adverse effects, however, e.g., on agricultural prices or food security, as discussed in Section 20.2.7. Proper implementation of bioenergy crop plantation projects is a key factor for their sustainability in terms of social, economic and regional development goals (see Sections 20.2.5 and 20.2.6). This section focuses on issues of ecological sustainability related to land demand of bioenergy crop plantations.

Tackling the question of how much bioenergy can be produced without harming the environment (European Environment Agency, 2006) and without creating adverse social and economic impacts (Section 20.2.6) requires a systems approach that takes into account the relevant interactions between various land uses and socioeconomic functions of biomass (food, fiber/materials, and energy). Some of these issues are particular interactions between food and bioenergy systems and the significance of constraints such as the conservation of ecologically valuable areas (e.g., biodiversity hotspots, wetlands, or forests) and areas under various kinds of nature protection.

From a systems perspective, two types of effects need to be considered:

- **Direct effects** refer to the environmental effects, positive or negative, of the energy crop plantation itself, i.e., processes happening on the area covered by the plantation. These effects are species-specific as well as site-specific and depend strongly on the former state of the area, in particular its former use by humans.

- **Indirect effects** are the effects of creating energy crop plantations on the global land system as a whole. These system-level effects, usually called ILUC effects, depend not only on the amount of bioenergy to be produced and on the area required for that, but also on the development of many other components of the global land system such as food demand, food crop yields, the livestock system, and many other factors. For example, depending on food demand and food crop yields, establishment of bioenergy plantations on land currently used for food production may imply that the food has to be produced somewhere else. If that is the case, and if there are environmental effects (e.g., increased GHG emissions) resulting from the creation of this additional food crop area, they have to be attributed to the establishment of the energy crop plantation. On the other hand, Nassar et al. (2011) concluded that there is no evidence that biofuels present ILUC effects in the case of Brazilian sugarcane ethanol.

Perennial grasses such as switchgrass, *Miscanthus* and short-rotation coppice are generally thought to be ecologically less demanding than the food crops used for first-generation biofuels – in terms of impacts on soils, soil erosion, biodiversity, nutrient leaching, pesticide application, etc. (Cherubini et al., 2009; Rogner et al., 2000). It must be noticed, however, that the example of Brazil with sugarcane-based ethanol shows that first-generation biofuels can be produced in a sustainable way when adequate policies are in place (Goldemberg at al., 2008; also see Box 20.5 on Biofuels Zoning in Brazil).

Environmental impacts associated with the creation of new plantations strongly depend on the prior state and use of the land. If cropland currently used for food or feed production is converted to bioenergy plantations using perennial grasses or short-rotation coppice, the direct environmental effects can be expected to be benign, as those energy crops generally have fewer detrimental impacts than food crops.

Globally, however, with growth of the world population and changes in diets towards more demanding, i.e., animal-based, foods, as most projections assume, the area required to grow food or feed crops will increase rather than shrink. Land-use change is, therefore, a central environmental issue associated with the expanding use of bioenergy crops (Sagar and Kartha, 2007; Firbank, 2008). Once considered a local environmental issue, land-use change has become recognized as a pervasive driver of global environmental change that affects ecosystems, biodiversity, the water balance, and the biogeochemical cycles of carbon, nitrogen, and many other substances and compounds (Foley et al., 2005; Lambin and Geist, 2006). On the other hand, other recent studies (Goldemberg, 2009; Goldemberg et al., 2008) conclude that the environmental impacts of bioenergy crops such as sugarcane in Brazil can be controlled. The FAO (2009b; 2009d) also discusses these issues in the above-mentioned study cases of Peru in Latin America and Tanzania in Africa, showing that these issues can be addressed with adequate policies. These issues have been discussed deeply in Sections 20.2.5. and 20.2.7. of this chapter.

The Millennium Ecosystem Assessment (2005) concluded that land and water use by humans has already reduced the ability of many ecosystems to build up resilience and deliver vital environmental services not related to biomass production, such as buffering capacity, water retention capacity, and self-regulation, among others. A comprehensive discussion of such effects is beyond the scope of this chapter (but see IAASTD, 2009; Lambin and Geist, 2006). Regarding water, the focus here is on two main water use impacts: effects on the GHG balance, in particular the carbon balance; and effects on biodiversity (see Subsection 20.5.3.3 below). The overall GHG balance of bioenergy includes three components: GHG emissions resulting from production of agricultural inputs (e.g., fertilizers, diesel for tractors, etc.) and from conversion processes from feedstocks to final energy (e.g., liquid fuels); GHG emissions from direct land use or land-use change effects; and GHG emissions from ILUC (UNEP, 2009).

The first component is well covered by established life-cycle-based methods. High-quality databases exist to estimate these effects, and data uncertainties are relatively small. It should be noted, however, that allocation rules (i.e., how emissions are allocated to each product if one process yields more than one output, which is common in bioenergy production process chains) are a methodological challenge here and need to be considered when interpreting results (e.g., Zah et al., 2007; WBGU 2009; UNEP, 2009; Fritsche et al., 2010; Macedo et al., 2008).

These issues are covered in Chapter 11, together with some recent estimates of GHG emissions related to land-use change or ILUC, and

will not be further discussed here. This section focuses on fundamental issues related to GHG emissions resulting from land use and land-use change. Comprehensive information on GHG emissions per unit of energy are given in Chapter 11 (see also UNEP, 2009; Fritsche et al., 2010; Macedo et al., 2008; Nassar, 2009). First, general issues related to land use (change) and the GHG balance of ecosystems are discussed, followed by the issue of direct versus indirect effects.

Land use and land-use change directly affect the exchange of GHGs between terrestrial ecosystems and the atmosphere. In order to better understand the carbon balance of processes related to land use (change), it is important to distinguish between stocks and flows. A stock is a volume of carbon present in a system at any given point in time, while a flow is the amount of carbon moved from one compartment (e.g., the soil or the phytomass of plants) to another (e.g., the atmosphere) within a defined period of time, usually one year. With reference to terrestrial ecosystems, the most important stocks are carbon in the soil and in phytomass (see Box 20.4).

For carbon, the global terrestrial gross primary productivity (GPP) is 123 GtC/yr, of which 60 GtC/yr is returned to the atmosphere through plant respiration. Of the remaining net primary productivity (NPP) of 63 GtC/yr, 53 GtC/yr is returned through heterotrophic metabolism. The remaining 10 GtC/yr is the net ecosystem productivity (NEP). A large portion of NEP is lost because of land use, biotic stresses, fires, and other disturbances. The fraction remaining after these losses, called net biome productivity (NBP), ranges between 0.3 and 5 GtC/yr (Jansson et al., 2010).

Photosynthesis removes carbon from the atmosphere, but a considerable proportion flows back into the atmosphere through respiration of plants and heterotrophic organisms (animals, microorganisms, fungi). If there is no land-use change involved, the situation is relatively simple: if photosynthesis is greater than respiration, then the system acts as a carbon sink; otherwise, it is a carbon source. As yearly flows are large, difficult to measure, and often almost balanced, most methods used to measure the net carbon balance of ecosystems over time determine the net flows into or out of the system as the difference between stocks at different points in time. Ecosystem theory generally assumes that ecosystems gradually build up carbon stocks in vegetation and soil as they mature until they reach an equilibrium (climax) point where photosynthesis equals respiration and stocks are stable (Houghton, 1995; Schimel et al., 2001).

Table 20.11 shows that almost all carbon is stored in the soil-organic carbon (SOC) component in croplands, temperate grasslands, and tundra ecosystems. Overall, stocks are highest in forests and lowest in croplands.

The data in Table 20.11 show that deforestation, as expected, results in a massive loss of carbon to the atmosphere because large stocks in the phytomass are released in a short time. Belowground processes are more complex and much slower. If the system is used as cropland, SOC

Table 20.11 | Typical values for carbon stocks of vegetation units per unit area. Data reported for forests refer to natural or near-natural conditions except for croplands; Carbon stocks in managed forests are substantially smaller.

Vegetation unit	Phytomass (kgC/m^2)	Soil organic carbon (SOC) (kgC/m^2)	Total (mean) (kgC/m^2)
Tropical forests	12 – 19	~12	~28
Temperate forests	5.7 – 13	~9.6	~19
Boreal forests	4.2 – 6.4	~34	~40
Tropical savannas	2.9 – 3.0	~12	~15
Tundra	0.35–0.7	~13	~14
Temperate grasslands	0.4–0.7	~24	~24
Croplands	0.2 – 0.3	~8.0	~8

Source: Watson et al., 2000; Saugier et al., 2001.

mostly declines, but in grasslands, SOC can be even larger than in forests, in particular if they are used extensively. Soil-related processes can continue over long periods of time until a new equilibrium is reached. These complexities are important here, because they are the underlying reason why it is very difficult to derive general conclusions from site-specific studies of the carbon balance of different crops. Further detailed information on this issue is shown in Box 20.4.

The carbon balance of crops, including energy crops, strongly depends on the prior state (and particular use) of the land. If, for example, land is deforested for bioenergy, then there is a large release of carbon before energy crops are produced. This "carbon debt" (Fargione et al., 2008) may be quite large, so GHG emissions of bioenergy crops from that source can exceed GHG emissions from fossil-fuel-based counterparts for years, decades, or even longer (Gibbs et al., 2008; UNEP, 2009). On the other hand, if perennial bioenergy crops are planted on degraded pasture lands, they may build up carbon stocks in the soil and act as strong carbon sinks while producing bioenergy (Goldemberg, 2009; Goldemberg et al., 2008; Goldemberg and Guardabassi, 2009; Macedo et al., 2008; Tilman et al., 2006). Moreover, the GHG balance also depends on a host of other factors, such as land-use intensity and management, crop type (perennial plants mostly build up larger carbon stocks in the soil and in phytomass than annual plants), climate, soil, landform (slope, etc.), and many more. Further information on these issues is given in Box 20.4 below.

Considering the time horizon adds further complexity. The usual assumption was that biomass production was carbon neutral except for land-use-related effects, because the CO_2 resulting from its oxidation had previously been absorbed by the plant through photosynthesis. This neglects the following intricacy:

If biomass is harvested and combusted, then the carbon is released immediately, often within one year. However, if biomass is not harvested and is left in the ecosystem, it may take years, decades or even centuries until the CO_2 returns to the atmosphere; indeed it might even be

Box 20.4 | Carbon Sequestration in Soils

World soils constitute the third largest global carbon (C) pool, after the oceanic pool at 38,400 Pg and the geological pool at 4230 Pg. The soil C pool, estimated at 2500 Pg to a depth of 1 meter, is 3.2 times the atmospheric pool of 780 Pg, and four times the biotic pool (trees, vegetation, etc.) of 620 Pg (Batjes, 1996; Eswaran et al., 1993; Falkowski et al., 2000; Lal, 2004; Pacala and Socolow, 2004; Lal, 2010).

The loss of the soil's C pool from 1850 to 2000 is estimated at 78 ± 12 Pg (Lal, 1999). Until the 1940s and 1950s, more CO_2-C was emitted from terrestrial ecosystems than from fossil fuel combustion. During 2009, 8 Pg CO_2-C/yr was emitted by fossil fuel combustion, and about 1.6 Pg CO_2-C/yr by land-use conversion. Anthropogenic activities that lead to CO_2 (and CH_4) emissions include deforestation, biomass burning, drainage of wetlands, soil tillage, excessive grazing, and extractive farming practices.

Soil processes that lead to gaseous emissions are: accelerated soil erosion, breakdown of structural aggregates, and decomposition/mineralization of soil organic matter. Two other soil processes that accentuate gaseous efflux from soil are: methanogenesis that leads to emission of CH_4 under anaerobic conditions, and nitrification/denitrification that lead to emission of N_2O.

Transfer of atmospheric CO_2 into other pools with a relatively longer residence time is called C sequestration. Thus, C sequestration in terrestrial biosphere (i.e., soils and biota) is a natural process based on photosynthesis of atmospheric CO_2 followed by humification of biomass into stable humic substances and organo-mineral complexes.

Important practices of soil organic carbon (SOC) sequestration are afforestation/reforestation, wetland restoration, establishment of a Conservation Reserve Program (CRP) or land retirement, restoration of eroded/degraded soils, no-till farming, cover cropping, application of biochar, and adoption of integrated nutrient management practices. The strategy is to create a positive ecosystem C budget. The rate of soil C sequestration ranges from negative or zero under arid and hot climates to about 2 Mg/ha/yr under cool and humid climates.

The global potential of soil C sequestration is estimated at 0.4–1.2 Pg C/yr in cropland soils (Lal, 2004) or about 1 Pg C/yr by converting 1.5 billion hectares from plow till into no-till farming (Pacala and Socolow, 2004). Improved management of grasslands (range land, pasture land) has an additional potential of C sequestration of about 1 Pg C/yr. Restoration of degraded and desertified soils has an additional potential of ~1 Pg C/yr. Restoration of peatlands (wetlands) is another important strategy for C sequestration. Adoption of these practices can be promoted through payments to land managers for ecosystem services.

Modern biofuels (e.g., ethanol, methanol, methane, and triglyceride oils) are an important alternative to fossil fuels. These are also called "green gold" fuels, because their feedstocks can be grown on farmland over and over again (Vorholz, 2006). Commonly used feedstocks of ethanol include corn grains (Pimentel, 2003) and sugarcane (Goldemberg et al., 2008). However, crop residues are also being considered as a source of cellulosic ethanol (Somerville, 2006). There are serious concerns about the use of corn grains for ethanol with regard to competition for food (Mufson, 2008), energy balance, and carbon foot print (Pimentel, 2003; Oliveira et al., 2005; Lal, 2008).

While the practical issues on cellulosic ethanol production are being addressed (Ragauskas et al., 2006), the impressive progress of ethanol production from sugarcane in Brazil needs to be objectively assessed, especially with regard to soil C dynamics. The agricultural input required for sugarcane production releases 2.27 Mg CO_2/ha/yr. Other sources of CO_2 emissions from ethanol production result from the pre-harvest burning of sugarcane and from the decomposition of vinasse. Total CO_2 emissions from ethanol production from sugarcane in Brazil are 3.31 Mg/ha/yr (Oliveira et al., 2005) compared with 5.03 Mg/ha/yr for corn-based ethanol in the United States (West and Marland, 2002; Shapouri et al., 2002).

The soil C budget for sugarcane production in São Paul State and elsewhere has not been widely studied. Plowing and other soil disturbances have negative impacts on the soil C pool by increasing the mineralization of soil organic matter and risks of soil erosion. However, the soil C pool can be increased by adopting reduced tillage, eliminating pre-harvest burning, and recycling wastes of the ethanol processing.

Source: Lal, 2005; 2006; 2010.

captured for geological time spans under certain circumstances (e.g., when carbon is stored belowground in wetlands under anaerobic conditions). Therefore, bioenergy production can only be considered "carbon neutral" in a strict sense if it results from additional plant growth that would not have occurred in the absence of bioenergy production and use (e.g., if the productivity of degraded land is increased over the previous state), if biomass is used that would be oxidized rapidly if left in the ecosystem, or if bioenergy use reduces biomass use in other sectors, e.g., if food or fiber consumption falls due to rising prices of agricultural products. These issues are currently being discussed intensively, and this debate might result in new accounting rules for GHG emissions of bioenergy (Bird et al., 2010; Pingoud et al., 2010; Searchinger et al., 2009; Searchinger, 2010; Goldemberg, 2009; Goldemberg and Guardabassi, 2009).

The above-discussed considerations generally apply to land use and land-use change, whether the land is used for food or energy crops or other purposes. Any production of biomass – no matter whether it is produced for food, as raw material, or for energy – requires land and may (or may not) result in land-use change. As long as changes in the production and consumption of biomass are studied in a systemic way – for example, by looking at changes in food, fiber and bioenergy demand over time – in a systems model that integrates plant production, all land-use effects of biomass conversion are direct, and no such thing as an "indirect effect" exists. The same applies for agriculture and industry, as well as final consumption.

ILUC effects need to be considered, however, when environmental effects of single resources, such as bioenergy crops, are to be evaluated without explicit consideration of the entire land system. Of course, the evaluation of ILUC effects involves uncertainties (Nassar et al., 2009; 2011) and can only yield approximate results, based on ceteris paribus assumptions.

In conclusion, appropriate planning and implementation of bioenergy crop plantations is of key importance. If bioenergy crop plantations can be situated on lands with low initial carbon stocks, such as degraded lands, or use perennial crops such as perennial grasses or short-rotation coppice and appropriate management technologies such as no-till agriculture, their GHG balance can be negative, or at least their GHG emissions can be low. If, on the other hand, inappropriate locations are combined with poor choices of crops and unfavorable management, GHG emissions can be very large and even exceed the fossil baseline. Therefore, adequate policies are needed to ensure that appropriate areas are used for bioenergy crops. The choice of crops should follow environmental zoning approaches, such as those currently used in Brazil (see Box 20.5 below) and in the Brazilian states of Minas Gerais and São Paulo (Joly et al., 2010).

The United Nations Department of Economic and Social Affairs (UNDESA) provides a range of recommendations that specifically address sustainability aspects of bioenergy (UNDESA, 2007). These include the use of energy crops that are suitable under local conditions and are able to grow on marginal and arid lands with limited inputs. UNDESA also favors energy crops that have a variety of by-products that would create additional income for farmers. Energy crops that are easily propagated and allow intercropping would also be important. Bioenergy should also benefit identified marginalized groups in a community.

In conclusion, adequate policies that are appropriately enforced can allow the reduction of negative, and the promotion of positive, environmental impacts of bioenergy crops.

20.4.3.2 Environmental and social effects of using by-products, residues, and wastes

Bioenergy production from agricultural by-products, residues and wastes presents advantages, as it does not: require additional land or land-use change; compete with food and fiber production; affect agricultural and food prices; or require many additional scarce inputs, such as freshwater (Berndes, 2008). Using biomass residues may help alleviate energy shortages and create employment opportunities (such as production of bioenergy crops); moreover, use of municipal solid waste (MSW) may reduce landfill requirements. However, there may also be negative environmental effects, depending on the respective biomass flow, as well as on technology and management.

The agricultural residue straw can deliver substantial amounts of energy. However, straw plays a vital role for soil fertility, soil carbon pools, and the mitigation of water and wind erosion (Lal, 2005; Lal, 2006; Wilhelm et al., 2007). WBGU (2008) assumes that about half of all crop residues could be used to produce bioenergy without compromising soil fertility. Removal of crop residues for energy purposes could also affect the GHG balance of cropping systems. There are currently studies under way evaluating how much of the residues much be left on the soil to avoid that (Hassuani et al., 2005).

The removal of biomass from forests, including forest residues, may affect forest ecosystems because the coarse woody debris is essential for biodiversity and ecosystem functioning (Harmon et al., 1986; Krajick, 2001; Shifley et al., 2006) and forest conservation objectives. The use of fuel wood and forestry residues should be jointly optimized. This can be managed through adequate capacity-building with local people, as is happening in remote villages in India (CENBIO, 2002).

Well-managed use of animal manures for biogas production can have significant positive environmental and social impacts. It reduces methane (CH_4) emissions,[13] while returning most plant nutrients and parts of the carbon back to the soil, thereby mitigating land degradation

13 Conversion of animal manures in biogas plants and subsequent application of the residues as fertilizer reduce methane (CH_4) compared to the storage and direct application of manures (Bhattacharya et al., 1997; Clemens et al., 2005).

Box 20.5 | Environmental Zoning in Brazil

Brazil began its large-scale sugarcane ethanol program, PROALCOOL, in 1975, when oil prices raised with the world oil crisis. Since then, many developments towards a sustainable production system have been achieved. These have resulted in important increases in both agricultural and industrial productivity (more than 3%/year, Goldemberg et al, 2008); as a consequence, production costs fell rapidly, making ethanol economically competitive with gasoline. At the same time, improvements in social and environmental legislation have been achieved, both at the federal and state level. Due to the expansion of sugarcane production in recent years, concerns about the direct impacts of land-use change led federal and state governments to adopt policies to determine suitable areas for this crop.

The state of Minas Gerais was the pioneer in this process and launched its economic-environmental zoning in 2007. The zoning is based on social, economic and environmental information that shows regional characteristics, potentialities, and vulnerabilities. It is an orienting tool that can support policymakers and entrepreneurs of different sectors (World Bank, 2011). In the state of São Paulo an agro-environmental zoning was based on studies related to soil and climate restrictions, topography, water availability, air quality, and existence of protected areas and biodiversity conservation areas; this assessment was the basis for a voluntary scheme with sugarcane producers, the Agroenvironmental Protocol. The text stipulates a set of measures to be followed, anticipating the legal deadlines for the elimination of sugarcane harvest burning and immediately halting burning practices in any sugarcane harvests located in expansion areas. It furthermore targets the protection and recovery of riparian forests and water springs in sugarcane farms, controls erosion and content water runoffs, implements water conservation plans, stipulates the proper management of agrochemicals, and encourages reduction in air pollution and solid wastes from industrial processes (Lucon and Goldemberg, 2010; SMA, 2011).

The federal government launched, in September 2009, the national agro-ecological zoning for sugarcane and, in 2010, for palm oil. This zoning identified the areas where sugarcane crop expansion can take place, and forbids sugarcane cultivation in 92.5% of national territory, including the Amazon Forest, Pantanal wetlands, and other native biomes. It identified 64 million hectares that comply with environmental and productivity requirements. The zoning was an intense program involving dozens of institutions and researchers of agricultural and environmental issues. In this process maps were produced showing soils, climate and rainfall, and topography. Land was classified and delimited by determining the areas of highest yield potential in detail (1:250,000), based on minimum productivity, with respect for the environmental regulations and which areas should be preserved, as well as trying to reduce competition with areas devoted to food production. According to these studies, there are in Brazil about 650,000 km^2 available for sugarcane and 300,000 km^2 for palm, without undesirable impacts (EMBRAPA, 2011a; 2011b).

and helping to maintain soil fertility (Rajabapaiah et al., 1993; Stinner et al., 2008). Moreover, energy from biogas can help to substitute for traditional biomass energy, which has tremendously negative health and environmental effects and currently contributes to millions of premature deaths due to respiratory diseases resulting from indoor pollution (Jaccard, 2005).

Using MSW for energy purposes lowers CH_4 emissions from waste deposits (landfills). Since waste disposal in landfills has other environmental impacts when it is not adequately controlled and enforced, such as soil and underground contamination, there can be local opposition to the construction of landfills near communities. Therefore, in some cases, incineration of MSW may provide an interesting solution for both solid waste disposal and power production.

However, effective air pollution control technology is needed to avoid large emissions of toxic pollutants such as dioxins and furans. Tight air pollution regulation that vigorously enforces the use of the most advanced abatement technologies to reduce toxic emissions is required to minimize possible negative environmental effects from the combustion of MSW (McKay, 2002).

20.4.3.3 Biodiversity

Different trade-offs on biodiversity may result from bioenergy production, depending on the adequacy of the policies in place, and their enforcement.

On a local scale, biodiversity effects depend on crops, former land uses, and management practices. Local biodiversity may benefit from biomass crops when intensive agricultural practices are replaced by low-intensity biomass production systems. In general, first-generation European agricultural crops have more negative impacts at the local level than both mixed cropping systems and bioenergy crops in developing countries (the Brazilian experience is an example of this; Goldemberg et al.,

2008), as well as second-generation perennials and woody crops (GLOBIO, 2010).[14]

Clearing valuable ecosystems such as native rainforests and wetlands to make an expansion of the agricultural sector possible would result in large losses of natural biodiversity. If feedstock production comes predominantly from large monoculture cultivation without appropriate environmental controls, it could reduce both the number of species and, with a growing specialization on particularly suitable varieties, even the number of varieties grown. These practices could result in a greater vulnerability of the agricultural sector to non-standard crop-growing conditions such as extreme weather patterns, pests, and diseases (Müller et al., 2007). The threat to wild biodiversity from agricultural crops and bioenergy growth is associated primarily with land-use change, as already mentioned. When areas such as natural forests are converted for feedstock production, the loss of biodiversity is significant, even if an expansion of crop land is a temporary phenomenon. A further concern is the introduction of invasive species for biofuel production. Agricultural biodiversity could be affected by large-scale monocropping practices and the introduction of genetically modified materials (FAO, 2008b).

On the other hand, the conservation and/or recuperation of native forests areas and other biomes as well as fauna corridors – such as riparian forests and the so-called environmental protection areas – are fundamental for any agricultural crop and, when introduced inside large-scale plantations, can contribute to preserving or rebuilding biodiversity (Goldemberg et al., 2008; EMBRAPA, 2008).

20.4.4 Challenges

Due to the uncertainties in future oil prices and energy policies, it is still too early to understand the dimensions of the markets for biofuels sufficiently to develop a realistic scenario that quantifies the trade-offs between increased biofuel production and the provision of food (Müller et al., 2007). However, there are positive perspectives for food prices in the future, as discussed in OECD/FAO (2009).

In the long term, tropical countries will likely play an increasingly important role in feedstock production, due to favorable biophysical conditions and generally lower costs of land and labor, so long as suitable trade arrangements and stable conditions for investment prevail (Cotula et al., 2008). Considerable improvements in land and water productivity are possible and can be significant. The example of achieving a significant increase in sugarcane productivity in Brazil shows that this is an objective that can be achieved if adequate investments are made (al-Riffai et al., 2010). In tropical farming systems, currently producing around the global average for developing countries, one can reach 2 t/ha for cereals.

In Africa, seven countries (Tanzania, Côte d'Ivoire, Burkina Faso, Ghana, Guinea, Mali, and Senegal) are participating in a UNDP Multifunctional Platform project that tackles lack of access to electricity and rural women's poverty through the provision of simple multipurpose diesel engines that are able to run on jatropha oil (Cotula et al., 2008). This project, as well as the BEFS project (FAO, 2010a; 2010b) for Peru and Tanzania (see Box 20.2), illustrates how tropical countries can implement bioenergy production if the needed overall conditions can be achieved.

As discussed in the sections above, the main challenge regarding land use is related to the increase in agricultural productivity in developing countries (mainly African countries) and the implementation of adequate policies such as agro-environmental zoning to allow the better use of land for each purpose considering the existing trade-offs. Socio-environmental assessments are fundamental for various options to meet future demands for food and biofuels.

In terms of water, challenges related to water trade-offs include the implementation of adequate strategies for water productivity improvements. This requires substantial efforts from authorities and different development agencies. A combination of incentives and sanctions are required to overcome social inertia and to demonstrate that it is a viable option. A considerable decoupling could be achieved over a period of a few decades. Technologies are generally known; the challenge is to invest in human and institutional capacity for adequate policies in all sectors, including environmental and social ones.

If improvements on the food consumption side are combined with those in water productivity on the production side, the estimated water need for food production in 2045 is estimated to be 6470 km^3/yr. Estimates for water need for bioenergy in 2050 vary considerably (4000–12,000 km^3/yr), but even the lower limit of such consumptive water requirements to produce biofuels is quite significant.

Increasing water productivity holds the key to future water scarcity challenges. Without further improvements in water productivity or major shifts in production patterns, or a more advanced allocation system within an Integrated Water Resources Management system, the amount of water needed for agriculture, industrial and domestic activities will increase by 60–90% by 2050, depending on population, incomes, and assumptions about water requirements for the environment. In agriculture alone, the total volume of water needed for crop production would be 11,000–13,500 km^3, almost double the 7130 km^3 of today (FAO, 2007). Water resources will be stressed even more from increased demand for biofuel. By 2030, world energy demand will increase by

14 The origins of the present GLOBIO model (GLOBIO3) go back to the GLOBIO2 model and the Natural Capital Index-IMAGE framework (NCI-IMAGE). Both approaches are universal, policy-oriented frameworks on the impact of human activities on biodiversity. To meet the challenge of evaluating the global targets on biodiversity, an international consortium, made up of the UNEP World Conservation Monitoring Centre, UNEP GRID-Arendal and the Netherlands Environmental Assessment Agency joined forces in 2003. They combined the GLOBIO2 and the NCI-IMAGE approach into a new Global Biodiversity Model: GLOBIO3. This model has been in use since 2005 (Globio, 2010).

50%, and two-thirds of this demand will come from developing countries. However, there is scope for an accelerated increase in water productivity. Water productivity in agriculture has increased steadily in recent decades, largely because of an increase in crop yields, and the potential exists for even more increases. However, the pace of such increases will vary according to the type of policies and investments put in place, with substantial variations in the impact on the environment and livelihoods of rural populations. A systematic approach to agricultural water productivity requires actions at all levels, from crops to irrigation schemes, and involving national and international economic systems, including the trade in agricultural products. It calls for an informed discussion on the scope for improved water productivity in order to ameliorate intersectoral competition for water resources and optimize social and economic outcomes (UN-Water/FAO, 2007).

"Virtual water" is the water consumed in the production process of an agricultural or industrial product (Allan, 1998). It is particularly important to water-scarce countries in their efforts to secure water for different sectors. Water for bioenergy production will become increasingly important. Taking virtual water into account in the trade balance may allow for water-scarce countries to import more water-consuming crops and produce lower water-consuming ones domestically. This may also include production of biofuels.

If improved water productivity is achieved through a more intensive application of fertilizers and other chemicals, improvements in a quantitative sense may lead to a deterioration of quality. Climate change is also a highly relevant issue but difficult to model in terms of water. Taking into account that water scarcity is already severe in many parts of the world and that growth of GDP and population and distribution are not in harmony with access to productive land and abundant water resources, the role of trade will be even more important. The virtual water perspective under those circumstances is even more important, as are the connections between production and consumption (Lundqvist et al., 2007).

With regard to hydropower, the construction of large dams often has extensive impacts on downstream areas of the river basin, including the terrestrial and aquatic ecosystems. Ecosystem restoration is a necessary measure to be addressed, and the impacts of decommissioning are complex and site-specific. The World Commission on Dams Knowledge Base demonstrates that in many cases large dams have resulted in:

- loss of forests and wildlife habitat, loss of species and degradation of upstream river basin areas due to inundation of the reservoir area, or of downstream river basin areas due to damming and subsequent loss of water for ecosystem maintenance;
- GHG emissions from reservoirs due to the anaerobic decomposition of vegetation and carbon inflows from the basin;
- loss of aquatic biodiversity, upstream and downstream fisheries and the services of downstream floodplains, wetlands and riverine, estuarine and adjacent marine ecosystems;
- creation of productive fringing wetland ecosystems with fish and waterfowl habitat opportunities in some reservoirs; and
- cumulative impacts on water quality, natural flooding, and species composition where a number of dams are sited on the same river.

The ecosystem impacts are more negative than positive and have led, in many cases, to irreversible loss of species and ecosystems. Efforts to date to mitigate the ecosystem impacts of large dams have met with limited success, owing to the lack of attention given to anticipating and avoiding impacts, the poor quality and uncertainty of predictions, the difficulty of coping with all impacts, and the only partial implementation and success of mitigation measures.

In brief, aiming to reduce the competition among the different end uses for land and water, the main challenges are related to the need for investments not only in technological aspects allowing the introduction of efficient and sustainable methods, but mainly in capacity-building in technical, economic, environmental, social, political and regulatory sectors related to this issues.

20.4.5 Environmental certification

Sustainability standards are frequently proposed for the processes of environmental permitting. Based on an agreed definition of sustainable development, specific criteria and provisions are formulated, either locally (according to community priorities and expectations) or externally (based on requirements of external markets). Different organizations have developed sustainability criteria and tools, e.g., the International Labour Organization (ILO) for acceptable labor conditions, the World Wildlife Fund for ecological factors, the World Bank for financial results, and the OECD and the UN for development policymaking and information (Lewandowski and Faaij, 2006).

Applying sustainability criteria to an environmental permitting process can be done either on a case-by-case basis or following zoning plans. The example of sugarcane zoning in São Paulo, Brazil (Joly et al., 2010), is described in Box 20.5. Several GIS datasets (e.g., climate, soil potentials, water availability and vulnerability, biodiversity protection and connectivity) led to a map with different restrictions on licensing enterprises, and subsequently to federal zoning for sugarcane and oil palm plantations in Brazil.

Considering land use, and specifically the case of biofuels, several initiatives seek to establish certification and sustainability standards. Some of these initiatives overlap, and they are all broadly consistent in their principles. Different systems have been developed by the Forest Stewardship Council (FSC, 2011), the European Retailers Produce Working Group (GLOBAL GAP, 2011), and Linking Environment and Farming (LEAF, 2011). Some schemes have stronger interfaces with bioenergy: the Roundtable on Sustainable Palm Oil (RSPO, 2011), the Roundtable on Responsible Soy Association (RTRS, 2011), and the São Paulo State Green Ethanol

Program (Lucon and Goldemberg, 2010; SMA, 2011). National policies in the EU are also supporting the assessment of sustainability and certification systems for biofuels (Ecofys, 2006). An important initiative is the Roundtable on Sustainable Biofuels (EPFL, 2007), which is developing certification criteria, led by Lausanne University and supported by the Swiss government. This initiative is currently facilitating agreement on a comprehensive set of principles for sustainable biofuels, including principles on respect for land and water rights, the socioeconomic development of communities, and food security. UNEP has also an initiative aiming to support wide adoption of sustainability criteria, avoiding breaching trade rules of the World Trade Organization (UNEP, 2011).

There are different systems and methods aiming at ensuring sustainability of bioenergy, most of which fall into the following categories:

- Demand-side, voluntary, consumer-oriented, bottom-up, providing a green label for "better products," appealing to individual perceptions, and usually covering good social practices (e.g., fair labor, small producers, from poorer regions) and organic/environmental standards (e.g., products less carbon-intensive, no deforestation in the production process, etc.).

- Demand-side, mandatory, top-down, sanitary measures and/or other requirements generally applied to imports; covering some key topics and products (e.g., absence of genetically modified organisms or proscribed substances and quality standards for a given biofuel commodity).

- Demand-side sustainability criteria, top-down general principles applied to a category of goods and services, such as biofuels, covering a broad range of topics, in many cases inspirational but also with the intention of becoming mandatory by law.

- Supply-side sustainability criteria, producer-oriented, generally voluntary schemes promoted by producer associations and/or governments, applied to main (in most cases few) topics of higher socio-environmental concern beyond law enforcement (e.g., life-cycle GHG assessments).

- Supply-side, voluntary, recognized Environmental Management Systems based on continuous improvement spirals, as in the case of the ISO 14000 series of quality standards.

An interesting example of a certification scheme already being applied is the one introduced by the Swedish company SEKAB. The company delivers about 90% of all ethanol in Sweden for E85 and ED95 (ethanol for heavy vehicles). SEKAB announced in June 2008 that it would buy certified sustainable ethanol from four Brazilian groups, in what the company said was the first deal of its kind. SEKAB said it worked with the Brazilian producers to develop sustainable and verifiable criteria for the entire life cycle of the ethanol, taking into consideration environmental, climate and social perspectives. SEKAB said the criteria are in line with demands highlighted in the ongoing processes being led by organizations such as the UN, EU, ILO and a number of NGOs. There are requirements concerning working conditions, labor laws, and wages – and zero tolerance for child labor, non-organized working conditions (slave labor), and the destruction of rain forests. Harvesting is to be at least 30% mechanized today, increasing to 100% by 2014, and an independent international verification company will audit all production units twice a year to ensure that the established criteria are met. Criteria will gradually be developed over the coming years and synchronized with international regulations when these are in place (Lucon, 2010).

It can be observed that there has been a proliferation of certification schemes; this is a positive development, demonstrating awareness among governments, citizens, consumers and producers of the risks and challenges involved in expanding biofuel production, as mentioned by UNCTAD (2008). The inclusion of land rights criteria in some private certification schemes is also welcome. It is too early, however, to see whether they will have a real impact. The EU and government schemes, which are potentially far more influential, have not addressed land issues – in effect, giving license to European companies to ignore principles of prior informed consent in land allocation for large-scale biofuel crop cultivation (Cotula et al., 2008).

In fact, the sustainability of biofuels is a key question, and certification criteria can be used to answer it. However, as discussed in UNCTAD (2008), there are a number of issues to be considered. The same types of sustainability standards should be considered for other energy sources, and also when comparing fossil fuels with biomass energy. Sustainability standards and certification schemes, to be implemented by developing countries, mainly Least Developed Countries, need strong capacity-building measures. Also important is the question of an increase in biofuel production costs due to certification, and who could cover it. In addition, UNCTAD (2008) raised the point that certification should not be used as protectionism to farmers in industrialized countries.

Recently the United States and the EU established regulations to stimulate the use of bioenergy, in particular biofuels, and to ensure the production and use of biofuels in a sustainable manner.

The EU has two major pieces of legislation: the Renewable Energy Directive (RED) and the Fuel Quality Directive (FQD). All member states were required to implement both directives by December 2010. RED requires a minimum of 10% renewable energy fuels in transport by 2020. It also commits the EU to report by the end of 2010 on the impact of ILUC on GHG emissions from biofuels and ways to minimize that impact. FQD's target is for fuel suppliers to reduce life-cycle GHG emissions by at least 65% by weight across all transport fuels by 2020.

Minimum compliance with the EU policies includes the following: reduce GHG emissions by 50% as of 1 January 2017 and by 60% for biofuels and bioliquids produced as of 1 January 2018; biofuels may

not be made from raw material obtained from land with high biodiversity values, high carbon stock or land that was peat land in or after January 2008; and biofuel feedstock grown in the EU must meet the EU's "cross-compliance" requirement. However, it must be noted that such requirements are only for liquid biofuels and do not include solid biomass (Georgescu, 2010).

The US Renewable Fuel Standard (RFS) program came into force on March 26, 2010, as required by the Energy Independence and Security Act (EISA, 2007). The program's objective is to increase the volume of renewable fuel blended into gasoline and other transportation fuels. Renewable fuels include ethanol, biodiesel, and other motor vehicle fuels made from renewable sources. All producers of gasoline to be used in the United States are obliged to comply with the annual Renewable Volume Obligation as determined by the US Environment Protection Agency (US EPA). For 2009, the RFS was 10.21%. Renewable fuel must reduce GHG emissions by 20% in life-cycle terms when compared to average transportation fuels in 2005. Similarly, biomass-based diesel and advanced biofuels must achieve a 50% reduction, and cellulosic biofuels a 60% reduction. The US EPA considers Brazilian sugarcane ethanol adequate in terms of carbon emissions, which opens significant opportunities for other countries also producing sugarcane ethanol (US EPA, 2010).

20.4 Conclusions and Policy Proposals

Whether for income generation or for local energy self-sufficiency, large-scale and small-scale biofuels production can co-exist and even work together in synergy to maximize positive outcomes for rural development. Existing experiences and practices should be disseminated to document successful experiences and to analyze the conditions that make them possible, mainly the spread of costs and benefits among local land users, investors, and government, Also, it is important to consider the extent to which such experiences can be replicated elsewhere (Cotula et al., 2008).

Overall improvements in food production may be achieved by reducing the losses and waste in the food chain from production to consumption. These losses occur in harvest, transportation, transactions, storage, handling, processing, and wholesale and retail sales, not to mention changed dietary habits (more proteins, i.e., closer to the top of the food chain) and overconsumption (more food intake than necessary). As discussed earlier in this chapter, adequate funding and capacity-building are key factors to achieve such objectives.

Decoupling and mitigating water competition between food and energy crop production is also possible (see Lundqvist et al., 2007). It is not axiomatic that expanding energy crop production leads to negative consequences relative to land, water, and other resources. Properly located, designed and managed biomass plantations can provide positive benefits, such as low water consumption and adequate choice of crops allowing production and transportation. There are options for decoupling future water needs for food and bioenergy production from increased food and bioenergy demands, through adequate planning and zoning. Effective institutions and strong capacity-building at all levels are needed for integrated land and water resources management, allowing the introduction of adequate policies to regulate the trade-offs in their use.

Land use policies should include: protecting small-scale farmers from loss of land due to pressure from large-scale producers; respect and protection of land tenure rights; use of "informed decision-making" and full participation of stakeholders when determining land-use changes; and assessing existing land-use policies in light of potential expanded bioenergy use (UNIDO, 2008).

For food, consideration should be given to annual production of main commodities, demand, prices, and trade, both for irrigated and rain-fed production. Food demand is a function of price, income, and population. There are different areas and yield functions for rain-fed and irrigated crops; crop area and yield functions include water availability as a variable.

Conflicts between food and bioenergy can be avoided through agro-economic-ecological zoning (as presented in Box 20.5), allowing adequate use of land for each purpose. The potential impact of bioenergy production on food prices is discussed in several studies and is quite controversial, but it is clear that such adverse effects can be mitigated by appropriate policies that aim at an integrated optimization of food and bioenergy production. Adequate capacity-building is needed, mainly in developing countries, to allow the implementation and enforcement of adequate policies, such as those to regulate biomass-intensive energy systems and hydropower (limitation, water availability, cooling tower, irrigation), together with agro-ecological-economical zoning to define potentials and best aptitudes for land use, as well as imposing environmental limits in harvested areas (related, for example, to conservation units, water use, monoculture, use of pesticides, burning practices).

In the case of trade-offs in water use, it is fundamental to ensure water for all, and this requires knowledge about science, ecology, and economics, as well as ethics and international cooperation. The trade-offs in water use involve large quantities and different activities, which may conflict with hydropower, thermoelectric or bioenergy production. Global freshwater distribution is unbalanced geographically, and supply is frequently affected by contamination, depletion, and increased competition for multiple purposes. The rapid increase in water demand (due to growing populations, incomes, and unsustainable consumption) must be viewed in the context of climate change, the effects of which are difficult to predict. Expanded exploitation of water resources is only a short-term option for addressing scarcity. In the long term, only ambitious policies, heavy investments in water conservation, and adequate and integrated management of multiple uses can be solutions to the long-foreseen crisis (Rogers, 2008).

Water use alternatives need to clearly consider: improvements in the efficiency and productivity of existing irrigation systems before planning and implementing new ones; adaptation and expansion of local and traditional water management solutions; more coordinated management of surface and groundwater resources; and improvement of the productivity of rain-fed agriculture.

Efforts to promote sustainable water management practices have primarily focused on the agricultural sector as the largest consumer of freshwater. Governments have several objectives in deciding the nature and extent of inputs in agriculture. These include achieving food security, generating employment, alleviating poverty, and producing export crops to earn foreign exchange. Irrigation represents one of the inputs to enhance livelihoods and achieve economic objectives in the agricultural sector with subsequent benefits for rural development. Just as strategies and approaches to rural development are context-specific, there are numerous and diverse alternatives to agricultural development and irrigation that need to be examined. The diversity relates to scale, level of technology, performance, and appropriateness to the local cultural and socioeconomic setting.

A number of policy, institutional and regulatory factors hinder the emergence and widespread use of an appropriate mix of options that would respond to different development needs, sustain a viable agricultural sector, provide irrigation, and offer livelihood opportunities to large populations. Appropriate policy options include:

- support for innovation, modernization, adaptation, maintenance, and extension of traditional irrigation and agricultural systems;
- protection or restoration of natural functioning of deltas, floodplains, and catchments in order to sustain and enhance the productivity of traditional systems in these areas;
- transferring management to decentralized bodies, local governments, and community groups for recovering tariffs and maintenance;
- agricultural support measures, mutually reinforcing and developing intersectoral linkages in the local economy to spur rural development;
- reducing transaction costs and risks for smallholder farmers in developing countries; and
- expanding access to international markets by reducing barriers and introducing supportive domestic policies (without trade distortions such as the tariff and non-tariff barriers to OECD markets).

Government policies and institutions play an important role in the promotion of particular water and agricultural/bioenergy appropriation technologies and methods. Each method has different implications for food production, food security at the local and national levels, and the distribution of costs and benefits.

The business-as-usual policy option entails continuing along the path taken so far. Each country would proceed in setting and revising policy frameworks in line with national interests, taking into account international implications of policy decisions only where these are compatible with domestic priorities (FAO, 2008b).

Certification can play an important role, mainly in the case of biofuel production, but without an internationally agreed standard, the desire expressed by many governments to start certifying sustainable biofuels may face serious obstacles, not least under international trade law considerations (FAO, 2008b).

In the short term (about 25 years), carbon sequestration in terrestrial ecosystems (notably in degraded and desertified lands through restoration and afforestation) is a prudent strategy. In the long term (over 50 years), utilizing carbon-neutral fuel sources (biofuels, solar, hydro, wind, geothermal) is the best option (Lal, 2010).

Clearer definitions of concepts of idle, under-utilized, barren, unproductive, degraded, abandoned and marginal lands (depending on the country context) are required to avoid allocation of lands on which local user groups depend for livelihoods. Similarly, productive use requirements in countries in which security of land tenure depends on active use need to be clarified so as to minimize abuse (Cotula et al., 2008).

Governments need to develop robust safeguards in procedures to allocate land to large-scale agriculture and biofuel feedstock production where they are lacking and – even more importantly – to implement these effectively. Safeguards include clear procedures and standards for local consultation and attainment of prior informed consent, mechanisms for appeal and arbitration, and periodic review. Safeguards should be applicable across agricultural and other land-use sectors, rather than only specifically to biofuels (Cotula et al., 2008).

Although bioenergy can have significant positive impacts on rural areas through the creation of jobs, the FAO (2008a) considers that an integrated approach to social protection should be adopted for rural households, combining traditional transfers (social safety nets) and policies that enable smallholders to respond quickly to the market opportunities created by higher prices.

In the very short term, however, the supply response to higher price incentives, especially by smallholders, may be limited by their lack of access to essential inputs such as seeds and fertilizers. In these cases, social protection measures, including the distribution of seeds and fertilizers, directly or through a system of vouchers and "smart subsidies," may be an appropriate short-term response. If implemented effectively, such a program will increase the income of small producers and may reduce price increases in local markets, thereby contributing to improvements in the nutritional status of net food-buying families.

Executive Summary

One of the objectives of the Global Energy Assessment (GEA) is to assess the means through which the potential negative economic, social and environmental impacts from energy use can be mitigated or eliminated, either by increasing the efficiency of energy use or by switching to primary energy sources and carriers. A large set of factors influence ultimate energy use beyond those related to income and affluence. These include non-economic and non-technological drivers such as behavior, lifestyle, culture, religion and the desire for improved well-being.

This chapter focuses on these underlying drivers and explores how they could influence energy use and choice of energy sources while maintaining desired levels of affluence or income. It reviews the factors that determine how socio-economic indicators of affluence and other non-technological drivers may translate into demand for energy services (for definition of energy services, see Chapter 1) and at the interventions, policies and measures (such as taxes, infrastructure, building codes, and access to information) that could modify or change lifestyles and preferences.

In addition to the consumption of goods and services and their quality, the chapter also focuses on two elements of lifestyle choices that have significant implications for energy use: diet and mobility (household energy use, another key element, is discussed in Chapter 10 while transport is discussed in Chapter 9). In general, income is often a common driver across these choices. However, modest decoupling between income and energy use can be observed at the aggregate level in many jurisdictions and time periods, by which energy use increases at a lower rate than income. This can be observed for many industrial countries but may not yield the same outcome in most developing countries for several reasons, especially when total energy accounts for significantly inefficient non-commercial energy use. It is therefore useful to look beyond income alone and explore underlying lifestyle choices and their energy implications. Behavioral change requires both knowledge contributions to change attitudes and policy implementation to provide incentives for action.

Concepts of well-being have important implications on how energy services demand and energy use are assessed. Applications of economics conventionally assume that knowledge about resource scarcity is reasonably good and reasonably widely understood. More complex notions of well-being are better able to take other factors into account even in situations of decreasing energy services.

Notions of well-being that are based only on material consumption of goods and services implicitly assume that resources needed for production of these goods and services are abundant and that either a technology can be invented to make them more productive or that new energy resources can always be found to replace depleting resources. This underlying assumption of high substitutability between different resources fails to capture more complex, multidimensional notions and differing characteristics of energy services that may actually hinder substitutability. This is of particular importance when addressing basic needs for a decent good life and the energy services demand to meet those. The assumption of substitutability is important, as wrong assumptions about it can, for example, lead to overestimations of projected well-being when the aggregate quantity of energy use is considered but not its qualitative composition.

The potential for increased sustainability that lies in strong decoupling of well-being from material consumption can be captured by notions of well-being that are not based on material consumption alone, as reflected in the gross domestic product (GDP) per capita indicator. This offers new policy options of potentially high leverage. A reduction in energy services demand does not necessarily reduce well-being and lifestyle changes can deliver some win-win options (e.g., walking and cycling) that reduce demand for energy services with the same or even improved levels of personal health and social well-being.

Life style changes are an effective and powerful approach to addressing sustainability issues, as they can provide multiple benefits like improved health, low fossil fuel based mobility, lower emissions, and nutrition, without reducing socio-economic status.

21.1 Introduction

A popular framework that can be used to understand the link between energy systems to emissions and the environment is the I=PAT framework detailed in equation below:

Impact (e.g., from CO_2 emissions) = Population × Affluence (GDP/capita) × Technology (kWh/GDP) × Emissions (e.g., from tCO_2/kWh)

Total energy use and its impact are magnified by population and affluence and are influenced by technology. They link emissions and environmental impacts from energy systems to the underlying drivers of population and affluence and the elements of energy systems – that is, the primary energy sources and supply-side and end-use conversion technologies required to meet demands for energy services (Ehrlich and Holdren, 1971; Hubacek et al., 2007).

In general, personal disposable income is often a common indicator for affluence and energy service demand. However, it can be observed that the link between income and energy use is weakening at the aggregate level in many jurisdictions and time periods. Weakening of the income-energy coupling means that energy use increases at a lower rate than income. While real global gross domestic product (GDP) increased by 1.6 times from 1990 to 2007, for example, total primary energy use increased by 1.4 times. The modest trend towards decoupling can be observed for many industrial countries but may not yield the same outcome in most developing countries for several reasons. It is therefore useful to look beyond income alone and explore underlying lifestyle choices and their energy implications. GEA is concerned with the means through which emissions and other negative impacts may be decoupled from affluence or income, either by increasing the efficiency of energy use or by switching to primary energy sources that have a reduced environmental footprint. Nevertheless, a large set of other factors influence ultimate energy use beyond these two key ones, including non-economic and non-technological drivers such as lifestyle, culture, religion, desire for improved well-being and behavior.

Conventional economic models assume that preferences are determined individually and do not change. This chapter focuses on the many underlying drivers of preference and explores how lifestyle choices can influence energy use while maintaining desired levels of well-being. It looks at the factors that determine how indicators of well-being and other non-technological drivers may translate into demand for energy services and at the interventions and policies that could modify or change lifestyles and preferences.

In addition, the chapter explores a more fundamental question of whether defining affluence in purely economic terms is an appropriate measure for well-being. Thus it explains the individual and social goals underlying energy use. To the extent that affluence or income is only one of the determinants of well-being, there may be further opportunities to decouple energy use from human well-being. The chapter includes a brief review of the emerging literature on well-being and on indicators and metrics that go beyond affluence in conceptualizing development. Thus, this chapter is about the potential for increased sustainability through changes in lifestyles and the resulting change in demand for energy services.

By focusing on consumers, a new perspective on energy system management is added that recognizes the importance of the psychological, sociological and cultural determinants of demand. Such an approach thus augments and complements the more common technological and conventional economic approaches used in the analysis of energy supply and end-use.

A focus on the consumption basket also allows the exploration of options for replacing one energy service with another. For example, in telecommuting the demand for mobility may be replaced by an increased use of electricity for information and communication appliances, perhaps leading to a reduced use of primary energy. In this view, the elements of the consumption basket of energy services are not independent, but their levels are assessed jointly based on relative costs and benefits given the prices, income, tastes and preferences, and social fabric within which a consumer functions.

21.2 Lifestyles and Energy Services Demand

Often the individual demand for energy services is expressed or assessed only at larger levels of aggregation, such as the household, community, or region. Converting to individual demand is only possible via averages (e.g., per capita average energy use to provide street lighting in a village). It is also clear that not all energy service use can be traced back to private individual consumption decisions (e.g., public/governmental provision of infrastructure services such as street lighting).

Consumer activities influencing directly the energy use (e.g., housing and private transport) account for more than 43.0% of total energy use (see Chapters 9 and 10, as well as Chapter 1, Table 1.2). Figure 21.1 shows the energy use of US citizens in 1997 for different energy services when accounted for from a life cycle perspective. Since many of the individual decisions will entail indirect energy uses, life cycle analysis can shed light on important use categories that are not directly accounted for or paid for by individuals. Figure 21.1 indicates consumer activities influencing directly energy use accounts for a lesser share in total energy compared to factors influencing indirectly the energy use. Housing operation uses the most energy among all consumer activities which is mainly contributed by the consumption of utilities (electricity/natural gas/fuel oil and other fuels/telephone, and water and other public services). For direct influences, personal travel is the most energy intensive, much of which is caused by short distance travel by automobiles and trucks.

Understanding the linkages between lifestyles and energy services demand offers insight into how changes in lifestyles may contribute to

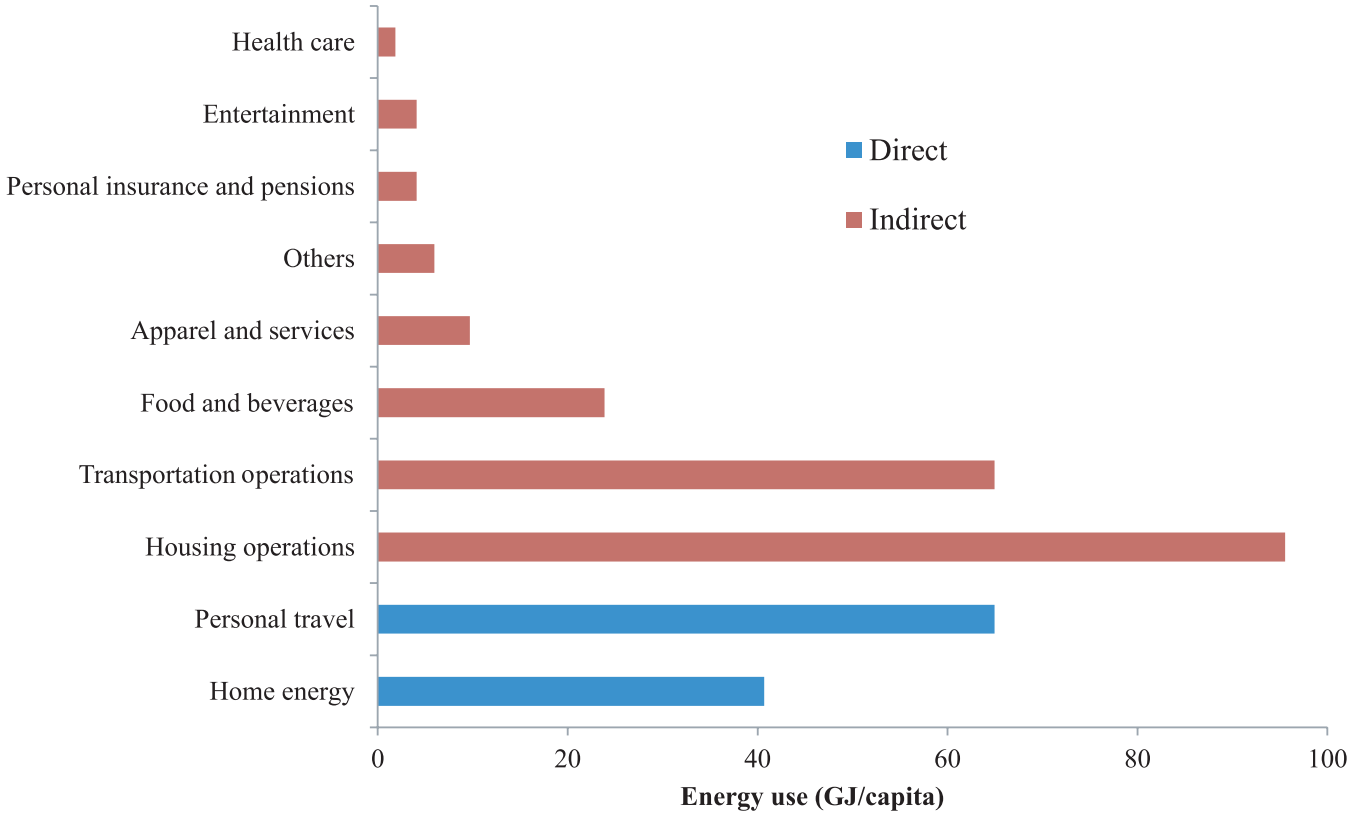

Figure 21.1 | Direct and indirect energy use by consumer activities in 1997. Source: Bin and Dowlatabadi, 2005.
Note: Home energy includes: space heating, other appliances and lighting, water heating, refrigeration and air conditioning. Transport operations include: vehicle purchases (net outlay) (cars and trucks, new/cars and trucks, used) gasoline and motor oil other vehicle expenses (vehicle finance charges, maintenance and repair, vehicle insurance, rent, lease, licenses, public transportation etc.). Housing operations include: shelter, utilities, and public services (e.g., electricity, natural gas, fuel oil and other fuels, telephone, water etc.) as well as housekeeping supplies, household furnishings and equipment (e.g., household textiles, furniture, floor coverings, major appliances, small appliances as well as miscellaneous houseware and household equipment). Personal travel includes: short and long distance travel by automobiles, trucks, air, etc.

reducing total energy use and is all the more relevant in today's internationally connected world through trade relations. Here, it is crucial to introduce the notion of well-being as the ultimate goal by which to judge supply-side or policy interventions in improving human well-being or sustaining a high level of well-being in a long-term, sustainable development context. Changes in lifestyles and energy services demand need to be assessed in relation to alternative concepts of well-being than those directly related to high economic attainments and spending. Referring to well-being also means addressing not only absolute reductions in energy services, which might be an issue for high-income consumers and regions, but also absolute increases in energy services, which are still necessary for a huge percentage of the population in developing countries.

Consider the case of private car mobility. The same level of the service (expressed as passenger-km per year or per capita km driven per year) may be associated with different levels of energy use, based on factors such as vehicle efficiency, age distribution of the vehicle stock, driving characteristics, and so on. Consequently, interventions that improve efficiency allow the reduction of energy use while maintaining the same level of consumption of the service.

From a policy perspective, however, it is not just the absolute level of the service that is important but rather the generation of utility from the consumption of the service or the production of goods and services where mobility serves as a factor input. Interventions that allow the same level of utility or welfare for reduced levels of mobility are also important from an energy and impact perspective. Such modifications of demand may often involve behavioral or lifestyle choices such as walking or cycling instead of driving for short shopping trips. At the same time, it is important to recognize that such choices may have benefits quite independent of their energy or environmental outcomes – for example, the positive effect on individual health due to increased physical activity. This example refers to industrial countries, however; the situation could be different in developing countries, where absolute levels of motorized personal mobility are very low and therefore an increase would clearly improve well-being.

Addressing changes in mobility services and technologies or in an energy carrier in a lifestyle context sharpens the vision for the full range of possible options for intervention, as the change in mobility and increase in well-being need not necessarily be based on private cars. Furthermore, an energy services and lifestyle approach emphasizes

the fact that mobility can be framed differently, namely via "accessibility" of certain goods and services (see also Chapter 9), which further broadens the set of possible options for action to improve well-being, in particular if the need to gain access to these goods and services is a determinant of well-being.

Consumer energy services demand is determined by needs and preferences for multiple services, which in turn depend on, in addition to income level and prices, home country characteristics, dwelling area and type, job and leisure activities, diet preferences, cultural context, religion, etc. A certain lifestyle is characterized by a bundle of these determinants combined with a more or less explicitly framed worldview, a set of values and convictions, preferences, and behaviors. It is embedded in some social context of identity and meaning. Thus, lifestyle can be considered as an organizing concept, making explicit that human beings live a life well beyond the monodimensional life of an economic agent responding only to income and price variables.

The importance of characterizing lifestyles is brought out in studies by Christensen (1997) and Alfredsson (2004) of households in the United States and Sweden. Assuming floor area of the dwelling as a proxy for overall affluence levels, for families of the same size and with similar floor areas, Christensen (1997) showed the wide variation in final energy use due to choices on mobility, diet, and space heating. For example, people living near their workplace or commuting by public transport and with a dietary choice of less than the US-average amount of meat and using renewable energy-based heating systems could reduce energy use by 88% compared to those travelling long distance and eating meat more than average level, while using fossil fuel based systems. Diet and mobility choices matter not only for energy use, but also for disease burden and public health. Particular dietary choices, e.g., above average meat consumption, have been associated with higher incidence of many diseases (Mann, 2000; Fung et al., 2004; Walker et al., 2005; Caspari et al., 2009; Sinha et al., 2009). Findings from Edwards and Tsouros (2006) identify an ongoing decline in physical activity across all age groups during the past several decades. This is largely due to the mechanization of work and daily tasks, the increased use of cars, increases in sedentary work, the use of labor-saving devices, and an increase in leisure pursuits not involving physical activity (such as watching television and using a computer). Physical inactivity causes an estimated 600,000 deaths per year in Europe and leads to a loss of 5.3 million years of healthy life expectancy per year due to premature mortality and disability (Edwards and Tsouros, 2006).

The Swedish study (Alfredsson, 2004) also showed that dietary choice, mode of transport[1], fuel type, and appliance choice for indoor comfort – all changes in pattern of consumption – generally reduce energy usage though may not reduce level of energy use significantly. If energy use reduction of the full green consumption basket is taken, it turns out to be less than the added value of reductions that can be estimated from each of the green end-use-specific lifestyle changes. This is because some benefits of a partial greening of lifestyle (such as dietary choice) by end-use type is taken back by the rebound effect of an enhanced level of energy services (such as mobility) of another end-use activity or efficient mobility service may be taken back by changing lifestyle in favor of international tourism.[2] However, studies have shown that this take back effect is high in societies with more unmet demand (Roy, 2000).

Assessments of lifestyles often focus on consumption and leisure time activities and how they contribute to creating identity and meaning (Geißler, 2002). The concept of lifestyle is thus also studied in connection with "social class" and status (Wind and Green, 1974; Sobel, 1981). Social dimensions and individual lifestyles are not disjoint; lifestyles are partly the consequence of deliberate individual choices and partly determined by social contexts as well as physical and economic boundary conditions (Harrison and Davies, 1998). These lifestyle types may often be grouped along the two dimensions of "social status" (lower, middle, higher) and "basic values."

A large amount of literature assesses lifestyle as a matter of combining different activities defining consumption patterns without regard to values, convictions, and social context (Herendeen and Tanaka, 1976; Rees, 1995; Vringer and Blok, 1995; Daly, 1996; Duchin, 1998; Biesiot and Noorman, 1999; Perrels and Weber, 2000; Pachauri and Spreng, 2002; Lenzen et al., 2004; Cohen et al., 2005). There, lifestyle categories are, for example, defined by expenditure types (Minx et al., 2009) and or through correlation in a narrow operational sense between level and pattern of consumption and socioeconomic parameters such as age, sex, gender, education, occupation, or income.

Households are an important target group in any energy conservation discussions. A study involving over 300 households in the Netherlands (Benders et al., 2006) indicated that direct energy needs – energy for space heating, electricity, and motor fuel – along with indirect energy requirements, which is defined as that needed for production, distribution, and waste disposal of consumer goods and services (e.g., production of food), amounted to as much as 80% of total energy flows. But the relationship between affluence, household characteristics, and energy use is complex. Household energy use and embodied energy through consumption (building energy use aspects) are discussed in Chapter 10.

1 Tourism is growing rapidly in Sweden with very distant places being increasingly popular. A Swedish family's carbon budget is totally dominated by a trip to one of these distant places.

2 The rebound effect is discussed in detail in Chapter 22.

The remainder of this section describes in greater detail two other elements of lifestyle choices that have significant implications for energy use: diet and mobility.

21.2.1 Diet

Dietary choices and delivery systems can lead to considerable variations in energy service demand and resultant energy intensity of food baskets. In high income countries food accounts for 17–18% of indirect household energy use (Vringer and Blok, 1995; Reinders et al., 2003; Cohen et al., 2005).

While satisfying the nutritional needs of humans accounts for a significant portion of total primary energy demand, the individual energy components of the food supply chain that fall in each sector are relatively small, such as cooking and refrigeration (the most important energy end-uses in buildings related to satisfaction of nutritional needs, along with the provision of hot water), and represent only a few percent of building energy use. Food systems cross the boundaries of many sectors and thus affect many chapters in the GEA: buildings (Chapter 10), transport (Chapter 9), and industry (Chapter 8), as well as rural issues (Chapter 19). Therefore it is especially important to consider energy services related to nutrition. Dietary choices depend on habits but also reflect acquired tastes over time. So net benefits and costs assessment of a dietary choice will vary over time and will change with changing acquired tastes. This section examines the implication of dietary choices (including cooking) for total energy used for the provision of nutrition. In low per capita income countries as per capita income rises, consumers will shift some consumption away from lower value cereals to higher value livestock products. In developed countries, where incomes and livestock product consumption are already high, consumers are expected to make relatively small adjustments between food consumption groups with changes in income levels (Cranfield et al 1998).

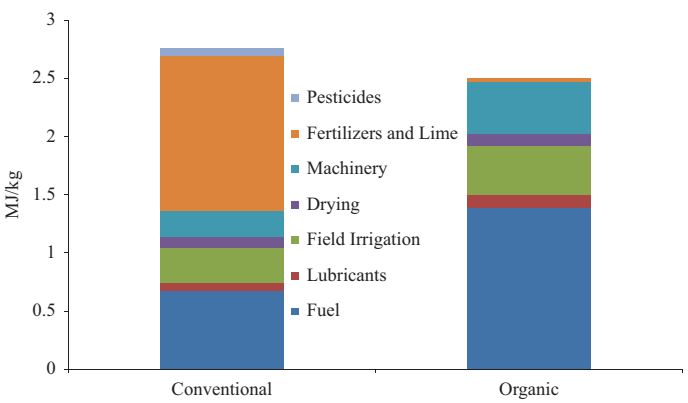

Figure 21.2 | Structure of energy inputs for conventional and organic farming systems. Source: Based on Jorgensen et al., 2005.

The total amount of energy required to provide human nutrition consists of the energy needed for agricultural production; land use and land cover change; the energy embodied in the raw food materials themselves and in the agrochemicals; the energy needed to transport the food components, water and equipment needed for food production; the industrial energy use related to food processing; and the energy used for refrigeration and cooking.

The embodied energy in the raw materials used for food directly correlates with the structure and nature of the daily diet. For instance, producing 1 kcal of grain and animal proteins requires about 2.2 kcal and 25.0 kcal of fossil energy, respectively (Pimentel et al., 2003). Thus the difference between the energy inputs for plant- and meat-based meals may exceed a factor of 10. Furthermore, the food produced by conventional agricultural methods requires a total higher energy input than organically produced food. Conventional agriculture production utilizes more overall energy than organic systems due to heavy reliance on energy intensive fertilizers, chemicals, and concentrated feed, which organic farmers forego (Ziesemer 2007). Figure 21.2 shows in some specific crops and practices in some countries in organic farming direct fossil fuel use might be higher because of relative high machine use for weeding and animal manure spreading compared to pesticides and synthetic fertilizers in conventional practices but overall energy use is less in organic farming. But in the same study (Jorgensen et al., 2005) it is shown indirect energy use is higher in conventional farming because of synthetic nitrogen fertilizer use. It is not only food production but also post-harvest practices and food delivery in which energy use needs to be examined. Both agricultural systems use separate but parallel systems, and only a few studies include data on packaging, delivery and so on. Studies (e.g., Bertilsson et al., 2008) have shown that choice of data, country context and their representation, accounting for energy use can misrepresent fuel use data across conventional and organic systems. A diet consisting mainly of locally produced, seasonal foodstuffs is significantly less energy-intensive than one based on "globalized" (and thus shipped) ingredients or produced in greenhouses. Thus an equally nutritious but plant-based diet using local, seasonal ingredients may require less total life cycle energy input than a meat-based diet using globally produced and not necessarily seasonal ingredients.

The literature on the impact of a dietary choices on energy and carbon footprint (such as Coley et al., 1998; Lenzen, 1998; Kramer et al., 1999; Carlsson-Kayama et al., 2003; Wahlander, 2004; Eshel and Martin, 2005; Baroni et al., 2006; Wrieden et al., 2007; Collins and Fairchild, 2007) focuses on the link between nutritional choices and energy use as well as ecological footprints of different diet types, mostly in industrialized countries. A key topic is the issue of meat consumption.

For many consumers, meat consumption is considered as a superior good – one that increases with rising income levels. People in

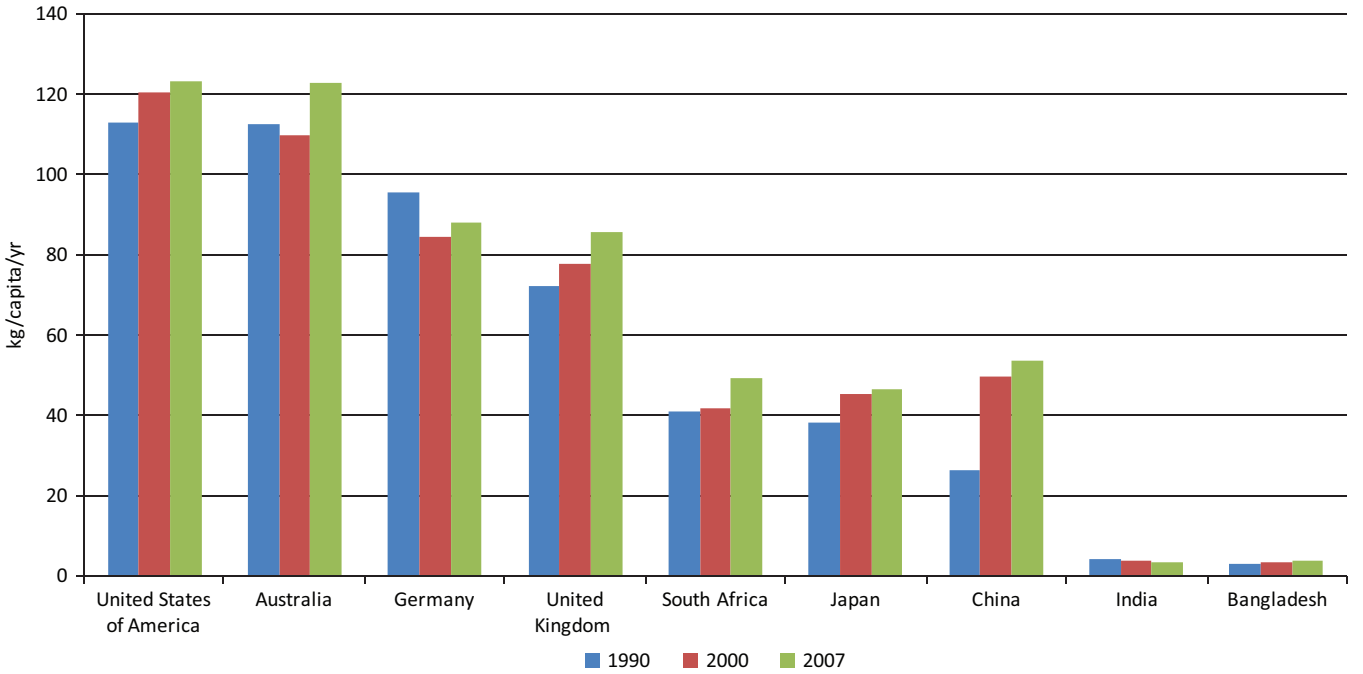

Figure 21.3 | Per capita meat consumption across regions. Source: Prepared using data from FAOSTAT, 2008.

low-income countries spend a greater portion of their budget on food, and when their income rises they increase their expenditures on different food items to a greater extent than people in wealthier countries, with the greatest increase being on higher-value food items such as dairy and meat (Regmi et al., 2001). The amount of food and foodstuffs that is not consumed but is thrown away or wasted through food preparation also increases with income, and this represents an increasing amount of embodied energy and other environmental pressures.

Population growth along with economic development has increased purchasing power, causing a demand not only for more food but also for different food varieties. Studies on human nutrition worldwide have indicated a nutrition transition toward more-affluent food consumption patterns (Gerbens-Leenes et al., 2010). Meat consumption is increasing globally, of which approximately 24% is beef. Beef consumption increases with income (Fiala, 2006). Per capita meat consumption varies widely across regions currently (see Figure 21.3) but is expected to rise with urbanization and income increases. FAO statistics show beef consumption has also the same pattern across regions. In China, while consumption change in proportion to income, change is lower for traditional pig meat consumption (0.15), for beef rate of change in consumption is more than the change in income (1.56) and for goat and poultry meat it is near proportional 0.88 to 1.05 (Masuda and Goldsmith, 2010). Proportional change would occur when value of ratio of change is equal to one i.e., rate of change in consumption is the same as rate of change in income. Urbanization and per capita income growth have contributed to these. In India a 1994 national food survey in 32 cities indicated that 74% of urban households were non-vegetarian and that meat consumption rose in 1980–90 at 4–8% (Landes et al., 2004). In Mexico, chicken consumption is expected to rise more than 64% in the next two decades. While household consumption of chicken meat for the higher-income group can be expected to rise by 0.18% for 1% change in total household expenditure, for the lowest ten percent of households arranged in order of expenditure the change in chicken meat can be as high as 1.65% for 1% change in total household expenditure (Salazar et al., 2005). Total meat consumption in the United States is the highest and, as in most of the world (except in Germany), has been growing at a steady rate (however, at lesser rate than, e.g., United Kingdom) for a number of years.

The specific energy use (SEU) in processed meat products is very high (Table 21.1). Ruminant meat production uses about 25 kg of plant protein to produce 1 kg protein as meat, whereas for pigs this relation is about 10 kg for 1 kg meat and for poultry is around 5 kg. This is in particular the case if animals are fed with concentrate feed and are not reared in pasture-based systems; however, the latter is an option for ruminants only but not for pigs and poultry (Smil, 2002). Over the past few decades, energy needs for transport, storage, and processing has increased, especially for meat products. A study in France, the United Kingdom, the Netherlands, and Germany indicated a significant increase (14–48%) in the energy use per tonne of product over the last 15 years (Ramírez et al., 2006).

Table 21.1 | Direct specific energy use and emissions for various processed meat products in select European countries.

Product	whole and chilled (MJ/t dress carcass weight)* SEU	whole and frozen (MJ/t dress carcass weight)* SEU	cut up, deboned, and chilled(MJ/t dress carcass weight)* SEU	cut up, deboned, and frozen (MJ/t dress carcass weight)* SEU	$kgCO_2$-eq/kg of meat type**

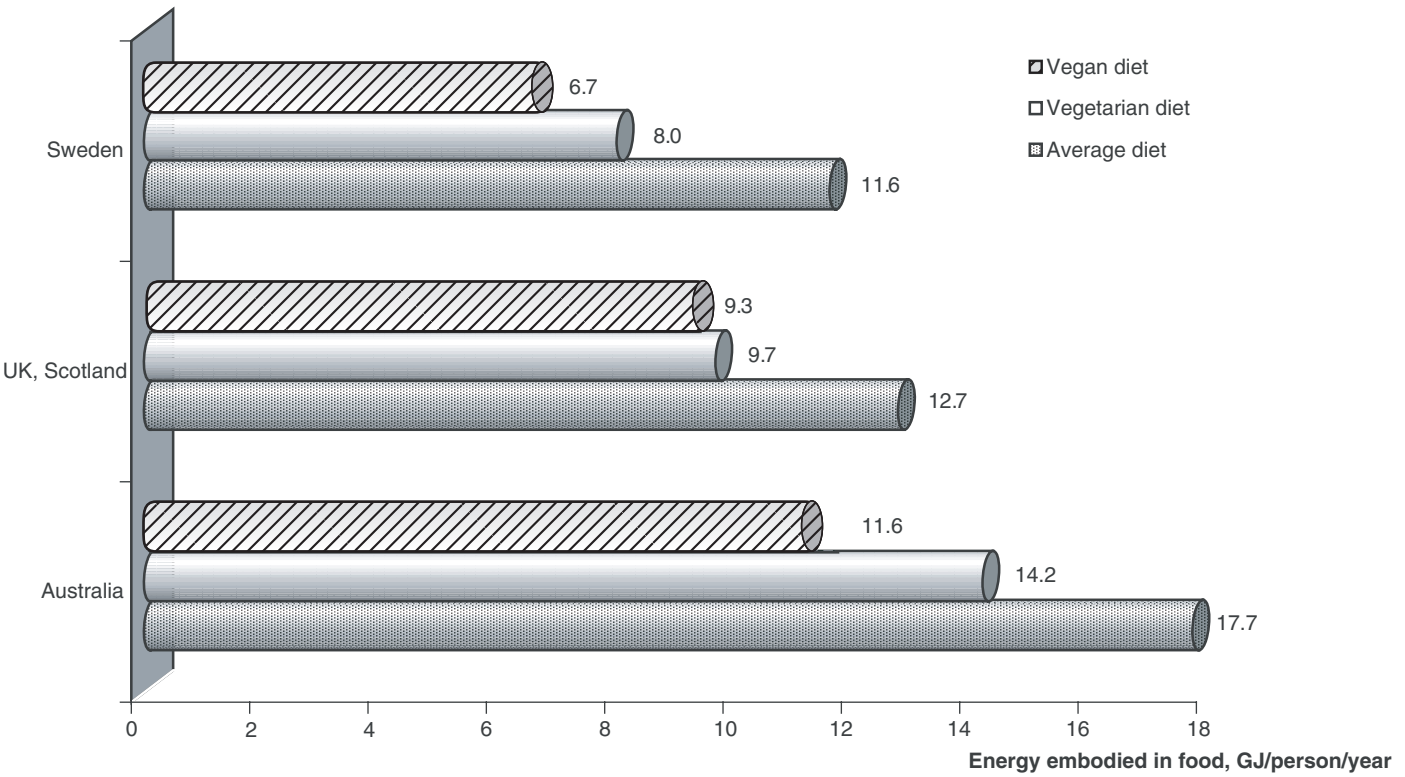

Figure 21.4 | Comparison of embodied energy in average, vegetarian, and vegan diets in Sweden (1999), Scotland (1995), and Australia (1994). Calories of fish, meat, and other animal products consumed in the average diets were replaced by a proportional increase in consumption of other food products in the vegetarian and vegan diets. Source: Coley et al., 1998; Lenzen, 1998; Wallen et al., 2004; Wrieden et al., 2007.

Figure 21.4 compares embodied energy in average, vegetarian, and vegan diets characterized with the same caloric value for Sweden, Scotland, and Australia. Embodied energy is sum total of energy use from cradle to grave of a product, i.e., energy used directly for production, transportation, marketing, as well as disposal and dismantling. There is a significant difference between energy inputs for these three diets. The difference between average and vegan diets equals 19.6 GJ/yr for a four-person family in Sweden, 24.4 GJ/yr for a similar family in Australia, and 13.8 GJ/yr in the United Kingdom – that is about 5.44 MWh/yr, 6.19 MWh/yr, and 3.02 MWh/yr respectively. These figures are similar to the average annual electricity use per household in these countries. However, the figure also attests that other determining factors that are related to the location may influence total nutritional energy use more than the dietary choice alone. For instance, a vegan diet in Australia is associated with as much life-cycle energy use as a standard Swedish diet.

The embodied transport energy in food is determined by shipping distances, transport mode, and vehicle efficiency (Saunders, 2008). With increased globalization, the length and complexity of food supply chains

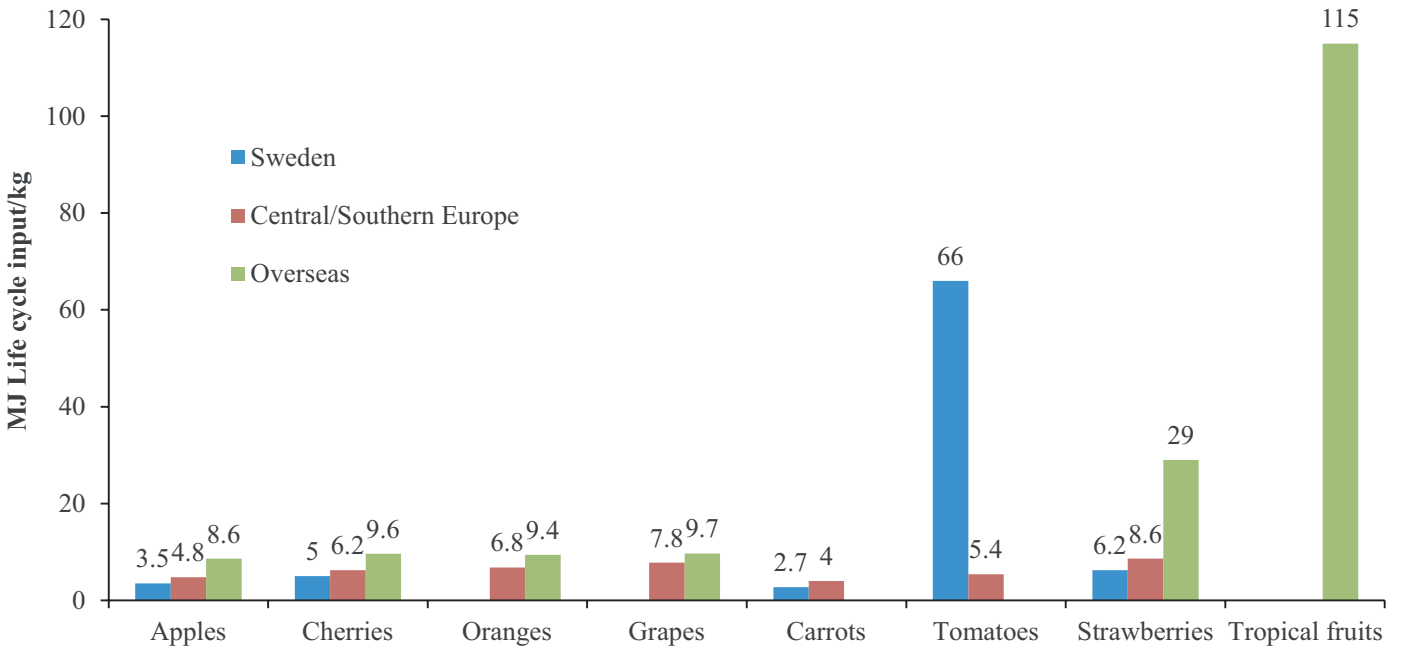

Figure 21.5 | Life-cycle energy inputs associated with local, regional, and overseas sources of food production for Sweden in 1999. Note: Tomatoes produced in Sweden were grown in a greenhouse while those in Southern Europe were open-grown; strawberries grown in the Middle East and tropical fruits were air-freighted. Source: Carlsson-Kanyama et al., 2003, in Saunders, 2008.

keeps growing (EC, 1999; Garnett, 2003), which results in increasing "food miles." Comparison with Table 21.1 suggests that two-thirds of total energy use is indirect.

Figure 21.5 compares the life-cycle energy input of fresh vegetable and fruits produced locally (in Sweden), regionally (in the European Union), and overseas. The figure illustrates that locally produced food is less energy-intensive than food shipped from a distance: the life-cycle energy input of Swedish produce differs from the overseas fruits and berries' input by factors of two (for apples, cherries) and five (for strawberries). Fresh food produced in a different country of the same region apparently requires a less transport-intensive supply system. For instance, Eastern or Southern European apples, cherries, and strawberries brought to Sweden require 1.2–1.4 times higher energy input than analogous Swedish products. In addition, it is interesting to compare the energy intensity of different production methods: for example, Swedish tomatoes grown in a greenhouse result in 66 MJ/kg of life-cycle energy input per kg, while open-grown Southern European tomatoes take 5.4 MJ/kg (Saunders, 2008), including the shipping energy to Sweden.

Another important driver of increased energy use in food production is the decrease of seasonally restricted consumption and the corresponding increasing demand for heated greenhouses or transport services. Increasing cooling demand, the globalization of the food system with corresponding transport distances, and the growing importance of processed convenience food and eating out are also important drivers.

21.2.2 Mobility[3]

The energy implications of lifestyle choice are closely related to certain mobility choice patterns. Vehicular ownership does not always mean high energy use, as the latter depends on mobility. With tourism demand rising, long distance mobility patterns are also increasing, especially air travel. The vehicle population in Beijing and Shanghai is about one-tenth that of Tokyo, while their total fuel use is one-third to one-half as high because of lower fuel economy and more miles driven. Both these components are very high in the United States.

Mobility per se is not always a goal in itself. It is about accessibility to various activities (home, work) and also for some to go places for individual recreation, or to the sources of services and products (medical appointments, shopping, etc.; see also Chapter 9). Passenger-kilometers traveled are increasing worldwide, with the United States alone accounting for 65% of total global passenger-kilometers traveled.

3 Please see Chapters 9 and 18 for a more detailed discussion.

Individual and household decisions on the choice of private space, suburban or city life, income, recreational demand, social status, conspicuous consumption, and so on all determine the level of mobility services demanded and the mode of transport chosen. Social theorists have also described how the disappearance of norms and economic limitations has gradually removed the restriction of individual choices and made "individual lifestyles" an appropriate way to describe differences in worldviews and consumption (Giddens, 1996; Beck, 1997; Jensen, 2008; Bauman, 1998). In societies with more value for individual space and freedom, private car mobility becomes of primary importance. The number of passenger cars is still increasing in industrial countries (World Bank, various years).

Despite increasingly more efficient engines and some attempts to promote smaller and lighter cars, motor power and the number of electronic appliances in automobiles continue to increase – with correspondingly increasing energy demand (Chapter 9). This is partly due to the aggressive marketing strategy of automobile production and distribution companies. Similar developments of increased energy services can be observed in public transport.

People in many countries will continue to depend on private cars for a long time. In countries such as the United States, widely spread-out urban living areas with low population density and inadequate public transport infrastructure necessitate private car mobility. Good practices in human settlement design – more densely populated areas; bicycle lanes; bans on parking in overcrowded areas, etc. – could counteract this development, but these are largely not replicated in newly growing and highly populated urban areas in developing countries. Furthermore, the private car seems convenient, as it is perceived to allow maximal personal freedom. So drivers systematically disregard the inconvenience of congestion and the value of using their time for other activities while they are on private transport.

21.3 Determinants of Lifestyle Choices

In many health disorders such as obesity, lifestyle choice itself is considered an extrinsic factor, as opposed to genetic factors which are intrinsic factors. Being an extrinsic factor, lifestyle choice is often times considered to be a decision variable and amenable to change. However, an in-depth analysis shows lifestyle choice itself gets determined by a host of other factors, some of which can be changed by individual decision (e.g., choice among available diet options, acquired dietary pattern) and some needs more landscape level intervention (e.g. culture, value, social norms) or macro policy (e.g., infrastructure design) intervention. Homogeneity in infrastructure and human settlement design has led to a convergence in energy service demand across various cultures and geography. Infrastructure design choices are top-down decisions and are beyond individuals. In many energy-supply system designs, the management level of consumer demand is taken as a given based on the assumption that preferences have an intrinsic character. But a lifestyle and consumption-based approach takes into consideration various extrinsic drivers for preference which changes over time. Consumer demand for energy is determined by, among other things, infrastructure design as well. For example, it is impossible to sit on a veranda in the cool of the evening if a mechanically air-conditioned home is built without one (Shove, 2003). Individuals cannot choose to switch off their own heating or cooling services if a building is centrally heated and air-conditioned.

A number of economic (e.g., the market price for land) and institutional factors (e.g., zoning) influence land use. Factor often seeming to be left out of individual decisions are human health and environmental co-benefits. Traditional walking, bicycling, jogging, and natural green spaces are getting taken over by energy-guzzling "modern" energy-intensive health services and highly irrigated green spaces; small traditional retail stores are getting replaced by air-conditioned shopping malls. Approaches based on supply-side economics or partial end-use activities fail to take into consideration the lock-in effect of infrastructure design, which constrains demand at very high levels and leaves no flexibility to generate behavioral responses. People's choice not to switch off standby power to reduce phantom load (Roy and Pal, 2009), for instance, may be due to lack of easy access to power switches in a house.

A variety of internal and external factors influence consumer choice in areas of importance for energy use. There is, for example, evidence that religion influences consumer attitudes and behavior in general (Delener, 1994; Pettinger et al., 2004). A number of studies demonstrate that religion influences eating habits (Mennell et al., 1992; Steenkamp, 1993; Steptoe and Pollard, 1995; Shatenstein and Ghadirian, 1998; Asp 1999; Mullen et al., 2000; Blackwell et al., 2001). In many societies, religion even plays one of the most influential roles in food choice (Musaiger, 1993; Dindyal, et al., 2004).

The impact of religion on food consumption obviously depends on the religion itself. Several religions forbid certain food, such as pork and meat that has not been ritually slaughtered in Judaism and Islam, or pork and beef in Hinduism and Buddhism (Sack, 2001). Although religions may impose strict dietary laws, the number of people following them may vary considerably. For instance, it is estimated that 90% of Buddhists and Hindus (Dindyal, 2003) and 75% of Muslims compared with only 16% of Jews in the United States strictly follow their religious dietary laws (Hussaini, 1993). Due to the largely vegetarian diet of Hindus, changes in these percentages can be of considerable relevance for energy demand as energy input difference between plant- and meat-based meals may exceed a factor of 10 (see Section 21.2.1). Evidence shows that embodied energy use in an average diet which contains both vegetarian and non-vegetarian items can be almost 1.3 to 1.5 times higher than a vegetarian diet

(see Figure 21.4). Differences in adherence to religious dietary prescription pertain, among other factors, to social structures, such as origin, immigration, and generation differences (Limage, 2000; Saint-Blancat, 2004; Ababou, 2005). At the same time, factors such as income convergence, markets, technology, media, and trade are leading to a homogenization in dietary patterns, thereby indicating a trend toward higher energy demand that may not be necessarily healthy.

Faiers et al. (2007) list the relevant theories and models that have been developed to explain these factors, building on a review by Jackson (2005). Further insights into the significance of these factors for consumer purchases of "green" products is provided by Ozaki and Sevastyanova (2011), who analyzed the purchase motivations of UK buyers of the Toyota Prius hybrid. They suggest that the various motivational factors could be grouped into five clusters: financial benefits; hybrid cars as exemplars of "environmentalism;" compliance with the norms of the community; attractiveness of new technology; and independence from oil producers by reducing petrol use. While their study underscores the importance of financial factors, the effects of social pressure and the aesthetic, experiential, and practical values associated with hybrid cars were also found to be important. This multidimensionality of purchase motivations highlights the importance of social, cultural, and perceptual factors in lifestyle choices, in addition to purely economic (or benefit-cost) calculations.

A cross-cultural analysis of household energy use behavior in Japan and Norway found certain similarities and differences in energy use patterns (Wilhite et al., 1996). People in both countries have good information about how much energy goes where in the home, but they exhibit an almost total lack of interest in energy efficiency and concern about the environment when shopping for appliances. In Japan, the bathing routine is extremely important to the Japanese lifestyle and at the same time very energy-intensive. Norwegians heat most of their living area most of the time, while the Japanese traditionally heat only where they are in the home and when they are there. Part of the explanation for this is culture and part is climate. When it is very cold outside, as it often is in the Norwegian winter, it is both physically and psychologically comforting to have it very warm inside (Wilhite et al., 1996).

Lyons et al. (2007) maintain that Ireland's consumption has not developed as in other European countries with increasing or high incomes but instead remains similar to that of Greece. In essence, as the rise in wealth and incomes has been very quick, consumers have not yet adjusted their spending habits and there is still room for convergence in consumption patterns. Although the Irish no longer have low incomes, they still behave, to a certain extent, as if they had.

Of particular relevance for energy services demand is the rural-urban divide especially in developing world. On average, rural incomes and expenditure levels are significantly lower than in urban areas. While a rural household's consumption pattern is biased toward food items, an urban household's expenditures have bigger shares in services (Ojha et al., 2008). Rural and urban lifestyles are influenced by the huge diversity in settlement design, infrastructure availability, and service provisions. Rural areas are more often served by decentralized systems and generally exhibit less motorized mobility and fewer modern amenities. Unless the energy-saving potential of lifestyle change is accounted for, homogenization in urbanization trends and human settlement design in newly developing areas will end up creating high-energy-using spaces. So infrastructure design needs to be diversified as well as culture-specific.

Identifying consumer preferences is a key challenge facing manufacturers and service providers. The media has been used as a powerful mass-communication tool for creating awareness and shaping public opinions. Two glaring examples of media effect on lifestyles are the successes of anti-smoking campaigns and campaigns, true across countries today, to use seat belts in cars. Wakefield et al. (1998) conclude that media can shape and reflect societal values.

21.4 Influencing Preferences and Consumer Behavior

Dietz et al. (2009) have estimated that behavioral changes involving the adoption and altered use of currently available in-home and personal transportation technologies in the United States could reduce carbon emissions by as much as 7.4%. This would require a range of nonregulatory interventions at multiple levels (individuals, communities, businesses), including interventions to address barriers to behavioral change (information, appeals, incentives) and the use of social marketing that combine mass media appeals with participatory, community-based approaches.

Many interventions to promote household efficiency do not succeed, at least to the extent expected, due to a failure to understand how people think about and make decisions regarding energy efficiency (Vandenbergh et al., 2010). For example, as Attari et al. (2010) demonstrate, householders systematically underestimate the potential for energy savings and as a result may conclude that the energy-saving actions may yield inadequate economic benefits. This happens as a result of the self-education that individuals use in making quantitative judgments about risk. Dietz (2010) suggests that linking the risk perception literature with the social psychological literature on consumption might improve the understanding of decision making regarding environmentally significant consumption.

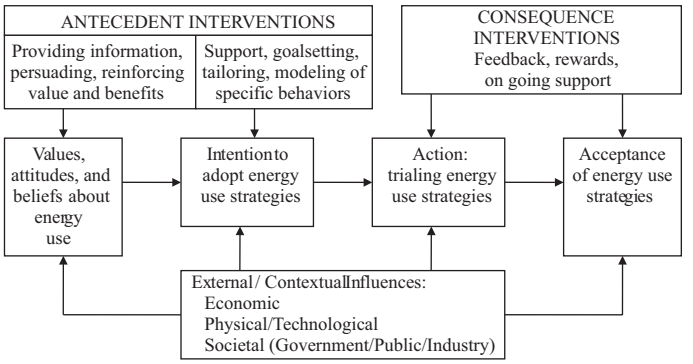

Figure 21.6 | A model for behavioral change for energy use. Source: Gardner and Ashworth, 2008.

21.4.1 Information, Knowledge, and Education

Behavioral change requires both knowledge contributions to change attitudes and policy implementation to provide incentives for action. In order to achieve constructive behavioral change toward energy use, one conceptual model (adapted from Gardner and Ashworth, 2006) indicates the potential for knowledge-based interventions to increase the intention to adopt energy use strategies. Such interventions also require an understanding of factors that can influence attitudinal and behavioral change, such as situation, habits, and experience (Vaughan, 1977). The processes used to accomplish change in people's attitudes and behaviors can include persuasion or reason – or a combination of these (Cooper and Hogg, 2002).

Several models and perspectives on how to change behaviors and attitudes are available, including cognitive dissonance theory (Oskamp, 2000), the theory of planned behavior (Ajzen, 1989), the theory of reasoned action (Ajzen and Fishbein, 1980), and the theory of consumer uptake and societal acceptance (Niemeyer, 2004). Figure 21.6 (adapted from Gardner and Ashworth, 2006) presents a synthesis of many of these models and approaches. One of the key issues that needs to be accounted for in any behavioral change model is the effects of external and contextual influences. These elements cannot be controlled for, yet they can have a lasting impact on behavior.

One key element that is not included in the model but that is essential to address when specifically engaging on consumption is the issue of threat. Engaging people on reducing energy use requires a constructive response from the community to actual or perceived threats. Moser and Dilling (2007) raise caution about using fear to change behaviors. Many studies have shown that fear may change attitudes and other forms of expression but it does not necessarily assist active engagement or the changing of behaviors (Ruiter et al., 2001; Moser and Dilling, 2007). Based on a summary of research (e.g., Das et al., 2003; Ruiter el al., 2004; Moser and Dilling, 2007), achieving a productive behavioral and attitudinal outcome requires community members to:

- feel personally vulnerable to the risk;
- have useful and very specific information about possible precautionary actions;
- positively appraise their own ability (self-efficacy) to carry out the action;
- feel the suggested action will effectively solve the problem (response efficacy);
- believe the cost associated with taking precautionary action is low or acceptable;
- view the reward for not taking the action as unappealing; and
- tend to consciously and carefully process threat information (i.e., engage in central/systematic processing as opposed to peripheral/heuristic information processing).

Ten years of experience at the Akatu Institute for Conscious Consumption in Brazil have indicated that it is necessary to show individual consumers or small groups of consumers that any one person or a small group of people can have an enormous impact (Worldwatch Institute, 2010: 107). This helps persuade consumers that even an individual can have a strong positive contribution toward sustainability by changing individual consumption habits – and more so if each individual acts as a mobilizer in society for new ways of consuming that could have a much lower impact, especially on nature. The environmental movement in the last 20–30 years has focused on this aspect of sensitizing individual consumers of their responsibilities. With networking's technological advance, virtual communities are becoming very popular and have a global presence, and they can be a good means to reach out to a community. Consumers are seen as being increasingly important in the design and implementation of public policy and decisions about the delivery of services (Entwistle and Martin, 2005) and also as peer monitoring groups.

Neighborhood efforts to reduce energy use work better with realistic instructions and assessments of the threat, diagnosis and strategies, social support, people's sense of personal control over their circumstances, low-cost alternatives, and regular feedback that allows people to see that they are moving in the right direction (Morse and Doberneck, 1995; Groopman, 2004). One example of an initiative aimed at increasing knowledge among citizens and supporting concrete action is the Energymark initiative of the Commonwealth Scientific and Industrial Research Organisation in Australia. (See Box 21.1.) It shows clearly that the holistic approach to energy service demand by targeting consumers rather than any end-use component can deliver behavioral change and reduce demand for energy services.

Box 21.1 | The Energymark Initiative, Australia

The Energymark process brings together small groups of people, meeting at their own pace, to discuss energy technologies and climate change. Individuals read scientific factsheets and share their thoughts, barriers, challenges, anecdotes, and first-hand experiences. There are two benefits of this process. First, it ensures a coordinated approach to researching public perceptions of climate change and energy technologies across Australia in order to generate insights and provide an empirical benchmark for other researchers. Second, engaging the public in this way ensures the information is more likely to be translated into action by individuals because they can relate to the concepts, discuss them openly, and change their behaviors accordingly.

In total, the Energymark trials had 1713 participants from various regions of Australia, including a wide range of age groups and balanced gender representation. Following the meetings, there was a significant change in participants' knowledge, attitudes, and intended and actual behaviors. For how long these are sustained can be judged by follow up programmes. A carbon footprint calculator provided evidence that the average carbon footprint was reduced by 20.5% due to involvement in the Energymark process. The groups took, on average, 8.5 months to achieve this. Based on the costing and abatement achieved, the program could save in total 7452 tonnes of CO_2 (i.e., 4.35 tonnes per participant) in 8.5 months at an initial investment of approximately US$500,000 (US$250,000 committed to operational expenses related to conducting the trial and US$250,000 for writing of the materials and establishing communication systems). Once the operational systems have been established, the cost associated with conducting more Energymark groups would be reduced. From the trial, the overall investment was 7.4US¢ to save 1 kWh through behavioral change, which is compatible with the current rate of electricity supply in Australia of around 8–16US¢/kWh.

21.4.2 The Role of Policies[4]

Detailed prescriptions and laws regulating individual consumption decisions could be supplementary to strengthen informational impact and serve as proxies for the beneficial reduction effects of carbon pricing and other instruments based on economic efficiency. Such prescriptions and laws can increase both technical and economic efficiency, while admittedly not reaching the first-best optimum. They could also be designed in an equitable way. They would, however, be very paternalistic and would interfere with individual freedom in an unacceptable way for a liberal society if implemented in due strength to trigger significant effects. Questions would arise about whether driving heavy private cars, eating meat, or traveling by airplane and private jet should be prohibited or drastically restricted.

Finally, there is a striking lack of political will, which may be the most important problem for the implementation of effective energy policy. Many energy policy instruments have exceptions, and existing gasoline taxes in almost all countries in varying degrees are way below the levels necessary for significant reductions, as can be derived from the research on price elasticities of demand for energy-intensive goods and services (see, e.g., Smith et al., 1995; Enevoldsen et al., 2007; Sterner, 2007). Stringent energy policy depends on the presence of societies that are willing to take on this burden (or chance), politicians who are willing to stand for such actions, and people who are willing to support such politicians and policies. This also limits the effectiveness of information provision as an energy policy instrument to target individual consumers, as can be seen from the mismatch of the current level of information and the actions taken by individuals. Both costs and benefits associated with any action has important role to play. The extent to which promotional efforts succeed and the degree to which people are willing to "curb their consumption levels for the greater good of the community" (Brown and Cameron, 2000) depend on the existence of an underlying bedrock of environmental commitment.

Additional intervention options are built around the insights mentioned in the previous sections: they target energy services demand and not energy use; they account for lifestyle and well-being aspects – which can become a hindrance as well as support for reduced energy services demand. Ultimately, these alternative policy instruments need to build and develop a strong commitment to the environment, as the classical policy instruments alone do not work to deliver full potential.

Alternative policy options are found in the context of sufficiency strategies, which make the levels of energy services themselves a topic for discussion and aim at lowering those. Sufficiency thus addresses the "level" of output (or consumption) per se – and not in relation to the inputs (as technical efficiency does). It asks whether an activity needs to be performed at all (excess meat consumption, multiple car ownership, or extraordinarily high mobility service demand) and not whether it is performed "efficiently." A combination of existing and additional instruments is most promising for reducing the externalities of energy use.

4 Policy issues are discussed in more details in Cluster IV (Chapters 22–25).

Table 21.2 | Well-being, lifestyle change, and energy savings potentials

Lifestyle Change to Enhance Well-being	Consumption Category Intervention Point	Barrier	Energy-Savings Potential	Policy/Action (individual and public)/Regulation	Co-benefits
Less wasteful electricity usage behavior	Phantom load on electricity supply	Infrastructure design	10% of average energy bill[1]	Manual switching off of standby power points Informational campaigns	Freeing electricity for redistribution or savings in fossil fuel use and resulting emission
Healthy dietary choice with prescribed healthy meat consumption[2]	Energy embodied in excess per capita meat consumption	Marketing strategy by meat processing industries, diet gurus	1.4% of global primary energy use	Informational campaigns with better health advisory based on upper limit for meat consumption	GHG mitigation strategy; freeing up water, land, health equity through allowing consumption to rise in below-average consumption countries
Healthy lifestyle practice like walking /bicycling/more public transport usage and maximum of one car per household//kilometers driven per household	Fossil fuel using transport mode	Distorted market price (land price driven by real estate market), policy failures like government subsidy for grazing lands, wrong evaluating criterion, like conventionally measured GNP	1.3% of global primary energy use[3]	Informational campaign on reduced mobility and ill health effects Less time allocated for watching TV etc. Infrastructure design Congestion-free walkway, parks/open spaces with greenery to replace energy-guzzling gyms	Larger global mobility with same fossil fuel use

[1] Roy and Pal, 2009.

[2] Limit of lean meat consumption per year recommended by American Heart Association is per capita per year 62.6 kg (Caspari et al., 2009). Currently FAO statistics show 54 countries have per capita annual consumption higher than the standard ranging between 63.2 (Mexico)-122.79 (USA).

[3] Estimated using information on energy use and alternative green lifestyles in Christensen, (1997).

The current debate on sustainable energy systems is largely dominated by technical and economic efficiency and clean energy strategies, while sufficiency plays a minor role only. Nevertheless, many official reports dealing with the question of how to reduce emissions and energy acknowledge the crucial importance of changes in lifestyles and consumption patterns (Duchin, 1998; OECD, 1998; Lundgren, 1999; Alfredsson, 2002; ECEEE, 2006; Kaenzig and Jolliet, 2006; IPCC, 2007; DEFRA 2008). This may be due to the fact that in most cases it is not clear what is meant by changed lifestyles or consumption patterns or how to bring about those changes.

It is not only individuals who have to be targeted. Lifestyles with certain levels of comfort and high energy services demand have not necessarily evolved from individual choices. The accomplishment of comfort is entwined with fashion and property development and design. It is increasingly difficult to buy a new car that does not come readily equipped with air-conditioning. Working only at the level of individuals thus may not lead to the transformational change in lifestyle needed for a more sustainable society. So change in top-down decisions in infrastructure design, as described earlier, and educating communities (as in the Energymark Initiative) might be needed.

Table 21.2 shows various alternative additional entry points to gain energy-saving potentials from the demand side to add flexibility to supply options through lifestyle change that are win-win options so far as the goal of sustaining well-being is concerned.

21.4.3 Role of Actors

National and international agencies: government, private, communities and civil societies should be encouraging the proliferation of regional (climate-sensitive) understandings of comfort and the development of a corresponding variety of local socio-technical regimes. The definition of comfort should be the subject of explicit discussion and debate. Ecologists (Diamond, 1997; Millennium Ecosystem Assessment, 2005) are revisiting the values of local ecosystems and trying to put higher value to niches in local systems. Multiple stakeholders are seen as being increasingly important in the design and implementation of public policy and decisions about the delivery of services (Entwistle and Martin, 2005) and also as a peer monitoring group. Stakeholders have been described as those who have an interest in a particular decision, either as individuals or representatives of a group. This includes people who influence a decision, or can influence it, as well as those affected by it. The community of stakeholders can become active with regard to some policy goals. Information campaigns can be embedded in several contexts, some examples are in the Energymark example described earlier.

Corporations and all kinds of organizations can also drive information campaigns. Corporation/organizations promote lifestyles that penetrate society through their own direct consumption structure, product labeling, and purchase policies. Labeling schemes (OECD, 2009) are an important initiative, as labels provide comparable information for consumers to make informed purchase decisions. Green Labels in

Europe aim at increasing greener procurement through the promotion of energy-efficient products and awareness-raising. Examples are the Swan label for over 50 different products, the Group for Energy Efficient Appliances label for home and office appliances, and the Blue Angel label for environmentally friendly consumer goods and services (OECD, 2009), as well as Energy Star labels for energy-efficient home appliances in India (BEE, 2011). Marketing strategies play a significant role, for instance, by selecting a limited range of products that are "approved" by a company as energy-efficient. Good practices, such as encouraging employees to use carpools, bicycles, or walking for health reasons and observing Environment Day[5], Earth Day[6], Biodiversity Day[7], and so on, have the potential to change behaviors. Such labeling has led to new product development as well.

In the past, environmental disagreements between corporations and environmental groups were addressed through long, drawn-out conflicts in the news media, open-ended lengthy administrative processes in government agencies, or costly litigation (Piasecki and Asmus, 1990). Today, a more cooperative spirit can often be observed. Emerging corporate citizenship practices benefit both businesses and the communities in which they operate. Corporate environmental citizenship activities often include donations and gifts for environmental programs and incentives for employees to work with community groups on natural resource conservation and protection. Clearly, information campaigns need also be led by civil society, educational institutions, and families. Schools have a mandate to motivate and inform students. This needs to be part of school curriculum which can involve parents' participation as well otherwise there will be counter information with the possibility of undermining the actions otherwise initiated. A holistic approach can only reinforce positive actions by diverse groups of actors.

21.5 Beyond Affluence to Well-being

Well-being denotes quality of life. Numerous indices have emerged to help measure well-being through various changes in quality of life. These are being used to make comparisons across groups, nations, and time. They also help determine whether these changes are sustainable, and they evaluate policies.

For a long time, and still predominantly today, human well-being tends to be associated largely with increased levels of consumption of products and services, a rising income and the purchasing power to support this increased consumption, and a rise in energy use. In this respect, income is the measure of wealth dividing the "rich" from the "poor." Consequently, conventionally gross national product (GNP) or gross domestic product (GDP) is the measure of choice and one that has dominated the literature.

This dominant economic notion has been challenged periodically over the years. One of the early challenges came during the 1970s, with the rise of public awareness about environmental and sustainability concerns. Serious doubts were raised as to whether traditional economic growth models were adequate in view of these new issues. This led to a broader discussion and debate about indicators of well-being. As a measure of aggregate economic activity, conventionally defined GNP or GDP does not capture social well-being, social inequities, or the depletion of natural resources. As a result of this debate, several new approaches emerged that have tried to include other aspects of well-being (Hanley et al., 1997; Hamilton and Clemens, 1999; Dasgupta, 2001).

Many of the new emerging approaches put greater emphasis on issues of poverty and provide new definitions of wealth, new ways to treat environmental degradation, and new indices to measure the quality of life (e.g., Dasgupta, 1975; IUCN, 1980; Norgaard, 1984; El Sarafy, 1989; Daly, 1990; Daly and Cobb, 1990; UNDP, 1990; Dasgupta and Maler, 1991; Commons and Perrings, 1992; Dasgupta and Maler, 1995; Hanley et al., 1997; Sen, 1999; Aggarwal et al., 2001; Dasgupta, 2001).

Measures of well-being can be classified (Dasgupta, 2001) according to whether they are based on constituents (outputs) of well-being such as health, happiness, or freedom or on the determinants (inputs) of well-being such as expenditures on food, nutrition, clothing, potable water, shelter, and access to knowledge or information. Economic literature has tended to focus on the latter, while moral philosophers and many in the social sciences have focused on the constituents of well-being. Newer indices have tried to combine both the determinants and the constituent elements of well-being.

Some recent proposals focus on the happiness index (Namgyal and Wangchuk, 1998). But many commentators, despite accepting the importance of happiness, have questioned these as being subjective, unobservable, and difficult to quantify (Kahneman et al., 1997). Theoretical and empirical research (Dasgupta, 1995, 1997; Frey and Stutzer, 1999, 2000; Narayan et al., 2000) has tried to establish more objectively the links between states of happiness and wealth or the lack therefore, employment, and the command of natural resources. Notwithstanding their deficiencies, some of these indices can be useful as supplementary tools to indicate potential entry points for policy interventions.

In response to the shortcomings of conventionally measured GNP and its tendency to measure aggregate "economic activity" rather than "social well-being," the United Nations Development Programme introduced the Human Development Index (HDI) (UNDP, 1990; 2010). Besides conventionally measured GNP (as a proxy for purchasing power based well-being), the HDI includes adult literacy and life expectancy at birth as additional crucial aspects of well-being. Despite the shortcomings of this index – it does not measure inter-temporal well-being and is still

5 http://www.unep.org/wed/

6 http://www.earthday.org/earth-day-history-movement

7 http://www.cbd.int/idb

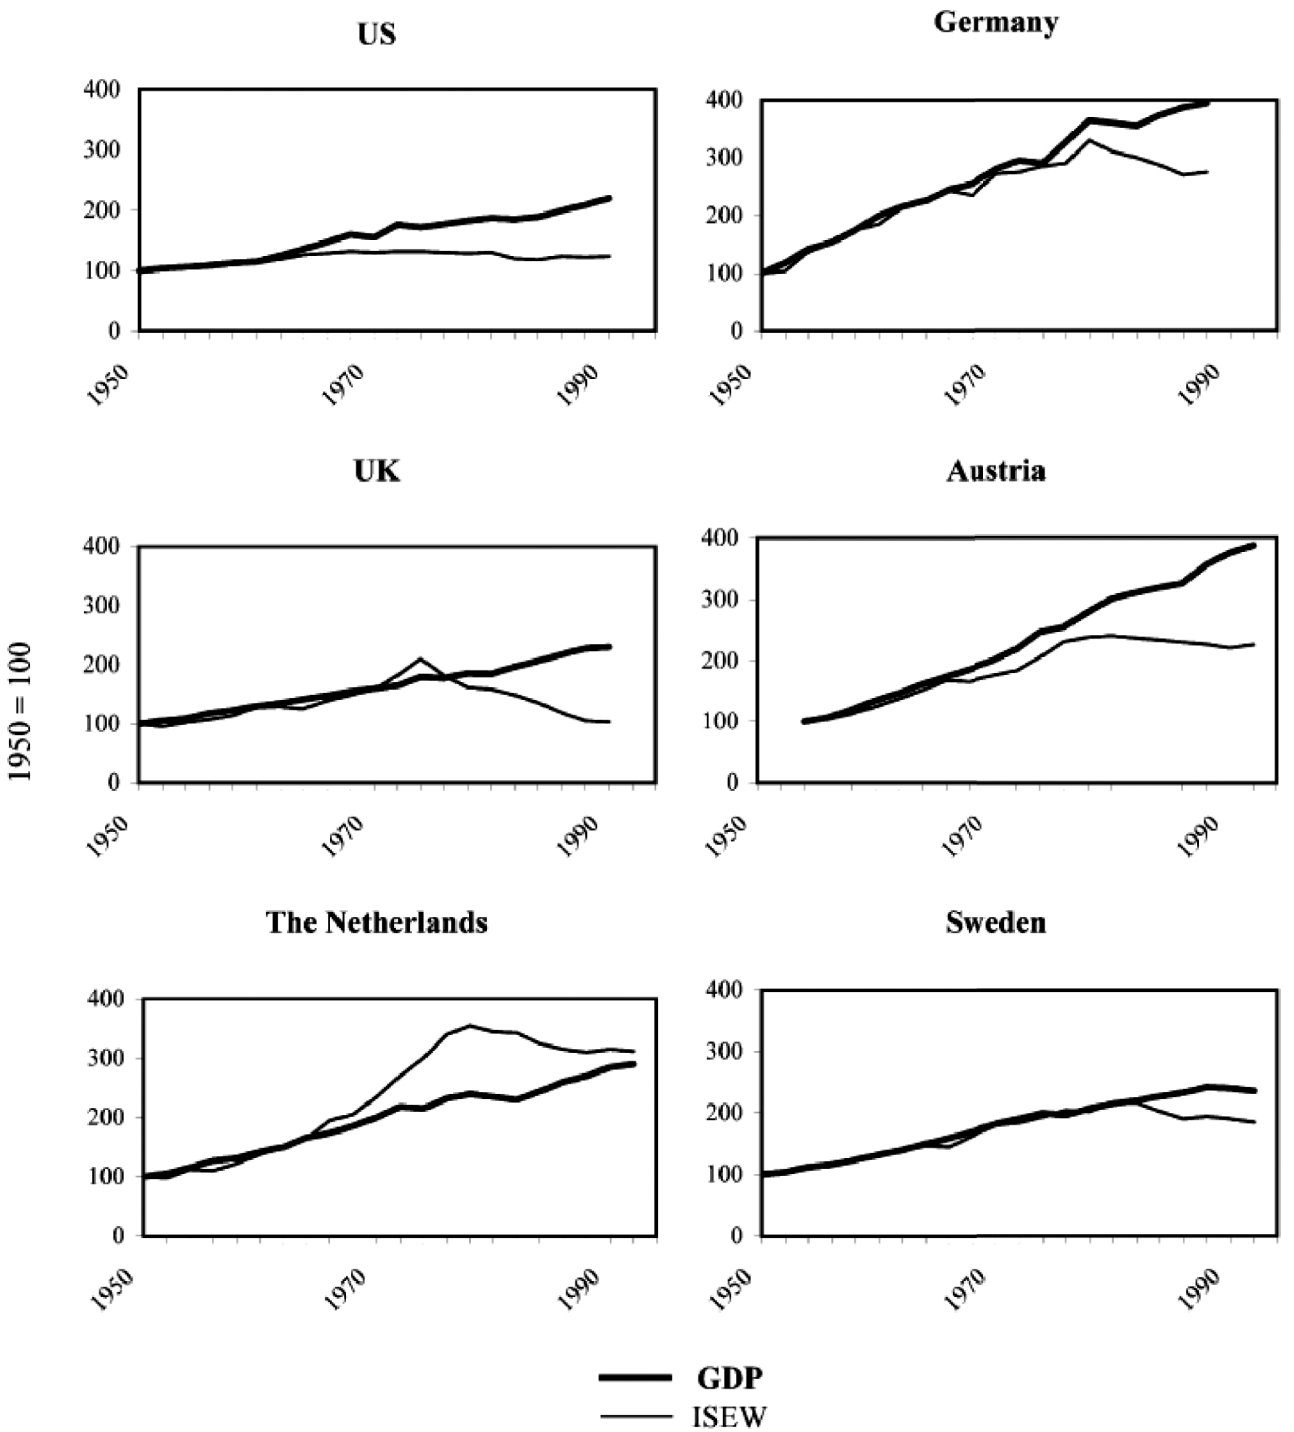

Figure 21.7 | Comparison of macro indicator: GDP and ISEW for the United States, Germany, United Kingdom, Austria, the Netherlands, and Sweden. Source: Lawn 2003.

too limited in terms of determinants of well-being – many consider the HDI a step in the right direction.

Regarding the use of consumption level as an index of well-being, studies have shown that in poor countries and communities, indices of consumption can serve as determinants of well-being and happiness. For rich countries and communities, however, the inclusion of current consumption as a measure of well-being may not be as useful or appropriate because current consumption may not be a contributing factor to happiness of people who have much more than the basic necessities (Esterlin, 1974). Empirical research also shows that the correlation between income and individual well-being becomes weak beyond a

certain level of wealth and that further increases of economic wealth do not necessarily increase individual well-being. Thus the need for more than one index to keep track of various constituents and determinants of well-being depends on the situation being considered (Nussbaum, 2000). However, the fact remains any composite measure can be non-robust to changes in weights on the components.

The concepts of well-being just described have important implications on how energy services demand and energy use are assessed. A focus on conventionally defined GNP/GDP alone is biased toward viewing changes and reductions in energy services demand as decreases in well-being. More complex notions of well-being are better able to take other factors into account even in situations of decreasing energy services.

Notions of well-being based only on consumption implicitly assume that there is high substitutability between different energy services, while more complex, multidimensional notions can capture differing characteristics of energy services that may actually hinder substitutability. This is of particular importance when addressing basic needs for a decent good life and the energy services demand to meet those. The assumption of substitutability is important, as assumptions about it can, for example, lead to overestimations of well-being when the aggregate quantity of energy use is considered but not its qualitative composition (Pachauri et al., 2004).

In the long run, however, transformational change is possible by changing the social value system and through the adoption of a better quality of life, as indicated by a Well-being Index in addition to, and other than, conventionally measured GNP, HDI or similar such new indices. Over the years a number of different indices have been developed to measure and compare the benefits and costs of growth. The first of these was Index of Sustainable Economic Welfare (ISEW). Over this time, the ISEW has been given a variety of different names and theoretical underpinning – for example, a Genuine Progress Indicator or GPI and a Sustainable Net Benefit Index or SNBI (Lawn, 2003). Empirical studies in the context of developed economies have demonstrated that there may be a threshold level for growth beyond which growth of macroeconomic system is not beneficial to human well-being. Divergence between the ISEW and conventional measures of GDP beyond a point is clearly shown in Fig 21.7. Beyond threshold, or peak, as shown by ISEW, SNBI and GPI, the suggestion is goal of these countries need to move away from growth objective to sustainable development goals. This peak is not observable in GDP measure which is the rising curve. These studies strongly support the need for refinement of new welfare & well-being measures. It also highlights the need to better link energy use with such alternative measures.

Finally, the potential for increased sustainability that lies in strong decoupling of well-being from consumption can be captured by notions of well-being that are not based on consumption. This offers new policy options of potentially high leverage. A reduction in energy services and energy use demand does not necessarily reduce well-being. And lifestyle changes can deliver some win-win options that reduce demand for energy services with the same or even improved levels of personal and social well-being.

Changes in preferences and attitudes of individuals are essential in long-term sustainable lifestyle change. In working toward sustainable energy futures, the role of the individual is crucial. "Sufficiency" is a key term in this discussion. Sufficiency directly addresses the individual, and its concepts of well-being and lifestyle aim at a thorough discussion of societal values (Muller, 2009). Leading a "sufficient" life means leading a life of moderation and prudence. This means developing awareness of the consequences of actions beyond monetized cost-benefit analysis and of markets beyond local or regional scope. Moderation would curb further growth in energy use with the corresponding externalities, including harm to others.

Numerous successful changes in lifestyles and acceptance of values such as "sufficiency" have taken place since World War II. Sufficiency notions have provided impetus for discussion and debate on society's values and the role of its citizens (Harvey, 1996; Goodman, 2010). Some of these successes provide a rich ground for exploring new measures and policies to encourage lifestyle changes in key areas of energy use in the near future as well as the development of new and more appropriate indices.

The literature on alternative indices of well-being is not conclusive enough operationally to replace conventionally measured GNP – the current index of economic well-being. There is a methodological and information gap on the energy outcome of alternative lifestyles at global and regional scales. Alternative consumption-based approaches need to be compared with supply-side-based approaches in terms of the implications for primary energy use. In public discussions, sufficiency is often related to renunciation. This nexus is always made on the basis of the current consumption level and lifestyle. Instead, efficiency-led strategies need to be tied to sufficiency to become a widely used strategy that changes values and notions of well-being.

More research is needed to assess the macroeconomic effects of large-scale switches to more-sufficient lifestyles over various time scales in the future. A key issue is how a large reduction in consumption could be absorbed by the economy without generating large unemployment. Simultaneous redistribution of labor could offer a solution, but further analysis of this is clearly needed.

Executive Summary

The Global Energy Assessment (GEA) emphasizes the importance of energy to all societies, which explains a longstanding tendency for governments to be closely involved in the energy sector. The nature and extent of this involvement – the degree and types of energy-related policies – depends on a government's ideological orientation, the particular energy resource endowment in its jurisdiction, the development level of its economy, and specific concerns of its society with respect to energy access, energy security, and the environmental and human health impacts of energy supply and use.

In every country, energy's critical role for the goal of sustainable development is widely acknowledged. This means that energy-related policies need to be assessed in terms of performance with respect to the social, economic, and environmental dimensions that are encompassed by the concept of sustainable development. Ideally, energy-related policies will make advances with respect to all three of these critical sustainability dimensions. But frequently policymakers are faced with difficult trade-offs in which improvement in one dimension is at the cost of another. Thus, the first goal of energy-related policy design should be to seek win-win opportunities for simultaneously advancing social, economic, and environmental goals. When this is not possible, the goal should be to apply decision-support mechanisms that integrate diverse social objectives and values into the policy design process, such as the application of multi-criteria analysis as described by Munasinghe (1992; 2009).

Cluster I of GEA presents social, economic, and environmental dimensions of sustainable development as related to energy. These include social goals (Chapter 2), environmental protection (Chapter 3), human health (Chapter 4), energy security (Chapter 5), and economic development (Chapter 6). GEA establishes specific normative goals in these areas, chosen to reflect broad societal aspirations with respect to (1) alleviation of poverty, including universal access to modern forms of energy; (2) improved human health, including quality of life indicators; and (3) environmental sustainability, including indicators of biodiversity, water quality, and air quality.

Cluster II assesses the potential contribution of energy to these normative goals with detailed analyses of the existing and potential energy system. This includes energy efficiency-reducing energy use, while sustaining and even increasing energy services. It also includes specific energy supply options associated with socially acceptable applications of renewable energy, safe uses of nuclear power, and cleaner uses of fossil fuels. Many of the chapters within this cluster describe detailed policies with respect to, for example, energy efficient buildings or the safe use of nuclear power or protection of human health.

Cluster III provides an integrating analysis of these energy options. Of particular note is the exploration in Chapter 17 of a set of scenarios or pathways showing the potential evolution of the energy system on a sustainable development trajectory. With reduced energy use – i.e., greater energy efficiency, conserver lifestyles, urban form changes, reductions in material and water use that cause reduced energy use – potentially making a great contribution, Chapter 17 includes one pathway in which the efficiency option is pushed particularly aggressively. This scenario is enhanced by the multiple co-benefits associated with less energy supply and use. A much-expanded role for renewable energy is likewise associated with multiple benefits in many jurisdictions, such as improved security of supply from diverse domestic sources and reduced greenhouse gas (GHG) emissions. Thus, a special emphasis on renewable energy plays a key role in some energy system pathways.

Finally, Cluster IV of GEA is focused on policy, the means by which humanity might realize these pathways of energy for sustainable development – pathways that require a rapid and dramatic transition of the energy system when seen from a global perspective. Cluster IV is comprised of four chapters; this introductory chapter (Chapter 22) surveys the spectrum of energy-related policy objectives and policy measures, including examples of government involvement in the energy sector to reach both general and specific objectives of energy for sustainable development.

Text boxes in this chapter provide examples of real world policy efforts to achieve energy-related objectives. The chapter includes key policies that must be applied to meet the goals of sustainable development. It also presents specific policies necessary to achieve the sustainable development energy pathways of Chapter 17. Some of these policies are generic, and could be applied in widely different contexts, while others are more focused.

This sets the stage for subsequent chapters that focus on three specific policy challenges, namely: (1) extending energy access in the developing world (Chapter 23); (2) stimulating energy system innovation (Chapter 24); and (3) building human and institutional capacity for energy transition, especially in developing countries (Chapter 25). Finally, it should be noted that most chapters of GEA include some discussion of policies, in some cases quite detailed.

22.1 Introduction

For the purposes of policy analysis and design, the energy sector has specific policy challenges. These represent a further refinement and specification of social, economic, and environmental sustainability dimensions. These challenges reflect issues emerging throughout GEA. Some of them are only addressed via policy analysis and mechanisms presented here in Chapter 22. Market power in the energy sector, especially due to natural monopoly conditions in network industries like electricity, is one particular concern. Another is the challenge of effectively managing wealth associated with valuable resource endowments, especially from oil and natural gas. Yet another concern is the challenge of the energy system's contribution to GHG emissions and the risk of climate change. While energy-related emissions of GHGs are just one of many environmental impacts and risks associated with the energy system, the threat of climate change requires a global effort. Thus, preventing climate destabilization is a public welfare problem on a global scale and the transition of the energy system is a critical component in addressing this challenge.

Eight specific energy-related policy concerns, identified below, are addressed in this chapter.

1. Because energy is such a critical input to the modern economy and development of society, *energy access* – at an affordable level to meet basic human needs and to offer opportunities for social and economic development – is a key objective. This is especially the case for developing economies and for energy services that benefit those at the lowest income levels. Because these segments of society are least able to afford energy systems on their own, often governments intervene to provide them publicly or through subsidies for an adequate level of service. Chapter 23 addresses this topic in detail.

2. One mistake of past policy efforts aimed at improving energy access was to assume that technology adoption and capital formation were mainly linear processes of innovation and investment that depended little on the surrounding social, cultural, technical, financial, and institutional environment. Research into past failures, however, has indicated that an "enabling environment" is critical, and this has led to an increasing policy emphasis on *developing energy-related social capacities*. This refers to improving human, technical, financial, social, organizational, and institutional capacities, which will be critical in fostering a major transition of the energy system from its current character to one in which energy access is widespread and human and environmental impacts are dramatically reduced from today's situation. Chapter 25 addresses this topic in detail.

3. One indicator of successful industrial economies is that they have organized their energy systems to ensure access to affordable energy for almost all members of society. But energy access does not necessarily ensure *energy security*, the assurance that this access will not be overly vulnerable to major technological problems, geopolitical conflict, terrorist sabotage, or other significant types of disruptions. In this chapter the key components of energy security – as described in Chapter 5 – are summarized, and policies to foster social and economic aspects of sustainable development are presented.

4. The production and delivery of energy is capital intensive, requiring large investments in finding, extracting, developing, processing, transporting, and retailing. Capital-intensive activities are frequently associated with economies-of-scale, meaning that a large facility or company can provide energy at lower cost than several smaller companies. In certain sectors, like electricity, these economies-of-scale foster "natural monopolies" (utilities), where vesting a single firm with monopoly service provision is the lowest cost option for society. However, firms that operate as monopolies lack the incentive to provide goods at marginal cost as compared to competitive industries. Therefore, governments may employ policies or different types of controls – e.g., a regulated corporation – to *manage energy-related market power*. In some other energy sectors, like the petroleum industry, strong economies-of-scale mean that a few companies may be able to dominate various aspects of the market. Some degree of policy intervention may again be desirable, although unlike a natural monopoly this may involve efforts to reduce market power rather than to countenance the establishment of a regulated or state-owned monopoly.

5. Governments face special challenges when *managing valuable energy resource endowments* and especially the substantial revenues they can generate. For countries that have few exports other than energy, government tends to play a special role in managing these exports and allocating the large earnings. The experiences with government management of these resources have varied widely. For some countries, highly valued energy resources, like oil and natural gas, have been a boon for national treasuries and a stimulus for economic growth. But such endowments can cause substantial challenges, as evidenced by mismanagement of resource revenues, negative effects on other sectors of the economy, and even rent-seeking corruption within government and industry. In the extreme, a "resource curse" can occur – the paradoxical outcome in which a country with a rich resource endowment remains poor, in part because of mismanagement of that endowment.

6. With the expansion of the world's economy, the need has grown dramatically to *reduce environmental and human health impacts* of the energy system. Energy use affects humans and the planet's ecosystems at all scales, from uncontrolled indoor air emissions when combusting solid fuels for domestic cooking and heating in unventilated areas, to rising sea levels, extreme weather events, and new epidemiological threats from climate change. Public

policy has a critical role to play in ensuring that the impacts and risks from energy supply and end-use are reduced, in some cases dramatically. Chapter 3 disscusses the relationship between energy and the environment while Chapter 4 addresses energy and health in further detail.

7. If humanity is to achieve significant progress in pursuit of objectives like improved energy access and security, or reduced environmental impacts, it will need to *accelerate the rate of innovation, development, and dissemination of desirable energy-related technologies*. Governments can pursue policies that aim to overcome barriers to such technological transitions, ranging from public support for research and development (R&D), to programs that assist the initial market penetration of targeted technologies, to educational and institutional developments that foster an enabling environment for adopting and sustaining new technologies. Chapter 24 addresses this topic in detail.

8. The increasing globalization of the world's economic system is equally reflected in its energy system. Oil has long been traded on a global basis and this is now the case for coal and natural gas. Some regions also trade electricity. At the same time, the environmental impacts of energy use are also becoming global, especially the risk of climate change, caused in large part by the production and combustion of fossil fuels. These international dimensions of many energy-related challenges require a much greater effort to improve *coordination and implementation of international energy-related policies*, a necessity that has been recognized during the past few decades by major energy sector participants.

These eight energy-related policy goals present governments with a complex array of issues. But the policy challenge is complicated further by the need for consistency between energy-related policies, on the one hand, and the host of other government policies focused on goals like poverty alleviation, economic development, education, health, national security, and macro-economic stability, on the other. Policy consistency is a great challenge and it always should be a major focus of the design and evaluation of policy options.

In addressing these energy-related policy goals, governments have various instruments available to them. While the potential options are numerous, in a generic sense, policy is usually manifested as:

- direct public ownership or control;
- regulations and standards;
- information, education, and public engagement to promote voluntary actions;
- financial charges, such as taxes and fees; and
- subsidies, such as grants, low-interest loans, and rebates.

In choosing among these policy options, governments can rely on key evaluative criteria that policy analysts conventionally apply when assessing policies (Hahn and Stavins, 1992). These criteria are used to assess the ability of different policy options to meet their goals in a number of different ways:

- *effectiveness* – the ability of a policy to achieve the intended objectives;
- *economic efficiency* – the ability of a policy to achieve objectives at the lowest possible cost to society;
- *administrative feasibility* – the ability of a policy to avoid imposing a functional burden on government that thwarts successful implementation, such as through bureaucratic ineffectiveness or excessive information and monitoring requirements;
- *equity* – the effect of a policy on income distribution and on disadvantaged groups within society;
- *political acceptability* – the extent to which a policy can garner sufficient political support to be enacted and effectively sustained;
- *policy robustness* – the ability of a policy to perform well under highly uncertain and widely contrasted futures; and
- *policy consistency* – the extent to which a policy works in concert and not in conflict with other policies.

Policy effectiveness is often more challenging than it appears to non-experts. One key reason is that governments and public decision-making processes are sometimes portrayed in a simple way that fails to recognize factors that can cause policy impairment and policy failure. In fact, the list of factors is quite large. Small groups who are negatively affected by a policy, which otherwise has a net social benefit, can block the policy if they have strong leadership or include powerful interests. This kind of challenge may impede the development of some forms of renewable energy, for example. Powerful groups in society may gain excessive influence over the bureaucracy or politicians and may act more in their special interests rather than in the broader social interest.

Once implemented, a policy may shift the incentives in society such that people act in ways that counteract a policy's intent; this is sometimes called "moral hazard" in policy design. Corruption of politicians or bureaucrats is always a risk, though hopefully less so in more open societies. Policies that seem good on the surface could have very high transaction costs that thus impede their successful implementation. Finally, if the benefits of a public good are accessible to all, there is a risk of free-riders, agents who do not contribute to the costs yet share in the benefits, which erodes the social will to provide the public good. All

of these factors must be considered when designing and comparing the effectiveness of policy options.

In the same vein, other policy evaluation criteria each present their own specific challenges. Economic efficiency is difficult to achieve when those who may be negatively affected by a policy pressure government to reduce the costs they would face under an efficient outcome. Careful policy design, however, can balance the equity objective and the efficiency objective by various redistributive mechanisms that reduce inequitable outcomes without blunting the economic efficiency requirement for clear pricing signals to suppliers and consumers.

When comparing or combining policy options, designers of energy-related policy need to assess performance against these criteria. Because no single policy is likely to outperform all others in all of these criteria, some form of multi-criteria decision analysis is an essential component of the policy development process. The outcome of this analysis will depend on the relative weights that decision makers, and society as a whole, place on each of the criteria. In some circumstances equity concerns may have an especially strong weighting, while in others it may be environmental effectiveness or economic efficiency. For a given energy policy objective, decision analysis is useful to analyze the multiplicity of policy options and of policy evaluative criteria and help the decision maker assess the trade-offs associated with one or a package of policies.

The following list provides a general description of some key trade-offs that policymakers must navigate when designing and evaluating policies for sustainable energy objectives.

- Policymakers must find an appropriate balance, in a given circumstance and setting, between the role of public authorities, on the one hand, and the delegation of responsibility for decisions about land-use, technology, and behavior to firms and households acting in a market context, on the other. Thus, in some cases, governments may wish to promote and support – with R&D, subsidies, and focused regulation – a specific technology or fuel in order to ensure its rapid dissemination. In other cases, governments may try to leave it to the market to determine which technology or fuel will actually emerge, especially when government is faced with great uncertainty about future technological evolution, costs, and preferences.

- Policymakers must find an appropriate balance between policies that are going to drive rapid change and policies that have a good chance of political acceptance. Ideally, a policy does well on both counts, but often some degree of trade-off is required.

- While policies should be as simple as possible from an administrative and bureaucratic perspective, it is important that they include sufficient sophistication in terms of experimental design, monitoring, and hindsight evaluation so that their effectiveness can be assessed and their design improved over time.

- Policy assessments are necessary to help navigate choices about policy design when there are vested interests making strong claims about evidence that may or may not be supported by rigorous research. Examples of such complex choices include a tax on greenhouse gas emissions versus cap-and-trade systems, or fixed feed-in tariffs that guarantee a price for renewable electricity versus renewable portfolio standards that guarantee a market share.

- Policymakers must find an appropriate balance between the benefits to current versus future generations from valuable energy resource endowments. The outcome of this trade-off analysis could vary considerably, depending on: (1) the current level of well-being in the country or region; (2) the expected longevity of the resource endowment; (3) the likely future value relative to the present; and (4) the capacity of a government to ensure benefits to future generations through saving and reinvesting current returns from resource exploitation.

- Consideration must also be given to the stringency of the targets set by a policy, such as the level of greenhouse gas emission abatement. Policymakers have to decide whether the future costs and risks of not taking action – e.g., on climate change – outweigh the costs and risks to society of immediate action. These decisions will involve an assessment of the trade-off between the current and future welfare of society based, in part, on the risk of a negative outcome in the future.

Within the context of all these factors, another influence on policy choice is the ideological expectation of the role of government in the energy system. Decisions in this regard often hinge on a larger political debate around control over the economy. Should governments play a strong role, or are they willing to keep a distance and vest outcomes in individual decisions made by the myriad of actors in energy markets? The answer to this depends on institutions, goals, values, and resource endowments that can vary dramatically by country and region. Policies that work for highly industrialized countries, with a long tradition of market economies and relatively effective public institutions, may be inappropriate – or at least merit substantial modification – in developing economies. Countries that place great concern on the assured delivery of particular quantities of energy may be less willing to trust markets than are countries where competitively priced energy and market allocation has been the norm for decades. Countries where much of the population has no access to modern energy commodities may be less willing to assume that deregulated markets can meet the needs of their citizens if they have failed to do so thus far.

These kinds of decisions about the role of government and public policy in the energy sector vary by country, but also by energy service and

commodity. Some countries, for example, have been wary about allowing market forces to govern commodities that the government considers strategic, even as they embrace markets in other parts of the economy. For most of the past few decades, the French government has played a dominant role in its electricity sector and in development of nuclear power, while playing a less dominant role in petroleum and natural gas. Energy policy in practice, therefore, requires that each country and region find the policy mix that best meets its goals and particular circumstances.

The following sections of this chapter include a detailed discussion of each of the eight energy-related policy goals described above. Each discussion includes descriptions and examples of policies available to further the goal, including case studies of real-world policies in different jurisdictions that present both successes and frustrations. Because three of these energy-related policy goals have separate chapters dedicated specifically to them – energy access, technology innovation, and capacity development (Chapters 23, 24, and 25, respectively) – the treatment here is cursory. Finally, it should be noted that most chapters of GEA include some discussion of policies, in some cases quite detailed.

22.2 Part I: Eight Energy-related Policy Goals

22.2.1 Increase Energy Access

Access to energy is one of the most urgent objectives for sustainable energy policy over the coming decades, which is why GEA dedicates Chapter 23 to this issue. Our treatment here is therefore limited to a brief description of the key issues for policy design.

About one quarter of humanity lives without access to electricity and more than a third has no access to liquid and gaseous fuels. The Millennium Development Goals for social and economic advancement will not be achieved without expanded access to clean and affordable energy. Access to energy is intimately linked with industrial productivity, communications, mobility, comfort, and other benefits that are key contributors to economic and social development. Access to electricity, in particular, contributes to higher levels of education, increased access to information, improved health care, and more effective institutions and communication networks. All of these improvements play a role in the alleviation of poverty and development of civil society (World Bank, 2000; UNDP and World Bank, 2005).

While markets can play an important role, universal access to energy is seen as a public responsibility because the benefits of its provision surpass those directly captured by individuals in their everyday participation in markets, extending to the wellbeing of all of society. During the twentieth century, governments in today's developed countries recognized the importance of access to electricity and used a combination of state enterprises and public subsidies to develop electricity production and distribution systems. Rural electrification subsidy programs were particularly important in the widespread electrification that occurred over just a few decades, largely through the activities of public corporations or publicly supported cooperatives.

While the key focus of these subsidies was often expansion of the grid into poorer regions and non-urban areas, there were also policies to ensure that a minimum amount of electricity would be affordable to low-income households. For this, utilities developed electricity tariffs such as lifeline rates: a low initial price for base levels of electricity consumption, with higher prices for any additional consumption.

Similar policies have been pursued by developing countries for providing access to electricity. These governments and utilities usually fund expansion of the electric grid into underserved areas and provide special rates for low-income households and farmers.

Unfortunately, in many countries, expansion of electricity access has not kept pace with population growth, diminishing the likelihood of achieving the Millennium Development Goals for energy access. There are multiple reasons for this failure. First, the magnitude of the objective is truly daunting, requiring a rate of investment and electric capacity expansion that far exceeds what was even achieved in the most successful of industrialized countries over the past century. Second, in some cases, publicly operated utilities and state enterprises have performed poorly, notably in terms of making bad investments, exercising poor management practices, providing unjustifiable cross-subsidies between customer classes, and countenancing corruption. Third, in some cases, private investment, whether local or foreign, has been misdirected or even detrimental to local socio-economic development.

Energy access policies may perform best when they find a balance between mobilizing market forces to provide funds for expansion of electricity generation and distribution systems, and involvement of governments and non-government organizations to ensure social development and access for society's poorest and most isolated members – access that would not occur if the sector were simply left to private markets. Moreover, it is essential to link energy access with policies that improve access to other government social programs such as education, health services, financial resources, and modern technologies. Only in this way can improving access to energy contribute effectively to full economic and social development.

Chapter 23 details policies that, among other things, seek to combine policy design and governance with social and market forces in ways that effectively advance access to energy. While certain types of policies can be applicable in many different cultures and environments, at different levels of technological adoption and economic development, it is often the case that policies need to be tailored to these specific conditions.

This is why Chapter 23 includes an array of policies and a degree of regional disaggregation in its policy prescriptions.

Examples of focused policies that combine a balanced role for government and markets include the following:

- For extension of electricity access into rural areas, a process that involves competitive bidding for state or utility subsidies can improve the chance that these will be used to maximum effect. For rural electrification, Chile developed a program in which subsidies were allocated on the basis of the maximum grid extension that would be achieved for a given amount of money. A similar program exists in Argentina called the Proyecto de Energías Renovables en Mercados Rurales (PERMER). These programs were intended to provide electrification to very isolated communities.

- Modest public and non-government support can help small rural businesses and rural households increase their access to energy investment financing. A frequently cited example is the Grameen Bank of Bangladesh, whose energy division, called Grameen Shakti, lends money for energy-related projects, such as solar home systems that involve installing photovoltaic solar panels to provide electricity in locations without access to an electric grid.

- Innovative institutional arrangements may be able to improve the efficiency with which electricity firms operate in developing countries, especially where the traditional, centrally-managed state electric utility lacks support within the local community. Unpaid bills and electricity theft are particular problems that have been reduced by establishing greater local control over management of the local distribution system. An example is rural electric cooperatives in Bangladesh, called Palli Biddyut Samitee.

When considering energy access, electricity is often the focus of attention. But there are also dramatic benefits from access to clean cooking and heating fuels for the poorest people in the world. Poor indoor air quality from open combustion of solid fuels is still a major source of human morbidity and mortality, especially among women and children who tend to have the highest level of exposure to these emissions (Chapter 4). Today, governments in many developing countries have programs that support in some way – e.g., education, technology subsidies, technical training – the shift from household combustion of solid fuels in open fires to cleaner and more efficient use of commercial fuels, like kerosene and liquid petroleum gases (LPGs, such as propane and butane). To this end, governments may directly subsidize cleaner gaseous and liquid fuels or the acquisition of stoves that use them. Or, government might directly subsidize the acquisition of stoves that still use solid fuels like coal and biomass, but without deleterious emissions that effect indoor air quality.

Thus, many African countries have programs to make LPGs and kerosene more easily available in rural and peri-urban areas and also to distribute improved charcoal burning stoves. If successful, such programs have the combined benefits of reducing time spent gathering biomass, reducing the environmental impacts of excessive exploitation of biomass, and improving indoor air quality with major benefits for human health, especially for women and children.

Box 22.1 | Free Basic Electricity Program in South Africa – Alison Hughes

Free Basic Electricity (FBE) was introduced in South Africa in 2003 to complement an aggressive electrification program (refer to Chapter 19). The policy was implemented after it was realized that poor households were using less than 50 kWh of electricity each month (DME, 2003a). FBE allows poor households with a legal connection to use 50 kWh of electricity each month at no cost. It has the effect of reducing the cost of a kWh of electricity and providing a safety net for consumers.

A challenge with the FBE policy lies in identifying recipients of the allocation. FBE is implemented by distributors, mainly through a blanket allocation to households consuming less than a certain quantity of kWh each month (DME, 2003a).

Pilot studies undertaken after FBE was first introduced have shown that the subsidy typically raised electricity use for lighting and other uses, allowed a more continuous use of electricity by households, and lowered the household energy bill. In this way, it can be seen as very effective. However, on average, the use of electricity increased by less than the subsidy amount of 50 kWh (DME, 2003b), which implies that poorer households continued to use alternative fuels for thermal services.

Criticism of the implementation of the policy is that it excludes many low-income households because families living in backyard shacks or whose homes are situated on land not zoned for settlement cannot receive the subsidy. It can also be argued that the policy should be extended to allow households access to units of any type of energy. This would benefit households by allowing them to purchase a fuel of their choice for cooking at a lower cost to society (Howells et al., 2005).

Box 22.2 | Bagasse-based Cogeneration in Mauritius – Stephen Karekezi

A clearly defined government policy on the use of bagasse, a by-product of the sugar industry, for electricity generation has been instrumental in the successful implementation of the cogeneration program in Mauritius. Plans and policies have been worked out over the last decade for the sugar industry in general. First, in 1985, the Sugar Sector Package Deal Act (1985) encouraged the production of bagasse for the generation of electricity. The Sugar Industry Efficiency Act (1988) provided tax incentives for investments in generation of electricity and encouraged small planters to provide bagasse for electricity generation. Three years later, the Bagasse Energy Development Programme (BEDP) for the sugar industry was initiated. In 1994, the Mauritian government abolished the sugar export duty, an additional incentive to the industry. A year later, foreign exchange controls were removed and the centralization of the sugar industry was accelerated. These and other measures are summarized in the following table.

Table 22.1 | History of Bagasse Policy in Mauritius.

Year	Policy initiatives	Key objectives/Areas of focus
1985	Sugar Sector Action Plan	– Bagasse energy policy evoked
1988	Sugar Industry Efficiency Act	– Tax free revenue from sales of bagasse and electricity – Export duty rebate on bagasse savings for firm power production – Capital allowance on investment in bagasse energy
1991	Bagasse Energy Development Programme	– Diversification of energy base – Reduction of reliance on imported fuel – Modernization of sugar factories – Enhanced environmental benefits
1997	Blue Print on the Centralization of Cane Milling Activities	– Facilitated closure of small mills with concurrent increase in capacities and investment in bagasse energy
2001	Sugar Sector Strategic Plan	– Enhanced energy efficiency in milling – Decreased number and increased capacity of mills – Favored investment in cogeneration units
2005	Roadmap for the Mauritius Sugarcane Industry for the 21st Century	– Reduction in the number of mills to six with a cogeneration plant annexed to each plant
2007	Multi-annual Adaptation Strategy	– Reduction from 11 factories to four major milling factories with coal/bagasse cogeneration plants (Belle Vue, FUEL, Medine, and Savannah) – Bio-ethanol production for the transport fuel markets. Spirits/rum and pharmaceutical products, e.g., aspirin – Commissioning of four 42 MW plants and one 35 MW plant operating at 82 bars - Promotion of the use of cane field residues as combustibles in bagasse/coal power plants to replace coal

As a result of consistent policy development and commitment to bagasse energy development in Mauritius, the installed capacity of cogeneration power has increased over the years. In 1998, close to 25% of the country's electricity was generated from the sugar industry, largely using bagasse. By 2001, of the total electricity supply in the country, 40% (half of it from bagasse) was electricity generated from sugar estates. It is estimated that modest capital investments, combined with judicious equipment selection, modifications of sugar manufacturing processes to reduce energy use in manufactured sugar, and proper planning could yield a 13-fold increase in the amount of electricity generated from sugar factories and sold to the national Mauritius power utility.

Bagasse cogeneration has delivered a number of benefits, including reduced dependence on imported oil, diversification in electricity generation, and improved efficiency in the power sector in general. It is available 100% of the time as long as bagasse production is in place, thus enhancing Mauritius' energy security. Bagasse, as a waste product, can lead to environmental problems such as fire hazards and methane emissions, which are considered potent greenhouse gases, if it is not disposed of properly. Thus, its use for power generation delivers significant local environmental as well as climate benefits. In addition, carbon dioxide produced by bagasse-based cogeneration is minimal, so it is considered a carbon-neutral option.

Cogeneration in Mauritius benefits all stakeholders through a wide variety of innovative revenue-sharing measures. The cogeneration industry has worked closely with the Government of Mauritius to ensure that substantial benefits flow to all key

stakeholders of the sugar economy, including the smallholder sugar farmer. The equitable revenue sharing policies that are in place in Mauritius provide a model for emulation in ongoing and planned modern biomass energy projects in Africa. By sharing revenue with stakeholders and the small-scale farmer, the cogeneration industry was able to convince the government – which is very attentive to the needs of the small-scale farmers as a major source of votes – to extend supportive policies and tax incentives to cogeneration investments.

Box 22.3 | Government Assistance Programs for Shifting from Traditional to Advanced Technology: Solar Water Heating in Barbados and Brazil – Lawrence Agbemabiese

Government assistance programs are needed to catalyze transitions to cleaner energy technologies. This is particularly true of developing countries where poorly developed market mechanisms consistently fail to bring critical financial and economic systems into proper alignment with new technological windows of opportunity (Kaufman and Milton, 2005). A brief comparative assessment of solar water heating (SWH) initiatives in Barbados and Brazil lends credence to the view that government assistance programs are critical for replicating successful models of clean energy transitions – beyond the current handful of developing countries where this has happened.

Barbados boasts one of the highest per capita rates of SWH system ownership in the world, with more than 35,000 installed systems serving close to 40% of all households. A very active government SWH incentive program, sustained over a long period of time, is one of the main factors responsible for this achievement. In 1974 "an informed Prime Minister … seeking ways to reduce oil dependency" of the country presided over the promulgation of the Fiscal Incentives Act (Perlack and Hinds, 2003). The Act exempted SWH raw materials, such as tanks and collectors, from the 20% import duty, effectively lowering the cost of installing a system by 5 to 10%. Simultaneously, the Act placed a 30% consumption tax on conventional electric water heaters. In 1980, an income tax amendment provided for the deduction of the full cost of a SWH installation. Though suspended briefly in 1993 as part of structural reforms, the deduction was reinstated in 1996, allowing homeowners to deduct up to 3500 Barbados Dollars (US$1750) per year to cover solar water heaters, among other home ownership costs (Perlack and Hinds, 2003). These tax incentives were paralleled by a government policy of procuring SWH systems for public buildings and publicly funded projects. This combination of incentives and programs achieved the desired result of triggering and accelerating demand for SWH in the country.

In contrast, the absence of such active and direct government support for the SWH industry in Brazil is associated with a relatively low rate of penetration of SWH systems in its energy market. The government does offer some tax incentives to households that purchase and install renewable energy technology, but these incentives are insufficient to bring SWH systems within the reach of the majority of Brazilian households, especially in poorer districts. With 20 years of experience and a large network of manufacturers, distributors, and retailers, Brazil has significant opportunities to dramatically increase the rate of SWH penetration. Compared to the case of Barbados, what is missing in Brazil appears to be the right set of end-user financing solutions backed by deliberate government assistance programs targeting poorer households.

Barbados, and a growing number of developing countries where solar thermal systems are becoming commonplace, share one thing in common: a history of strong political support, expressed through consistent market-transformative policies favoring technologies tailored to local needs. For solar water heaters, the more effective measures have included (re)structuring building and construction codes specifically designed to create or expand markets, building manufacturing capacity of local enterprises for certain components, and creating new financial incentives for suppliers and consumers.

While there are no doubt other factors at work, it is hard to deny the role government policy, including direct assistance programs, have played in some developing countries in the transition to cleaner energy technologies.

22.2.2 Develop Capacity for Energy Transitions

Whether the focus is the provision of electricity or access to cleaner fuels, a critical issue is the extent to which a given jurisdiction has the social, cultural, technical, financial, and institutional environment to develop, adopt, and sustain desired technologies and energy forms. This is why GEA devotes Chapter 25 to the issue of capacity development. Our treatment here is limited to a brief discussion of key issues for policy design.

Evaluations of failed efforts to rapidly expand energy access in developing countries suggest that these efforts foundered in part because of inadequate attention to capacity building in both developed and developing countries. Key elements of capacity development include general education, technical training, trade and cooperative associations that support an array of energy technologies and services, effective financial institutions that support a diversity of corporate sizes and organizational arrangements, a trusted legal system, innovator rights, and protection for investors. Addressing these fundamental necessities will lay the foundation for a transition to a more sustainable global energy system.

Societal efforts to shift the energy system to a different technological trajectory can benefit from a systems perspective that conceptualizes energy systems as socially embedded and historically shaped by the habits, practices, and norms of the actors within them. As new renewable energy technologies emerge in niche markets or are introduced in new environments,[1] earlier institutional frameworks and standards can raise barriers that slow the process of energy transition, as illustrated by case studies of distributed energy systems, off-grid energy solutions, and current practices in patenting (Geels, 2002; Martinot and Birner, 2005; Jacobsson and Lauber, 2006; Bergek et al., 2008).

The long term nature of energy transitions implies that capacities at the actor and systems level will change over time. Change in capacity requires feedback, flexibility, and complementarity in the design of strategies and policies for energy transitions. It demands an openness to new approaches in the formulation of legal and institutional frameworks that stimulate the development and diffusion of renewable and cleaner energy technologies, and closer attention to building capacities needed for continuous learning and innovation. Capacities that enable users, innovators, and policymakers to access knowledge and information, evaluate choices, build coalitions, and limit the negative impacts of change are critical components in an energy transition process.

To assist in this process, Chapter 25 introduces the "capacity matrix" as a tool for conceptualizing capacity development from a broad, systemic perspective. This perspective looks at habits and practices of the actors, existing norms, policies, and standards, as well as technical skills and access to information that impact on energy transitions. The capacity matrix is used to highlight the range of capacities needed in technologies, such as smart grids, small hydro for off-grid environments, wind power, and biodiesel from algae. The matrix is applied to analysis of capacity building in case studies throughout Chapter 25.

Policies for capacity development thus emphasize the dynamics of change in energy transitions, based on the capabilities, habits, and practices of all actors affecting the energy system. This is true not only in the case of helping developing countries accelerate their adoption of clean, efficient energy supply and use technologies, but also in the case of helping industrialized countries with the profound transition that is required for a more sustainable energy system. To this end, Chapter 25 includes a degree of regional disaggregation in recognition of the fact that there is no one-size-fits-all strategy for capacity development, but rather that efforts must be tailored to specific attributes of a given continent, region, country, and even sub-national locales.

22.2.3 Enhance Energy Security

While energy access emphasizes the provision of energy to individual households and communities, energy security is primarily a national-level concern focused on the uninterrupted provision of nationally vital energy services at affordable prices. As argued in Chapter 5, the transport and electricity sectors are key for all countries, whereas residential heating and industrial energy are important for many. Current energy security strategies are often focused on ensuring uninterrupted supply of forms of energy appropriate for these few sectors: liquid fuels for transport, primary energy sources and infrastructure for electricity generation, and various forms of energy for the residential and industrial sectors.

While some energy analysts argue that markets can provide sufficient energy security, others point out that in many contexts long-term security is a public good that can be "undersupplied," even by perfectly functioning markets. For example, in the absence of government regulations, markets often do not ensure adequate investments in spare generation capacity, overall system reliability in the face of extreme natural events, or may tend to favor procuring energy from politically less-reliable suppliers.

Chapter 5 distinguishes between different types of energy security concerns:

- systemic risks inherent in the design and operation of energy systems, including availability of resources, reliability of energy infrastructure, and rapid growth in energy demand;
- risks associated with control over energy resources and threats of hostile actions; and
- unexpected risks which more resilient systems are better able to withstand.

1 The concept of "newness," as used here, includes technologies that are new to a country, region, or user, though they may not be new to the world.

Governments can address these security and reliability concerns with a number of instruments and strategies. To address systemic risks, system design and operation should focus on reducing the likelihood of major system failures. Because this type of risk is internal to the system, governments have a large role to play in ensuring that their own domestic energy system is reliable. In this sense, these are domestically-managed risks. An electric grid, for example, should be designed to have reliable reserve capacity, regular maintenance of existing facilities, and an economically justified level of back-up generation and transmission systems to reduce the chance of system failure.

Energy demand management and forecasting is an important component of ensuring that energy supply expands at a pace that matches the growth in demand. Because energy supply facilities frequently require large investments and a long time to complete, energy forecasts should extend at least a decade or two into the future. While individual energy companies – e.g., electric, oil, natural gas – are usually active in forecasting, government should also play a role in providing a forecasting framework with assumptions about its own investments and energy needs, plus a means of coordinating the forecasts of these different entities. An aggressive energy efficiency strategy can also slow the pace of demand growth, which eases timing pressures on new supply investments.

In the case of non-electric energy demand, various requirements for domestic stockpiling of energy supplies – e.g., storage facilities for oil, natural gas, and coal – and for easier access to energy imports in the case of a failure of one component of the delivery infrastructure – such as multiple pipelines, transmission interconnects, and port facilities – can all contribute to reducing structured reliability risks.

Longer-term systemic risks are often associated with the availability, accessibility, and acceptability of primary energy resources on the national, regional, or global levels, and may be addressed by switching to more abundant, accessible, and acceptable energy resources. In some cases such a switch would mean from non-renewable fossil fuels to renewable energy sources, but this depends on the relative abundance of resources in a given location. In all changes, the decision of government to foster a particular energy source should only be taken after a risk-based economic assessment of such a strategy. In some cases, the costs of reducing structural risks are not justified by the benefits they may provide.

With respect to risks from foreign actions, some governments pursue energy self-sufficiency in order to increase energy security by fostering development of domestic energy supplies. This is an approach that European and the United States governments have debated from time to time (Kalicki and Goldwyn, 2005). But efforts of these countries pale in comparison to the commitments made in the policy that Brazil has pursued since the late 1970s, when it launched a strategy of substituting domestically produced vehicle fuel from sugar cane for oil imports, which it perceived as too costly and volatile. Again, such a decision should be supported by risk-based economic analysis. While this was an implicit aspect of the Brazilian decision, a more explicit analysis can make the policy decision more apparent. Of course, policies, such as that of Brazil should be assessed on the full range of potential implications, including, in this case, macroeconomic effects and environmental impacts at local and global levels.

Energy self-sufficiency can be exercised at the sub-national or local level as well. Thus, many cities throughout the world, in both developed and developing countries, are pursuing decentralized energy strategies that involve greater energy efficiency – in buildings, land use, and infrastructure – with more local supply of energy. The latter may entail, for example, small-scale, urban cogeneration of power and heat for local distribution, on the one hand, and on-site solar power for electricity, water heating, and space heating, on the other. While this strategy is generally not intended to eliminate risks from external disruptions, it can reduce the degree of vulnerability to such risks.

Another strategy for addressing risks from foreign origins is through increasing national control over imported energy resources. For example, Chinese national energy companies pursue acquisition of oil-related assets and companies around the world as a way to increase leverage over the international oil market and secure oil supplies to China. The United States maintains a large military presence in the Persian Gulf region and off the coast of West Africa to minimize the risks of hostile actions against oil production and trade. Needless to say, such ambitious strategies are only available to a handful of major economies and their net benefits are not certain.

Another strategy of increasing control over energy imports is "multi-sourcing" energy supply to minimize dependence on a single source or a particular region, and/or long-term, fixed price supply contracts to protect supply sources from price instability. For example, various pipelines (Nabucco, Nord Stream, etc.) proposed and constructed to link natural gas deposits in Russia and Central Asia to European markets are intended to increase the diversity of supply routes and energy exporters, thus minimizing the consequences of potential disruptions of any one export source or transit route.

Various international institutional arrangements may also increase energy security. These range from long-term bilateral supply contracts – especially prominent in the Eurasian natural gas market – to multi-national institutions and protocols for coordinated action. The latter include the Organization of the Petroleum Exporting Countries (OPEC), which aims to stabilize oil markets and returns to oil producing countries, the International Energy Agency (IEA), established in 1974 by the Organisation for Economic Co-operation and Development (OECD) countries to coordinate oil supply strategies, and the European Energy Charter Treaty, which focuses on diverse forms of energy traded in Eurasia.

Box 22.4 | Strategic Oil Reserves – David Victor

Over the three decades since the Arab oil embargo of the early 1970s, most of the large oil-consuming nations have accumulated substantial strategic oil reserves. The United States alone has spent nearly US$50 billion in today's money to build and maintain a huge strategic stockpile of crude oil. Other large oil importers – notably in Europe and Japan – have also spent heavily to accrue their own reserves. Large new oil consumers, notably China, are in the early stages of building strategic reserves.

In theory, a well-coordinated system of oil caches can provide a buffer against harmful shocks to the world oil market, which makes them important tools of economic policy as well as elements of an effective foreign policy. In theory, oil importers can use their reserves to prevent exporters from brandishing the oil weapon when markets are tight while also making their economies less vulnerable to trouble along critical supply routes, such as the straits of Hormuz, through which about one-third of all the world's oil exports travel.

Because oil is a fungible global commodity, making effective use of oil reserves requires international coordination. That logic inspired the creation of the International Energy Agency (IEA), an arm of the OECD, in 1974. IEA is a forum for governments to discuss energy policy and, in crisis, to coordinate release of strategic oil and other emergency measures.

IEA members have drawn up contingency plans to release strategic oil at critical times, such as the eve of the 1991 Gulf War; in anticipation of the calendar rolling over to 2000 and causing unknown computer glitches that could affect energy supplies; shortly after September 11; and in the aftermath of Hurricanes Katrina and Rita in 2005. IEA members actually collectively released strategic oil reserves twice: two and a half million barrels per day in 1991 and two million barrels per day for 30 days in 2005. Like most deterrents, strategic oil reserves are rarely used in practice.

Historically, all IEA members have been drawn from the ranks of OECD membership. But the rise of emerging economies as large oil consumers – notably China, which is building its own oil reserve – is forcing IEA members to find new more flexible ways to engage countries outside the OECD.

Today's oil market is very different from the one that existed when governments created oil reserves and had more direct control over the quantity and price of oil. Today, oil prices arise through trading on complex financial markets, and this new market has led to calls for changing the systems for managing oil reserves and treating them akin to the array of other financial instruments that governments manipulate as part of economic policy.

Source: Victor and Eskreis Winkler, 2008.

Finally, robustness and resilience concerns are addressed through preparing for supply disruptions in order to minimize their impacts. All IEA members stockpile oil to protect against short-term supply disruptions. Natural gas is also stored in an increasing number of European states. Oil importers, such as European countries and Japan, levy high taxes on oil, which serves to decrease the oil intensity of their economies as a cushion against the macro-economic effects of oil price volatility.

22.2.4 Manage Energy-related Market Power

The conversion and delivery of energy is capital intensive, requiring huge investments in finding, extracting, developing, processing, transporting, and retailing. Capital-intensive sectors of the economy are often associated with a degree of market power, meaning that one or a few firms have considerable influence over the market. Market control by one firm is a monopoly. Market power held by several firms in concert is an oligopoly. Capital-intensive activities are frequently associated with economies-of-scale. For instance, a large facility or company can provide energy at lower cost than several smaller companies. In certain cases, these economies-of-scale foster natural monopolies (utilities), where vesting a single firm with monopoly service provision is the lowest cost option for society, resulting in that service being provided by either a public monopoly or a regulated private monopoly (Berg and Tschirhart, 1988).

With grid networks, as in the delivery of electricity, natural gas, and district heat, natural monopoly conditions are common. In many other settings that are potentially competitive, such as oil and natural gas

extraction, high capital intensity and strategic political and economic considerations sometimes lead governments to countenance market dominance by a few large firms or even just one state-owned firm. Likewise, industrial activities that exhibit strong economies-of-scope – meaning that a firm producing one good or service is well-positioned to be the low-cost producer of related goods or services – can result in market power for just a few corporations. In sum, sectors that exhibit significant economies-of-scale, economies-of-scope, and oligopolistic conditions create difficult decisions for governments about the level of public intervention and effort in establishing market competition in society's best interest.

22.2.4.1 Electricity Sector

For most of the last century, conditions that favored monopolies were assumed to exist in various components of the electricity sector. Governments have responded in various ways.

In some cases, governments created publicly owned electric utilities. This strategy often reflected the fact that governments were the only entities willing to bear the risks associated with the construction of electricity networks in remote regions and linking distant sources of supply and demand. This strategy has also rested on the assumption that state-owned corporations would operate with the interests of the public in mind, although there has always been a concern that such corporations can become powerful entities unto themselves, unresponsive to broader public goals and perhaps poorly managed.

In some cases governments have allowed private ownership by a single, monopoly utility, one that is regulated by government or an independent utilities commission to set tariffs and approve major investments. Under the conventional utility commission, cost-of-service regulatory approach, the commission conducts public hearings in which the utility must justify, sometimes in great detail, the prudency of its investments. If approved, the commission will allow the utility to set rates that should, if the firm is effectively operated, enable it to recover its costs plus a return on investment that reflects the risks it faces.

These systems have generally worked where applied, notably in the United States and a few other power markets such as Hong Kong. But regulated private utilities are sometimes wary of taking risks with new technology, and regulators face difficulty in getting the information they need to play an effective role (Viscusi et al., 2005). Concerns have also been raised that this regulatory approach leads to overinvestment in basic infrastructure but lacks incentives for making improvements to operating efficiency (Stigler, 1971). As a consequence, utility regulators are moving toward performance-based ratemaking, an approach that does not limit the rate of return between rate hearings. This encourages the utility to continuously pursue profit maximizing efficiency gains, which the regulator will only translate into lower customer rates after a considerable period of profit-taking by the utility – five years or perhaps longer.

Governments might redesign the network to separate parts of the energy supply chain that are amenable to competition from those where a monopoly is optimal. In the 1990s, most governments that tried to apply market forces did so by restructuring (Newberry, 1999). They unbundled the generation of electricity and often also the sale of electricity and gas to final consumers (where markets might be able to operate satisfactorily) from transmission and distribution (where competitive markets are often impractical).

The last two decades of attempts to restructure electric power systems, accompanied in some countries by a shift from central state ownership and planning toward a greater role for private entrepreneurship, is a useful period for exploring the larger questions of how energy systems and economies can be organized. The mixed experiences with electricity sector reform over the last two decades have shown the dangers, in some cases, of allowing assumptions about the inherent performance of markets to dominate real-world evidence about the special characteristics of a complicated industrial sector like electricity.

As part of separating generation from other components of the electricity system, restructuring advocates have called for the unbundling of generation assets into enough individual entities with separate ownership – private firms, municipal governments, cooperatives, and perhaps some retention of state ownership – that electricity supply competition might be possible. At the same time, the grid system would remain a monopoly in most cases; that is, independently regulated if owned by private firms. This model of electricity reform would comprise the following elements (Joskow, 2006):

- vertical separation of competitive market segments from regulated segments;
- horizontal restructuring of generation to ensure effective competition;
- horizontal integration of transmission and network operations and designation of a single system operator;
- creation of spot energy and operating reserve markets for real-time system balancing;
- unbundling of retail tariffs to separate competitive from regulated costs and prices;
- creation of independent agencies for regulating the network prices and services, including access; and
- establishment of transition mechanisms to deal with unforeseen challenges of reform.

The electricity system in England and Wales is considered to have been very close to this textbook model, and the reforms there have functioned fairly well according to most – but not all – independent experts (Joskow, 2006). However, reform efforts in some jurisdictions have been associated with major problems in terms of supply reliability and price stability. California's electricity crisis of 2000–2001 stands out as an extreme example. In California, wholesale prices were manipulated upward by some electricity traders in the spot market while local distribution utilities were not allowed to increase retail rates correspondingly. The traders were able to bid high prices for providing power, as they took advantage of supply shortfalls related to an exceptional number of units shut down for maintenance and low hydropower supply with low water conditions on the west coast of North America restricting supply. High wholesale prices combined with retail prices capped by regulators caused a rapid increase in debt of distribution utilities, and the supply shortages caused localized blackouts. While the California electricity crisis had many root causes, one was poor policy design that made it nearly impossible to enter into long-term contracts for power, which were more competitive than the short-term spot market, and the reluctance of federal regulators to intervene in the marketplace to stop short-run supply and price manipulation (Wolak, 2003).

There is still no widespread agreement about the optimal form for the electricity market. In any case, opposing ideologies and the diversity of electricity systems in different jurisdictions will ensure continued diversity of market designs. Nonetheless, some issues and lessons are generally recognized. In particular, the electricity sector has characteristics that impede and even prevent development of the degree of competition found within many more conventional commodities. There will thus continue to be an important role for the independent regulation of transmission systems, and even a role for the regulation of investment, pricing, and operation of some parts of the generation system. This regulation is necessary to:

- prevent spot market manipulation;
- ensure adequate short-run reserve capacity;
- ensure adequate investment in new generation supplies;
- determine optimal transmission capacity and operation;
- ensure transmission access for all eligible suppliers, including small-scale renewable energy; and
- promote coordination between electricity systems to maximize efficiency and reliability.

Policies for managing the electricity sector have generally focused, as does the above discussion, on the potential for integrating some degree of competition into electricity generation and retailing in large grid systems. However, in developing countries, and even in rural areas of developed countries, there are areas where isolated mini-grids are the norm and will, in fact, become more important in the future. Proper management of these systems is also necessary and requires different management strategies (Victor and Heller, 2007).

22.2.4.2 Oil Sector

There is a close relationship between the policy response to natural monopoly markets and the policy response to other forms of market power. Many of the market concerns in energy supply arise not only when monopolies reign, but when competition is imperfect, often because of the very large size – and capital commitment – in the energy industry, and also because many energy services are priced in global markets where it is difficult to ensure true competition. OPEC members agree to constrain their collective output in order to stabilize international oil prices at levels above those of pure competition. Because they collude overtly, this type of oligopoly is commonly referred to as a cartel. More conventionally, oligopoly exists in markets where a few firms dominate, with opportunities to collectively behave like a monopoly even without the overt collusion practiced by OPEC members.

There are many other settings in which such collusion could arise and governments organize to oversee the market and restore competitive outcomes. Oil refining and distribution have often been seen as activities with sufficient economies-of-scale that an oligopoly would develop in place of more aggressive competition. Anti-trust action can help ensure a competitive marketplace. Where that is not possible or is ineffective, governments may regulate prices to approximate those of relatively competitive markets, although other considerations, such as national economic performance, may also be important.

In the oil sector at the global scale, there has been a significant shift toward state ownership of oil companies. Indeed, today, most of the world's largest oil companies are owned by governments and trace their origins to decisions by governments to assert control over oil revenues by creating state-controlled oil companies, in many cases because they did not trust private enterprise, much of it foreign-owned. The experience to date is that these national oil companies vary widely in performance and strategy, and they also vary enormously in ability to actually meet the goal of government to exert greater control over the oil sector. National oil companies are also discussed in the following section on the management of valuable energy resource endowments.

Box 22.5 | Electricity Market Reform in Australia – Brian Fisher

In Australia before the mid-1990s, the electricity supply chain, comprising generation, transmission, distribution, and retailing, was owned and managed either by government monopolies spanning the entire chain, or by monopolies at the generation and transmission stages linked to monopoly businesses operating in the distribution and retailing sectors, usually with a franchised "catchment" of customers.

The ownership and management structure provided a protected environment for the industry and there were various indications that electricity was not being provided at least cost. A government-commissioned report released in 1991 cited "poor investment decisions" and "gross overstaffing," as well as reserve plant margins well above international standards, as indicators of inefficiency within the industry (Industry Commission, 1991). This and other factors spurred a wave of disaggregation, privatization, and corporatization, as well as the establishment of an interconnected market in parts of Australia and the introduction of retail contestability for the majority of consumers.

In the southern and eastern states of Australia – where networks are now interconnected – a central initiative of reform was the creation of a common electricity market. The market was managed by NEMMCO (now the Australian Energy Market Operator [AEMO]), a company established in 1996 and owned by the relevant state and territory governments. Broadly, NEMMCO resolves the supply schedules of generators with the demand schedules of purchasers to create a spot price for electricity. It then issues dispatch orders to generators indicating how much they are to produce, taking account of capacity constraints and likely transmission losses. In terms of retailing, even the smallest consumers of electricity in areas covered by the common electricity market have a choice of retailer, with the exception of those in Tasmania, where full contestability was expected by 2010. Western Australia and the Northern Territory are too far from the integrated market in eastern Australia to take part, but Western Australia has operated its own wholesale electricity market for the south-west of the state since 2006.

Most elements of transmission and distribution have not been opened to competition on the grounds that these stages have "natural monopoly" characteristics. Each state has a monopoly transmission business, and has either adopted or retained a framework whereby distribution within a region is generally handled by a single entity. Some entities have interests in both distribution and retailing.

Average labor productivity across Australia in the generation sector had more than doubled by the time the majority of deregulation reforms were underway or completed in the late 1990s. There were also significant reductions in the wholesale price of electricity. Modeling by the Australian Bureau of Agricultural and Resource Economics suggested that annual gross domestic product would be US$2.9 billion higher (in 2008 dollars) in 2010 than it would have been had electricity market reform not been undertaken (Short et al., 2001).

Box 22.6 | South Africa's Institutional Failures and the Power Crisis – Alison Hughes

There is widespread consensus in South Africa that December 2007 heralded an era of crisis in the South African electricity industry. December and the following months were characterized by rolling blackouts. For the first time in South African history, large users such as gold mines lost their electricity supply for extended periods. The underlying cause of the crisis is an inadequate reserve margin. After a long period of excess capacity, the reserve margin was allowed to drop to 6% in 2007 from 31% in 1994. While there are periods where load shedding is not necessary, it will be many years before an adequate reserve margin is restored and electricity supply stabilizes.

The reasons behind the crisis are complex. Short- and medium-term causes can be traced back to a decision to restructure the electricity sector in 1998, which involved breaking up the state monopoly utility Eskom into competing generation companies. At the same time, government wanted to encourage independent power producers to enter the market, and placed a moratorium on Eskom building new

generating capacity. A new institutional framework was prepared, but in 2004, government performed a policy u-turn and announced the scrapping of the restructuring program. The rationale was two-fold: (1) government wanted state-owned enterprises to play a larger role in national development; and (2) no private investment was forthcoming for new capacity, since neither a market system nor a framework for concluding long-term power purchase agreements was put in place. Eskom was given the go-ahead to bring a new peaking plant online and mothballed coal plants are being returned to service, but no new generation units were scheduled for operation before 2012.

Another underlying cause behind the crisis was the long-term prevalence of ultra-low electricity prices, which were below long-run marginal cost and fell in real terms during the 1990s. South Africa has always relied on low-cost energy to attract energy-intensive industry and foreign investors, and has pursued a long-term policy of low energy prices. The national regulator continued this trend by keeping electricity price increases close to, or below, inflation, reflecting the average cost of Eskom producing the electricity. The pricing policy was in part due to significant over-build of generating capacity by Eskom in the 1980s, partly funded through an indirect subsidy from the country's Reserve Bank. Through the pricing policy, demand-side management and energy efficiency were dis-incentivized, load grew faster, and new investment in generating capacity was deterred.

22.2.5 Manage Valuable Energy Resource Endowments

In some countries, the natural endowment in valuable energy resources, especially conventional oil and natural gas, are of such a magnitude that energy is one of, if not the, most important sectors in the economy. As experience has shown, however, a spectacular energy resource endowment can be both a blessing and a curse. On the one hand, the revenues from the resource can allow governments to provide high levels of social services like education, health care, and welfare. On the other hand, the resource windfall can produce so many challenges, as mentioned earlier, that analysts sometimes refer to this endowment as a resource curse (Collier, 2007).

Sarraf and Jiwanji (2001) note several factors leading to resource curse type outcomes. Higher returns to investment and labor in the resource sector can cause capital shortages and wage inflation that harms other sectors of the economy, even though these other sectors would otherwise have wealth-generating potential long after the demise of a non-renewable resource like oil and natural gas. This resource dependency may be inconsequential if the resource is slated to last a century or more. However, it is extremely important in cases where the resource will be largely depleted within just a few decades.

Resource price volatility can cause great uncertainty in government revenues. Periods of high prices tend to be associated with expansion of government expenditures and borrowing, while periods of low prices are associated with cutbacks in government activity and the accumulation of debt.

Periods of high resource prices can also be associated with the rapid expansion of the resource sector itself, which can overheat an economy, in either industrialized or developing countries, and affect the competition for labor and capital with other sectors – referred to as "Dutch disease" – and also create pressure to develop the resource more quickly than should occur from a sound technological perspective. In addition, rapid development and export puts an upward pressure on the exchange rate, which, in turn, makes it more difficult for other sectors of the economy to compete, both internationally and domestically. Developing a resource too quickly can lead to wasteful resource exploitation. An example would be to develop oil and gas reservoirs at accelerated rates that result in lower recovery of the resource than could have been achieved by development at a slower pace.

The wealth generated by a valuable energy resource is an inducement to corruption, where unscrupulous public officials and representatives of domestic and foreign firms vie for resource rents (Leite and Weidmann, 1999). This activity can be so widespread that the distribution of resource wealth to the public at large is far below what it should be, with perhaps even a negligible benefit. Even without pervasive corruption as an outcome, it is relatively easy for ineffective governments to garner political support by distributing some of the rents to key interests and thereby avoid more rigorous oversight of governing institutions (Sala-i-Martin and Subramanian, 2003). Although it need not be the case, a society with a resource windfall can actually be worse off in terms of its economic health and the strength of its social fabric than it otherwise would have been without the resource.

Governments that have successfully handled resource endowments have done so by developing various policy instruments and strategies to address the special challenges of managing energy and mineral resource wealth to the benefit of current and future generations. Some lessons are outlined below.

Governments should not use the resource rents for excessive energy subsidies to domestic consumers, but instead maximize the return from resource assets, in both domestic and international markets. Thus, domestic energy would be sold at international prices. The rents from the domestic and export sales of the resource can then be distributed to

citizens as improved public services and infrastructure or even as direct resource rent payments, which is more economically efficient – and usually more equitable – than a strategy to return the rents via large subsidies to domestic energy users.

Governments can pursue some degree of economic diversification, but should only do so where there are sound prospects for the sustained development of alternative activities. There are many unfortunate examples of governments using windfall resource revenues to subsidize economic development initiatives that have no hope of standing on their own once the subsidy is later withdrawn. But there are also examples of governments helping innovative domestic firms to develop niche markets in activities that are related to resource extraction, which can be marketed internationally, or in completely new industrial activities where the country can have a comparative advantage once it passes the initial start-up hurdles.

Governments should establish mechanisms that reserve a significant share of the revenue from the resource for the future. Obviously this strategy is more affordable for rich countries – for example, Norway and its oil and gas resource revenues – or for countries with a huge resource endowment relative to the size of their population, such as the United Arab Emirates with its large oil revenues relative to its population size. The revenue that is set aside should be invested cautiously in trusts or sovereign wealth funds that are diversified to reduce the risks of wealth depletion via exchange rate shifts or mis-investment.

Governments should establish mechanisms that allow them to access some of the accumulated surplus when resource prices are low. For example, a stabilization fund would not be money set aside for future generations, but would instead be a fund that grew during times of relatively high resource prices but which government could use to sustain key levels of services during times of low resource prices. This would reduce volatility in government expenditures that would otherwise have resulted from volatility in resource prices. However, while this approach seems sound, it is difficult to apply in practice. It is impossible to know in advance when prices are above or below their long-run average, since technological change and/or resource depletion could mean that the long-run price trend in the future will be very different in an upward or downward direction. Only with hindsight can governments determine the extent to which their strategy was providing a proper counter-cyclical balance of building up and drawing down surpluses from the resource.

Governments should create mechanisms that provide transparency in all transactions involving government officials and resource firms in order to minimize the risks of resource-motivated corruption. This objective can be advanced by legislating open accounting systems that enable watchdog organizations like Transparency International to put pressure on large, multi-national oil and gas companies to "publish what they pay" in dealings with national oil companies and governments.

Governments can create mechanisms by which part of resource revenues are returned directly to communities located in the resource areas, in part to compensate for negative effects of resource development, but also to give communities a stake in the efficient extraction of the resource and to maximize the revenues it is capable of generating.

Many oil-rich countries capture much of the economic rent associated with this high-value endowment by having national oil companies play a key role in the sector. The rents appear as profits for these companies. However, a well-designed system of resource rent taxation is important, even in cases where public ownership is predominant, because this provides transparency as to the economic value of the resource. Resource rent taxation should also not be limited to oil. Coal, natural gas, and even favorable hydropower sites can all be associated with substantial resource rents. Countries with a long experience of resource rent taxation tend to have evolved toward rent collection mechanisms that combine ex ante and ex poste obligations. In other words, companies submit competitive ex ante bids for rights or access to the resource – mineral rights, exploration rights, hydropower sites, wind farm sites – and then, during production, also pay a percentage of total revenue or net revenue.

Box 22.7 | Oil Funds – Carolyn Fischer

The Norwegian experience with oil funds is often held up as a best practice for the way a country should manage the revenues it generates from the production of oil. In Norway, the vast majority of resource revenues are transferred to a Petroleum Fund, which is used to generate income and diversify risk by investing exclusively in foreign bonds and equity. As a small, open economy, Norway would not be able to absorb the oil revenues into its own economy, so it has chosen to maintain its existing tax structure and save the wealth for future needs, such as funding the social security system. This strategy contrasts with that of Alaska, which uses most of its oil revenues to fund state government expenditures and keep taxes low. The rest is invested in the Alaska Permanent Fund, which generates dividend income for all citizens of the state.

For developing countries, current needs are arguably more pressing than future ones. High-return strategies then involve investing in human capital and critical public infrastructure, rather than equities, with the caution not to invest beyond the absorptive capacity of

the economy or to protect unsustainable businesses. Botswana, a major diamond exporter, represents a success story in this sphere, where the primary mechanism of revenue management is not an explicit savings fund or allocation scheme, but rather a solid approach to budgeting. The multi-year National Development Plan process aims to stabilize government spending growth and to prioritize spending. The focus has been to expand essential public services and infrastructure – e.g., electricity, water, roads, police, health care, and education – and to provide credit to state-owned enterprises, which, in turn, have made commercial loans. At the same time, the government has accumulated international reserves and earmarked budget surpluses for stability spending in leaner years, and it has managed liquidity and the exchange rate to avoid real appreciation.

In other countries, development benefits of resource extraction have been elusive. In response, some companies have engaged directly in development and compensation programs to improve community relations. Overall, good governance seems a necessary component for resource riches to become a broad-based economic blessing, and not a curse.

Box 22.8 | Resource Rent Taxation – Brian Fisher

The concept of economic rent is outlined in many places, but in this context the definition given by Stiglitz (1996) is most pertinent. Under competitive conditions, the economic rent accruing to a mining firm is the difference between its revenue and its costs, where costs include a "normal" return to capital – the minimum return needed to hold the capital in the mining activity. Economic rents may persist in the mining industry because there is not a perfectly elastic supply of non-renewable resources.

Brown (1948) proposed a tax that is calculated as a fixed proportion of net cash flow each year, where net cash flow is defined as the difference between revenue and total costs. Total costs include all capital expenditure during the particular year but exclude interest payments. In years when "rent" calculated in this way is positive, the government receives a fixed proportion of that rent. In years when the mining company incurs a loss, the government would rebate a fixed proportion of that loss.

The characteristic that distinguishes the resource rent tax proposed by Garnaut and Ross (1975) from a Brown tax is that there is no provision for the government to pay a rebate on losses. Instead, losses may be carried forward, and increased by a "threshold" rate of interest, until they can be deducted from future profits. Taxation is then triggered when the net cash flow from the project is positive. In cases where future profits are insufficient to offset past losses, then the private firm will bear those losses.

The rate of resource rent tax applied in the Australian petroleum sector, for example, is 40%. Although many of the profit-based royalty systems in place around the world are not good approximations to a pure resource rent tax, it is interesting to note that in most cases the tax rate is set below 15% (Otto et al., 2006).

22.2.6 Reduce Environmental and Human Health Impacts

As discussed in Chapters 3 and 4, humanity is increasingly aware of the impacts and risks to the environment and human health from energy supply and use, including indoor air pollution, local and regional air pollution, pollution in fresh water and oceans, direct damage to landscapes and ecosystems, and the major transformation of the earth's climate, with its own implications for weather, ecosystems, coastlines, human economies, and human health. In assessing these effects, some analysts find it helpful to distinguish between "extreme event risks," on the one hand, and "ongoing impacts and risks," on the other.

Extreme event risk refers to events that have an extremely low probability of occurrence but could have an extremely severe impact. Examples include a large oil spill from an ocean tanker, a major refinery explosion or gas leak, or severe radiation exposure from a nuclear accident. Policymaking for extreme event risks can be especially challenging because people tend to focus on the severe consequences of the event itself and forget to consider the very small likelihood of the event (Bier et al., 1999). Nuclear power experts, for example, often express frustration with the public's fixation on the potential human impacts of a nuclear accident while seemingly accepting a much higher ongoing rate of human harm from coal combustion (Matysek and Fisher, 2008).

Ongoing impacts and risks, like the risk of coal mining accidents, refer to operational occurrences that are fairly well understood and accepted as part of the regular impact of a particular activity. The amount of land alienated by an open pit coal mine is easily known. The impact of acid emissions on natural systems, infrastructure, and buildings is quite well understood. Scientific understanding of the impact of greenhouse gas emissions on the earth's climate has improved significantly over the past few decades, although there is still considerable uncertainty about the magnitude of temperature changes associated with different GHG atmospheric concentrations. In fact, because of this uncertainty, GHG emissions present both ongoing impacts and well-understood risks, but also an extreme event risk – runaway global warming. This extreme event has a low probability, but it is not low enough for an increasing number of experts and policymakers (Stern, 2006; Weitzman, 2009).

Ongoing impacts and risks from a particular activity can affect land, air, and water, although some effects are concentrated in one particular medium. A key challenge is balancing and mitigating these effects, as no energy source is completely free of environmental impacts.

On land, impacts and risks are associated with the exploration, extraction, processing, and transportation activities in fossil fuel mining and production, uranium mining and production, and renewable forms of energy like biomass, hydropower, wind, and solar. Specifically, these impacts include open pit coal mines, the well-dotted landscape of an oil and gas producing region, the land required for energy biomass plantations in agriculture or forestry, the land flooded for major hydropower dams, and land required for transmission lines and other networks. As humanity increasingly turns toward renewable forms of energy, land use conflicts arise also for the siting of wind power and run-of-the-river hydropower facilities.

In the air, emissions from the combustion of fossil fuel products and biomass have local, regional, and global impacts. Incomplete combustion of refined petroleum products and biomass leads to indoor emissions of carbon monoxide, black carbon, and volatile organic compounds, in addition to methane leaks, all of which can impact human health. Improved combustion will reduce these emissions and normally also reduce GHG emissions, since these are either direct or indirect GHGs.

In water, there are threats from fossil fuels to ground water, rivers, lakes, and oceans from urban runoff, urban sewage, permitted industrial effluents, and industrial accidents, including oil spills in fresh water and oceans. Discharge of water used for cooling in thermal power plants, including nuclear plants, leads to thermal pollution of waterways. Air emissions from coal-fired generation can lead to acidification of lakes and elevated mercury levels in fish and other aquatic life. Hydropower development, including small-scale, run-of-the-river hydropower, can disrupt rivers and the life systems they support.

The diversity of these threats calls for a multiplicity of policy instruments, the choice of which depends on which medium is under threat and whether the source of the threat is local, regional, or global (Kemp, 1997; Jaffe et al., 2002; Harrington et al., 2004; Newell, 2008; Wei and Rose, 2009). The introduction of this chapter laid out a broad list of government policy types. This range is narrowed somewhat to the following list for discussing options for energy-related environment policy. These include:

1. information programs that inform firms and households of the environmental benefits and perhaps personal financial benefits from certain types of investments and behavior, such as energy efficiency, an approach that extends to sweeping campaigns of public education and engagement;

2. financial penalties (emissions pricing) that discourage rather than prohibit emissions;

3. subsidies that promote changes in investment and behavior by firms and households;

4. regulations that prohibit certain activities, technologies, or energy forms, or that regulate in ways that provide some degree of market incentives for innovation and adoption of more sustainable energy technologies, such as tradable quota obligations or tradable emission permits; and

5. direct actions by governments and their agencies at all levels to fund public sector R&D, upgrade public buildings, facilities, and equipment, improve infrastructure, and develop social capital, such as education, training, etc.

22.2.6.1 Information Programs and Public Engagement

Information programs promote environmentally beneficial energy choices by using both moral suasion and financial self-interest arguments. Moral suasion arguments might focus on global or local environmental benefits for current or future generations. Financial self-interest arguments might convince firms to promote "greenness" as a way of gaining or sustaining market share. Or, with better information about energy use rates and costs, firms and households might realize that some investments, like energy efficiency and conservation, may provide a financial gain over the long term. The challenge for information programs is to compete with all other sources of marketing information, much of which ignores the environmental and even long-term financial benefits of certain energy supply and demand choices and most of which now tries to convince consumers that all of their choices are "green."

One of the challenges is policymakers may assume that information programs can be effective on their own in stimulating a voluntary shift toward profoundly different technologies. Governments in OECD countries have relied to a large extent on information programs to incite

actions by firms and households to make choices that affect environmental performance, but these have been considerably less effective than hoped for (Karamanos, 2001; Khanna, 2001). One of the lessons, in the case of climate policy, is that information on its own – without supporting emissions pricing and regulations of technologies and fuels – is unlikely to drive technological transformation toward lower carbon emissions. Recognition of this reality has shifted the thinking of policy advisors toward finding ways of combining policy options so that information programs work in concert with other, more compulsory types of policies. At the same time, some advocates of this approach emphasize the need for wide-ranging campaigns that engage key interest groups and sectors of the public – for instance, youth, rural inhabitants, etc. – in attempts at profound perceptual and behavioral change, and to increase the acceptability of stronger policy instruments, such as carbon taxes or cap-and-trade systems.

22.2.6.2 Emissions Pricing

Policies like emissions taxes, tradable emissions permit prices, or other types of financial charges seek to provide a price signal that reflects to some degree the value of the impacts and risks to the environment and human health from various types of emissions and effluents. Taxes and other charges can also be applied to specific technologies, such as inefficient vehicles or batteries, where the revenues can be used to fund recycling and the disposal of toxic materials.

Decades of price elasticity studies by economists support the argument that emission taxes can be an effective policy for environmental improvement. Economists also point out that emissions pricing is the most economically efficient policy and that this approach also scores well in terms of other policy criteria, such as administrative feasibility. Yet it is politically difficult for policymakers to implement the level of emissions pricing that would cause the kind of price changes necessary to drive profound technological change in the necessary time period. In some cases, therefore, emissions pricing may need to work in concert with other policy options.

Sweden deserves attention in this context. Emissions of carbon dioxide have dropped by 8% over the years 1990–2007, while GDP grew over 40%, largely as a result of the introduction of carbon taxes in 1990 that, among other things, drove changes in fuel use for district heating away from oil and toward woody biomass.

22.2.6.3 Subsidies

This policy approach was first discussed in the section on energy access, where it was noted that governments have subsidized: (1) electric grid extensions to provide access to electricity for rural and remote areas; (2) the prices of electricity and fuels, such as kerosene, as poverty reduction schemes; and (3) certain technologies like low emission stoves. Subsidies are also applied to energy supply innovation (R&D), commercial development and dissemination of favored technologies, and energy forms for strategic or economic development reasons, such as nuclear power, new fossil fuel production technologies like offshore oil and unconventional oil, and renewables like hydropower and, more recently, wind and biofuels.

With the growing concern for climate change, however, the rationale for some types of subsidies has been questioned. The effect of research and production subsidies on the international price of a key commodity like oil is difficult to estimate. But since high-cost oil production technologies, like the tar sands in Canada, have received such subsidies in the past, there is reason to presume these have had a downward effect on the international price of oil and therefore an upward influence on GHG emissions. In contrast, the effect of subsidies to fossil fuel consumption is easier to estimate. These subsidies existed in many countries a few decades ago, and were especially notable in the countries of eastern Europe and the former Soviet Union. Today, such subsidies remain in other non-OECD countries – such as OPEC members – to provide lower prices, especially for gasoline and diesel. They also exist in non-OPEC developing countries to help certain customer groups, such as the subsidized price of electricity for farmers in India. The IEA (2010) estimates that, globally, the subsidies to fossil fuel consumption exceeded US$300 billion in 2009, and that reductions in these subsidies could lower fossil fuel consumption and associated GHG emissions by 5%.

While energy access is still seen as a legitimate reason for targeted and temporary energy use subsidies, there is now wider recognition that such subsidies should be aligned with policies for GHG abatement. This means that subsidies for fossil fuel consumption should be phased out and subsidies might only be allowed when they either foster non-emitting forms of energy or energy efficiency.

Indeed, subsidy programs for energy efficiency have been significant in OECD countries, especially in the electric sector. Electric utilities in the United States alone spent over US$20 billion on electricity efficiency in the two decades from 1985 to 2005. However, as with information programs, hindsight evaluations of subsidy programs for energy efficiency have increasingly challenged the efficacy of this type of non-compulsory policy. In the case of energy efficiency, for example, it can appear on the surface that each high efficiency device acquired with the help of a government or utility subsidy contributes to a more efficient energy system. However, this can be deceiving.

First, a certain number of higher efficiency devices are acquired even in jurisdictions without energy efficiency subsidies, as some technologies naturally evolve toward more efficient models. Anyone who would have purchased an efficient device anyway, but nonetheless receives a subsidy, does not actually increase the efficiency of the energy system from what it otherwise would have been – a business-as-usual trajectory. These subsidy recipients are therefore called "free riders," and their participation rate must be subtracted before the true effectiveness of the

subsidy policy is known. Economists and policy analysts also use the term "adverse selection" to explain this problem.

Second, the acquisition of a more efficient device may provoke a rebound effect, which is a feedback between improvements in energy efficiency and the demand for energy services. Researchers have described various components of the rebound effect (Sorrell et al., 2009). To simplify the discussion, these are compressed into direct and indirect rebound effects.

With the *direct rebound effect*, energy efficiency investments lower the energy operating costs of energy-using buildings and equipment, which may lead to greater use. This response may occur even if the efficiency investment is not profitable; it is simply a demand response to lower operating costs. If, however, the efficiency investment is also profitable, then it increases net income. Expenditure of this additional income may cause increases in demand for the original energy service. Thus, profitable efficiency investments can induce substitution and income components of the direct rebound effect.

The *indirect rebound effect* refers to second-order developments induced by energy efficiency. The literature describes various components of indirect rebound. For simplicity, we focus on three:[2] (1) by lowering energy demand from what it otherwise would be, energy efficiency should decrease the price of energy, which could increase demand for some energy services; (2) profitable energy efficiency investments increase income, which could increase the demand not just for the original energy service, as noted above, but also for other energy services; and (3) innovation and adoption of energy-efficient technologies for a given energy service could provide spillover effects that increase the demand for other uses of energy, some of which could be completely new.

This third form of indirect rebound warrants elaboration. In essence, improvements in the productivity of a factor of production are normally associated with increases in demand for that factor. Thus, labor productivity gains are associated with increased demand for labor. Fouquet and Pearson (2006) provide an energy example by tracing the historical relationship between productivity gains in lighting services and its demand. They note that in the United Kingdom since 1800, the cost of lighting services fell to one-three-thousandth its initial level while per capita use grew by 6500 times. Although this correlation does not ensure causality, there is a strong likelihood that the dramatic drop in the cost of lighting that resulted from efficiency gains played a not-insubstantial role in the rising demand for lighting services over time. Thus, improvements in the efficiency of basic lighting technologies may accelerate the emergence of and demand for related energy services like decorative lighting and security lighting, just as improvements in the efficiency of refrigeration technologies may accelerate the emergence of related energy services like wine coolers, water coolers, portable freezers, and desktop fridges.

While all researchers can agree with the concept of rebound, there has been considerable debate about its significance and its empirical measurement can be difficult and controversial. The reason is that changes in the cost of energy services caused by energy efficiency would be just one of many factors determining the demand for energy services during a given period. The Fouquet and Pearson (2006) study, noted above, demonstrates a correlation between lighting productivity gains and the demand for lighting. These productivity gains no doubt had a role in increased per capita demand for lighting in the 200 years since 1800 in the United Kingdom. But incomes rose dramatically during this time also, raising the question of the relative importance of rising incomes versus falling costs due to productivity gains in causing the increased demand for lighting. Some research papers or special issues of journals have tried to assess the magnitude of direct and indirect rebound effects (Sorrell et al., 2009; Schipper, 2000). In general, these surveys have given inconclusive results, but suggest that some energy end-uses are more prone to rebound effects than others, and that direct rebound effects are not particularly large for most energy services, but that indirect rebound effects could be very large over long time periods, including the development of new, but related, energy services.

Research into free riders and rebound effects with energy efficiency policies suggests that these can be quite substantial, indicating that subsidy programs too may need to be combined with other more compulsory policies like emissions pricing and technology and fuel regulations (Loughran and Kulick, 2004; Gillingham et al., 2006; Arimura et al., 2009). Finally, subsidy programs have administrative costs and these too need to be considered in the cost-effectiveness calculation, although increasingly utilities and even some governments are now doing this.

Short-term subsidies also suffer from the question of timing. Since energy-using devices are durable goods, firms and consumers can accelerate or delay purchases they would make anyway to coincide with the timing of the subsidy. This shifting behavior increases the cost relative to the benefits of one-off subsidy programs, like the recent "cash-for-clunkers" program in the United States and other countries. Even subsidies that are renewed can suffer from the perception of intermittency. In the case of the United States, production tax credit for renewable electricity generation, uncertainty about policy renewal is compounded by uncertainty about profits, since positive income is required to take advantage of the tax credit.

Given these issues with subsidies when used on their own, one strategy that policymakers are turning to is a combination of subsidies and taxes. For example, some jurisdictions have experimented with vehicle fee bate schemes, in which high emission or high fuel consumption vehicles pay a tax and this revenue is used to provide a subsidy to low emission or low fuel consumption vehicles. The subsidy, while still subject

2 The literature is not consistent. Some of the indirect components described here are sometimes described as direct rebound effects. And sometimes, the income effect on a given energy service, which is ascribed above to direct rebound, is considered to be part of the indirect rebound effect.

to free-riders, helps with political acceptability, while the tax may have more of an effective role.

Even without help from taxes, subsidies can be effective if substantial and well targeted. One of the most compelling recent examples is the "feed-in electricity tariff" that has enabled several European countries to rapidly increase the role of renewables like wind power in the generation of electricity. This tariff guarantees a higher price for electricity from renewables and therefore provides stable revenue projections that help independent power producers secure financing and adequate capital.[3]

Subsidies are also a means by which industrialized countries can transfer funds to developing countries in order to assist in the transformation toward a more sustainable energy system. Foreign assistance in the form of low interest loans to develop fossil fuel, nuclear, and hydropower resources has been provided for decades by governments and international agencies like the World Bank. With the growing concern for climate change, however, new mechanisms have been created, such as the Global Environment Facility and the Clean Development Mechanism, the latter as part of the Framework Convention on Climate Change. These types of subsidies are discussed later in Section 22.2.8 on sustainable energy policy coordination at the international level.

22.2.6.4 Regulations

In some cases, regulations as a policy instrument can be strongly prescriptive in nature, such as an outright ban on a technology or resource use. Concern for the risks of an extreme event, like a nuclear accident, has led some governments to prohibit the development of nuclear power. The potential for nuclear weapons proliferation has prompted some of the world's major powers to use trade threats and technology embargoes to hinder the development of nuclear power by other countries. Concern for the loss of land and harm to migratory fish from large hydropower developments has led some governments to ban such projects, and even to dismantle some existing hydro dams.

Most countries regulate to some degree particulate and gas emissions from the combustion of fuels, including both fossil fuel products and biomass. Energy efficiency standards are applied in most countries to regulate appliances, buildings, vehicles, and industrial equipment. Regulations that affect the safety of oil tankers, petroleum refineries, and transmission lines are also commonplace.

Regulations are sometimes applied in flexible ways in order to reduce the cost of compliance by allowing exchanges between those subject to the regulation. One type of market-oriented regulation is an emissions cap-and-trade policy. A cap is set, with penalties for non-compliance, as with other regulations. The cap is allocated – freely or by auction – in the form of permits or allowances and, because these are tradable, the trading price provides a price signal to emitters, just like an emissions tax. Each emitter has the option of reducing emissions, and selling surplus allowances to other emitters, or not reducing emissions and instead purchasing the needed allowances from someone else.

There is considerable debate about the relative merits of cap-and-trade versus emissions taxes. Cap-and-trade provides greater certainty about the emissions outcome of the policy. This is seen as desirable from the perspective of ensuring the realization of an environmental objective. In contrast, emissions taxes provide greater certainty about the effect of the policy on energy prices faced by firms and consumers. This is seen as desirable from an investment and economic efficiency perspective. Emissions taxes are likely to be much more stable than emissions prices that emerge from the market in which emissions permits are traded. In reality, however, it is possible to design cap-and-trade systems with a price floor and price ceiling and to allow banking and borrowing of emissions permits in order to reduce the tendency for emissions price volatility.

Another type of market-oriented regulation is an obligation to achieve a minimum market share of a particular good or production process. An example is a low-emission standard for vehicles that obliges producers to achieve a minimum market share for the sale of a desired type of vehicle, with an allowance for producers to trade among themselves to achieve the aggregate minimum sales requirement. Similarly, a renewable portfolio standard in electricity sets minimum market shares for renewable electricity generation, with credits for producers to trade among themselves in achieving the aggregate target. Effectively, these policies combine a subsidy for renewable energy with a tax on non-renewable energy generators.

22.2.6.5 Direct Action by Government

While the policies discussed thus far mainly involve governments trying to induce alternative behavior and technology choice by firms and households, there are also opportunities for governments to take direct action. Senior levels of government invest in R&D and can establish funding criteria that emphasize environmental and human health objectives, especially with respect to energy-supply and -use technologies. All levels of government own buildings, vehicles, and equipment, and they can require specific technological choices in terms of environmental and human health impacts. Governments can even use their purchasing power to influence the commercialization choices of manufacturers. Thus, public procurement strategies can make major equipment acquisitions contingent upon the ability of one or more competing manufacturers to produce new technologies that meet aggressive targets for energy efficiency or low environmental impact.

Local governments determine land use through planning, zoning, and building, permitting authority provision of public transportation options

3 It is important to note, however, that subsidies come from somewhere. If they are provided by government, they are generated mostly through taxes elsewhere in the economy. Conversely, they may be provided as cross-subsidies from other customers or industry.

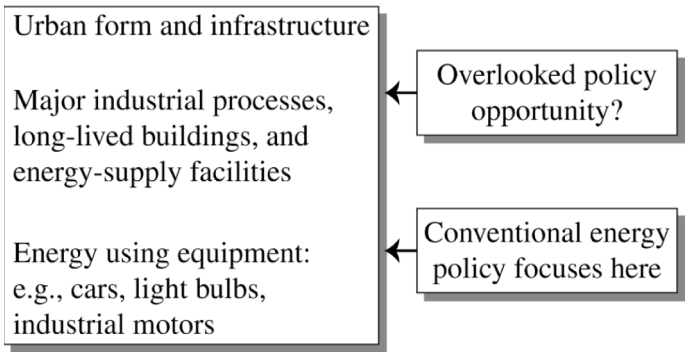

Figure 22.1 | Hierarchy of energy-related decision-making. Source: Jaccard et al., 1997.

within and between urban centers, responsibility to help energy utilities site transmission and other network lines, and urban and regional control over zoning and development. An example in this area is the rising interest in community energy management, an effort by local government especially to coordinate regulations and land use decisions affecting building and facility characteristics, siting of buildings, and infrastructure investments in ways that minimize the use of energy, maximize synergies between systems, and provide opportunities for the greater use of energy forms that are more environmentally benign.

Figure 22.1 shows a hierarchy of energy-related decisions. While energy policy has traditionally focused on the buildings, industrial facilities, and equipment in the middle and lower part of the hierarchy, it is increasingly recognized that there is considerable opportunity for municipal and sometimes more senior levels of governments to influence the evolution of urban form through land-use zoning, development permitting, siting requirements, building codes, and infrastructure investment in public transportation, district energy, and even urban liquid and solid waste collection and disposal systems. Decisions at higher levels of the hierarchy are more often taken by government, given its ultimate control over land use and major infrastructure. Also, decisions at higher levels tend to have longer-term impacts. The rate of turnover of urban form is much slower than that of vehicles or the equipment used inside buildings. This makes policies affecting the top of the hierarchy all the more urgent, given the rapid transformations that are required for a more sustainable energy system.

A final consideration is that many environmental impacts and risks cross international borders, which can make it extremely difficult to create effective policy because this requires that many countries coordinate their objectives and efforts to achieve multi-national or global public good. Depending on their level of economic development and resource endowments, countries could have very different perspectives. China is less interested in reducing coal use in order to reduce GHG emissions than is a country such as Japan, which, unlike China, is poorly endowed in terms of coal resources. The challenge of achieving a coordinated international effort with respect to the environmental impacts of energy supply and use arose in the 1980s with the cross-border challenges of acid rain and the control of acid emissions. Europe and North America made headway on this challenge, but the focus has now shifted to the need for international coordination of GHG emissions control. This special problem is addressed in Section 22.2.8 below on energy policy coordination at the international level.

Box 22.9 | Key Policies for GHG Abatement: Cap-and-trade Versus Carbon Tax – Mark Jaccard

When addressing an environmental externality like GHG emissions, economists have a preference for policies that provide a single price for GHG emissions from all activities in the economy. Thus, economists' two favorite policies are either a tax on emissions or the allocation of rights to a fixed quantity of emissions. In the latter case, tradable emission allowances are allocated by auction or a political process, perhaps reflecting historical emissions and other criteria. In any given period, those who have reduced emissions enough to hold a surplus of allowances can sell them to those who find it cheaper to purchase these instead of fully reducing emissions to match allocated allowances. Borrowing and banking of some allowances may also be permitted. The combined effect is that the market for tradable allowances, if it covers all emissions in the economy, would provide an economy-wide price signal in the same way as would an economy-wide GHG emissions tax.

The two policies differ in that the emissions charge provides price certainty while the emissions cap provides quantity certainty. The former gives investors confidence about the future price of emissions, but it leaves uncertain for government the actual emission reductions that will be induced by a given tax level. The latter gives certainty to government about the level of future emissions, but the price of tradable permits will be uncertain.

There are vigorous debates about the relative merits of these competing approaches (Weitzman, 1974). In practice, however, they may not end up that different. The level of emission taxes is uncertain to the extent that governments will inevitably adjust taxes as they observe the reductions induced by a given level of tax. And emission caps may be implemented in conjunction with price floor and price ceiling strategies that increase confidence about the price while reducing certainty about the future level of emissions. Also, governments may apply caps to industry but taxes to other sectors of the economy.

While taxes and caps are usually discussed in terms of national or regional application – a regional example being Europe – the global nature of the climate risk has led to debate about which approach is best from a global perspective. The Kyoto Protocol is based on the idea that countries can negotiate national caps and then establish allowance-trading mechanisms. Critics of this approach claim that it will be less difficult and more effective to apply harmonized carbon taxes around the globe rather than trying to extend restrictive caps from the Annex I countries of Kyoto to all countries on the planet (Nordhaus, 2007).

While taxes and caps are largely seen as policy substitutes, there is a fairly widespread belief that dramatic GHG reduction by mid-century requires the combination of a tax or cap policy with additional policies that accelerate the rate of technological change. One such policy is the allocation of large public subsidies to the initial developments of new capital-intensive technologies, such as the first full-scale CCS systems, the prototypes of new nuclear power systems, and technological innovations that provide reliable energy storage for renewable energy. Another policy is the use of regulations to guarantee market shares for new and emerging technologies that otherwise have higher costs than conventional, GHG-emitting technologies. An example is the renewable portfolio standard, which guarantees a growing share of the electricity generation market for renewables.

Box 22.10 | Information as a Policy to Influence Sustainable Energy Choices – Charlie Wilson

Information policies have been widely used to promote the adoption of sustainable energy technologies as part of broader behavior change strategies. Through the 1980s and 1990s, for example, United States utilities spent over US$20 billion providing information and incentives in response to a perceived shortfall in both households' and firms' knowledge of widely available and cost-effective investment opportunities.

Information-based approaches to promoting energy technologies remain widely used today, but have been improved by a wealth of empirical findings on the "who," "how," and "what" of information provision.

Lessons on *who* should provide information and *how* they should provide it are inter-related. Information disseminated from person to person, particularly if such people are trusted peers or social role models, is more effective at changing behavior than information spread through mass media channels. The perceived trustworthiness and credibility of the information provider is also important. So too is consistency. Clearly inconsistent policies weaken the credibility and thereby effectiveness of information – e.g., policies to reduce energy prices vs. information policies on cost-effective, energy-efficient technologies.

The *what* of information provision relates to form and content. "Folk" behavioral models that describe how people actually think about energy clearly demonstrate the importance of information that is simple and salient; i.e., it stands out in some way and is easily comparable. Efficiency ratings on product labels can be a good example of this. Targeted or otherwise personally-tailored information is also effective. In contrast, information that is technical, detailed, factual, and comprehensive is often glazed over, or interpreted subjectively and selectively, often to support pre-existing beliefs.

Another important role for information is to provide feedback on behaviors undertaken or technologies adopted. The transition underway from aggregated monthly utility bills to real-time energy use monitors enabled by smart metering will greatly improve the value of information as feedback on energy-related behavior: consider the analogy of being informed of your total food expenditure once a month, as opposed to receiving an itemized bill each time you shop.

Well-designed information policies may successfully raise awareness and support positive attitudes toward sustainable energy technologies. But the ultimate success in changing behavior is limited by contextual factors. High investment costs, coupled with limited access to capital and strong consumer preferences for immediate rather than delayed financial benefits, are a common example. Other contextual constraints include: regulations (e.g., planning guidelines); economic incentives (e.g., falling energy prices, sales taxes); social norms (e.g., larger homes); habits and routines (e.g., daily washing and cleaning); and community governance traditions (e.g., resisting outside developers).

The stronger these contextual constraints, the weaker the effectiveness of information policies. In general, therefore, information policies are effective only as part of a broad and consistent multi-pronged policy framework to promote the diffusion of sustainable energy technologies. As an example, information policies are a useful rapid response to a window of opportunity presented by some external shock, such as rapid oil price rises or supply disruptions.

Paradoxically, the best form of information provision results from peoples' actual experiences, and only comes with widespread diffusion. The communication of positive experiences through networks of families, friends, and peers is the most effective means of supporting social learning, increasing familiarity, forming favorable attitudes, and reducing the perceived risks of sustainable energy technologies.

Box 22.11 | Community Energy Management and Transportation in Curitiba, Brazil – Mark Jaccard

While the rapid urbanization in developing countries presents monumental challenges, it also provides unique opportunities. A myriad of incremental, and seemingly unimportant, decisions about urban land use and infrastructure taken today will profoundly determine the ability of tomorrow's burgeoning urban centers to achieve sustainable energy systems. Curitiba, Brazil, provides an example of how effective planning can have a positive impact on a community's development, particularly in terms of energy use for transportation.

A city of over two million, Curitiba has, since the 1970s, channeled growth along five axes radiating from the city center. Each axis has a bus expressway and parallel roads for vehicles. Land use zoning has concentrated high-density development to the five axes, especially centered on interchange bus terminals that are located about every two kilometers along each axis. Passengers from lower density areas take feeder buses to these terminals, where they transfer to the express buses for travel to the city center. Costing about 1/200th per kilometer of a conventional subway system, the bus expressway nonetheless achieves comparable performance in terms of ridership and travel times. While Curitiba has a high rate of car ownership for Brazil, almost 75% of commuters use buses, resulting in 25% lower vehicle fuel consumption than similar Brazilian cities. Reduced fuel consumption contributes to the city's relatively low level of urban air pollution, and reduced vehicle use for commuting fosters a more pedestrian-oriented city center. The express bus system is operated primarily by private companies under guidelines from, and in partnership with, the municipal government.

Box 22.12 | Masdar, CCS, and Enhanced Oil Recovery – Michael Ohadi

The United Arab Emirates (UAE) is the world's second largest emitter of greenhouse gas per capita. In 2006, the Government of Abu Dhabi launched an initiative, the so-called Masdar initiative, with a primary goal to promote advanced and clean energy supply and substantial reduction in the CO_2 emissions to the environment.

The Abu Dhabi Government is pumping billions of dollars into the clean energy Masdar initiative with the double aim of capturing CO_2 emissions from major sources of CO_2 production and injecting it into oil reservoirs for enhanced oil recovery purposes. The long-term goal is to prepare the world's third-largest crude exporter country with economic diversification and a future less dependent on a supply of crude oil.

CCS technology refers to the capture of carbon at the source, then compressing and liquefying and finally transporting it by pipelines to safe and permanent storage in geological formations. The nature and size of the reservoirs of Abu Dhabi, as well as the short distance between CO_2 emission sources and oil reservoirs, created an opportunity for a reliable and technically feasible CCS project.

The UAE embarked on the Masdar CCS project and the CO_2 emission reduction program in 2007. The project aims to slash the emirate's CO_2 output by about one-third by 2020. In its first phase, the project aims by the end of 2012 to capture five million tonnes of CO_2 from power plants and industrial facilities and to transport the CO_2 to oilfields for enhanced oil recovery (EOR) applications. Injecting CO_2 in the oil reservoirs will maintain underground pressures, thus resulting in enhanced recovery of the crude oil. EOR is receiving more attention in recent years with further maturing of the oil reservoirs in the country. The world average of oil recovery is estimated at 35%, which in essence means 65% of recoverable oil is being left behind if it is not recovered through advanced technologies, such as use of injected CO_2 and other enhanced oil recovery techniques. Currently natural gas is being injected in some of the Abu Dhabi reservoirs for enhanced oil recovery purposes. It is estimated that over one billion standard cubic feet of natural gas per day is currently being injected into oilfields for enhanced oil recovery that otherwise can be used for power generation or petrochemicals.

The Masdar CCS project has already launched a pilot plant project in which CO_2 is captured from a source and is being injected in one of the oil reservoirs. Data on CO_2 diffusion and its impact on the enhanced oil recovery of the reservoir are being collected. The project involves close collaboration between the Masdar Institute, Abu Dhabi National Oil Company and its subsidiaries, the Petroleum Institute, and other academic and industrial collaborators from around the world.

The project is being developed over a multiphase road map, with the feasibility study undertaken in 2007 and the Front End Engineering Design (FEED) phase begun in August 2008. The fully developed CCS project will use CO_2 from power stations, refineries, and other industrial sources. The following emitters are planned in the first phase of the project: a major power plant, an aluminum smelter, and a steel plant. The combined phase one capacity is five million tonnes of CO_2 per year with an approximately 300-kilometer CO_2 pipeline network to carry the CO_2 to the injection site(s).

Masdar's CCS activities have considerable potential to be expanded in Middle Eastern countries where significant carbon capture potential can be located under the Kyoto Protocol. The Masdar initiative can serve as a role model for similar developments in other Middle Eastern, as well as other regional and industrialized, countries. It is an example of a clean and peaceful energy initiative that has multiple win-win objectives, including utilization of CO_2 for enhanced oil recovery to free up more oil while liberating substantial amounts of natural gas for power production and other purposes, and finally economic diversification and job creation opportunities.

22.2.7 Accelerate the Rate of Energy-related Technological Change

Innovation and technological change are essential contributors to a sustainable energy future. Energy technology innovation is addressed in detail in Chapter 24 and, as noted above, the broader social and institutional capacity on which technological change is predicated is covered in Chapter 25. Below is a summary of the context, rationale, and criteria for policy to foster innovations that are critically needed to address the joint challenges of global environmental change and the energy service needs of all of humanity.

22.2.7.1 Characteristics of Innovation and Technological Change

In its most general sense, technology is a system of means to particular ends (e.g., Grubler, 1998). Technologies comprise both physical creations – plants, equipment, devices – and information and knowledge systems – know-how, skills, experiences. Technology is thus a specific form of knowledge that can be embodied (an appliance) or disembodied (know-how). The respective importance of these two forms changes over the life cycle of a technology from invention through research, development, and demonstration to niche market applications and, ultimately, pervasive diffusion. Through this lifecycle from innovation to deployment, technological knowledge needs to be created, developed, and applied. It can also depreciate or be lost if not actively managed. Innovation policy is therefore fundamentally concerned with stimulating and managing this process of knowledge generation, application, dissemination, and feedback, and thus needs to embrace a systemic perspective (e.g., Carlsson et al., 2002). This includes the continuous feedback between different stages of a technology's lifecycle, which typically characterizes successful innovation processes. Technologies are also inherently dynamic, and the innovation process is characterized by high degrees of uncertainty. This requires adaptive policy approaches that recognize the dynamics of technological change, and allow for experimentation, foster diversity, and accommodate failures.

22.2.7.2 The Rationale for Public Technology Policy

Policy intervention in the innovation process is primarily justified by the public good characteristics of knowledge and thus the potential positive

spillovers beyond the innovating agent. Additional sources of market failure exacerbate this public good problem (Jaffe et al., 2005).

New knowledge can be expensive to generate, but cheap to imitate. As a result a "free-rider" problem exists in which private firms under-invest in innovation, as the benefits cannot be fully captured. Without intervention, these knowledge spillovers result in under-allocation of resources to innovation. This problem applies to all technologies, but is exacerbated for energy technologies due to the high capital costs and development lead times, which magnify the risks for innovators, and the potentially limited returns in regulated markets. Literature related to innovation has repeatedly found that social benefits from innovation exceed the benefits accruing to private innovating firms several-fold: social rates of return are persistently and significantly higher than the private returns from innovation (Freeman, 1994). Policy intervention is needed to correct this market failure, particularly as the limited data available on private-sector R&D investment suggests a decline over the last 20 years against an ever-rising backdrop of public concerns on energy security, access, and environmental impacts.

Other sources of market failure increase the need for government intervention. Positive interaction effects may exist in cases where both under-pricing of the environment (lack of pricing or regulation to reflect negative externality costs) and under-pricing of knowledge (positive externalities of information) make the financial attractiveness of innovation investment much lower than its true value to society. Increasing returns, due to network effects and economies-of-scale of incumbent technologies, delay the deployment of nascent technologies, and possibly lead to under-investment at earlier stages in the innovation process. Information asymmetries between technology producers and technology adopters make deployment sub-optimal in early stages when technologies are unproven. Principal-agent problems – for example, between owners and occupants of buildings needing thermal retrofit to improve efficiency – hinder deployment, even after technologies prove to be reliable.

However, successful innovation depends on much more than overcoming market failures. A systemic view on innovation highlights the fact that innovation entails a series of collective, embedded processes involving many actors, networks, and institutional settings that can fail at many different levels and need to be addressed by policy intervention (Hekkert et al., 2007).

22.2.7.3 Policies for Innovation

Policies for innovation can: (1) directly target the innovation process; (2) support the innovation system; or (3) unintentionally impact innovation while targeting an unrelated concern.

Direct policies for innovation vary according to the target and timing during the innovation process. Policy is needed at each stage of this process. The role of government is most evident at the earliest stage of basic science and research. Together with the private sector, governments are also engines of applied energy R&D. But governments also need to play an important role in leveraging private sector investment at the early commercialization stages by supporting demonstration activities to reduce risks and market formation to underwrite demand.

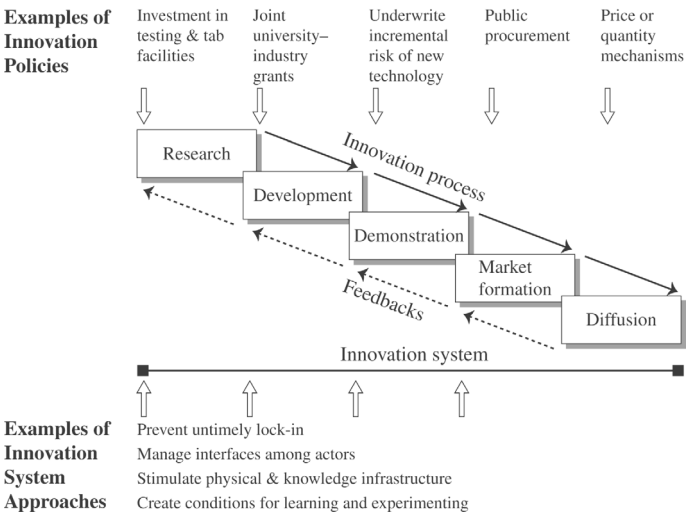

Figure 22.2 | Overview of policies for innovation. Source: developed by GEA authors.

This innovation process is situated within an overarching system comprising the actors, institutions, and networks involved in developing and commercializing a technology (see Chapter 24 for details). Innovation policies must also target the successful functioning of the innovation system (see Figure 22.2 for examples).

Policies on issues such as education, taxes and subsidies, and market regulation can all exert an important, yet indirect, influence over both the supply of, and demand for, innovations. This reinforces the need for consistency not just between direct innovation policies but also between the broader regulatory and institutional environments for innovation.

Policies supporting the supply of innovations or the development of technologies include investments in R&D, intellectual property protection, laboratory and testing infrastructure, training and skills, university–industry collaborations, formal and informal mechanisms of knowledge exchange, technology roadmaps to guide the direction of innovation, and financial incentives such as tax credits for private investments. Not all innovation, however, derives from formal R&D activities. Problem solving and incremental improvements in existing technologies are also of importance and can be stimulated and supported by public sector policies that lead to the creation of outreach, extension, and technical support programs. Policies supporting the demand for innovations as commercialized technologies include demonstration projects, public procurement, market niche creation (supply obligations), market incentives via changes in relative prices (via environmental taxes or feed-in tariffs), standards and regulations, direct financial support, education,

and marketing. These "supply push" and "demand pull" policies are complements and not substitutes. Innovation success stories are typically characterized by comprehensive and consistent policy support through the entire innovation process. Although these criteria can be generalized, particular innovation policies must take into account specific local conditions or be otherwise tailored to the technological or market characteristics of an innovation.

22.2.7.4 Principles for Innovation Policy Design

Selecting innovation policies is necessarily context-specific. However, the literature (Grubler et al., 1999; Norberg-Bohm, 2000; Nemet, 2009) and the sample of energy technology case studies reviewed in Chapter 24 points to a number of guiding principles or policy criteria that are considered generic to all technology domains and adoption environments. These are:

Innovation policies need to be aligned and consistent. This should be true both within a given innovation system and between different innovation systems to maximize spillover benefits. Alignment implies a set of policies that are co-ordinated and free of contradictions. A prime counter-example is the current emphasis of public support for low carbon innovation alongside the much larger subsidization of fossil fuel technologies.

Aligning incentives for energy technology innovation is aided by an explicit and systemic innovation strategy. Such a strategy will inevitably face trade-offs between policy objectives, as is the case with standards and incentives to promote energy efficiency while maintaining downward pressure on energy prices.

Innovation policy frameworks and supporting institutions need to be stable and independent. This is the means of effectively managing the process of technology knowledge generation, application, and maintenance. Independence avoids the resistance to change and learning of the vested interests, which grow up around incumbent technologies. Policy objectives and instruments require continual re-assessment and potential adjustment toward long-term transformative goals.

Stability wards against the eventual loss of knowledge. Erratic policy support and signals can lead to rapid knowledge depreciation. Governments play an essential role in managing expectations of the demand for innovation by providing policy signals that are credible and consistent over a multi-year period to reduce the uncertainty of private sector investments reliant on distant payoffs. Policy instability acts as a barrier to commercial innovation, and can accelerate knowledge depreciation. Stability does not preclude policy dynamism and flexibility to respond to new information. But it does, however, mean patient and consistent goals backed up by predictable funding support for various stages of the innovation lifecycle.

Superior policy requires a commitment to good data. Innovation policy needs to be founded on a clear understanding of how the innovation system operates, what it requires in terms of inputs, and how to assess its effectiveness in terms of outputs. Understanding and assessing innovation systems requires far better data on innovation activities than are currently available. For example, technology-specific private sector R&D data are almost entirely lacking. Systematic and comprehensive information disclosure as a condition of policy support can help redress the current scarcity of reliable innovation outcome data. As an example, subsidies for demonstration projects and niche market deployment could be contingent on documentation and public disclosure of both successes and failures in order to facilitate wider learning.

Policy should support the different stages of innovation, and the feedbacks between them. Traditionally, innovation policies have targeted specific stages of the innovation process while neglecting the essential feedbacks between them. As an example, publicly-funded testing and demonstration facilities for new technologies can ensure disclosure of unbiased performance benchmarks to guide technology R&D. (For example, see the case study on wind power in Chapter 24.) Feedback from market deployment experience can also benefit technology design and manufacturing quality assurance. (See the case study on solar photovoltaics [PV] in Chapter 24.) Increasingly, policies to support information sharing and knowledge feedbacks need to consider the globalized nature of technology markets.

Innovation policies should facilitate widespread experimentation. Successful diffusion is underpinned by knowledge generated through the development, design, construction, and operation of a technology. Inherent uncertainties make this a process of experimentation. Experimentation leads to incremental improvements and learning-related cost reductions, and also underpins the success of increasing unit sizes or overall production volume to capture economies-of-scale. Indeed, the capital intensity, risk, and opportunity costs of many large-scale energy technologies should orient experimentation toward relatively small-scale versions of technologies in a diverse portfolio to reduce the consequence of failure. By comparison, narrowly-targeted policy support for single design large-scale demonstration projects – such as breeder reactors – is high risk.

Experimentation can, and also perhaps should be, multifarious, involving an array of different actors, forms, and stages of the technology's lifecycle. Governments should intervene to manage the natural commercial tendency to rapidly hone in on a dominant design that confers market advantages and potential cost reductions.

Innovation policies need to focus on portfolios rather than single technologies. The magnitude and array of energy system challenges, combined with inherent uncertainty in the innovation process, requires a broad portfolio of technologies. Such portfolios need to balance each technology's option value – or social benefits in case of successful diffusion – and risk, in terms of both innovation failure and investment.

These portfolio decisions will require a combination of expertise from public and private sector innovation actors. Formal scientific tools for innovation portfolio design and analysis are increasingly available, but need further development as well as an institutional home for application.

Generic principles for innovation portfolio design include: (1) incorporate options from across the entire energy system, especially including the traditionally under-researched and under-funded energy end-use technologies, and avoid an overemphasis on any single, "magic bullet" option; (2) manage resource constraints by focusing on granular, less capital-intensive technologies such as end-use innovations and smaller scale supply options; (3) link large-scale, capital intensive, and high risk innovations into global innovation portfolios that enable international coordination and cooperation; (4) avoid pre-empting the outcome of decentralized market-based technology experimentation while counteracting private sector biases toward early selection of a dominant and rapidly scalable technological solution; and (5) promote technologies that show good prospects for gains from learning-by-doing in application and economies-of-scale in production.

22.2.8 Coordinate and Implement International Energy-related Policies

Globalization of the world's economic system is associated, as is to be expected, with the globalization of its energy system. Globalization can have benefits, but it can also present major challenges.

First, globalization of the world's energy system has not had a significant benefit for the poorest people on the planet. The rate of foreign direct investment in the energy sectors in developing countries remains at only a fraction of the level needed if most people in the world are to have access to electricity and modern fuels over the next few decades. Governments have tried to make gains in this direction, in part through collective funding mechanisms like the World Bank and the International Monetary Fund, and in part through encouraging the establishment of domestic environments more favorable to foreign investment. But these strategies, thus far, have not provided the investment funds that are needed. The key issue, from a policy strategy perspective, is to find a way to make globalization work for the poorest people in the developing world.

Oil's price has been set internationally for decades, but now this is also increasingly the case for coal, natural gas, and sometimes even electricity. Globalization of the world's energy system can contribute to increased energy security, widening the options for any given country to meet its energy needs. But globalization of energy trade can also have the reverse effect, especially as individual governments lose the ability to ensure energy supplies for domestic markets at relatively stable prices. For example, while individual governments cannot prevent oil price spikes, like that of 2008, working in concert they may be able to reduce some of the energy price volatility that has occurred in the past.

Finally, when it comes to international energy policy coordination, the issue of climate change is becoming increasingly critical. Addressing the risk of climate change through GHG emissions reductions is a collective public good that can only be achieved with collective action. Most countries, perhaps starting especially with the world's largest emitters and most powerful countries, must work together to successfully reduce emissions. Thus far, the international community has put a great deal of effort into widespread negotiations, largely through the United Nations sponsored Framework Convention on Climate Change, but this has not yet produced truly significant action by those countries who have made commitments, and not yet induced enough significant emitters, like the United States, China, and India, to agree to substantial emissions cuts.

While some see globalization as largely a force for improvement in the world, others see it as the cause of problems and argue that policies should try to prevent or restrain globalization. Still others argue that globalization is inevitable, albeit undesirable, so the only alternative is to work within this reality and not resist it. Finally, some believe that with careful policy strategies, the forces of globalization can play a critical role in addressing the very challenges it presents. More of this latter perspective is discussed in the description of globalization-related policy instruments and strategies.

If globalization is to significantly increase energy access in developing countries, these countries and international agencies need to improve the climate for foreign investment in energy supply while at the same time ensuring that such investment meets the need for clean, affordable energy. Thus, international institutions like the World Bank need to keep reforming the criteria by which they support energy policies, although some significant progress in this direction has already been made in recent years.

If globalization is to enhance rather than reduce energy security in developing and developed countries, significant changes in international energy security regimes will be required. The current focus of energy security institutions such as the IEA and the OPEC on short-term fossil fuel supply stability is both increasingly ineffective – as demonstrated by recent price volatility – and untenable in the face of persistent systemic challenges associated with rapid demand growth and increasing geographic concentration, if not outright physical scarcity, of petroleum resources. Moreover, stability, inherently preferred by energy security regimes, is at odds with the rapid and radical change expected of energy systems to meet sustainability objectives. The future international energy security regimes should therefore be able to overcome these limitations by expanding focus away from the supply-side and fossil fuel orientation of today. They should also be able to provide for a meaningful dialogue between energy importers and energy exporters, including such emerging major energy users as India and China and such major energy suppliers as Russia.

Another key area for international coordination and cooperation is to enhance security measures that prevent the diversion of the peaceful uses of nuclear energy to the production of nuclear weapons by governments or terrorists. While much progress has been made in this direction over the past decades, the challenge becomes all the greater as the number of countries with nuclear capabilities increases (for further information, see Chapter 14).

Of increasingly dominant importance is that two decades of efforts have thus far failed to result in an agreement on the establishment of a global architecture for concerted international action on GHG emissions to address the risk of climate change. Many of these efforts have focused on the creation of international agreements to reduce emissions, notably the 1992 Framework Convention on Climate Change and the 1997 Kyoto Protocol. This top-down approach seeks to achieve widespread agreement among almost all countries, whether they be big or small contributors. In the long run, participation by virtually all countries will be required, if only to prevent the disintegration of agreements by a growing number of free-riders (Barrett, 2003; Aldy and Stavins, 2007). But as a starting point for reaching an international agreement with meaningful commitments and effective policies, some have argued that it may be easier to limit negotiations to a small number of countries that account for most emissions or that have the financial ability to contribute significantly to the global costs of reduction (Victor, 2001). Perhaps in a bottom-up approach, a group of 20 major emitters, like the United States, China, India, and some European countries, or the European Union as a whole, should first try to negotiate targets and policies that could form the basis for an eventual international architecture that other countries would gradually join. Other issues that need to be addressed include the effect of institutions like the World Trade Organization on efforts to achieve a meaningful global effort to reduce GHG emissions.

22.2.9 Key Energy-focused Policies[4]

For the eight previously delineated energy-related policy goals to be achieved, energy services, technologies, and operating practices of the global energy system must evolve in specific directions. Certain outcomes need to occur in terms of energy efficiency, renewable energy, fossil fuels, and nuclear power. These key energy-related outcomes represent the means for achieving the energy-related goals. A survey of the various chapters of GEA, and especially Chapter 17 on scenarios for a sustainable global energy system, suggests four outcomes of particular importance:

- The global energy system needs to become much less energy-intensive for a given level of energy services, i.e., much more energy efficient.
- The global energy system needs to rapidly shift toward renewable sources of energy, used with minimal harm to the environment and humans, such as the need for food production.
- Wherever fossil fuels are used, the environmental and human impacts and risks from their use need to be minimized.
- Wherever nuclear power is used, its energy-related and weapons-related risks to the environment and humans must be minimized.

In this section, generic policies are outlined that offer a means of achieving sustainable energy. In Section 22.3.1, some of the key policies that are likely to be effective in achieving these outcomes are presented. Additionally, Chapters 23, 24, and 25 focus especially on critical areas of policies for energy access, policies for capacity development for energy transition, and policies for accelerating energy-related technological change. The policies in Chapter 22 have been selected because: (1) they have broad applicability in terms of the urgent need for rapid technological and behavioral change; and (2) they have either already demonstrated effectiveness in real-world applications or they appear to perform well against many of the key policy evaluative criteria listed in the chapter. Many of the other chapters discuss policies, especially the ones focused on specific technology and resource options.

For advancing each of these four means to sustainable energy – efficiency, renewable energy, clean fossil fuels, and safe nuclear power – a critical policy challenge is to ensure that valuable innovations successfully navigate the hazardous steps from invention, to commercialization, to widespread market penetration. Thus, while policy support for basic and applied R&D is needed, policy support is just as important in the demonstration and initial commercial phases; when additional support can help lower the production and operating costs of new technologies and establish, or help to establish, market niches that will stimulate investor interest in the technology. Finally, market pull policies are needed to carry the product through to widespread dissemination. The policies listed under each of the four means to sustainable energy, in the following Section 22.2.9.1, cover the various phases of this technology life cycle.

22.2.9.1 Reducing Energy-intensity of Energy Services

As noted throughout GEA, much of humanity requires a dramatic expansion of energy services. For sustainability, this expansion must coincide with a significant reduction in the energy intensity of these services. Even with such a reduction, the global energy system is likely to grow significantly by mid-century as the global population and the per capita energy demand of the billions of people with minimal energy services continues to grow.

A reduction in energy intensity can occur in basically four ways. First, even without a technological change it is sometimes possible to reduce

4 See also Chapters 8–14.

energy use while retaining an energy service at a given level. For example, it is possible to design urban form and land use so that total or average commuting distances are decreased.

Second, there may be cases where people can be helped to find ways in which their quality of life can be sustained even while their demand for certain energy services actually declines. An example would be encouraging people to adopt indoor thermal comfort zones ranging from 18–26°C, with people living in hotter climates allowing warmer temperatures and people in cooler climates allowing cooler temperatures instead of keeping temperatures at a fixed level. Another example would be reduced consumption of meat, since less energy is required to produce most non-meat foods. For an increasing number of people in rich countries, reducing meat consumption is a dietary change associated with improved health.

Third, a shift to more energy-efficient technologies will reduce energy use per capita, everything else held equal. Of course, there is a challenge with more efficient technologies in that they tend to have higher up-front costs and energy service demands will increase (the rebound effect) as the operating costs of providing these services fall. Well-designed policies may be able to reduce this likelihood, which usually involve price changes that reinforce the goal of reducing energy use.

Fourth, a restructuring of the economy toward services, more recycling of materials, and cascading uses of energy, and away from material- and energy-intensive inputs and final products can all help to reduce energy use for a given level of energy services.

The following prominent policies can contribute to these four ways of reducing energy intensity:

- *GHG emissions pricing* in the form of carbon taxes and/or cap-and-trade schemes that raise the price of energy and make it more profitable to reduce energy use;
- requirements that prescribe *community energy management* by municipal authorities, involving coordinated efforts to reduce energy use via land-use zoning decisions, development permits, and siting requirements, and the link to public transportation and other infrastructure planning and development – including an overall goal of reducing the need for private vehicle use, especially in urban settings (transportation demand management);
- *education programs* by governments, utilities, non-governmental organizations (NGOs), industry, the media, academics, and others to foster a conserver lifestyle with respect to energy and material throughputs;
- government *energy efficiency information and subsidy programs* for all types of equipment, appliances, products, and buildings. When efficiency programs involve subsidies, they must be carefully designed and monitored to reduce the likelihood of high free-rider rates, even though some degree of free-riding is inevitable. Revolving green funds for energy efficiency investment can provide a subsidy in the form of low-interest capital that is mostly recaptured through payments by the recipient as their energy bills are reduced through efficiency;
- in the case of electric, gas, heat, water, and sewer utilities, efficiency programs administered by the utilities themselves, called *utility demand-side management*, that might be motivated and applied relatively efficiently by regulations that entail tradable mechanisms, such as tradable energy efficiency performance standards or certified amounts of energy saved (referred to in Europe sometimes as "white certificates");
- *building code* changes that, over a specified time period, set increasingly stringent requirements for new and retrofitted structures in terms of energy use and emissions. This should affect all buildings and structures in residential, commercial, institutional, and industrial sectors;
- *efficiency regulations* that set an aggressive but reasonable phase-out schedule for the market availability of less energy-efficient industrial equipment, household appliances, transportation vehicles, and other equipment;
- *professional training* of architects, engineers, designers, and installation contractors in methods and installation of energy-efficient devices;
- use of *public procurement* and co-operative procurement of energy-using devices as opportunities to create a first market for energy-efficient products and building concepts, or increase the market volume for the best already in the market;
- *funding and encouragement of research, development, and demonstration* of more energy-efficient solutions;
- regulations that prohibit the sale of products and equipment that use energy when not in operation (called *standby power or phantom power regulations*);
- regulations that *limit the use of packaging* in retail sales that has substantial energy implications in terms the cumulative effects of production, distribution, and transportation of goods;
- in addition to increasing the retail price of various forms of energy to reflect environmental costs, utilities should be mandated by government or by independent regulators to establish tariffs that price marginal energy use, such as peak electricity or the last units consumed in a billing period, at its marginal cost of production. This form of *non-linear pricing*, also called marginal cost pricing and time-of-use pricing, tends to provide a further incentive for reduced energy

use, especially in jurisdictions where the long-run cost of new supply is higher than the average present costs of operating the electricity system. For residential and commercial customers, this might be associated with the widespread distribution of rates that rise with greater energy use per billing period and/or rates that reflect peak and off-peak costs of service. And where the ability of low income customers to pay is also a concern, non-linear pricing can be combined with lifeline rates as a form of cross-subsidy between customers; and

- governments, especially at the municipal level, provide *transit pricing options*, such as a subsidized annual transit pass, that motivate commuters to rely on public transit for commuting and many other mobility needs.

In order to ensure that these policies are meeting the desired goals, governments must set targets for reducing energy intensity, assess the amount of energy saved through each policy, and monitor the progress toward meeting these targets.

22.2.9.2 Accelerating the Growth of Renewables

Although depletion of low-cost fossil fuel resources may lead to rising average prices for oil, natural gas, and perhaps even coal over the next decades, one cannot assume that energy markets will, as a consequence, rapidly shift the global energy system to renewables from its current 80-–85% fossil fuel dependence. First, as long as a relatively plentiful resource like coal can still use the atmosphere as a free waste receptacle for GHG emissions, this resource will remain highly competitive with renewables for the production of electricity and even vehicle fuels. Second, incumbent technologies, such as those using fossil fuels, benefit from path dependence, in which society's technological, social, and institutional capacity is geared toward the continued success of that technological path. Third, in the same vein, renewables face many barriers to massive scale-up, some of which relate to overcoming the path dependence in favor of fossil fuels, others of which relate to the specific characteristics of renewables – namely, that frequent low-energy density implies significant claims on the land base and that their intermittency requires additional, costly investments for energy storage.

For these reasons, policies to induce a rapid scale-up of renewable energy must: (1) ensure that renewables are economically attractive for investors; and (2) ensure that non-cost barriers to renewables are reduced. Policies to price GHG emissions such as taxes and cap-and-tradable permits increase the financial attractiveness of renewable energy. These policies are constrained, however, in that it is politically difficult in developed countries, and even more so in developing countries, to burden energy users with rapid energy price increases in a relatively short timeframe. This explains why jurisdictions have also provided targeted subsidies (feed-in tariffs) and market share regulations (renewable portfolio standards) to support renewables, in addition to GHG pricing initiatives. As for the non-price barriers to renewables, policymakers are increasingly realizing that these are also very important and have started to focus policy efforts on issues like regional land-use, including planning for siting hydropower, wind, and solar facilities; urban land-use, including solar access laws, siting of buildings, and building codes for solar hot water and passive solar heating and cooling; utility regulation, for transmission expansion and connection rights; and even technical training and education. Below are some key policies.

- *GHG emissions pricing* via carbon taxes and/or cap-and-trade schemes provide the clearest means of fostering renewables since these will raise the relative cost of GHG emitting forms of energy. Revenues from emissions pricing can be recycled to firms and households as income tax cuts or additional government program expenditures, but they could also be used to support emerging renewables technologies.

- *Feed-in tariffs* for renewables guarantee prospective independent power producers that all power they generate will be purchased by the grid at a fixed price. If the price is adequate, this provides a powerful inducement to equity and debt financing and explains why jurisdictions with feed-in tariffs have mostly had success in rapidly expanding renewables-based electricity generation. Feed-in tariffs may also be tailored to different renewable technologies according to their costs.

- *Market share mandates* provide a guaranteed market share for renewable energy, but they do not guarantee a price. They operate by creating confidence for investors in a steady and growing market for renewable energy. In the case of electricity, such mandates are commonly known as Renewable Portfolio Standards (RPS). Most market share standards offer the same credits to all eligible technologies, which tends to benefit the most commercially competitive technology, such as wind or corn-based ethanol, while providing no support to emerging technologies. In part for this reason, many renewables advocates argue that the feed-in tariff is a more effective policy. However, it is possible to create "tranches" for minimum shares for different forms of renewables or different types of technologies – such as a minimum market share for solar PV electric and a minimum market share for solar thermal electric.

- *Biofuel mandates* set a minimum content for fuels from biomass in gasoline, diesel, and perhaps eventually other fuels like heating oil and jet fuel.

- *Performance standards*, or intensity standards, set a maximum emissions content per unit of energy. These standards can also be tradable, leading to an average emissions content. An example in the renewable fuels context is low carbon fuel standards. While market share mandates may be effective in expanding renewables, they do not distinguish among the carbon, or other performance, of alternative fuels, be they renewable or non-renewable; if the ultimate goal is reducing emissions or emissions intensity, tradable performance standards are more effective. However, it may be noted that

measuring the carbon performance of renewable fuels remains controversial.

- *Regional land-use and water-use planning* is important for scale-up of some renewables because of the potential land-use conflicts that renewables introduce. This might include river basin planning with hydropower, coastal zone planning with wind farms, land-use planning for concentrated solar power and biomass energy, and water-use planning for biomass energy. It is important that society understand that all energy options involve impacts and risks and to this end local communities must have meaningful participation in both regional planning and energy planning.

- *Electric transmission regulation and infrastructure planning* must focus on maximizing the opportunities for renewables. This includes transmission expansion that is tailored to the location of renewable resources and grid connection rules that address the particular needs of renewables.

- *Urban land-use zoning and infrastructure planning* are critical in removing barriers to decentralized renewables, via solar access rights, wind turbine siting rights, grid connection rights, and other key laws and policies.

- *Zero- and low-emission vehicle standards* can mandate a rising market share for vehicles fuelled by alternatives to end-use combustion of gasoline and diesel, such as biofuels, hydrogen, and electricity, all produced with zero- or low-life cycle GHG emissions.

- *Zero- and low-emission building standards* can mandate a rising market share for buildings that rely exclusively or almost exclusively on passive and active renewables and waste heat for heating, cooling, and ventilation.

- *Electric distribution utilities* must facilitate decentralized renewables electricity production via net metering, smart grids, and other policies.

- *Information programs, education, and other forms of capacity development* have a role to play in accelerating the growth of renewable sources of energy.

Similar to policies designed to reduce energy intensity, governments must set targets for the growth of renewable energy, assess the amount of energy supplied through each policy, and monitor the progress toward meeting these targets.

22.2.9.3 Transitioning to Cleaner Uses of Fossil Fuels

The global energy system is dominated almost everywhere by fossil fuels, but the global endowment of fossil fuels is uneven. Some countries have negligible fossil fuel resources and are thus prime candidates for a transition to renewables and – possibly – nuclear, and some, like Sweden, France, and Brazil, are already moving down this path. However, countries with rich fossil fuel endowments are less willing to consider abandoning this high energy-density resource and are thus increasingly interested in technological developments that may enable continued use of fossil fuels, albeit with low or zero emissions of pollutants and especially GHGs.

This latter step requires converting fossil fuels into electricity, heat, and perhaps hydrogen while capturing and permanently storing the carbon, mostly in the form of CO_2, probably in geological formations deep in the earth. Carbon capture and storage (CCS) is expensive and will not occur without policies that price GHG emissions. Again, because of political constraints on GHG pricing, the zero- or low-emission use of fossil fuels will require additional support. Some of the following leading policies have already been enacted on an experimental basis, but these efforts would need to be intensified significantly over the next decades to realize a dramatic shift to low- and zero-emission uses of fossil fuels.

- Governments, as noted above, can implement *GHG emissions pricing* via carbon taxes and/or cap-and-trade systems. These will reduce the use of fossil fuels but also foster commercialization efforts with CCS in some jurisdictions, enabling societies to assess with less uncertainty the viability and acceptability of this option.

- Governments can *reduce all subsidies to conventional combustion of fossil fuels, which will improve the relative competitiveness of renewables and nuclear alternatives*. This includes fuel price subsidies, subsidies to private vehicle use for urban and inter-urban travel (untolled roads), especially if fuelled by gasoline and diesel from fossil fuels, and a host of subsidies to industrial, commercial, institutional, and other combustion uses of fossil fuels.

- Governments can provide demonstration and commercialization subsidies, allocated via competitive bidding perhaps, for the initial, high-risk investments in CCS.

- Some cap-and-trade systems for emissions pricing allow firms to pay into a *technology fund* for those emissions that exceed permits. These funds can be used alone, or in concert with other government subsidies, to support early CCS projects.

- Governments can offer to *pay above-market rates* for electricity, heat, or hydrogen from projects that produce these from fossil fuels with CCS. This would be similar to the feed-in tariff for renewables.

- Governments or utility regulators could *ban construction of new coal-fired electricity plants* that lack CCS or that are not "CCS ready." Some jurisdictions in developed countries have explicitly adopted this policy. Some utility regulators in the United States and elsewhere have implicitly adopted the policy by disallowing coal-fired

plants under the basis that they pose financial risks for ratepayers from future increases in GHG emissions prices.

- *Emissions performance standards* can give electricity generators the option to reduce emissions per unit of electricity either by a growing share of renewables and/or nuclear or by a growing reliance on CCS.

- *Life cycle carbon fuel mandates* can give fuel retailers the option of reducing the net GHG emissions from fuel use by increasing the content of biofuels or perhaps by including some hydrogen that is produced from fossil fuels with CCS.

- *Land-use planning* can facilitate socially and environmentally acceptable siting of underground carbon storage and CO_2 pipelines. There is also a need for land-use planning to safeguard against potential impacts of carbon storage on other uses for the subterranean, such as geothermal energy, or at least consider a balance between the possible uses.

- Governments need to *legally clarify geological rights* to underground pore spaces for CO_2 storage.

- Governments need to *establish short- and long-term liabilities and risk management and monitoring responsibilities* at CO_2 storage sites and on CO_2 pipeline right-of-ways.

22.2.9.4 Fostering the Safer Use of Nuclear Power

Views on the value and risks of nuclear power differ greatly and are often polarized. Some see nuclear power as a risky technology whose potential harm far exceeds any possible benefits it might provide, such as low GHG emissions. These perceived threats from nuclear power include catastrophic accidents at nuclear plants, either through operational failures or terrorist attacks, inability to safely transport and permanently store radioactive wastes, and the exploitation of civilian nuclear expertise for the proliferation of nuclear weapons.

Depending on the severity of these concerns about nuclear power, its regulatory burden for design, permitting, operation, and decommissioning can be such that nuclear power is a high-cost option for electricity generation. However, where local, national, and/or international public policy is able to allay these concerns, then nuclear power can be a competitive energy option. But everything hinges on risk preferences among the public and decision-makers, particularly with respect to trading off the extreme event risks of nuclear power with the ongoing impacts and risks of its alternatives. The following policies, therefore, focus on how to ensure safe use of nuclear power that is both real and perceived.

- At the international level, governments and the nuclear industry need to continue to improve the *mechanisms for monitoring and controlling the use of nuclear power* and the reprocessing of nuclear fuel to prevent the acquisition of expertise and materials for nuclear weapons production.

- Governments need to collaborate in the *establishment of permanent storage sites* for radioactive materials.

- *By facilitating collaborative investments*, governments can help the nuclear industry settle on two or three dominant designs that have the best chance of achieving regulatory approval and should thus reduce regulatory costs, which have been very high in jurisdictions like the United States.

22.3 Part II: Policy Portfolios for Sustainable Energy

22.3.1 Implementing Policies for Sustainable Energy

So far, this chapter has presented a summary of policies required to achieve the sustainable energy pathways of GEA. While these pathways are described in detail in Chapter 17, policies for sustainable energy are spread throughout GEA. This section provides further guidance on policies that are essential in some form, depending on the jurisdiction and its particular goals and challenges.

Throughout GEA, the issue has been raised that there is an urgent need to identify and promulgate key criteria that can be used to select the type and intensity of sustainable energy policies that are required to make rapid progress toward universal access to energy and a rapid transition to a cleaner, less risky global energy system.

There are two important characteristics to note about energy-related policymaking. First is the importance of understanding policymaking as an organic, iterative process. Policymaking must be a continuous learning exercise since one can never predict precisely how a policy will work. Thus, policymakers need to think experimentally when designing and implementing policies. This might mean, for example, deliberately creating real-world variations by implementing different policies or policy variants in different locations within a given jurisdiction in order to generate more useful data on policy effectiveness. To this end, the steps of policy monitoring, policy evaluation, and policy redesign are essential to good policymaking.

The second is the critical role of institutions and governance. Without effective institutions and governance practices, policies have little chance of success. Assessments of policy design and policy effectiveness cannot be divorced from efforts to improve governance. This includes: (1) increasing transparency and public involvement to reduce the risks of corruption; (2) developing higher standards for education; (3) monitoring and evaluation of the civil service; (4) ensuring effective, independent controls by the legal system; and (5)

strengthening the policymaking functions of democratic processes in various ways.

This section outlines policies that can achieve the eight goals for sustainable energy policy discussed earlier in this chapter. Again, these are:

1. increase energy access;
2. develop capacities for energy transitions;
3. enhance energy security;
4. manage energy-related market power;
5. manage valuable energy resource endowments;
6. reduce environmental and human health impacts;
7. accelerate the rate of energy-related technological change; and
8. coordinate and implement international energy-related policies.

Each of the goals demands its own unique policies, but policies must be implemented in a coordinated, integrated, and mutually consistent fashion. Chapter 17 presented pathways for achieving these goals in terms of the contributions from different actions, such as increased energy efficiency, switching to more desirable fuels and technologies, better prevention and control of pollutants, and stimulating major investments to increase energy access and improve energy security. The pathways include: (1) one that strongly emphasizes energy efficiency; (2) one that focuses on a cleaner, more sustainable energy supply mix; and (3) one that is a mix of these two contrasting strategies.

The policies presented here have been selected to ensure achievement of the GEA pathways. A dominant focus is the substantial, coordinated effort required for making major economy-wide advances in energy efficiency. This includes focused, somewhat aggressive policies. Such policies are needed to induce rapid innovation, tighten efficiency regulations in energy supply and demand, and increase energy prices. The policies must create a culture of conservation among consumers and firms, change land-use zoning to increase urban density, and integrate mixed land-uses so that transportation service demands decline while low energy-using transportation modes flourish.

Achievement of greater energy efficiency, alongside a rapid increase in the use of renewable energy, cannot be pursued in isolation. These goals must be intrinsically linked to broader social and economic development goals on the one hand and to environmental protection and restoration goals on the other. Providing adequate access to modern forms of energy is a critical contributor to social and economic development that can substantially improve the standard of living of the most disadvantaged people on earth. At the same time, a rapid transition to an energy system with negligible greenhouse gas emissions is critical for preventing destabilization of the earth's climate system.

At the policy level, a similar relationship exists. Energy-focused policies must not be conceived and implemented in an isolated fashion, but instead coordinated and integrated with non-energy policies for socioeconomic development and environmental protection. These latter include policies that foster sustainable urban areas, preserve forested land and biodiversity, reduce poverty, provide environmentally acceptable transportation of goods and people, ensure vibrant communities, and improve human health.

An emphasis on policy integration is a common theme throughout GEA. This explains why the Millennium Development Goals are a key consideration in the design of policies for energy access, capacity development, clean energy for households, and emissions reduction at the urban and regional levels. It also explains why broader development goals that push for accelerating the rate of energy technology innovation are a key consideration in the design of policies.

While virtually every chapter in GEA provides specific policy suggestions, this chapter and the following three (Chapters 23–25) focus especially on issues related to policy design and implementation. The section that follows combines policies from these chapters with policies found throughout GEA to produce a portfolio of policies associated with the sustainable energy pathways of Chapter 17.

To this end, the following is divided into three sections. This section, Section 22.3.1, provides a portfolio of key energy policies to address the eight major energy policy goals identified in GEA. Section 22.3.2 provides a set of policies focused especially on energy efficiency. They explain how additional policies could intensify energy efficiency efforts in order to meet the aggressive targets of the most ambitious efficiency-focused pathways. Section 22.3.3 summarizes the links between policy objectives, policy types, and investments required for the rapid transformation of the global energy system. This transformation necessitates a rapid increase in energy access in the developing world, improvements in energy security in all energy systems, and, finally, the adoption of energy technologies with much lower environmental and human impacts.

This section does not recapitulate the long list of policies contained throughout GEA, which is a very large list with, at times, specific recommendations for specific situations from social, cultural, technological, and geographic considerations. Instead, what is provided is a summary of the salient policies associated with each of the key goals, in general, and a rather precise set of policies necessary to achieve the ambitious energy efficiency improvements described in Chapter 17, in particular. Thus, these policies are not distinguished by level of economic development, type of political system, institutional arrangements, or other critical factors in real-world policy design, implementation, and review.

For case studies, literature references, and arguments to defend specific policy designs, readers can refer to the policy chapters (Chapters 22–25), as well as to specific policy discussions in individual chapters throughout GEA, depending on their specific area of interest.

22.3.1.1 Increase Energy Access

As explained in Chapter 23, because increasing access to modern forms of clean, affordable, and efficient energy is an issue of equal importance to both developed and developing countries, in urban slums as well as rural hinterlands, there is no single set of policies that can increase energy access. The following portfolio of policies was put together with developing countries particularly in mind, where access to energy tends to be lower than in developed countries. While these policies are energy-focused, their effectiveness depends on coordination with broader policies in pursuit of social and economic development – investments in education, human health, poverty reduction, social and cultural support, sound institutions, and effective government.

- Competitive bidding to allocate funds to private, public, or cooperative grid owners or managers to extend high voltage transmission lines to unserved regions or communities and to extend low voltage distribution lines to unserved households via low hook-up fees. Funding could come from government or utilities.

- Competitive bidding to allocate funds to private, public, or cooperative enterprises to provide electricity services in isolated communities or regions that are too remote for connection to the grid. This may involve subsidized installation of household devices, like solar arrays, or larger community-based systems that may use any type of renewable energy or perhaps low-carbon fossil fuels and may cogenerate electricity with heating and/or cooling services.

- Lifeline rates that ensure a basic low price for an initial quantity of electricity, with higher rates for additional amounts.

- Electric utility tariffs that provide cross subsidies from one rate class of electricity customers to another to ensure electricity access for the poorest customers. Utility funds could be augmented by public sources of revenue.

- Public funding (grants, micro-financing) for the acquisition of stoves, heaters, and other devices that use clean-burning gaseous and liquid fuels or that can combust solid fuels (coal, charcoal, biomass) without deleterious emissions that adversely affect indoor air quality or the air quality in sensitive urban and rural airsheds.

22.3.1.2 Develop Capacities for Energy Transitions

Energy capacity development does not achieve energy transitions via a few simple policies (see Chapter 25). It requires a holistic approach that recognizes the complex interconnection of capabilities, habits, and norms of actors at all levels of the energy system. This is why Chapter 25 introduces the capacity matrix as a tool for conceptualizing how capacity development from a broad systemic perspective can play a critical role in energy transitions. It is also why there is considerable regional disaggregation in Chapter 25 – to reflect differences in cultural norms, technical skills, and access to information, not just between developed and developing countries, but also depending on the specific attributes of a given continent, region, country, and even sub-national locales.

- An energy capacity strategy must be tailored to the specific characteristics of a given location if it is to succeed in provoking a rapid transition of the energy system toward a more sustainable path. While this strategy would address basic needs for education and training, it should also be adapted to the cultural norms and practices of that location.

- Developed countries need to improve mechanisms for supporting capacity development in developing countries, including financial support, technical training, sharing of industry, trade, institutional experiences, and public education.

22.3.1.3 Enhance Energy Security

Policies by different levels of government and different institutions all have a role to play in helping reduce or respond to energy security concerns. Energy security concerns are categorized in Chapter 5 as structural, sovereignty, and resilience. Policies to address systemic risk emphasize improved management of energy system design and operation. Policies to address risks from foreign sources emphasize avoiding or mitigating external control of energy supply or hostile actions that might disrupt supply from external sources. Finally, resilience or robustness of an energy system is a critical attribute for improving energy security prospects.

While energy security is often presented as a focus of industrialized countries, where a high level of reliability is essential for modern communications and production systems, it is also of great importance for developing countries. Micro-enterprises that lack back-up self-generation are particularly vulnerable to blackouts that are a daily occurrence in many parts of the developing world. The recommendations below are designed to address these various energy security risks.

- Electric utilities should make timely supply additions and provide regular system maintenance to ensure adequate reserve capacity and back-up generation to reduce the chance of unprovoked system failure.

- Regional cooperation can play a vital role in ensuring energy security in a sustainable manner. Energy trading can help meet energy demand while maximizing scarce natural resources in the sub-region. By utilizing different peak times of neighboring countries, regional power trade can reduce the need to build new power plants in each country. Transmission interconnections that enhance reliability by allowing for exchanges between contiguous

grids should be developed up to the point where their marginal potential benefits in terms of risk reduction equal their marginal costs of provision.

- Electric system operators should provide tariffs and foster technologies that reward generators and consumers who can modulate their electricity flows in to and out of the grid in immediate response to signals from the operator.

- Diversity of primary energy supply should be pursued when the costs of additional diversity are likely to be below the expected benefits depending on an assessment of contingent reliability risks. This desired diversity may be by energy form (reduced reliance on oil or some other form of energy) or by supplier (reduced reliance on supplies from one region or country).

- National governments could develop alone, or in concert with other governments, mechanisms to stockpile energy resources that have significant risks of supply disruption or price volatility so that they can release these into the market (domestic or international) at times of scarcity, thereby reducing price volatility and supply insecurity.

- During periods of unusually high energy prices, governments may decide to protect the most vulnerable users from extreme energy price increases, but they should be careful not to completely constrain prices for energy suppliers and users as this would mute market responses (increased supply, decreased demand) that are normally triggered by high prices and that eventually lead to a new equilibrium of secure supply at prices that may be acceptable even if somewhat higher than before.

- When it can be shown to increase energy security at a reasonable cost, governments could push for an increased share of local energy supply through incentives such as tax advantages, regulatory flexibility for municipalities to encourage distributed and decentralized energy supply, and grants and loans for feasibility studies and capital costs related to district energy systems, as well as support for knowledge and technical capacity building.

22.3.1.4 Manage Energy-related Market Power

Significant economies-of-scale in some parts of the energy system – transmission and distribution of electricity and natural gas, oil pipelines, district heat networks – mean that market power can be socially desirable from an economic efficiency perspective. In such natural monopoly cases, the policy challenge is to regulate public or private monopolies so that their market power does not distort upstream or downstream phases of the industry where competition may be effective, such as oil and gas production, electricity generation, retail energy commodity markets, and energy service markets. In other parts of the energy system, economies-of-scale do not create natural monopoly conditions, but they make it likely that the industry will be dominated by a few large firms. The petroleum industry is especially known for oligopoly forms of market power, which may call for various policies to protect the public interest.

- Whether transmission and distribution monopolies are publicly or privately owned, oversight by an independent monopoly regulator is likely to be in society's interest. The regulator should have expertise in economics, engineering, accounting, and environment and the authority to review for prudent utility decisions about investments, rate levels, rate design, and associated environmental and social trade-offs.

- Government and/or the monopoly regulator should ensure that monopoly power in one phase of an industry does not confer power over other levels of the industry, especially if competition is desired for these levels. This requires a separation of grid operation and regulation from electricity generation activities, even if this separation is more functional than corporate and even if some aspects of electricity generation are still treated as a natural monopoly.

- Government and/or the monopoly regulator could require the monopoly to play a role in delivering energy efficiency programs and increasing public awareness of economic, environmental, and social considerations in business and household choices of technology and lifestyle that affect energy use. Alternatively, another entity could be given responsibility for energy efficiency.

- If governments pursue competition in electricity generation they need to understand the special nature of electricity, in particular the need to balance all demand and supply on the grid instantaneously. An authority should be created to administer the competitive market, regulate electricity supply and demand, and prevent the short-term exercise of market power in ways that cause dramatic price spikes to the detriment of some customers.

- Government and/or the monopoly regulator need to make sure that the electric monopoly has the capability and authority to plan and operate the grid in an economically, socially, and environmentally sustainable manner. This capacity increases in importance with the need for dramatic transformation of electricity supply – for instance, many small-scale, decentralized generators, some of them located in urban areas, some in isolated regions that are favorable to renewable electricity generation – and electricity demand, such as smart meters that communicate between private energy-using devices and the grid operator, and electricity generation downstream of the meter in private buildings.

- In non-monopoly cases of market power, as sometimes occurs in electricity generation, oil and gas industries, anti-trust regulatory policies must be strong enough to ensure that a few large firms cannot: (1) distort markets in ways that reduce long-run energy security;

(2) allow industry to capture excess profits from consumers via price inflation; or (3) interfere in some way with effective governance. Where the firms are associated with a particularly valuable energy resource like petroleum and natural gas, policies are also required to effectively manage this public endowment (as outlined in the next Section 22.3.2) and provide a competitive environment to promote private sector investment.

- Market power sometimes equates to political power – the ability to influence public policies in favor of a particular industry or firm. Subsidies are one manifestation of this power. While subsidies are sometimes a valuable policy tool for advancing economic and social objectives, governments must be vigilant over time that subsidies not work at cross purposes to other objectives and do not become entrenched long after their justification has passed.

- The policy portfolio should seek to eliminate or substantially reduce subsidies, such as tax breaks and royalty reductions, which work at cross-purposes to overall policy goals. For example, if the intention is to reduce reliance on fossil fuels, subsidies to oil and gas exploration and development should be eliminated, as should subsidies to the coal mining industry.

22.3.1.5 Manage Valuable Energy Resource Endowments

Depending on market conditions and international prices, petroleum and natural gas can provide massive revenue streams in countries that are particularly well endowed with these premium sources of energy. While these lucrative rents could be a short- and long-run benefit to society, this is not always the case. Sometimes the resulting rent-seeking behavior contributes to corruption and poor governance – the resource curse – and the boom and bust cycle of commodity prices swings the economy from periods of excess wealth and waste to periods of severe recession. Policies are needed to manage the revenues in ways that maximize the long-run benefits from valuable resource endowments and prepare the economy for the time when these resources are depleted or lose their value. Also, the influx of foreign investment capital pushes up the value of the currency, threatening the survival of other domestic industries. Policies are needed to help these other domestic industries survive if they have the potential to provide sustainable benefits to the economy.

- Policies should control the rate of resource exploitation so that its demand for labor and capital (with resulting inflationary effects) does not irreparably undermine other sectors of the economy (e.g., renewable resources, technology, and services) that otherwise have good prospects of providing value long after the resource is depleted.

- Policies should maximize the collection of economic rents (surplus profits) from the resource for present and future generations. Rents can be captured via royalties and income taxes on private firms and/or by a significant role for state-owned energy companies. In the latter case, management incentives and transparency are necessary to ensure that these companies are efficiently operated and accountable.

- Some part of resource rents could be streamed into sovereign wealth funds that are invested domestically and abroad in an effort to maximize the stream of expected benefits to future generations. This means a balanced portfolio of riskier and safer investments. Foreign investment with these funds can also help reduce upward pressure on the value of the currency, thus helping other domestic industries stay competitive. A poorer country will want to invest more of the rents domestically in infrastructure, education, and social services for the present generation, as this is likely to offer good potential for benefiting present and future generations. But resource rents should rarely be used to subsidize domestic energy prices, as this only dissipates the rent in inefficient current energy use.

- Some of the resource rents could be used to help the economy smooth out the boom-bust cycle of commodity prices. But such efforts should be limited and cautious, since it is impossible to know whether future resource prices will be higher or lower than current levels. These rents can also be used to sustain an economy once the resource is depleted.

- Policies should ensure transparency of resource rent flows and the budgets of government ministries, state-owned operations, and foreign resource companies in order to minimize the opportunities for rent dissipation through corruption. An example is to use principles from the extractive industries transparency initiative.

- Collected resource rents can also be used to repair environmental damage and can be allocated to communities most negatively affected by resource exploitation.

22.3.1.6 Reduce Environmental and Human Health Impacts

Energy supply and use involves a wide range of risks and impacts on humans and the environment. Energy use plays a large role in poor urban air quality and poor indoor air quality from open burning of solid fuels, which negatively affects human health. Energy extraction and processing can have substantial and sometimes devastating effects on the landscape and on soil and water resources. And, increasingly, the role of the current energy system in increasing atmospheric concentrations of greenhouse gases will cause rapid destabilization of the planet's climate, weather, water resources, and ecosystems, as well as human land-use and their social and economic systems.

While some of these energy system effects are known and fairly predictable, others present risks with very high uncertainties, which complicates and hinders the development of collective actions to reduce

environmental and human risks. A sustainable energy policy portfolio would, at a minimum, include the following elements.

- A mix of regulations, information programs, and subsidies are needed to stimulate the rapid adoption of household energy using devices (stoves, heaters) that have virtually zero indoor emissions. While fuel subsidies may be used in a limited fashion, it is generally preferable to provide subsidies and low-cost financing for the acquisition of equipment, such as efficient, zero-indoor-emission stoves (using gaseous, liquid, or solid fuels) and efficient electric light bulbs to replace the indoor combustion of kerosene and other fuels for lighting.

- Urban air quality must be protected or restored by regulations on emissions from fuel combustion in buildings, industry, and vehicles in urban settings. Some regulations may be highly prescriptive (specifying combustion technologies such as the use of catalytic converters, restricting certain fuels, or requiring connection to district heating and cooling systems), while others may focus on the absorptive capacity of a given urban airshed for a particular pollutant. The latter case could involve the establishment of airshed emission limits, perhaps involving a cap-and-trade system. Or, it could involve the establishment of emission taxes of some kind.

- As with urban air quality, regional air quality must be protected by technology and/or emissions regulations or by direct emissions pricing. Again, some form of cap that is directly related to absorptive capacity has the best chance of meeting environmental objectives. A cap-and-trade system can, however, be difficult to achieve, depending on the complexity of emissions sources and the administrative capacity of the institution that will administer and oversee the trading system.

- Extractive activities and land/water uses – e.g., coal mines, oil and gas fields, hydropower dams, diversions and reservoirs, nuclear plants, storage sites for radioactive wastes and captured carbon dioxide, wind farms, solar electricity farms – should be subject to a permitting and regulatory framework that assesses their benefits against a precautionary consideration of their impacts and risks. In some cases, this may result in regulation and controls placed on the activity in order to reduce impacts and risks and, in some cases, in the complete rejection of the activity.

- Policies are needed to accelerate the development of renewable forms of electricity generation. These include possibly a feed-in-tariff that provides a minimum price for electricity from renewable sources and/or a renewable portfolio standard that sets a minimum but growing market share for renewable electricity. In order to maximize the effectiveness of a feed-in-tariff, it should identify the source of funding and have a clear sunset provision that pushes project developers to lower the cost of power.

- Policies fostering energy from biomass should recognize the trade-off between biomass-for-food, biomass-for-fuel, and the conservation of biodiversity. Subsidies to corn-based ethanol have encouraged inefficient production of biofuel with greater than necessary pressures on food prices. Better policies would encourage the use of biomass residues and only the most efficient biomass feedstocks and conversion processes.

- Policies to foster the safe development of nuclear power can help reduce the reliance on fossil fuels and associated greenhouse gas emissions. But development of nuclear power requires an integration of policies for developing technological and institutional capacities for producing nuclear power in a given country. It also requires ongoing development of existing international institutions and processes for ensuring that nuclear technology is not diverted to weapons production.

The following policies focus on key, specific sources of greenhouse gas emissions, namely fossil fuel use in industry, buildings, the transportation sector, and the generation of electricity.

- GHG pricing (via cap-and-trade and/or carbon tax) provides the essential major long-run mechanism by which energy systems gradually shift toward low carbon emission technologies, fuels, and activities. However, policies are also required that drive initial development of new technologies that must pass scale-up thresholds to the point where experience and learning drive down costs and accelerate adoption. Major public subsidies may drive early development of carbon capture and storage from large point-sources of GHGs, such as coal-fired electricity plants, oil sands plants, coal-to-liquids plants, and some industrial plants. Another approach is to apply niche market regulations that require specific sectors to gradually increase the percentage of carbon they process that is captured and stored, called a carbon capture and storage performance standard. The goal of such an approach is to create incentives for the pursuit of an increasing number of profitable CCS projects.

- Governments must use targeted policies to swiftly overcome a lack of regulatory clarity and challenging financial barriers if they want to succeed in CCS deployment on a commercial-scale. Key policies include: (1) allocating public funds to a number of different industries to share in the initial, high-risk investments associated with the first commercial CCS projects; and (2) developing a regulatory environment conducive to CCS in terms of property rights and liabilities. For instance, governments or utility regulators could prohibit construction of new coal-fired electricity plants that lack CCS or that are not CCS-ready. Such a policy approach would occur initially in developed countries with a lagged application, along with funding support, and in developing countries as part of an international agreement. Furthermore, the creation of CCS-specific measurement and crediting protocols will be key to ensuring that CCS projects are as tradable or valuable under national GHG regulatory frameworks as other qualifying emission reduction options.

- Governments need to develop property rights and regulatory policies that clarify short- and long-term management responsibilities and liabilities for geological storage of carbon dioxide, just as they have established these for the storage of other undesired gaseous and liquid by-products.

- Regulatory policies (e.g., land-use zoning, building codes, development permitting, and local emission standards) are needed to drive a shift toward low- and zero-emission buildings. In some cases this can be done in concert with low- and zero-emission decentralized energy supply. New urban developments should be required – initially most stringently in developed countries – to be low- and zero-emission of local air pollutants and GHG emissions via the local production of energy from solar, wind, biomass, and other sources and through import of energy from zero-emission external sources. These requirements could be gradually phased in to drive the retrofit of existing buildings and redevelopment of existing urban areas.

- Vehicle emission standard policies can require manufacturers and retailers to achieve minimum levels of sales of low- and zero-emission vehicles. This can start at modest percentages initially to allow the establishment of a niche market that enables learning and experience to lower production costs, but it should be enabled to grow substantially over the next two decades toward market domination. Alternatively, vehicle emission standard policies can set average emission standards for new vehicles.

- Similar niche market emission standards should be applied to other modes of transport, namely buses, trucks, off-road vehicles and mobile equipment, boats, trains, and airplanes.

22.3.1.7 Accelerate the Rate of Energy-related Technological Change

Some of the previous sections include policies that would help to drive rapid technological change. These include an economy-wide GHG emissions price that changes the incentives for innovation of new technologies and for their adoption. Also promoted are certain types of regulations, such as renewable portfolio standards and other niche market regulations for low- and zero-emission vehicles, which also help motivate industry to innovate and market technologies with desirable attributes from an environmental or social perspective.

In this section, it is reiterated that policymakers should ensure that a sustainable energy policy portfolio consistently applies an innovation system perspective, which will be further emphasized in Chapter 24.

- A sustainable energy policy portfolio should combine supply-push and demand-pull policies to ensure that adequate resources are available for innovation. This means, for example, subsidies, tax credits, and patents law on the supply side. On the demand side, polices should encourage sufficient market demand to move innovations from the new technology phase to significant initial levels of early adoption, and eventually toward industrial competition. The portfolio should recognize the importance of innovation spillovers, ensuring that technological breakthroughs can be widely applied. It should also ensure that patent law does not hinder rapid innovation.

- Subsidies might be used in some cases to bridge the gap between development and commercialization. But this should be done only when such subsidies are expected to lead to lower costs for technologies that will have a good chance of success in the future energy system in which market prices have been corrected to reflect environmental and social externality costs. From the outset it should be clear that such subsidies are temporary via the use of sunset clauses or other termination provisions.

- A policy portfolio must try to find an appropriate balance between picking winners and letting the market decide. The vehicle emission standard provides an example in that it picks a winner by requiring that vehicles be low-emission or zero-emission, but gives flexibility to innovators and market adopters by not specifying whether such vehicles are driven by electricity, biofuels, or hydrogen. Likewise, the renewable portfolio standard picks a winner by forcing the market growth of renewable electricity, but it lets innovators and the market decide by not specifying which renewables should dominate.

22.3.1.8 Coordinate and Implement International Energy-related Policies

Globalization of the world's economic system goes hand in hand with globalization of its energy system. Prices for energy commodities are increasingly set internationally, starting initially with crude oil but now extending to natural gas, coal, refined petroleum products, and bio-fuels. Even electricity prices are increasingly influenced at the international level within European and North American markets. Political disputes between countries (Israel and Arab OPEC countries; Russia and Ukraine) can threaten energy security and energy prices in far-distant consuming countries. At the same time, the environmental impacts of energy use have become global, especially with the key role of fossil fuel combustion in rising GHG emissions. Finally, international energy policies, as well as international aid, should bear in mind the urgent need for energy access and clean energy in developing countries.

- A sustainable energy policy portfolio must include effective mechanisms by which developed countries can assure a rapid transfer of financial, technological, and institutional resources to developing countries for energy system development and transformation. Key international and multi-national institutions, such as the World Bank, the International Monetary Fund, divisions of the United Nations, and development banks such as the Asian Development Bank, African Development Bank, and Inter-American Development Bank,

must ensure that their policies contribute in a consistent and effective way to all of the key energy policy goals of GEA (access, security, managing market power, environment, etc.).

- A sustainable energy policy portfolio must also include mechanisms by which countries can coordinate efforts to reduce energy price volatility (although it cannot be eliminated). These include diversifying suppliers, stockpiling energy, establishing back-up electricity and fuel supply systems, developing inter-regional electricity and natural gas trade, and discouraging the use of energy as a political weapon.

- At the international level, governments and the nuclear industry need to continue to improve their mechanisms for monitoring and controlling the use of nuclear power and the reprocessing of nuclear fuel to prevent acquisition of expertise and materials for nuclear weapons production. For instance, proliferation resistance could be increased through policies aimed at phasing out reprocessing as rapidly as possible, and placing enrichment plants under multinational management and restricting them to stable regions. Governments need to collaborate in the establishment of regional storage sites for radioactive materials. Design of the repositories should be subject to international standards and oversight to ensure that the import of spent fuel from richer countries to poorer countries would not create undue environmental hazards (see Chapter 14).

- A sustainable energy policy portfolio must include one or more mechanisms to ensure that global concentrations of GHGs in the atmosphere do not reach levels that are highly risky for human and environmental health. These mechanisms could be, for instance, country-specific targets for GHG emissions established through international negotiations based on almost universal agreement. Or, the mechanisms may be targets and obligations negotiated by individual sectors, such as specific requirements for coal-fired electricity plants to gradually incorporate CCS, or for the airline industry to gradually increase the bio-fuel share of jet fuel, or for the vehicle industry to have a rising share of zero-emission vehicles worldwide. As indicated, international coordination is necessary to mitigate emission leakage and other issues that may arise from only a subset of countries being covered by these policies.

22.3.2 Policy Portfolio Focused on Energy Efficiency

Chapter 17 presents scenarios that are distinguished in part by the degree to which energy efficiency contributes to a sustainable energy system. In part three of this chapter, the focus is on presenting the type and intensity of policy effort required to realize a global sustainable energy pathway through dramatically lower levels of energy use.

Since this is not a precise policy modeling exercise, the policies here are not calibrated to the intensity levels that would exactly match the scenarios in Chapter 17. What is presented here, instead, are descriptions of policies that can accelerate energy efficiency trends, along with suggestions on the intensity with which such policies would need to be applied in order to achieve the most ambitious energy efficiency scenario.

It is important to note, however, that achieving an aggressive energy efficiency scenario is not just a question of turning up the intensity on policy levers. If societies are to achieve development paths in which efficient technologies are rapidly innovated and adopted, while at the same time there is widespread acceptance of a conserver lifestyle, there must be social acceptance of energy policies that drive not only technological change, but also changes in some key behavioral expectations. One major example is the ownership and rate of use of private vehicles. Such a level of change is more likely to succeed if it is fostered by the development of an enabling environment. This requires the creation of a broadly shared vision that would permeate a given society's institutions, infrastructure, education, technical capacities, financial and market conditions, laws, regulations, and social norms.

The rebound effect is a critical consideration when assessing the potential for energy efficiency policies to dramatically reduce energy use. Efficiency regulations on their own are likely to increase the rebound effect – because of lower operating costs and efficiency innovations that stimulate new energy devices and services – unless they are compensated by policies that increase energy prices to reflect environmental and social externalities and that shift energy rate structures (in the case of tariffs set by electric, natural gas, and district heating utilities) to reflect the full long-run cost of new supplies. These kinds of policy changes will be challenging to enact. In the description below of ambitious energy efficiency policies, the emphasis is on those that offer the best prospects of delivering this major transformation in the relatively short period of a few decades.

There are a number of ways of presenting energy efficiency policies – by level of government, by type of policy, by source of energy, by intensity of the efficiency effort, or by end-use sector. In this section, energy efficiency policies are organized by end-use sector. They also include upstream policies affecting individual energy supply systems for electricity, fuels, and heat. Thus, this portfolio of energy efficiency policies has the following sections: industry; appliances and devices (office equipment, personal products); buildings; urban form; transportation; and agriculture.

As with the previous section, the policies in this section represent only a subset of the possible policies in a sustainable energy policy portfolio. A more detailed description of policies, with many case studies of successes and failures, is provided by the other policy chapters and indeed in most other chapters of GEA. Any particular government should collect key information on the use of energy in industry, transport, commercial, and residential sectors if it is to develop effective policies for its own energy efficiency pathway.

In all policy cases discussed below, it is assumed that energy forms with GHG emissions associated with them, at the point of use or during production – as in the case of electricity generation – will experience rising prices over the coming decades due to economy-wide GHG emissions pricing policies, i.e., tax or cap-and-trade. In the same vein, regional and local air and water pollutants are assumed to face rising costs through externality pricing policies and regulations that affect the cost of emissions and effluents.

Most analysts argue that pricing policies are the most efficient and effective way to drive much of the investment and behavioral change needed for a major transformation of the energy system. Others argue, however, that pricing policies alone are insufficient to achieve the desired policy objectives. They contend that complementary regulations, subsidies, public investments and other policies are needed to realize a rapid and profound transformation of technologies, fuels, buildings, urban form, infrastructure, and industrial plants.

Thus, depending on one's perspective, the policies listed below can be seen as potential complements to pricing policies, intended to accelerate efficiency actions that would be stimulated by rising prices. Complementary policies must be designed and implemented carefully, however, to reduce the risk that they will have a negligible effect or even negative unintended consequences.

22.3.2.1 Energy Efficiency Policies for Industry[5]

Development of GHG emissions pricing and other policies that internalize the costs of environmental harm and impact on humans will provide additional incentive for industry to adopt more efficient energy-using technologies. Additional policies may accelerate the adoption of high efficiency technologies, but they must be applied carefully. In some cases, their incremental effect will be zero once prices have been corrected to reflect environmental harm. In some cases, they may actually work at cross purposes with price-adjusting policies.

- Governments and utilities can design utility tariffs to ensure that the marginal tariffs facing customers reflect the true marginal costs of providing them with energy. Depending on the characteristics of the energy supply system, this involves time-of-use rates and/or inverted block rates in which marginal tariffs reflect an appropriate weighting of short- and long-run marginal costs.

- Governments can set regulations that are updated (for example, every five years) to prohibit market access to the least efficient third or half of technologies for a given service, such as motors, fans, conveyors, blowers, boilers, cogenerators, and process-specific equipment.

- Governments can implement "golden carrot" policies and/or niche market regulations that use financial incentives or regulation, or a combination of both, to encourage industry to develop and adopt technologies that are more efficient than the current stock.

- Governments can establish efficiency performance standards for major industries. Or governments can mandate processes that require new investments to achieve a best available technology efficiency standard. Also, phased retrofit of already installed process technologies can be required.

- Governments can provide free audits for smaller firms that find it too costly to inform themselves of energy efficiency options and audits for a fee for medium and larger firms.

- Governments can require firms of a certain size to have full-time energy managers responsible for identifying efficiency opportunities.

- Governments and utilities can provide up-front funds or financing arrangements to ensure that capital constraints are not a barrier to energy efficiency investments.

- Local governments can plan and regulate the location of industrial activities in order to maximize opportunities for waste heat transfer and other synergies between industries to reduce material and energy use.

- National and international industry associations can ensure that industries throughout the world are informed of the most energy efficient processes and technologies.

- Some modifications to patent laws may help improve innovation and a relatively quick transfer of energy efficient technology for industries in different countries.

22.3.2.2 Energy Efficiency Policies for Appliances and Devices[6]

While energy intensive industries are normally very sensitive to energy price – and therefore its technology choices will be affected to a considerable extent by emissions pricing policies – the same is not always true to the same degree with commercial and residential energy users. One reason is the difficulty and cost in getting adequate information about the efficiency of alternative equipment relative to the potential savings for a small-scale energy user. Another reason is the challenge for small consumers in demonstrating to financial institutions the lower operating cost benefits resulting from up-front investments in energy efficiency. In contrast, large industries are continually engaged in explaining the benefits and costs of their investments to financial organizations. A third

5 See also Chapter 8.

6 See also Chapter 10.

reason is the split incentive that often exists between the landlord, who pays for appliances and some devices, and the commercial or residential customer, who pays the energy bills. The following policies seek to address these challenges.

- Governments and utilities can ensure that marginal tariffs facing customers reflect the marginal costs of providing them with energy. Depending on the characteristics of the energy supply system, this involves time-of-use rates and/or inverted block rates in which marginal tariffs reflect an appropriate weighting of short- and long-run marginal costs. With the falling cost of meters, such tariffs are now possible for even the smallest customers.

- Governments can set regulations that are updated every five years to prohibit market access to the least efficient third or half of appliances and devices. Alternatively, these regulations can ban or mandate the phase out of certain types of less efficient technologies, such as incandescent lights.

- Governments can set regulations that prohibit appliances and devices that use electricity while not in use (turned-off, sleeping, or in standby mode).

- Governments can require efficiency rating labels on appliances and devices to raise public awareness about operating costs of such devices relative to average efficiency.

- Governments and industry associations can work to reach internationally sanctioned appliance and device standards to prevent inefficient products being phased out in industrialized countries from being transferred to developing countries, with the consequence of locking such countries into a regime of inefficient energy use and high operating costs.

- Governments can implement golden carrot policies and/or niche market regulations that use regulation or financial incentives (or a combination of both) to require manufacturers to develop and market appliances and devices that push the envelope to yet higher levels of efficiency than have thus far been experienced. This can perhaps be done initially with a subset of consumers.

- Governments and utilities can provide subsidies for early adopters of high efficiency appliances and devices, although such programs should only reward the adoption of technologies that are unlikely to have otherwise been adopted, because free-riders are a well known challenge to subsidy policy effectiveness.

- Governments and utility regulators can ensure that utilities and energy service companies have an incentive to play a key role in promoting energy efficiency among customers of all classes, particularly small-scale customers who lack resources and knowledge to access energy efficiency. This involves initiatives such as: (1) decoupling utility profits from sales; and (2) creating tradable "white certificates" by which utilities can trade energy efficiency credits among themselves as they compete to achieve energy efficiency targets set by regulators.

22.3.2.3 Energy Efficiency Policies for Buildings[7]

Buildings use approximately one-third of all the energy used globally and are responsible for about one-third of the total energy-related emissions of GHGs (including emissions from electricity production). Because the building stock turns over slowly and because energy efficiency is much less costly if it is built in at the time of design and construction, policies usually distinguish between those affecting new buildings and those affecting existing buildings.

- For new buildings, governments can establish a set schedule for tightening over time the energy efficiency standards for the building shell; heating, ventilation, and air conditioning (HVAC) system; and domestic water heating systems to reach very low levels of energy use. The phase-in period for the strictest efficiency standards could be shorter in developed countries (a decade) than in developing countries (two or three decades in urban areas), although country-, region- and city-specific criteria could lead to very different timeframes. The phase-in period for the efficiency requirements and their stringency would be tightest for the highest efficiency scenario.

- For new buildings, governments can use development charges and siting requirements to ensure that buildings are sized and located appropriately for optimizing heat gains and losses of the building shell, depending on climate and the building's heating or cooling needs, with respect to its ambient surroundings. These can also be applied, in many cases, to maximize opportunities for waste heat recovery and/or district heating supply.

- Governments can require all existing buildings to have an energy audit at the time of sale that shows prospective buyers how the building ranks on a scale showing energy efficiency performance and GHG emissions. This would include estimated future energy costs associated with rising emissions charges. Audit results should be clearly highlighted in information related to advertising and execution of sale.

- Governments can provide subsidies (tax credits, grants, low-interest loans) for retrofits in existing buildings that drive emissions to zero and/or external energy inputs to zero for a given building. In developed countries, funds can be acquired through local improvement charges and assigned to a property rather than a person. For developing countries, funds could be acquired from domestic sources and perhaps through international transfer mechanisms like the Clean Development Mechanism (CDM). For scenarios of high-energy efficiency, retrofit subsidy programs should be much more substantial.

7 See also Chaper 10.

22.3.2.4 Energy Efficiency Policies for Urban Form

The energy efficiency of the built environment can be improved substantially through urban planning that combines land-use planning, transportation management, and a synergistic approach to the provision of energy and water services (see also Chapter 18). Such a "community energy management" approach is characterized by increased urban density and especially associated with infrastructure for public transit and district heating, mixed land-uses that reduce the need for mobility and increase the attractiveness of walking and cycling, and coordinated developments that maximize the potential between and within buildings for energy cascading – the use of waste heat. This approach can reduce use and increase reuse of water and sometimes other materials, thus indirectly reducing energy use for these services. Attractive, high-density living also increases energy efficiency by reducing the ratio of external walls to floor space in residential dwellings. Community energy management policies include the following.

- Local governments can set land-use zoning and development standards to foster targeted densities and mixed uses to reduce travel and transportation needs, energy efficient buildings, and cogeneration.
- Local governments can negotiate explicit energy performance standards into permits for re-zoning and new buildings.
- Local and regional governments can foster strategic alliances between energy utilities and developers, with explicit energy planning requirements in official community plans.
- National and regional governments can legislate the requirement that energy planning be an explicit function of local and perhaps regional governments.
- Governments can provide technical and financial support for the integration of energy considerations into traditional community planning processes.
- Governments can tie infrastructure grants to the implementation of community energy management strategies.
- Governments can reduce or eliminate minimum parking stall requirements for new developments and increase local taxes on parking spaces.
- Along with reducing incentives for vehicle traffic, governments can increase the provision of public and mass transportation.
- Governments can require the coordination of energy supply and energy use planning and investment such that cogeneration and district heating systems are expanded.
- Governments can set taxes to ensure that new dispersed developments pay the full costs they cause to energy and water utilities, transportation services, urban livability, and the environment.

These community energy management policies are relevant to all countries. However, it must be recognized that developing countries face special challenges because of rapid rates of urbanization and the lack of institutional, professional, and financial capacity to perform the tasks required – i.e., planning, zoning, and regulation, as well as developing adequate infrastructure for energy, water, sewage, transportation, and other potential collective services, like district heating and cooling. Thus, in developing countries energy efficiency in urban planning would include the following:

- Policies to support local planning, control, and perhaps ownership (municipal utilities, co-operatives, local entrepreneurs) of energy and other utility networks. This has been shown to reduce line losses due to theft and thus improve the operating efficiency of the grid.
- Policies are needed to provide mechanisms for municipal financing and micro-financing of local developments and improvements to infrastructure for energy and energy-related services like transportation, water, and sewers by using efficient technologies that reduce energy and other operating costs. These policies would include support for more effective public investment, which may be leveraged and managed to increase private investment through ensuring stable and sufficient returns on capital.

22.3.2.5 Energy Efficiency Policies for Transportation[8]

A key aspect to developing effective transportation energy efficiency policies is to integrate individual policies and regulations into packages that benefit from a synergistic interaction among the components. Two types of policy portfolios can improve the overall energy efficiency of private transportation. In the case of personal transportation, the first portfolio approach consists of policies that improve vehicle fuel efficiency. The second consists of policies aimed at reducing private vehicle travel and increasing the use of public transit, walking, and cycling within cities and of trains for long distance travel. In the same vein, with the transport of goods, one approach is to make trucks, trains, boats, and planes more efficient. While another approach is to encourage mode shifting to the mode that is most energy efficient for a particular mobility need.

It should be noted that policies to improve vehicle and transport equipment efficiency can work in opposition to policies to encourage mode shifting. More efficient vehicles have lower operating costs and become even more attractive relative to alternatives. This is why vehicle efficiency policies need to be combined with policies that keep the cost

8 For more on energy and transport, see Chapter 9.

of vehicle use high by reflecting congestion costs (road pricing), environmental effects (emissions pricing), and urban livability (vehicle-free streets, parking charges, parking restrictions, vehicle registration fees).

- Governments can set vehicle efficiency regulations. Such regulations can apply universally to all vehicles or can be flexible by allowing different levels of efficiency, as long as vehicles collectively achieve an average level of efficiency. This latter is the case of the Corporate Average Fuel Economy (CAFE) Standards introduced in the United States in 1975.

- Governments can use financial penalties and financial incentives alone or in combination. In the latter case, a feebate policy levies a one-time or annual charge on less efficient vehicles and uses the resulting revenue to provide a one-time or annual subsidy to efficient vehicles.

- Governments could guarantee to purchase the most efficient vehicles for their own vehicle fleets, thereby providing a guaranteed market for the next generation of new vehicles.

- Local governments can implement road pricing to reduce vehicle use and urban congestion. This may include tolls on key bridges or highways, or an electronic zonal pricing system covering a major urban agglomeration. In the case of tolls on bridges and highways, a reduced or zero rate for high-occupancy vehicles encourages more passengers per vehicle and thus a more efficient vehicle use rate. Local and regional governments should make sure that private vehicles on roads face tolls that reflect the costs they incur, including environmental and human health externalities.

- Governments can require vehicle insurance companies to charge distance-based insurance rates, determined by annual odometer readings.

- Governments can rationalize traffic signals to optimize vehicle traffic flows.

- Government regulations can set efficiency standards for modes of transport of goods (trucks, trains, boats, planes). These can have design flexibility similar to that outlined above for personal vehicles.

- Government regulations and pricing can foster modal shifting toward more energy efficient modes of transport of goods, such as a shift from trucks to trains, when possible.

22.3.2.6 Energy Efficiency Policies for Agriculture

Agriculture can be energy intensive, especially the industrialized version practiced today in many parts of the world. Direct energy use in agriculture results from farm equipment, buildings, irrigation, and post-harvest processing. Indirect energy use in agriculture results from the production of fertilizers and pesticides. In the United States, about a third of all energy used in agriculture relates to commercial fertilizer and pesticide production. Potential energy savings in the agricultural sector can be achieved through changes in on-site transportation, reduced tillage, and improvements in irrigation, drying, dairy and livestock production, and horticulture, among others.

- Governments can provide information, low interest loans, and grants to foster the use of more efficient technologies and techniques in agriculture. But as with all subsidies, care must be taken not to provide support that has little effect because it pays farmers for efficiency measures they would have undertaken anyway.

- Governments can provide training for farmers and farm personnel in ways of reducing energy use.

- Governments can tighten regulations on some types of agricultural practices, such as irrigation technologies, pesticide use, and herbicide use, in ways that would indirectly reduce energy use.

- Governments and utilities can change tariff structures to encourage energy efficiency in all farming practices.

- Governments can levy taxes on fertilizers and on fuel for tractors.

22.3.2.7 Decentralized Energy Policies and Energy Efficiency

The human population is urbanizing rapidly. Cities are now responsible for two-thirds of total primary energy use. As demand for energy services continues to grow, the energy infrastructure that cities depend on will need to be expanded, upgraded, or replaced. This provides governments with opportunities to build energy efficiency or reduced energy service demands into long-lived infrastructure, plants, and equipment. This includes everything from urban form, to energy supply, to major energy end-uses.

Expanding, upgrading or replacing energy infrastructure also presents an opportunity to move toward more decentralized, low emission energy systems. Decentralization may contribute to the goal of low cost energy access with a minimum of negative social and environmental impacts. At the same time, local awareness of energy supply can increase, and that can foster a greater emphasis on energy efficiency.

Decentralized energy systems include locally-focused mini-grids that connect small-scale local supply with local demand and energy self-sufficient industries. Decentralized energy systems can reduce the need for expensive, expansive energy grids and increase the reliability of the system. It can also provide reliable energy to communities currently not connected to the grid.

Government at all levels can support the development of smaller-scale, local energy supplies. Support can come via implementation of incentives, such as tax advantages, regulatory flexibility for municipalities and utilities to encourage distributed and decentralized energy supply, and grants and low-interest loans for feasibility studies and capital costs related to development of district energy systems. Governments must also support knowledge- and technical capacity-building. Local governments should be involved in the development of decentralized energy systems because they often build, own, and operate decentralized energy systems. The following policies can contribute to decentralized energy supply:

- Development permit area guidelines can require decentralized renewable energy systems external to buildings, such as the installation of ground-source heat pump systems, to reduce total energy use.

- Tax exemptions for development projects using local renewable energy sources can be incentives to owners and developers to promote decentralized energy retrofits on buildings or neighborhood-scale initiatives. This might include solar water heaters, heat pumps, or heat recovery systems.

- Development cost charge (DCC) reductions or exemptions, conditional on inclusion of decentralized energy generation, can provide financial incentive for developers.

- Local governments can adopt a rezoning policy that encourages decentralized energy generation in new developments. Such a policy would indicate clearly which attributes will be sought by governments when making rezoning decisions, creating incentives for developers to include decentralized energy in their plans.

- Local improvement charges can promote the use and finance the installation of renewable energy systems in existing buildings and developments throughout a community. For instance, these can be used to pay for the installation of solar hot water systems in the community.

- Local governments can use service area bylaws to provide, and charge for, decentralized energy generation and services.

- Governments can enact regulations that require renewable technologies, like solar water heating or rooftop photovoltaic systems on new buildings.

- Local governments can offer or expropriate land for the construction of local energy generating plants.

- Electric utilities can adjust their grid extension policies so that communities that are beyond eligibility for grid connection receive technical and some financial support to develop mini-grids. Public-private partnerships of various types may be effective in this area.

- Developed countries should promote the transfer of new technologies related to decentralized energy to developing countries.

- Utility regulators need to adopt flexible, lighter approaches to utility regulation so that small-scale operations that are nonetheless defined as utilities – such as the provision of energy supply to a building, a development, a group of buildings, or a remote community – do not face the typical regulatory burdens of conventionally-sized utilities.

- International and national aid agencies may want to focus energy-related aid efforts into supporting with capital and expertise the development of decentralized energy systems in developing countries. But care should be taken so that this does not come at the expense of expanding large-scale systems, if that is more cost effective.

22.3.3 Linking Policies and Investments

It is sometimes assumed that one can measure a policymaker's commitment to a particular issue by the amount of public funds they are willing to commit. In the case of energy policy, this assumption would be misleading in some instances. Good energy policy can sometimes require little or no expenditures, as in the case of effectively managing and regulating the interplay of monopolistic and competitive forces in the electricity sector or effectively managing a valuable resource endowment. However, when it comes to the rapid expansion of the energy sector necessary to provide adequate energy access to billions of un-served and under-served people, and to the much-needed transformation of the global energy system to one with a much smaller environmental impact, effective energy policies will need to stimulate a great deal of investment from the public and especially the private sector.

Chapter 22 emphasizes the need to price harmful energy-related emissions so that energy prices reflect environmental costs. Properly pricing energy to include the value of environmental harms and risks can drive massive investments in cleaner energy technologies and in energy efficiency. Chapter 24 describes a slate of policies that can create an enabling environment for profound energy technology system innovation. But these policies will be especially effective in developed countries where lack of energy access is less of an issue. In developing countries, policy must also result in a profound investment in energy supply.

Chapter 6 describes the types of investments that are required for the global energy system. Chapter 17 links the magnitude of these investments to specific pathways in terms of potential development of energy efficiency and the expansion of energy supply from renewables, nuclear

Table 22.2 | Investment needs and policy mechanisms.

	Investment (billions of US$/year)		Policy mechanisms			
	2010	2010–2050	Regulation, standards	Externality pricing	Carefully designed subsidies	Capacity building
Efficiency	n.a.[1]	290–800[2]	*Essential* (elimination of less efficient technologies every few years)	*Essential* (cannot achieve dramatic efficiency gains without prices that reflect full costs)	*Complement* (ineffective without price regulation, multiple instruments possible)[3]	*Essential* (expertise needed for new technologies)
Nuclear	5–40[4]	15–210	*Essential* (waste disposal regulation and, of fuel cycle, to prevent proliferation)	*Uncertain* (GHG pricing helps nuclear but prices reflecting nuclear risks would hurt)	*Uncertain* (has been important in the past, but with GHG pricing perhaps not needed)	*Desired* (need to correct the loss of expertise of recent decades)[5]
Renewables	190	260–1010	*Complement* (renewable portfolio standards can complement GHG pricing)	*Essential* (GHG pricing is key to rapid development of renewables)	*Complement* (feed-in tariff and tax credits for R&D or production can complement GHG pricing)	*Essential* (expertise needed for new technologies)
CCS	<1	0–64	*Essential* (CCS requirement for all new coal plants and phase-in with existing)	*Essential* (GHG pricing is essential, but even this is unlikely to suffice in near term)	*Complement* (would help with first plants while GHG price is still low)	*Desired* (expertise needed for new technologies)[5]
Infrastructure[6]	260	310–500	*Essential* (security regulation critical for some aspects of reliability)	*Uncertain* (neutral effect)	*Essential* (customers must pay for reliability levels they value)	*Essential* (expertise needed for new technologies)
Access[7]	n.a.	36–41	*Essential* (ensure standardization but must not hinder development)	*Uncertain* (could reduce access by increasing costs of fossil fuel products)	*Essential* (grants for grid, microfinancing for appliances, subsidies for cooking fuels)	*Essential* (create enabling environment: technical, legal, institutional, financial)

1. Global investments into efficiency improvements for the year 2010 are not available. Note, however, that the best-guess estimate from Chapter 24 for investments into energy components of demand-side devices is by comparison about 300$ billion per year. This includes, for example, investments into the engines in cars, boilers in building heating systems, and compressors, fans, and heating elements in large household appliances. Uncertainty range is between US$100 billion and US$700 billion annually for investments in components. Accounting for the full investment costs of end-use devices would increase demand-side investments by about an order of magnitude (see Chapter 24 for details).
2. Estimate includes efficiency investments at the margin only and is thus an underestimate compared with demand-side investments into energy components given for 2010 (see note 1).
3. Efficiency improvements typically require a basket of financing tools in addition to subsidies, including, for example, low- or no-interest loans or, in general, access to capital and financing, guarantee funds, third-party financing, pay-as-you-save schemes, or feebates as well as information and educational instruments such as labeling, disclosure and certification mandates and programs, training and education, and information campaigns.
4. Lower-bound estimate includes only traditional deployment investments in about 2 GW capacity additions in 2010. Upper-bound estimate includes, in addition, investments for plants under construction, fuel reprocessing, and estimated costs for capacity lifetime extensions.
5. Note the large range of required investments for CCS and nuclear in 2010–2050. Depending on the social and political acceptability of these options, capacity building may become essential for achieving the high estimate of future investments.
6. Overall electricity grid investments, including investments for operations and capacity reserves, back-up capacity, and power storage.
7. Annual costs for almost universal access by 2030 (including electricity grid connections and fuel subsidies for clean cooking fuels).

power, and perhaps fossil fuels, provided that emissions can be captured and safely stored. The following table from Chapter 17 summarizes, in a very general way, the link between policies and investment levels.

Detailed information on this table is provided in Chapter 17. Here we simply reiterate a few key points. The energy investment columns refer to investment levels needed for different pathways. Thus, a high-energy efficiency pathway would require over US$500 billion/year of new investment. In contrast, since there are pathways in which nuclear power stagnates, its annual investment could be as low as US$15 billion/year, a sharp contrast with the almost US$400 billion/year for an energy pathway that includes a substantial role for nuclear power. In the same vein, CCS could be abandoned in some energy pathways, while in others its rapid adoption could require almost US$100 billion/year of new investment.

The policy mechanisms of the table provide an admittedly crude simplification. There are only four policy types (regulations, pricing, subsidies, capacity building) and their role and relationship to each other is evaluated in only four ways (essential, complement, desired, uncertain). In reality, there are many variations within these four policy types, and indeed, there are policies that are hybrids in combining elements of both.

Likewise, depending on how they are designed and implemented, some policies can be complements in some cases and substitutes in others.

With these caveats, the investment table nonetheless provides a summary of the amount of investment required under various energy pathways and kinds of policies needed to drive this investment. In so doing, it gives a general sense of points made throughout this chapter, namely that: (1) strong pricing and regulatory policies will be required for the major energy transitions called for in GEA; and (2) policy coordination is essential for this effort to be effective.

Executive Summary

A number of factors contribute to the lack of access to modern forms of energy. They include low income levels, unequal income distribution, inequitable distribution of modern forms of energy, a lack of financial resources to build the necessary infrastructure, weak institutional and legal frameworks, and a lack of political commitment to the scaling up of services. An absence of specific policies oriented to poverty alleviation often explains inequitable economic growth and, consequently, inequality in access to and use of energy. In recent years, several developing countries have defined targets aimed at improving access to electricity, but many developing countries still have no modern forms of energy access targets in place that address meeting basic energy services, including modern fuels for cooking and mechanical power.

As Chapter 2 argues, developing countries require adequate access to modern energy, especially among the poor, in order to meet the Millennium Development Goals (MDGs) as well as their own national development objectives. In line with GEA objectives, Chapter 17 pathways are designed to describe transformative changes toward a more sustainable future. A specific feature of the GEA energy transition pathways is that they *simultaneously* achieve normative goals related to all major energy challenges, including environmental impacts of energy conversion and use, as well as energy security and energy access. 'Energy access' refers to those challenges clearly described in Chapter 19, which will be addressed in this chapter.

Affordable and sustainable universal access to modern forms of energy depends on the evolution of income level and income distribution. Urbanization processes and population growth are the other variables that play a key role, but both cannot be addressed and solved by energy policy alone. Clearly, without a significant growth of per capita income in developing countries, ambitious targets on access to modern forms of energy will face barriers that are both significant and hard to overcome. As such, policies to improve energy access should be part of the strategies on poverty reduction and income distribution. Isolated solutions are not effective. Without an integrated approach to facilitate the inclusion of excluded populations as a means to alleviate poverty, the intended outcomes will not follow.[1] Reaching universal access to modern forms of energy within a period of 20 years needs robust strategies, policies and measures integrated in long-term national programs with clear targets, dedicated and guaranteed funds, and an adequate institutional framework.

If widespread energy access is to be achieved in just a few decades, energy policies would need to work in concert with economic development policies by harnessing the collective efforts and investment potential of markets, international organizations, central governments, regional governments, cooperatives, and local organizations. Large amounts of funding are needed to provide a major clean-energy infrastructure and to leverage private funding through a more sound investment environment. For the poorer regions, grants would in many cases be needed to, in combination with targeted energy subsidies for the lowest-income populations. Policies would need to support local participation in developing and managing energy systems, as this approach has been shown to have the best chance of providing a stable environment for new investment and reinvestment in increased energy access.

A variety of policies and measures applied around the world have provided considerable experience and knowledge. Overall, no single institutional model or strategy can be recommended as the right one, as evidenced by the success or failures of different models for access to modern forms of energy.[2]

---

1 For example, decentralized, energy technology itself is a package comprised of "hardware and software." The "hardware" includes the energy technology and physical project components. The "software" includes community mobilization, participatory development of the energy technology itself, capacity-building for the use of production technology and scaling-up through market development.

2 The experiences of the eighties and nineties in energy structural reforms, when the proposals coming from international financing institutions were very similar, ignoring national and local circumstances, led to the demonstration and conviction that "one size coat does not fit all," specially in institutional, regulatory and property right issues. Lessons learned from success stories are very important and they will be address in different sections of the chapter, without being prescriptive.

A major shift appears to be urgently needed in the way countries approach the formulation, planning and implementation of policies designed to facilitate access to energy and, particularly, to meet the energy services of poor people. Current supply-side approaches that simply take as their starting point the provision of modern forms of energy or equipment of a particular type are less successful in reaping the full potential of social and economic improvements that follow from improved energy access. A solid knowledge of the energy services that are a priority of the target population is a crucial prerequisite to identifying the right response with energy source and technology. This often requires innovation, testing and experimentation at both technological and institutional levels. Lack of appreciation of such approaches at the policy level may curtail progress, as many policymakers may follow approaches that do not take into account the contextual differences. The integration of centralized and decentralized options of advancing universal energy access also needs to be explored more carefully.

Fuel subsidies alone will be neither sufficient nor cost-effective in terms of achieving ambitious energy access objectives. Often, financial mechanisms, such as end-user finance, would need to complement subsidies to make critical end-use devices, connection costs for network systems like electricity and natural gas or LPG (liquefied petroleum gas) cylinder costs affordable to poor people. Up-front costs of the equipment and appliances are, in many cases, the most important barrier to access. Policies that address this will make it easier for households to cover the fixed capital costs associated with a switch to cleaner fuels.

The promotion of joint actions involving local communities and authorities, NGOs and energy utilities, both in rural and urban areas, have demonstrated to be a favorable enabling environment to advance access objectives.

Reforming the way energy is financed and sustainably operated has potentially important outcomes in the efforts to reduce inequity. Some principles, such as supporting energy planning, making infrastructure investment, creating incentives for commercial lending, generate soft loans, launching promotional campaigns, and providing technical assistance, have been identified for certain markets. Centralized agencies can also assist by improving this coordination and helping to create needed local institutional and organizational capacity.

Finally, this chapter does not aim to be prescriptive in policymaking, but seeks to introduce the challenges, conditions, and key issues that should be taken into account in the quest for a policy on access to modern forms of energy.

23.1 Chapter Roadmap

Universal access to modern forms of energy is one of the most urgent objectives of energy policies in the coming decades. It is inextricably linked to improved welfare, because energy services have a direct impact on human needs, productivity, health, education, and communication. Lack of access to modern forms of energy and the related lack of access to energy services contribute to and are a consequence of poverty, constrain the delivery of social services, limit opportunities, and often erode local environmental sustainability. Universal access to modern forms of energy has clear implications for the achievement of the MDGs, and beyond. It will help address environmental challenges, guarantee adequate levels of health, increase energy security, and promote economic development.

Several factors contribute to the lack of access to modern forms of energy. They include low incomes, unequal distribution of incomes and of modern forms of energy, lack of financial resources to build the required infrastructure, weak institutional and legal frameworks, and a lack of political commitment to the scaling up of services. An absence of specific policies oriented to poverty alleviation often explains inequitable economic growth and, consequently, inequality in access to and consumption of energy. Many developing countries have no energy access targets in place, particularly for those of its components that do most to reduce poverty. In recent years, several countries have defined targets aimed at improving access to electricity. A few, however, addressed targets on meeting basic energy services, including modern fuels for cooking and mechanical power. These, of course, are crucial if the basic needs of poor people are to be met. Access to energy should also be considered within the broader objective of equity. Access to modern forms of energy contributes to this objective.

The role of the state in the energy system varies by country. What is clear, though, is that public policies are the non-transferable responsibilities of government. Governments would need to put in place feasible and effective policies with defined objectives, targets, and strategies that are appropriate to their needs and conditions, and need to apply appropriate measures and incentives to ensure their proper implementation. At the industry level, some countries consider oil and natural gas as strategic goods to be controlled and managed directly by government through public utilities, while accepting that the private sector has an important role in the power industry. In practice, energy policy requires each country and region to find a policy mix that best meets its goals and particular national and regional circumstances, needs and priorities.

In line with the Global Energy Assessment (GEA) framework and goals, this chapter takes 'universal access to electricity, liquid, and gaseous fuels (modern forms of energy) to satisfy households' energy services' as an objective for energy access policy.[3]

The key challenge for this chapter is therefore to examine the various options of policies and strategies that facilitate universal access to modern forms of energy by 2030. The terminology employed in this chapter, such as 'access,' 'modern forms of energy,' and 'rural or urban energy' is consistent with the use of these terms in GEA, and no further definitions are added here.[4]

Section 23.3 and 23.4 introduces two contextual issues. First, the social dimension of access to energy, including the relationships between energy and poverty, the macroeconomic conditions that relate to inequity and poverty, and their influence in the energy system. Second, it examines the key challenges and barriers to increasing access to modern forms of energy.

The situations, conditions, circumstances, levels of access, sociocultural contexts, history, and other factors vary between regions and countries. Developing proposals that take account of experiential learning demand consideration of regional contexts. Sections 23.6–8 provide a picture of the situation, lessons learned and policies applied in sub-Saharan Africa, Asia, and Latin America. Regional experts offer suggestions and recommendations based on their own experiences.

Sections 23.10 and 23.11 seeks to summarize key findings and lessons learnt and present recommendations to facilitate and improve access to modern forms of energy.

23.2 Introduction

Access to modern forms of energy is a key element in poverty alleviation and an indispensable component of sustainable human development. Roughly, 1.3 billion people still have no access to electricity and some 2.7 billion people rely on traditional biomass (IEA, 2011). More than 99% of people without electricity live in developing regions, of which four out of five live in rural South Asia and sub-Saharan Africa (Baker Institute, 2006).

This widespread lack of energy access makes it reasonable to conclude that the present structures and processes within the energy sector are not functioning for the benefit of poor people. Macro energy policies in developing countries tend to focus on commercial energy carriers: electricity, coal, gas, and petroleum products. Urban users are the primary beneficiaries. Although the urban poor may also benefit to some extent, the rural poor – who are the majority of poor people in most developing countries – generally do not benefit for the most part.

3 This assessment should not be understood as access to basic energy services, but to an adequate level of satisfaction of energy services according to the social-cultural, economic and environmental framework. Of course access to modern forms of energy is a necessary but not a sufficient condition for poverty alleviation and development.

4 The exception is if a concept requires a particular interpretation within the framework of Chapter 23 but for others please see Chapter 1.

Developing countries require adequate access to modern energy, especially among the poor, in order to meet the MDGs as well as their own national development objectives. In line with GEA objectives, future pathways are designed to describe transformative changes toward a more sustainable future. A specific feature of the GEA energy transition pathways is that they *simultaneously* achieve normative goals related to all major energy challenges, including environmental impacts of energy conversion and use, as well as energy security and energy access. 'Energy access' refers to those challenges outlined in Chapter 19 which will be addressed in this chapter.

Grid extension to rural areas is very expensive and off-grid or renewable programs supply relatively small quantities of electricity to rural communities. Oil products, such as kerosene or LPG, depend on road transport, which can be seasonally unreliable, and transport costs may increase the fuel cost considerably. Consequently, rural households and industries rely heavily on locally supplied biomass fuels. Energy planners and policymakers in developing countries, while usually aware of this process, rarely address the roots of the problem coherently.

The situation can be explained partly by a lack of understanding of the processes in rural areas and, in particular, by a failure to appreciate the positive contributions that access to modern forms of energy can make to sustainable livelihoods. To some extent, it is also explained by the fact that some issues related to energy, such as biomass, are not the responsibility of energy ministries, because its sources are normally the responsibility of forestry and agriculture ministries. Lack of cross-ministry cooperation is frequent. Poor understanding of the dynamics of rural energy, along with inadequate institutional cooperation, can result in a weak systemic capacity at the government level.

Energy sector reforms, both globally and in developing countries, have had specific consequences for poor people. Such reforms were not oriented to social objectives having no or negative impact on access to energy.

Next sections consider the main energy access dilemmas. It discusses relationships between poverty, development, and energy access at the macro level, and between energy policies, aggregated policies, and specific objectives, such as access to modern forms of energy. It identifies the key challenges and barriers that an energy policy must negotiate.

23.3 The Development Gap: Socioeconomic, Poverty, and Inequity Context

This chapter builds strongly on the concepts of social issues, MDGs and energy (discussed in Chapter 2). It demonstrates linkages with health and energy (Chapter 4), energy, economy, and investment (Chapter 6), scenario/pathways (Chapter 17), and energy access for development (Chapter 19). Findings from these chapters have fundamental implications for this chapter, which in turn strongly influences the discussions of policies, rationales (Chapter 22), and policies for capacity development (Chapter 25).

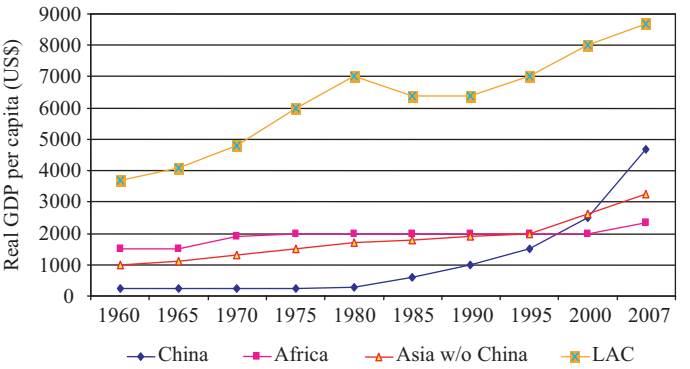

Figure 23.1 | Real per capita income of developing countries by region. Source: Based on data from UNDP Human Development Report, 2009.

At the macroeconomic level, the link between adequate energy services – in quantity and quality – and economic development (as measured by gross domestic product (GDP)) is relatively clear, although the direction of causality may or may not always be so (Ghosh, 2002; Wolde-Rufael, 2006). A more in-depth discussion on this causality is given in Chapter 6. Generally, no socioeconomic system provides an adequate welfare environment without available, affordable, and secure energy carriers. The relationship between per capita energy use and GDP per capita is a clear indicator of the importance of energy in development. Of course, the lack of adequate energy supplies is a barrier to development.

In the 47 years, from 1960 to 2007, GDP per capita in Africa grew at less than 1% per year, in Latin America and the Caribbean (LAC) at less than 2% per year, and in Asia, excluding China, at around 2.5% (Figure 23.1). Between 1981 and 2005, sub-Saharan Africa was the only region that did not see a decline in poverty levels.[5] In absolute terms, the number of poor people in Africa has nearly doubled and, if this trend continues, by 2015 one in two of the world's poorest people will live in sub-Saharan Africa, compared with one in ten in 1980.

The weakness of the economic system[6] is a major challenge to universal access to modern forms of energy, and to achieving the MDGs. Feasible,

5 Global poverty has fallen sharply on the strength of China's growing prosperity over the past two decades. The proportion of the world's population living in poverty fell by half – from 52% in 1980 to 26% in 2005. In the past 20 years, poverty has been declining at 1% annually (Collier, 2007).

6 The weakness of an economic system results from all or many of the following elements: lack of a long-term vision; low competitiveness; lack of scientific and technology development, knowledge, and capacity in general; high concentration of income and welfare; low saving and investment capacity; weak physical infrastructure; unemployment; degree of informal economy; lack or inadequate management of natural resources; inadequate or inefficient institutional framework; weakness of the external sector, among others. There are five dimensions to this: knowledge, natural resources, social, economics, and politics.

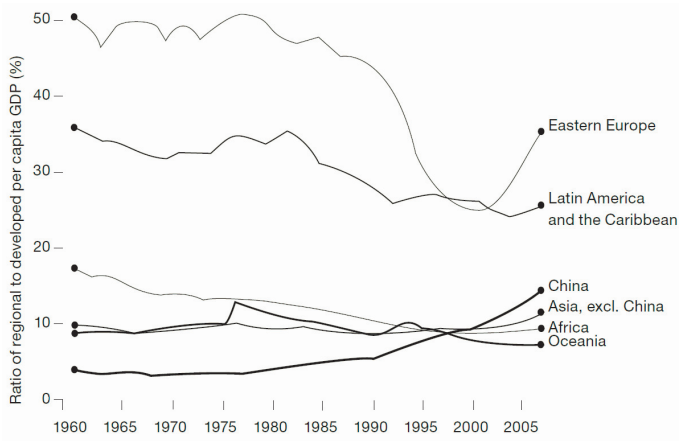

Figure 23.2 | Per capita GDP in relation to Organisation for Economic Cooperation and Development (OECD) countries. Source: UNDP Human Development Report, 2009.

affordable, and sustainable access to modern forms of energy requires an enabling macro- and microeconomic environment to guarantee such an ambitious target as universal access to modern forms of energy by 2030.

There is a clear relationship between low GDP per capita and low access to modern forms of energy. In addition, the disparity in per capita income between the richest and poorest of the world's nations has widened (Figure 23.2). According to UN Habitat (2011), nearly one billion people who live in slums lack both essential physical and social infrastructure. In this respect there has been a lack of convergence between the developed and developing world in the past 50 years, with some exceptions.

Without a significant growth in developing countries' real per capita income, ambitious targets on access to modern forms of energy will become hard to achieve. GEA pathways assume not only an important increase in GDP per capita of developing countries, but also a convergence among the developing and developed world (Chapter 17).

Improved income distribution, at both the global and domestic level, should go hand-in-hand with the creation of feasible, affordable, and universal access to modern forms of energy and cleaner cooking by 2030.

23.4 Key Challenges and Barriers to be Addressed by a Policy for Access to Modern Forms of Energy

The complex and multidimensional character of the development concept is broadly known, but qualifying it as sustainable makes the concept still more intricate. This is not just because it is hard to agree a universally acceptable and applicable definition, but because the dynamics of a largely complex system must be qualified. These multiple dimensions are strongly related to the reality of a specific socioeconomic system, in which they interact dynamically with each other.[7]

It is evident that the current situation may not be considered as socially sustainable, particularly given extremely low incomes and the challenges in accessing the most basic services, such as health, education, housing, and energy. In respect of energy, greater sustainability demands an understanding of the access to, and coverage of, basic energy services – in terms of both quantity and quality. This should include not just household needs, but the needs of essential services, such as health, education, and drinking water.

Energy policies should be consistent with policies on employment, income, foreign affairs, institutional structure, social objectives, environment, science and technologies, regional development, financing, to name a few. General policies influence the feasibility and effectiveness of sector policies, such as energy. There must be complementarity between energy strategies and other cross-cutting policies, other sector policies, and general development policy. They cannot be developed in isolation. And to be effective, they should include specific definitions of interventions and of the system as a whole.

In consequence, it is not sufficient to address energy access as a list of strategies and measures, but also as the need to establish the analytical framework by identification, through a diagnosis, of the barriers that should be overcome for universal access to modern forms of energy.

An evaluation of the extent of the challenge should note some of the key conclusions and recommendations of a UNDP/WHO (2009) report on the energy access situation in developing countries summarized below:

- The global development community must take specific and far reaching measures to massively scale up initiatives to expand access to energy services for poor and un-served people.
- The quantity and quality of statistical information related to energy access need major improvements and further efforts to address this need
- In order to expand access to energy services, especially cooking and heating services, as well as access to mechanical power in rural and remote areas, more dedicated and broad-based efforts are needed.
- The use of targets is a key to providing a framework for tracking progress and accountability. These targets, in turn, need to be part

7 Complexity and, in many cases, the unique conditions of the socioeconomic systems are a key reason to avoid the proposal of prescriptions that should run overall without taking into account national circumstances and specific factors of the energy system. Prescriptions in the energy policy of the type "one size fits all" promoted during the 1980s and 1990s and still today, are the best example of the consequences of ignoring the characteristics and conditions of the target systems.

of viable energy access strategies, backed by appropriate priorities, policies and programs, and financial resources, if they are to be realized.

- If massive efforts are not made to expand the range, quality, and quantity of energy services available to poor people, many countries – particularly those with large pockets of population with low rates of access to modern forms of energy, are unlikely to achieve their development aspirations.

Although electricity use has expanded and programs are in place to spread distributed generation technologies and modern fuels, often these efforts have been plagued by numerous problems, and the scale at which the growth is occurring is barely sufficient to keep up with a universal access to electricity and modern cooking fuels target by 2030. In many cases, the barrier exists in the policies themselves, along with the institutional arrangements that impact energy services. The importance of institutional factors for implementation and sustainability, especially in rural interventions, is widely cited (e.g., World Bank, 2008a; Green Nine, 2004).

The following section examines the importance of various challenges, and how they should be considered in defining policy objectives and strategies.

23.4.1 Political Failure

In general, a policy's failure to obtain the expected results is due to one or more of the following: failure of diagnosis through lack of information, failure to identify the barriers to be overcome or the main problems that the policy should address, or inadequate strategies, instruments, and measures to address the problems and barriers. Of course, lack of political will and government commitment to prioritize investment in energy should also be considered as a failure, or a short-term view of the energy system.

Planning and policy implementation are often based on inadequate diagnosis, which means no clear identification of the problems and barriers. Consequently, strategies, instruments, and measures fail to address the objectives. A proper analysis of why the situation is as it is and how it will evolve is vital. This is the most important phase of designing and implementing an energy policy. Even with decades of experience of the analysis of human needs, the approach to addressing energy use remains based on supply and technology. In general, the wrong question is asked: how can electricity or photovoltaic (PV) panels or other technology or energy sources help to facilitate access to energy? There are other questions that would need to be asked first. Which human needs are the ones that need to be prioritized? What role can energy play in meeting these needs? What is the best combination of technology and energy to meet these priorities? What is the capacity of target users to incorporate the sources and the technology? What other conditions would need to be put in place to ensure the proposed solutions' affordability and sustainability? How will demand change when access to modern forms of energy becomes a reality? Are the sources and technologies sufficiently flexible to address future needs? If not, what will be done? Attention would need to be given to the needs of the target populations and on the energy services to be provided.

Inadequate diagnoses are commonly related to a lack of clear understanding of the energy access situation in countries, including regional and national trends, rural/urban disparities, and the range of energy sources typically used in poor households, and are a barrier to a comprehensive situation analysis.

Biomass represents a major share of energy use by poor people in rural areas. It is collected at zero monetary cost, mainly by women and children, and therefore falls outside national energy accounts. In the formal statistical data bases, several times it becomes invisible. This invisible collection of energy source means that decision makers are rarely aware of its significance. Policies and strategies therefore fail to address the issue adequately.

Do policymakers have sufficient understanding of where to begin improving access? What improvements will be valued by poor households and communities? To answer these questions requires some understanding of how energy is obtained and used today and of future trends, both for final use and for productive activities. Also essential is knowledge of poor households' requirements for better energy services, and their willingness to pay for them.

Improving access to modern forms of energy for poor people will require greater attention on two fronts. First, policymakers and their advisers need to use as many energy data as are available to design strategies that, at least, do not close off energy options valued by poor people or distort incentives to supply and use better services. Second, they need to design policies and strategies that elicit access and energy use information effectively, to give enabling conditions for any proposed solution.

23.4.1.1 Availability and Use of Adequate Energy Access Data

Data collection on these issues was – and remains – weak. Of late, policy advisers and donor agencies have worked to improve their understanding of poor people's needs and to tailor actions to their preferences. But the data gap remains wide. Niez (2009) cites, "sound statistical data … and a clear description of the [energy services] situation" as the first precondition for successful rural energy access policies.[8]

8 This does not mean that the main barrier for energy access is lack of data, but in the absence of the real dimension and quantification of energy needs, the design and implementation of policies and strategies could have poor results in the actions proposed, the assessment of impacts and the effectiveness in addressing the priorities from the target population point of view.

Table 23.1 | Basic energy use in different bioclimatic zone.

Bioclimatic zone	Urban or rural	With or without access to electricity	Final energy use by household (kgoe)*	Useful energy use by household (kgoe)	Annual Electricity consumption by household (kWh)
Hot	Urban	With	243	124	1596
		Without	596	100	0
	Rural	With	658	131	1521
		Without	1069	130	0
Moderate	Urban	With	380	162	1492
		Without	706	151	0
	Rural	With	1034	170	1388
		Without	1451	174	0
Cold	Urban	With	606	262	1416
		Without	961	255	0
	Rural	With	2062	287	1353
		Without	2504	293	0

Available information shows that poor households rely on highly varied energy sources. They often incur real costs that are far higher than those for equivalent energy from, for example, electricity networks. Evidence suggests that poor people are, indeed, often willing to pay for more modern forms of better energy. Identification of this situation, and meeting that demand, therefore becomes a major challenge. Information as to the economic capacity to afford access to modern forms of energy is generally lacking.

A valid example is the estimation made for LAC on the quantification of basic energy services and the right to energy (Bravo, 2004):

> "Any quantification of basic energy services is space specific, time related, and influenced or determined by environmental and sociocultural conditions. It is not possible to fix global, regional, or national values for basic energy services. There are three elements around any energy service: human need, appliance or equipment, and energy source.[9] In basic energy services for household consumption, only indoor energy services are included.
>
> Basic energy services are lighting, cooking, water supply, water heating, space heating, and food conservation. The requirement for each energy service is determined by sociocultural conditions, urban, rural, or peri-urban localization, biogeographic and climatic conditions, access to energy sources, types of appliances available, building characteristics and family size, and other factors. In addition, the capacity, efficiency, and annual use of appliances determine the useful and net energy consumption.
>
> The total basic energy use estimated for different situations are summarized in Table 23.1. This demonstrates the importance of environmental conditions and access to an energy source, such as electricity. Of course, the structure of energy services differs by zone, urban, or rural location, and access to electricity.
>
> Similar studies could be useful to determine the amount of basic energy services needed to assume reasonable conditions of human dignity, and should offer a figure for the right to energy. A comparison with current levels of use in useful energy could be useful to measure the extent to which the needs are met and could feed into policy and strategy development."

There is substantial variation in energy use patterns, depending on climate, local fuel resources, the country's economic history, location (urban, rural, or peri-urban), and other factors (Box 23.1). Excessive focus on supply, along with incomplete understanding of the real and priority needs of poor households, can limit proposals for positive change.

Poverty often leads households to use a mix of energy sources that are suboptimal from the economic, financial, health, and environmental perspectives. They also tend to use less modern forms of energy than they would be willing and able to if supplies were commercially available at prices that are fair such that the suppliers are able to recover their costs. Such situations are often explained by an inability to afford the up-front costs of the appliances needed to satisfy the energy services, or the costs of connecting to grids, in the case of electricity.

Households in most developing countries are getting smaller and may have fewer wage earners, which reflects factors such as higher per capita incomes, smaller family sizes, greater access to education, and increasing urbanization. People living in these smaller households are less likely to be poor and therefore more likely to have disposable income to spend on modern forms of energy. But smaller households also mean that each new electricity connection may benefit fewer people than in

9 The energy services beyond the basic may be different combinations of appliances and sources.

Box 23.1 | Factors Relevant to Energy Access

Understanding what type of energy carriers and end use technology are available, who uses them, how much they cost, and the benefits they provide to users, are factors to consider when assessing energy access. For instance, energy access can include measures related to:

- The quality and quantity of energy provided. Data regularly collected by statistical agencies generally do not provide detailed information on the quantity (e.g., hours of use and availability) and quality (e.g., rated voltage and frequency) of the energy services provided, although these may be available from utilities and other sources.
- Energy end-use appliances and equipment and the services they provide. Data on the availability of certain household and agricultural equipment – lighting using different energy sources, water pumps, refrigerators, and different types of stoves – are available from some international surveys, and would be useful to collect, but are beyond the scope of this report.
- Socioeconomic profiles of energy users and energy affordability. Data on income levels and geographic location of energy users are often available from statistical agencies, but other socioeconomic data on users – prices of energy services, gender-disaggregated data, and disaggregation for key sectors such as businesses, schools, and health centers – may not be.

the past. This has implications for the design of programs to increase access. Understanding how this will evolve in the medium and longer terms is crucial to generating reliable market estimates.

These findings come from partial analyses in various regions, and should be examined further and verified in region and country specific contexts before policies on access to modern forms of energy are developed and implemented. The absence of a good and reliable diagnosis could be a key barrier to the success of a policy or strategy.

23.4.1.2 Coherence and Convergence between Objectives and Strategies

To ensure coherence and convergence between objectives and strategies is a necessary, but not evident, issue in policy design and implementation.

The most recent policy failures, at least in addressing the social dimension of a sustainable energy policy, are the structural reforms implemented in the past 20 years in the electricity and in other sectors of the energy system. The emblematic role given to market forces, the private sector, and the transfer of decision making to decentralized stakeholders should be assessed in relation to the results and in how they helped or did not help to increase access to modern forms of energy. Reducing the governmental role in controlling and managing a strategic good such as energy is, indeed, a key issue for important consideration in this decision.[10]

Divestiture of public utilities and energy resources, changes in the regulatory framework, openness to foreign investment, and abandonment of long-term planning were just some of the strategies proposed and implemented as a panacea to promote sustainable development.

One rationale for the reforms was that they would enable increased access to modern forms of energy and even facilitate rural electrification (Bouille and Wamukonya, 2003). Injection of new capital and the increased efficiency that would come with the need for private sector returns was viewed as essential to create the infrastructure necessary to bring electricity to rural areas and shore-up existing distribution systems.

An in-depth GNESD (2006) [11] study explains that:

> "… the reasoning behind such initiatives was simple: streamlined and restructured energy sectors, being more efficient and less costly, would widen access to energy services and produce benefits for health, education, nutrition and entrepreneurship for all. In this context, the role of government is reduced to creating an enabling environment within which private sector mechanisms develop and provide services."

The failure was largely the result of a policy vacuum as far as the needs of poor people were concerned (GNESD, 2006). The key negative impacts on poor people include reduction in electrification rates and increased

10 A careful reading of the fundamentals and considerations in the laws that made reform possible demonstrates very similar arguments, and proposed an *urbi et orbi* approach.

11 The main values of the GNESD report are the broad representation of countries involved, deeper analysis made by centers of excellence of the countries or regions, the use of a common methodology, and a collection of common findings. The countries included in the analysis were Kenya, Uganda, Senegal, Mali, South Africa, Zimbabwe, India, Philippines, Thailand, Bangladesh, Vietnam, China, Argentina, Peru, El Salvador, and Brazil.

Table 23.2 | Comparison of results of analysis of selected indicators for the Argentina, El Salvador, and Peru case studies.

Selected indicators	Argentina		Peru		El Salvador	
	Pre-reform	Post-reform	Pre-reform	Post-reform	Pre-reform	Post-reform
Electrification levels (%)	91	95	38	62	62	76
Annual electrification rates (%)	2.04	1.03	7.8	5.8	6.6	4.1
Average household consumption (kWh/month)	155	205	136	106	104	112
Poor household lifeline tariff (USc/kWh)	4.35	11.77	6.8	17.2	4.8	8.6/16.8[12]

tariff levels. See, for examples, some Latin American cases (Table 23.2). This was largely due to a "one size fits all" approach, whereby wholesale policy transfer was applied with little consideration for context, national circumstances, technical issues, or degree of development and maturity of the energy system.

The International Monetary Fund (2008) concluded:

> "As of 2006, more than 80% of sub-Saharan African countries had enacted a power sector reform law, 75% had experienced private participation in power, about 66% had corporatized their state-owned utilities, more than half had established a regulator, and more than one-third had independent power producers reform programs typically followed an orthodoxy that aimed at creating competition among private electricity suppliers, but few energy markets in Africa are large enough to support the multiple suppliers needed for a competitive environment. As a result, despite reform measures, utility performance continues to be disappointing and associated hidden costs can absorb as much as 2% of GDP."

If the proposal for future strategies follows the 1990s paradigm, some lessons learned could help to avoid the same mistakes, at least in the power sector:

1. Ring fencing, or protecting, the funds for providing electrification for poor people. In several countries funds have not been protected, Kenya being the best example. Brazil and South Africa emerge as model examples of how to ring fence. In Brazil, two important measures were implemented. First, the Electricity Act has made it mandatory for all electricity distribution concessionaires to contribute to the Global Reversions Reserve (RGR – Brazil) – the national electrification fund. Second, the allocation of funds for electrification by the Reserve was predetermined by region and matches the electrification needs of specific regions.

2. Sequencing of reform. Is it better to embark on wide-scale electrification of poor populations prior to privatization, or vice versa – privatizing and thereafter launching an electrification program? In countries where wide-scale electrification was undertaken prior to market-oriented reform such as privatization, notably South Africa, Zimbabwe, Mauritius, Thailand, and Philippines, a significant proportion of poor people gained access to electricity.

3. Explicit focus on poor people. With some exceptions, reforms in most countries examined in the Energy Access study (GNESD, 2006) did not focus explicitly on poor people. There are several ways in which reforms could ensure that poor people become a critical consideration of the reform process. Examples include Brazil, South Africa, and Bangladesh. One way to ensure that reforms explicitly focus on poor people is by enacting laws that ensure they gain access to electricity. This was the approach adopted in Brazil, which has three key laws that focus on poor people.[13]

4. Establishing dedicated institutions for poor people to have electrification is another way that reforms could ensure an explicit focus on poor people. This approach appears to have been successful in Bangladesh and South Africa. In Bangladesh, the Rural Electrification Board was established, with one of its key mandates being to widen access to electricity and to ensure poverty alleviation in rural areas (Shrestha et al., 2004a). In South Africa, the National Electrification Program was designed formally to target underprivileged groups under the apartheid regime, who constituted the majority of poor people.

5. Participation of poor people in the electrification process. Apart from ensuring an explicit focus on poor people, their involvement in the electrification process appears to be equally important. With the exception of South and Southeast Asian countries, there appears to be limited involvement of poor people in other regions covered by the Energy Access study (GNESD, 2006).

The key challenge is not to tie policies to paradigms that do not include a clear diagnosis of the national circumstances and the technical, socioeconomic, and cultural situation,[14] and to avoid

12 Depending on level of consumption and localization (rural or urban) the tariff range is between both figures.

13 Policy oriented to the poor during the Lula presidential period reduced the number of people living below the poverty line in Brazil by 30 million (Coutinho, 2007).

14 Proposals to introduce competition and unbundling in power systems that have less than 1000 MW of installed capacity are an example of the lack of logic in such a paradigmatic approach.

Table 23.3 | Urban and peri-urban key issues.

Category	Urban	Peri-urban
Institutional	Government representation, good infrastructure, single municipality, information systems	Absence of the state, poor infrastructure, unregulated land use, across different municipalities, poor information on land use and population growth
Land use	Regular settlements, vertical buildings, few better-off shantytowns	Many irregular settlements, many shantytowns, housing projects
Demographic	Low or negative population growth, job offers, older population	High population growth, unemployment, pressure over public infrastructure, younger population
Environment	Presence of parks, better sanitation and environmental conditions	Sanitation problems, deforestation, pollution of water sources, invasion of protected areas, landslides

prescriptions that appear as magic solutions without evidence of success in similar circumstances.

23.4.2 Population Dynamic: Urban and Peri-urban Access to Modern Forms of Energy

Urban energy, peri-urban energy, and rural energy make up part of the analyses of access to modern forms of energy, or the provision of adequate energy services. But is there a clear definition of each category? Is there common agreement on the meaning of each category? Which is the most challenging from the perspective of access to energy?

An urban area is characterized by a higher population density and many human features not found in areas that surround it. Urban areas may be cities, towns, or conurbations, but the term is not commonly extended to rural settlements, such as villages and hamlets. Internationally, the standard determinant of a rural area is population density. Therefore, rural areas are defined as those with low numbers of people who live on any given area of land.

However, the most challenging issue is the definition of peri-urban populations. In short, they could be considered as the transition zones, or interaction zones, where urban and rural activities are juxtaposed, and landscape features are subject to rapid modifications, induced by human activities.

For many African countries, peri-urban literally means the area around an urban settlement. It is distinctive in its diversity, with a mix of land uses and residents. It is rural in appearance, but many residents will have jobs in the nearby urban area to which they commute. Houston (2003), also cited by Buxton et al. (2008), defines the peri-urban areas on the basis of population density, employment in non-agricultural industries, and population mobility. Barr (2005) defines a similar region in terms of "rural amenity landscapes," by analyzing the relationship between rural land value and agricultural production value. Differentiation between urban and peri-urban conditions can be considered in various ways (Table 23.3).

Why are peri-urban areas important for access to energy? The challenge is twofold. First, agreement is needed on what peri-urban means. And second, population growth in developing countries is largely concentrated in peri-urban areas, which accentuates the key challenge of infrastructure development, including the energy infrastructure.

Population dynamics in developing countries show that an increasing share of the total population is found in peri-urban areas. In addition, a deficit exists in peri-urban information. The information deficit results from invisibility or the trend to ignore poverty. This refers to a situation in which policymakers are located elsewhere, where there is a lack of media coverage and focus, plus inadequate registration by urban information systems. This can lead to poorly located schools and healthcare facilities, crowded public facilities, the state's inability to regulate land use, and a lack of infrastructure such as water and energy.

Recognizing that urban, peri-urban, and rural situations imply different challenges, the peri-urban situation is the most complex. It challenges the planning of sustainable and affordable access to modern forms of energy. The multidimensional characteristics of peri-urban areas demand an integrated policy approach, including to energy access.

In relation to LPG, recent studies show different situations, all of them with the common issue of the need of intervention through public policies. There is a generalized situation of irregularity in the energy provision: LPG is not available in some places, it is expensive and the subsidized cylinder is found to be adulterated (Bariloche Foundation, 2008). LPG was found prominent in economically well-off households, however LPG had issues like affordability and delays in refill attached to it. Due to lack of awareness, LPG was perceived as a dangerous fuel. Access to biomass and kerosene was relatively easier than LPG or electricity as the latter required a valid residence proof and had higher upfront costs. Lack of awareness of the harmful effects of using conventional biomass stoves and lack of willingness to give up biomass usage due to its ease of access and the non-continuous supply of other fuels, were key factors driving continual usage of biomass even in households having other cooking fuel options. Kerosene was found to be the baseline fuel used in all households however due to factors like not-well-targeted subsidies, market distortions and need for ration cards to acquire it, and the fuel had accessibility issues (TERI, 2008). In spite of LPG not being a very common source of fuel among the urban poor population, trends indicate that its use and dissemination is steadily growing. LPG has a very high upfront cost which is normally beyond the reach of the majority of the urban poor. The overall cost of a simple cylinder with its related accessories is

approximately 10 to 15 times the national per capita income. This has greatly affected the dissemination of LPG mainly among the urban poor. In addition, although the cost of refilling the LPG cylinders is normally affordable and within reach of the urban poor population, the prices are dictated by the world oil prices which fluctuate from time to time. This causes uncertainty about its use within the target group. The safety aspect and reliability (volume found in each cylinder may vary substantially pertaining to the use of LPG is also of great concern among the urban poor (Karekezi et al., 2008)). In spite of LPG not being a very common source of fuel among the urban poor population, trends indicate that its use and dissemination is steadily growing.

The key access issues for the urban poor in the slums studied in Delhi were high upfront costs, insecurity of tenure of land and the lack of recognition and permanence of many slums in Delhi. Mistargeted subsidies, market distortions, lack of accountability on part of service providers and no monitoring mechanisms were identified as the other pressing issues hindering access. Broader issues included lack of database on urban poor and their energy use patterns, unclear institutional responsibilities and lack of policies targeting clean energy access to the urban poor (TERI, 2008).

Almost 85% of the world's urban population has access to electricity. Indeed, in some parts of the developing world, namely North Africa, East Asia (including China), the Middle East, and Latin America, the level of urban-energy access is nearly universal. About 95% of population growth over the next 30 years will occur in urban areas. Thus, fast population growth and urbanization and rising demand for electricity will exert tremendous pressure on infrastructures and create strong demand for new investment. Unless appropriate steps are taken to meet that growing demand, the urban poor are certain to lose ground in access to electricity.

In urban areas, extending electricity access to poor people is a matter first and foremost of getting the policies right. The infrastructure is generally already in place in most of the world's large urban centers, except in Africa. Therefore, energy companies need to make fewer new capital investments. But even with lower capital costs and higher incomes in urban areas, poor people still often cannot afford the connection fees or monthly rates – even if conditions in these areas are more favorable in terms of distance to the network and density of population. However, in addition to low incomes, other issues are crucial for a sustainable supply, notably at the management level and also the dubious legal status of many peri-urban settlements.

Consequently, supportive policies are needed that make service expansion to the urban poor sustainable. The problem of reaching poor people in urban areas generally requires a change in the mindset of urban utilities, as serving poor populations often calls for special policies, investments, and innovative technical and financial solutions.

Urbanization growth rates are surpassing national growth rates in many countries (Box 23.2). Many urbanites are settling in peri-urban areas, which are generally illegal. Planning for service provision, including modern forms of energy, tends to exclude such areas. Initiatives for service provision in such areas can be *ad hoc*, and have minimal impact. This is escalating poverty and crime in these areas, and retards development. At the very minimum, governments would need to provide regulatory guidance to enable access to energy services in peri-urban areas.

In recent years, several international forums have addressed the issue of peri-urban electricity problems (Rojas and Lallement, 2007). Poor people pay extremely high prices for electricity, often to illegal entrepreneurs. Often safety issues are ignored by such entrepreneurs and service levels are usually very poor. The solutions to these problems are not insurmountable. However, implementation has been lagging in many countries, and there is a need to address these issues more directly.

In addition, the lack of income may sometimes be more of a deprivation in urban than in rural areas. In the latter, poverty is usually accompanied by traditional or pre-modern ways of life. Access to energy through the use of firewood may be partially guaranteed, but in ways that are highly undesirable because of the effect on health and on the work of women and children, and also because of the correlation with other deficiencies, i.e. access to education, health services, and water.

23.4.3 Rural Energy and Electrification

Rural energy is a complex issue that encompasses a broad and diverse spectrum of resources – from petroleum fuels and coal to biomass and renewable energy – that spans multiple sectors, including forestry, electricity, and health. Many new projects are developing the technical capacity to tackle rural energy issues in all their complexity.

International agencies have sometimes taken short cuts to address this problem, and have advocated projects with a narrow technology focus. However, to focus on single technologies does nothing to develop markets, companies, or non-governmental organizations (NGOs) to support rural energy development. Such an arrangement is not conducive to solving the problem of universal access. Whatever experience is gained by a specific project cannot be applied to subsequent projects because of lack of continuity. Moreover, single efforts generally seek exceptions to regulatory policies, but are unable to change them. As a result, it is not possible to see the long-term effects of such projects in the form of greater access to quality energy services.

The development of rural energy policy institutions could provide advice and support for how to better focus the use of funds. Their role would be to promote sound policies for rural areas and innovative pilot projects. It must be understood that, for the most part, rural energy is an unprofitable business, because in many cases there are costs involved in market development that cannot be borne by private sector companies. However, by using a combination of loans and subsidies, both large- and small-scale businesses can become viable to better promote

Box 23.2 | Urban Poverty Today and Tomorrow

"Over the past half century, the world's urban population increased from around 730 million in 1950 to over 3.15 billion in 2005. Around 1 billion, or nearly one-third of the world's urban population, are now believed to be living in slum conditions. With virtually all population growth until 2030 taking place in urban areas, that number is likely to double.

In India, an alarming accompaniment to increasing population and urbanization has been the deepening of urban poverty, growth of urban slums, and the deterioration in basic service delivery. Slums in Delhi include informal settlements that are either squatter or illegal colonies where people live on undeveloped and unserved land without secure tenure or access to basic services.

In Argentina, over 13% of the population of Greater Buenos Aires lives in slums. Here, as in other cities, there is a parallel growth of rich, well-serviced neighborhoods and gated residential communities close to dense inner city or peri-urban slums that lack even the most basic of services. There is parallel growth of slums, country clubs, and closed wealthy neighborhoods (often with private security services). As slums grow even within the city, high-income housing seems to bridge these neighborhoods.

Kenya is experiencing very rapid urbanization. Over 40% of the population is urban, a figure that looks set to rise to around 50% by 2050. Around 34% of the urban population lives below the poverty line and income distribution shows a large disparity between poor people and non-poor.

In South Africa, urbanization is already ahead of the global trend. The 2001 census showed an urbanization level of over 56%, leading to major problems in terms of infrastructure, unemployment, and poverty.

In Thailand, people migrate from the countryside to urban areas in search of better employment opportunities and higher income: 81% of the dwellings in the Bangkok region house people who have migrated from other regions or slums. Most slums are in the city's core areas, but there are indications that this is changing with slums in core areas decreasing and new ones arising in urban fringe areas."

Source: GNESD, 2008.

a wide range of rural energy services, from LPG and grid electricity to improved stoves and tree growing. Moving forward requires a combination of research, production and delivery, support, and monitoring and evaluation, all of which must be done through a variety of businesses – including rural electric cooperatives, NGOs, private sector companies, and local municipalities – interested in serving rural energy customers.

In the case of electrification, the choice is between a large-scale infrastructure and the local delivery of energy. The current dominant development model focuses on achieving macroeconomic growth. This results in a predominance of attention to, and investment in, large-scale energy infrastructures to provide energy for growth. There is a need to redress the balance, with much more attention and investment directed toward the supply of local energy services for poverty reduction in local communities. A policy that takes account of both the infrastructure for energy development and energy access priorities is needed.

The rate of electrification in rural areas is very low, particularly in sub-Saharan Africa. This inhibits social and economic development in these areas. A combination of three drivers helps to explain this – the density and dispersion of population, the distance to the network, and the income of the population, all of which are particularly unfavorable in these rural areas. These drivers influence the decision between grid or off-grid rural electrification. The decision-making process would need to consider what inherent limits they place on the extension of the grid, as a way to motivate the use of off-grid approaches.

In rural electrification, the key financial barriers and challenges to attract both local and foreign private companies incorporate additional barriers to the issues mentioned (ACP-EU, 2009):[15]

- Rural electrification is often not a profitable business, and there will be limited interest in such activities from a purely financial point of view, in particular since many countries require that a nationwide uniform tariff be applied.
- As it can be politically unacceptable to raise tariffs, these are often not adequate for the financial sustainability of the economic models, for both national utilities and independent producers.

15 Although these statements are related to Africa, they are still valid for other developing regions.

- The investment capacity of national utilities is often limited, which restricts their ability to maintain the existing network and, in the best case, to create commercially viable grid extensions. The financial situation of these utilities is often weak through a combination of factors: inadequate tariffs, low levels of revenue collection (commercial losses), technical losses, inefficiency and obsolescence of the power systems through inadequate maintenance, low level of consumption, and low rate of interconnection, among others.

- Lack of financing schemes, or poor implementation of existing schemes, dedicated to increased investments in rural access, such as cross-subsidies between urban and rural areas, special levies to benefit rural electrification, and public guarantees for loans.

- Inadequate project size. Programs are often too small to be attractive to financing institutions and, even more so, to international private investors.

- Lack of interest from local banks for rural electrification because of a lack of knowledge and of confidence in this sector. This can be explained by the fact that local financing institutions are used to working in sectors they already know and whose risks they can measure and charge for, on a short-term period, and to working with established clients. Local loans are expensive and a short-term approach to financing is not suitable for financing long-term assets.

- Lack of credit-enhancement schemes, such as various bank guarantees and co-financing instruments for private investment in rural electrification.

- Risk of unmanageable escalation of exploitation costs, because of the higher price of fossil fuel, for example. Even when these can be included in the tariff, escalation may cause a loss of customers and a reduction of receipts, and therefore inhibit planned expansion.

- The exchange risk for imported goods, which are paid for with foreign currency but with receipts in local currency.

In summary, the two main challenges for financing rural electrification are:

- How to ensure the service's long-term financial viability.

- How to divide risks among stakeholders in a sustainable manner.

The choice of short, medium, and long term outlooks is another significant consideration. In the short and medium term, the only way to reach isolated households that do not have electricity is through single-household systems and small electricity providers, using both renewable and conventional energy sources.

Off-grid household programs in Bangladesh and Sri Lanka demonstrate that it is possible to implement large-scale, off-grid projects that complement strong grid-electrification programs (Govindarajalu et al., 2008). The challenges of off-grid projects in both countries have taken advantage of private sector institutions, NGOs, and microfinance institutions that operate in rural areas. Also, they have required centralized institutional support. In Sri Lanka, financing is provided though microfinance institutions, banks, and leasing companies for renewable energy systems that are provided by the private sector and NGOs. Today, off-grid solar home systems (SHS) and village microhydropower (MH) grids provide electricity to 3% of all Sri Lankan households (World Bank, 2008b). This solution would need to be considered as short term, because SHS consist of PV modules with capacities that range from 30–60 W_p watts and therefore offer limited access.

Small grid systems vary widely, from MH to locally generated private distribution. To grow and thrive, such systems often require external technical and financial support. The challenge is, therefore, to assure the program's affordability and sustainability. Off-grid electricity has the drawback of high cost compared to that of grid electricity in urban areas, along with low financial capacity or willingness to pay for modern forms of energy in many remote or rural areas where access is lacking.

Although their institutional forms vary, successful grid-extension programs generally require financially and technically strong utilities.[16] To ensure sustainability, distribution companies must address the issue of increased technical losses and low revenues creatively, or with the introduction of cross-subsidies. In Jujuy, Argentina, for example, the utility reduced fixed costs by creating two companies, with a common management, for the grid and off-grid electricity public service. This minimized the need for government subsidies. The extension of cooperative electricity has been successful in Argentina, Bangladesh, and the Philippines.

23.4.4 Scale of Investment for Universal Access: Scenario Target

The GEA pathways carried out in Chapter 17 sought to assess options on how to achieve 'almost universal access to electricity and modern cooking fuels by 2030'.[17] This includes the diffusion of clean and efficient cooking appliances, extension of both high-voltage electricity grids and decentralized microgrids, and increased financial assistance from industrialized countries to support clean-energy infrastructures. The costs of almost universal access estimated by GEA are substantial, some US$36–41 billion/yr until 2030.

Several estimates have been made for the cost of universal access to energy services at the global, regional, and project levels (Table 23.4). In general, estimates focus on electricity – fewer data are available for fuels

16 See Barnes (2007), for more examples.

17 The target is "almost universal access" because reaching the remotest rural populations is exceedingly expensive and urban electrification costs are not included.

Table 23.4 | Cumulative investments to facilitate access to modern forms of energy.

Geographical focus	Goal	Cost estimates (billion US$)		Source
		Electricity	Cooking	
Global	Universal energy access	700 [i]	56	OECD/IEA (2010)
	Improved access to reach MDG 1	223	21 [ii]	OECD/IEA (2010)
	Universal energy access	35–40/year [iii]	39–64 [iv]	AGECC (2010)
	Universal electricity access	~55/year	1.8/year	Saghir (2010)
	Universal electricity access	35/year		IEA (2009)
	Improved access to clean cooking [v]	858		Birol (2007)
	Universal electricity access [vi]	200		World Bank Group (2006)
	Improved electricity access to reach the MDGs	665		IEA (2004)
	Universal electricity access			IEA (2003)
Regional/local				
Africa	Improved electricity access [vii]	17/year [viii]		African Development Bank (2008)
Sub-Saharan Africa	Improved energy access	6–15/year		BREW-Hammond (2010)
	Increase household electricity access to 35%	4/year		UN-Energy/Africa (2007)
East African Community (EAC)	Improved energy access [ix]	1.5	0.262	East African Community (2006) [x]
Economic Community of Central Africa States	50% electrification	1.45		CEMAC (2006)
Economic Community of West African States (ECOWAS)	60% electrification, 100% improved cooking fuels, access to mechanical power in 100% of villages	2.1	2.8	ECOWAS (2005)
South Africa	Electrificacion	US$1000 per connection [xi]		Eskom (2009), Niez (2009)
Kenya	Electrification	US$1900 per household [xii]		Parshall et al. (2009)
Botswana	Electrification	US$1100 per household [xiii]		Krishnaswamy and Stuggins (2007)
Mali	Rural electrification	US$776 per connection [xiv]		AMADEER, quoted in Foster et al. (2010), p. 199
Senegal	Increased electrification rate from 47 to 66%	0.86		ASER (2007)
Bangladesh, Cambodia, Ghana, Tanzania, and Uganda	Improved energy access in line with the MDG targets	US$13–18 per capita/year [xv]		Sachs et al. (2004)
South Asia	Universal access to LPG		449	IIASA [xvi]
Brazil	Promoting LPG access to underprivileged households		0.5 [xvii]	Jannuzzi et al. (2004)
(Unspecified)	Electrification	Above US$1200 per connection [xviii]		Practical Action (2007)

[i] Including both rural and urban grid connection, generation, transmission, and distribution; minigrid generation and distribution; off-grid generation.
[ii] Including advanced biomass stoves, LPG stoves, and biogas systems.
[iii] Based on IEA (2009b).
[iv] Improved cookstoves, 11–31; biogas, 30–40; LPG, 7–17. Includes capacity-development costs.
[v] LPG cylinders and stoves to all the people who currently still use traditional biomass.
[vi] Includes breakdown by major regions.
[vii] Reliable electric power to 90% of sub-Saharan rural population, 100% of the sub-Saharan urban population, and 100% of the both the rural and urban populations in the Northern African middle-income countries.
[viii] Considering only new generating capacity, including generation as well as transmission and distribution.
[ix] Reliable electricity for all urban and peri-urban poor; modern cooking practices for 50% of population currently using traditional cooking fuels; energy services for all schools, clinics, hospitals, and community centers; mechanical power for heating and productive uses for all communities.
[x] Including capital expenditure, programs, and loan guarantees.
[xi] The average is expected to increase as the electrification process moves to communities in more remote rural areas.
[xii] Average cost per household in a so-called realistic penetration scenario, with US$1500 and US$2615 for infilling and grid extension, respectively; based on modeling of grid extension.
[xiii] Based on project experience.
[xiv] Based on project experience from AMADER (Agence malienne pour le développement de l'énergie domestique et l'électrification rurale).
[xv] Including costs of end-use devices, fuel consumption, electrical connections, and power plants.
[xvi] Updated analysis based on the methodology described in Ekholm et al. (2010).
[xvii] Subsidies for LPG access to underprivileged households in 2003.
[xviii] New connection to electricity, based on case studies, varies from country to country, and can be as much as US$6000 in some cases.

Source: Bazilian et al. (2010) and references therein.

for caloric uses. A recent report summarized a wide range of estimates (Bazilian et al., 2010). Electrification costs range from US$5–40/capita/yr, "reflecting the large uncertainties associated with such evaluation and the sensitivity to certain assumptions." The report suggested a general underestimation of the financial effort to satisfy universal access to modern forms of energy. Most estimates consider only capital costs and do not include fuel and operation and maintenance (O&M) costs.

Several issues influence the results. The most important include the combination of grid, off-grid, and minigrid in the structure of the system, population density, urban and rural population mix, annual level of consumption per capita, and mix of generation technology and generation fuel.

For mechanical power, the available information is very poor.

The annual costs for universal electrification vary between US$12–134 billion/yr, accordingly to per capita annual consumption estimates.[18] Total estimates, including those for cooking, run from US$14–135 billion/yr. Many of the countries that require the most effort to achieve universal access are those with GDP per capita less than US$1000, a range in which lie many of the LDCs with low access to modern forms of energy.

The question is not only how much the global investment would need to be or how high the other global costs are, but where the investment has to be made, and recovered, taking into recognition the economic capacity of the target population and of the country as a whole.

Table 23.5 is a preliminary indicator of the required effort, only in terms of investment, by some developing countries if they are to satisfy universal access by 2030. Considering figures of Table 23.4 and depending on the family size, the cost of connection to electricity could be up to two times the annual income of the household.

The magnitude of the resources involved and the need to recover them during the lifetime of the investment is, perhaps, the major challenge for some developing countries.

23.4.5 Funding Gap and Financial Constraints

The great majority of people without adequate access to energy live on less than US$2/day, which makes it difficult for them to access good services, including energy services. Energy access is not without cost and the initial expenditure on electricity connections or better technologies can be high. A large funding gap in providing energy access for poor people has not been addressed seriously by existing financial mechanisms and financing institutions.

Table 23.5 | Population without access to electricity and Per Capita GDP – some Sub-Saharan African Countries.

Country	Share of population without electricity access (%)	GDP per capita 2008
Burundi	97	138
Liberia	97	216
Chad	97	863
Rwanda	95	465
Central Africa Republic	95	459
Sierra Leone	95	332
Gambia	92	497
Malawi	91	313
Uganda	91	455
Niger	91	391
Burkina Faso	90	578
DR Congo	89	185
Guinea-Biassau	89	264
Tanzania	89	520
Mozambique	88	477
Kenya	85	660
Ethiopia	85	657
Lesotho	84	1248
Mali	83	468
Zambia	81	436
Madagascar	81	439
Togo	80	828
Guinea	80	1224
Benin	75	216
Cameroon	71	863

Source: UNDP Human Development Report, 2010.

Lack of access to (affordable) capital in many countries is a problem that exists at every scale, from national governments and large utilities through to households. Until the 1990s, most developing countries relied on the international financial institutions, the World Bank, and regional development banks for investment in the energy sector. However, during the 1980s the World Bank promoted private investment. Countries responded by reforming the sector and initially private investors moved in, especially into the larger economies. However, not only did private funds start drying up in 2000, but most investors generally avoided additional generation capacity, which contributed to power and economic crises, as evident in Brazil (Bouille and Wamukonya, 2003; Millán, 2006; Woodhouse, 2005).

The level of success in private sector financing has been rather limited. In Africa, for example, private sector financing accounted for an average

18 Low, urban 100 kWh/cap and rural 50 kWh/cap; medium, urban 456 kWh/cap and rural 152 kWh/cap; high, urban 456 kWh/cap and rural 360 kWh (Bravo, 2004). See also the reference for the estimation of basic energy services for LAC.

Box 23.3 | Private Activity in Energy Reaches a Record High

In 2009, there were 139 energy projects with private participation that reached financial or contractual closure in 21 low- and middle-income countries, involving investment commitments of US$58.5 billion. In addition, energy projects implemented in 1990–2008 attracted new investment of US$10 billion, bringing a total investment commitment to the energy sector of US$68.5 billion in 2009.

Private activity, however, was concentrated in just a few countries and electricity generation projects. Brazil and India accounted for 67% of investment and 43% of new projects, and for all of the growth in private activity in 2009. Electricity generation accounted for 79% of investment and 80% of new projects. 100% of the non-electricity projects were in China, while Chinese electricity projects focused on the grid and mainly BOT or BOO systems.[19]

In East Asia and the Pacific, two countries (China and the Philippines) implemented 22 new projects that represented US$7.6 billion in investments. China had seven natural gas distribution projects and five power plant projects with a total investment of US$3.1 billion. The Philippines implemented nine power plants (mainly divestitures[20]) and a concession for the national electricity transmission company, with a total investment of US$4.5 billion.

In LAC, four countries (Brazil, Chile, Costa Rica, and Peru) implemented 43 new projects that represented US$20.5 billion in investment commitments. Of these projects, 31 were for electricity generation and 12 for electricity distribution. Most projects and investments were located in Brazil: 26 power plant projects and 11 electricity transmission projects, representing US$19.4 billion investment. In addition, investment commitments to projects implemented previously in the region came to a total of US$4.6 billion.

In South Asia,[21] four countries (Bangladesh, Bhutan, India, and Pakistan) implemented 38 new projects with a total investment commitment of US$22.4 billion. Thirty-five of these projects were power plants along with three electricity transmission lines. Most activity took place in India with 23 projects and US$21.0 billion in investment. In Pakistan, 11 power plant projects reached financial closure, eight of which were emergency rental power plants. Additional investment in previously implemented projects in the region totaled US$2.2 billion.

In sub-Saharan Africa, four countries (Ethiopia, Kenya, Liberia, and Uganda) implemented five electricity generation projects that represented US$212 million in investment. Three were emergency rental power plants in Ethiopia and Kenya, while the other two were the Kakata power plant (a waste-to-energy project) in Liberia and the Buseruka hydropower plant in Uganda.

In addition to the 139 projects that reached financial or contractual closure in 2009, at least 124 projects were awarded throughout the year, but did not reach closure by December 2009. Those projects were distributed across the regions, with 41 in East Asia and the Pacific, 19 in Europe and Central Asia, 44 in LAC, 16 in South Asia, and four in sub-Saharan Africa.

Source: World Bank Group (2010).

of just US$300 million/yr over the decade 2000–2010, against a total requirement of US$4 billion/yr. The sustainability of private sector players has been minimal, with many exiting within a few years of their entry.

Overall, private sector investment in the energy sector has accounted for 15.6% of the total private sector participation in sub-Saharan Africa from 1990 to 2006 (World Bank Group, 2010). Nearly all this investment has been concentrated on national – and hence urban – needs. Attracting the private sector into rural areas has proved to be extremely difficult (see Box 23.3 for a summary of private investment in developing countries).

The conclusion from the Private Participation in Infrastructure Database of the World Bank (World Bank Group, 2010) is that there is no evidence to date on the role that the private sector could play in improving access to modern forms of energy, particularly in rural areas. Consequently, the

19 BOT = build, operate, and transfer; BOO = build, own, and operate. This system, in general, means that price and quantity is guaranteed by the government, and there is no risk.

20 Divestiture means that they were not new investment, only the transfer of property from the public to the private sector.

21 South Asia is one of the regions with the lowest level of access to electricity and is, at same time (according to the data of the World Bank), the region with the lowest investment from the private sector in electricity.

task of bringing in private capital and moving from rhetoric to reality remains a major public policy challenge.

A further factor that hinders access to modern forms of energy is the high up-front cost. Subsidies have been used, but it is evident that they are not always sufficient to enable poor rural and peri-urban populations to access modern forms of energy just because subsidies address energy costs, but not capital costs related to the equipment necessary to satisfy energy services.

Electrification access is also hindered by the initial connection and operational costs. Local energy entrepreneurs face a capital access problem in trying to establish businesses to meet rural energy needs. In particular, banks have a difficult time assessing the risks of these loans.

23.4.6 Capacity, Management, and Institutional Gap

Managing the process of delivering energy services for poor people requires ample public institutional capacity, specifically at the subnational and local/community levels. These include:

- analytical ability to create district-level rural energy policies and plans that are appropriate to specific locations and are, at the same time, aligned to national energy access visions, targets, and budgetary allocations;
- ability to manage financial resources transparently and accountably;
- technical capability to guide, regulate, and train non-state implementing actors (e.g. local NGOs) to initiate, deliver, and manage energy systems, energy services, energy users, entrepreneurs, and small-scale energy financing institutions; and
- ability to collect and manage data to establish a baseline and to monitor ongoing performance.

The current reality is that the majority of public institutions in developing countries have only limited capacities to handle these tasks. Moreover, a prevailing vacuum in institutional platforms for the delivery of energy services at the local level is often transferred to the national level, which makes capacity development efforts uncoordinated and often ineffective, thereby exacerbating efforts to scale up the programs.

Furthermore, without these capacities, transaction costs and operational risks increase considerably for potential actors, particularly private actors, to invest in energy activities in rural areas. This restricts their business opportunities and, at the same time, deprives rural people of access to modern forms of energy to meet basic human needs.

Institutional, systemic, and individual capacity developments – along with reinforcement of many different stakeholders' existing capacities – are needed if the energy system is to be instrumental in bringing about sustainability. In a broad sense, capacity refers to the ability of individuals and institutions to make and implement decisions and perform functions in an effective, efficient, and sustainable manner (UNDP, 1994). This definition has three important aspects. First, it indicates that capacity is not a passive state, but is part of a continuing process. Second, it ensures that human resources, and the way in which they are utilized, are central to capacity development. Third, it requires that the overall existing context and functions of organizations be a key consideration in designing strategies for capacity development (UNCED, 1993).

A UNDP study, related to energy access in rural areas (UNDP, 2010), report on experiences from Nepal that showed that the focus needs to be on: "(1) planning, oversight, and monitoring; (2) policies and regulations; (3) situational analysis; (4) stakeholder dialogues, communication, and community mobilization; (5) setting up and enhancing institutions; (6) training program implementers and community members; and (7) implementation and management" and remarks that "developing capacities in all these areas is essential for making the scale-up of rural energy access a reality." In addition, a key conclusion is that "Upfront public investments are needed to develop national and local capacities for scaling up rural energy services delivery, and can catalyze private financing."

The challenges require innovative answers to old and new problems. They also require a search for more flexible and pragmatic strategies, approaches, tools, instruments, and action to obtain results in a new framework. The new operating environment in which energy solutions must be found suggests a new and essential role for government in terms of its responsibilities to make markets and the energy system work to satisfy, among others, the objective of universal access to modern forms of energy.

23.4.7 Gender and Energy

Inequity along gender lines is one of the main factors that drive the establishment of gender focused programs (see Chapter 2). The issue is predominantly a phenomenon of developing countries, and the gender and energy approach is justified on the basis that women's end uses of energy is different to that of men, and that providing energy to women will improve their livelihoods.

This approach has resulted in interventions that focus more on energy than on the service, and more on the woman than on her context. As such, the technological approach (UNDP, 2004), namely improved biomass stoves, ethanol stoves, or solar homes systems, taken in isolation of the development context, may achieve only marginal results.

The challenge, and the reason that this chapter does not give a particular focus to the gender perspective, is to recognize that access to

modern forms of energy (and the energy problem in general) is not a household or gender-specific problem, but a development issue related to poverty and inequity. This shift acknowledges and calls for a paradigm change toward a full understanding of the macro- rather than the micro-development framework. Such a program, rather than the project-funding approach advocated and implemented by donors, could offer a good start if planned in a down–up approach in which local sector staff are involved in structuring from the outset.

Is the problem of gender in developing countries related to low income? The gender and energy approach is justified on the basis that women use energy differently from men, and that providing energy to women will improve their livelihoods. Some have also argued that energy is a basic good, implying that women are entitled to it as much as to health and education. There are arguments against energy as a basic good, but as an important input for satisfying basic needs.

The gender and energy approach focuses on the impacts suffered by women in gathering firewood. The doubt is, though, that by contextualizing and defining the energy problems from such perspectives, the approach may have masked the real issues and misdirected resources. Energy is an input to development, but an insufficient condition for development. Wamukonya remarks, "that women suffer energy problems maybe the case. That they are experiencing these problems merely because they are women is subject to debate. While there may be traditional cultural factors tying women to certain tasks, and hence curtailing employment mobility and flexibility, improvements in income levels are particularly important in determining the relationship between energy and women. In households with higher income, women can employ men or women to procure energy and where alternative modern forms of energy carriers are available, they switch to these fuels."

The challenge and remaining doubt is if the gender and energy issue and gender equity is an energy problem or a much broader socio-cultural and economic challenge. Apparently, the approach has to have a broader view than to look only for ways to substitute biomass for cooking.

The challenge, and the reason that this chapter does not go deeper on the "energy gender perspective," is to recognize that access to modern forms of energy (and the energy problem, generally) is not a household or gender-specific problem, but a development issue that is related to poverty and inequity.

This shift acknowledges and calls for a paradigm change towards a full understanding of the macro rather than the micro development framework. The program rather than the project funding approach, being advocated and implemented by donors, could offer a good start if planned in a down-up approach where local sector staff are involved in structuring from the outset.

23.4.8 Climate Change, Green Economy, and Poverty

For billions of people struggling with poverty, access to affordable energy services is of higher priority than climate change. Evidence suggests that increasing energy access to poor people would entail a small increase in the level of emissions[22].

It is expected that additional electricity will be, partially, centralized generation, partially mini-grid solutions and the remaining by isolated off-grid solutions. In the case of mini-grid and isolated off-grid, the majority should be provided by renewable.

Given that the priority objective is poverty alleviation through access to modern forms of energy, it would be more useful to look for synergies and convergence with global objectives of climate change and clean energy. Looking for a convergence and win-win actions in energy access, climate change, and poverty alleviation, GNESD has summarized some key findings in policy papers. These include:

- diversifying energy generation sources, with a wider mix of energy sources;
- promoting proven renewable energy technologies for electricity generation; and
- setting renewable energy targets in the energy mix.

Such measures could be a major contribution to reducing vulnerability to climate change and at the same time improve access to energy.

23.4.9 Decision Making under Uncertainty

Despite decades of rural energy programs, interventions, and research on rural energy, a number of gaps remain in our understanding of the dynamics of energy choice of poor households and the welfare impacts of access to modern forms of energy. This has made it more difficult to create sound public policy and to mobilize efforts that sufficiently and appropriately address the problem.

The report by UNDP/WHO (2009) remarks that "understanding what type of energy carriers and end use are available, who uses them, how much they cost, and the benefits they provide to users, are factors to consider when assessing energy access." As mentioned before, to solve such uncertainties a clear diagnosis is needed.

22 World Energy Outlook 2011 devoted a special chapter named "Energy for All: financing access for the poor." According to such report "achieving the Energy for All Case requires an increase in global electricity generation of 2.5% (around 840 Twh)…" "in 2030, CO_2 emissions in the Energy for All Case …are 0.7% higher than in the Baseline Scenario." The figures include LPG to replace Biomass in cookstoves.

There is a lack of information, especially based on field studies, on the quality and quantity of energy used and provided, energy end-use appliances and equipment, and the services they provide, as well as the socio-economic profile of energy users and energy affordability. Examples of this problem include:

- Costs and benefits of modern cooking fuels. Many programs and projects are justified on the basis that the benefits outweigh the costs. For clean cooking fuels, the costs include all the capital and programmatic costs, while benefits range from improved health outcomes that impact household finances to the impact on the health-care system itself. A recent set of reports and guidelines from UNDP/WHO (2009) has helped clarify how to estimate these costs and benefits, and has provided a global set of estimates. But much work remains in refining the methods and determining these values in particular circumstances.

- Ability versus willingness to pay for energy services. It is common to find projects and programs based on consumers' willingness to pay. However, the outcomes tend to demonstrate that this is a misinformed approach, as ability and willingness differ in reality. For example, the ability of poor people to pay for SHS is often based on theoretical calculations of the savings they would make by not buying kerosene. Yet reality shows that outlays on purchasing kerosene are made in small amounts and income restrictions act as a barrier to making periodically structured payments toward SHS (Green Nine, 2004).

- Opportunity costs of biomass collection. The time spent by households in collecting biomass is assumed to have an opportunity cost, because that time could be used on other activities, such as income generation or education. However, to determine the value of that opportunity cost and how it plays into households' decisions is still an active area of inquiry (Campbell et al., 1997; Arnold et al., 2003, 2006).

Therefore, estimates of benefit and potential penetration are based on theoretical or on controlled experiments and not on reality, or from taking a social[23] instead of an economic approach as the framework for estimating benefits. In many cases, inadequate knowledge and diagnosis results in poor estimations.

23.4.10 Oil Price Volatility

Crude oil prices behave much as any other commodity. They experience wide price swings in times of shortage or oversupply, through political instability, and for many other reasons (see Chapter 5). The crude-oil price cycle may extend over several years in response to changes in demand, as well as Organization of the Petroleum Exporting Countries (OPEC) and non-OPEC supply.

Since 1973, crude oil prices have swung wildly. They reached levels that few predicted and then dropped precipitously, before rising again and falling in response to global economic crises. This has a direct impact on low-income energy services.

Most rural and peri-urban populations rely heavily on kerosene or LPG. Indirectly, the prices of other goods they depend on are influenced by oil prices. Developing countries are notably more dependent on imported oil and oil products. Many countries subsidize oil to keep the products affordable.

Also, escalating and unpredictable petroleum prices have placed many countries in a dilemma on how to protect the poor communities. The costs of direct subsidies are, in many cases, unsustainable. The recent instability in the price of petroleum fuels has, in some cases, actually caused households to switch back to traditional fuels.

Oil-exporting countries like Venezuela, where the market is controlled by the public utility Petróleos de Venezuela, S.A, do not fix domestic prices and consider the opportunity cost based on international prices. A similar situation is given in Ecuador, where Petroecuador controls the domestic market.

In Nigeria, the structural reforms implemented during the 1990s, including privatization of the state oil company, increased deregulation of petroleum prices, and domestic crude-oil allocation to the Nigerian National Petroleum Corporation would be paid for at export parity with immediate effect. The objective was to attract investment from international oil companies and improve profitability. Also, using the case of Nigeria and analyzing the impact of oil-price volatility, Moser et al. (1997) arrived at the following conclusion:

> "Inflation rate depend on shocks to output and the real exchange rates. However, the findings demonstrated that fluctuations in oil prices do substantially affect the real exchange rates in Nigeria. Also, it was found out that it is not the oil price itself but rather its manifestation in real exchange rates and money supply that affects the fluctuations of aggregate economic activity proxy, the GDP. Thus, we conclude that oil price shock is an important determinant of real exchange rates and in the long run money supply, while money supply rather than oil price shocks that affects output growth in Nigeria."

This is another example of the impact of the policies of liberalization, privatization, and deregulation implemented during the 1990s (Moser et al., 1997; Onayemi, 2003; Olomola and Adejumo, 2006).

Some countries, such as Chile, China, and Indonesia, have used direct cash transfers to cushion poor households against petroleum price hikes. However, most developing countries can ill afford such measures.

23 Considering the benefit for the economic system as a whole, but also the direct benefit that the target population involved in the project will receive (economic benefits).

23.4.11 Final Remarks on Challenges

It is neither our intention nor possible to cover all the challenges and barriers to access to modern forms of energy.[24] National circumstances, specific conditions, drivers related to the target population, energy chains addressed (electricity or oil products and natural gas), the organization of the energy system (public, private, mix), institutional structure (policy authorities, regulatory bodies), constitutional aspects (property rights on natural resources), and availability of energy sources are just some of the challenges.

The initial challenge is to avoid defining a policy approach based on ideological preconceptions[25] or preconditions, because they leave aside or ignore potential solutions. Strategies, instruments, measures, and actions need to be the consequence and result of adequate analysis, and offer a pragmatic path toward affordable access to modern forms of energy.

It is important to be as accurate as possible in estimating costs. An underestimate gives a false notion of what is possible within a given period. Estimates and, consequently, the achievement of targets will depend on proper understanding of the relationships between the investment needed, the economic capacity of the country, the financial instruments, and the capacity of the target population to afford the costs.

A third set of challenges is found in the capacity to design and implement public policies, along with a lack of information about the energy services to be addressed in terms of quantity, quality, location, time, logic, and means.

Rapid urbanization, both historical and current, poses a further challenge in agreeing where, how, and what type of infrastructure should be developed. There are sociocultural issues related to the behavior of rural populations moving to peri-urban areas and maintaining their rural customs to satisfy energy services. The increasing and different needs of urban and rural environments, along with the prerogative to keep rural populations in rural areas, are among the challenges that would need to be part of any public policy process, along with the objective of meeting human needs.

Robust decision making in public policies is another key challenge in the quest for feasible measures and actions. The volatility of oil prices,[26] however, brings uncertainty to the equation. Oil products are immediate, feasible, and natural substitutes for biomass and other caloric energy services. In many countries, oil is the main source of energy for power generation. Ethanol and biogas may be considered as options, but massive development in the production of such energy sources and associated appliances must be put in place immediately if they are to represent a solution for the 2.7 billion people using solid biomass as their main source of energy for cooking.

23.5 Introduction Regional Analysis

Although the aim of GEA, and of this chapter in particular, is to approach the global problem of access to modern sources of energy, the specific situations and realities of each region and country cannot be ignored. The magnitude and characteristics of the problem, the underlying reasons, the national and regional contexts, the current and historical circumstances that have influenced the situation, the policies and strategies that have contributed to solving problems (or, in some cases, to aggravating them), the socioeconomic structures, and the characteristics of energy systems, to cite only some of the many dimensions, necessarily imply that suggestions or recommendations would need to take account of the different realities and potentials. It is important to avoid the mistakes of the recent past, such as promoting particular institutional models without appropriate consideration of the peculiarities of the individual environmental, socioeconomic, and energy systems.

Section 23.4 identifies some of the principal challenges and barriers to meeting the objective of universal access to energy by 2030. It is important to prioritize a full understanding of the unique characteristics of different regions and countries.

The lack of access to modern sources of energy is dramatic in most sub-Saharan African countries and in much of South Asia and other Pacific Asia (Table 23.6). In these regions, the national and regional response capacities are different from those in LAC, where more

24 The energy systems have multiple dimensions as part of their own nature. Environmental, national constitution, and legal frameworks, sociocultural, economic, strategic, institutional, political, human health, security, technological, temporal, and energy reserves are the key dimensions addressed in different ways in different countries.

25 Such as "a free market is the best way for an efficient allocation of resources" or "private sector contribution is the only way to address access to modern forms of energy."

26 In many cases oil prices act as reference prices for the other energy sources (renewable and non-renewable).

Box 23.4 | Access to Modern Forms of Energy

"Access to energy services is still low in developing countries and this lack of access disproportionately affects the least-developed countries (LDCs) and sub-Saharan Africa.

- Three billion people – almost half of humanity – still relies on solid fuels: traditional biomass and coal. In LDCs and sub-Saharan Africa, more than 80% of people primarily rely on solid fuels for cooking, compared to 56% of people in developing countries as a whole.
- Two million deaths annually are associated with the indoor burning of solid fuels in unventilated kitchens. Some 44% of these deaths are children; and among adult deaths 60% are women. In LDCs and sub-Saharan Africa more than 50% of all deaths from pneumonia in children under five years and chronic lung disease and lung cancer in adults over 30 years can be attributed to solid fuel use.
- Access to improved cooking stoves is also very limited. In LDCs and sub-Saharan Africa, only 7% of people who rely on solid fuels use improved cooking stoves to help reduce indoor smoke, compared to 27% of people in developing countries as a whole.
- One-and-a-half billion people are still living in darkness – over 80% of them in South Asia and sub-Saharan Africa. More than 70% of people in LDCs and sub-Saharan Africa lack access to electricity, compared to 28% in developing countries as a whole."

Source: UNDP/WHO, 2009.

favorable macroeconomic conditions, development levels, maturity of energy systems, and contexts of regional cooperation offer a better framework in which to implement and succeed with oriented policies.

Access to electricity also varies dramatically among countries in the same region. For example, in LAC, 62% do not have access in Haiti, but only 2% lack access in Brazil. In sub-Saharan Africa, in countries such as Chad, Liberia, and Burundi, more than 95% of people lack electricity access, while only 25% are without access in South Africa, and less than 1% in Mauritius (Box 23.4).

Access to modern fuels for cooking, meanwhile, also varies dramatically among developing countries in the same region. In Asia, for instance, less than 10% of people in Bangladesh have access to modern fuels, but access is almost universal in Malaysia. In sub-Saharan Africa, less than 1% of people in Burundi, Liberia, Mali, Rwanda, Somalia, and Uganda have access to modern fuels, but 83% of people in South Africa have access.

There are significant differences in the availability, control, and management of energy sources among regions. The roles of the public and private sectors differ substantially within the same regions. Systemic, institutional, and individual capacities to implement policies and strategies are not the same. A long history of intervention by public utilities and governments in many LAC countries, for example, implies a different culture and approach to energy issues than in countries without such experience.

23.6 Africa Review: Successes, Failures, and Proposals

23.6.1 Introduction

In Africa, access to energy services varies greatly between regions, between rich and poor, and between rural and urban populations (see Chapter 19). North African countries have achieved universal access to both modern cooking fuels and electricity, with the exception of Mauritania. In sub-Saharan Africa, the situation is very different and only 17% of the population has access to modern fuels. This ranges from 0.3% in Burundi to 96% in Mauritius. At 26%, sub-Saharan Africa is the region with the lowest levels of electricity access (UNDP/WHO, 2009).

23.6.2 Access

Of the sub-Saharan African population, 26% have access to electricity, but only 6% use electricity for cooking because they cannot afford the relatively high electricity tariffs. In fact, the average power tariff of US$0.13/kWh is around twice that found in other parts of the developing world, and almost on par with that in the countries of the OECD.

To alleviate power shortages many sub-Saharan countries rely on short-term leases of diesel generators for emergency power, which leads to high average electricity costs of more than US$0.20/kWh (Eberhard and Shkaratan, 2010).

Access to electricity reflects the wide rural–urban and income divide. In sub-Saharan Africa, 71% of urban and 13% of rural residents have access, and only 4% of the lowest income quintile, as compared to 74% of the highest, have access (Banerjee et al., 2009).

From 1997 to 2007, sub-Saharan African countries invested in their infrastructures and the economy grew at about 5% per year while the power sector was growing at only 3% (Foster and Briceno-Garmendia, 2010). In 2010 sub-Saharan Africa spent US$45 billion on the power sector (just half the amount required to catch up with other developing areas) and US$30 billion of annual spending is domestically financed from the pockets of African taxpayers and consumers (Foster and Briceno-Garmendia, 2010).

The electricity generation capacity of the region with a population of 800 million is only 68 Gigawatts (GW), comparable to that of Spain with a population of 45 million, and when South Africa is not counted the total amounts to only 28 GW (Eberhard and Shkaratan, 2010). Access varies across regions and countries. North African countries, except Mauritania, have achieved universal electricity access, but in sub-Saharan Africa 561 million people, equal to 74% of the population, have no access to electricity, a figure that rises to 89% in rural areas (UNDP/WHO, 2009). The per capita consumption levels are only 457 kWh annually, on average, which reduces to 124 kWh without South Africa, compared to 1155 kWh in the developing world and 10,198 kWh in high-income countries (Eberhard and Shkaratan, 2010). When present electrification rates and population growth rates are projected to 2030, more people (654 million) will be without electricity in 2030 than in 2009 (587 million) (OECD/IEA, 2010).

Sub-Saharan Africa has adequate modern forms of energy resources (hydropower, oil and gas) for its population, but they are largely unused and 83% of the population still cook with solid biomass on open fires (UNDP/WHO, 2009). Most of the electricity generated in Africa (76%) is from thermal and/or fossil fuels (particularly from coal and oil), 22% is from hydropower, and the rest is from other sources – nuclear (South Africa) and geothermal (East Africa). All oil and gas producing countries in sub-Saharan Africa export fossil fuels. For example, in Mozambique 84% of the population still cook with solid biomass and only 12% have access to electricity, yet at the same time the country is exporting gas and electricity. Low population densities and dispersed settlement patterns in rural areas make affordable access very difficult. In Nigeria, a major oil-exporting country, 75% of the population still cook with solid biomass and have no access to modern cooking fuels.

Africa's energy situation is paradoxical in that the continent desperately needs energy for economic growth and poverty reduction, yet it is a net exporter of energy.

In addition to access to energy, both energy security and regional cooperation are among the key energy priorities in all reviewed national policy papers. Also, there is a growing interest in biofuels production and trade as an alternative option to fossil sources of energy. Efforts toward access to electricity and cooking fuels might be impacted by an additional burden of more expensive imported petrol and its derived products.

Table 23.7 | Number of people who rely on fuelwood and charcoal for cooking in assessed Sub-Saharan African countries.

Country	Population in 2006 (millions)	People who rely on fuelwood and charcoal for cooking	
		(millions)	%
Angola	16.6	15.7	95
Cameroon	18.2	14.2	78
Chad	10.5	10.2	97
Congo	3.7	2.9	80
Côte d'Ivoire	18.9	14.7	78
Equatorial Guinea	0.5	0.3	59
Gabon	1.3	0.4	33
Mozambique	21.0	16.9	80
Nigeria	144.7	93.8	65
Sudan	37.7	35.2	93
Total	273.1	204.0	75

Source: IEA, 2008.

To increase access to energy services, governments have to improve the performance of the sector in areas of governance, infrastructure, access to finance, and increasing regional trade. Also, income levels of both the rural and urban poor have to rise to make the transition from solid biomass to modern fuels and their appliances affordable.

23.6.2.1 West Africa

West African[27] countries are endowed with very significant energy potentials (oil, natural gas, uranium, hydropower, coal, renewable energy). There are major oil and gas reserves in Nigeria, Cote d'Ivoire, and Ghana. The most important reserves of oil and gas are concentrated in Nigeria. Hydropower potentials are important in Nigeria, Guinea, Ghana, Liberia, Cote d'Ivoire, and Mali. The main sources are the Niger, Senegal, and the Volta Rivers. In addition, solar resources are available and significant throughout the region and all year long.

In West Africa, electricity consumption is among the lowest in the world (on average 139 kWh/yr/capita compared with an average of 1020 kWh/yr/capita in North Africa) while the world's average is around

27 Africa is generally divided into five subregions: North Africa, West Africa, Central Africa, East Africa, and Southern Africa. The regions have formed economic communities and some countries are members of more than one regional community.

2400 kWh/yr/capita.[28] This low consumption is mainly a result of the low access to electricity services, especially in rural areas.

Annually, per capita electricity consumption in West Africa is slightly higher than the sub-Saharan African average. Cape Verde, Ghana, and Cote d'Ivoire have the highest electricity-access levels. They have implemented energy policies to improve access at affordable prices. The highest levels of access resulted from public policies to improve access to electricity while ensuring affordable pricing: the lifeline tariff in Ghana and subsidies in Cote d'Ivoire.

Lessons learned show that social tariff, social electrification, moderate residential tariffs, and subsidized connection were key instruments for their success. Government subsidies to LPG have been a key incentive for a large diffusion of the use of this product for cooking. Different mechanisms were used, such as cross-subsidies, specific funds, funds from the general treasury, and others.

23.6.2.2 Central Africa

In Central Africa, energy potentials are large and diverse. After Nigeria, the region has the most important oil producers in Africa – Angola, Equatorial Guinea, Gabon, Congo, and Chad. The oil reserves in Central Africa are estimated to amount to some 11.4 billion barrels representing 11% of Africa's reserves. The gas reserves are estimated to be more than 430 billion m^3 (3% of Africa's reserves), and are located in Cameroon (37% of Central Africa's reserves), Congo (23%), Rwanda (12.7%), Angola (10.6%), Equatorial Guinea (8.5%), and Gabon (7.8%). However, this resource remains underexploited (CEMAC, 2006).

The region also has very important hydropower resources (1000 TWh), which is around 60% of Africa's potential. This potential is located mainly in the Equatorial zone: DR Congo ranks first with 100 GW, Cameroon is second, followed by Congo, Gabon, and Equatorial Guinea. Elsewhere in Central Africa, Rwanda has geothermal resources and there are significant methane deposits in Lake Kivu on the border between Rwanda and DR Congo.

Although the region is richly endowed with large modern forms of energy resources, wood, charcoal, and forest residues make up 70–90% of primary energy supply, and up to 95% of household energy use in some countries. A large majority of the Economic Community of Central African States (CEMAC/ECCAS/CEEAC) population uses wood energy harvested without regard for its sustainability, which is burned in unhealthy conditions.

With the exception of Gabon, where 68% of the population uses it for cooking, the use of LPG is still limited to urban areas of most of sub-Saharan Africa. In fact, this product (bottled in small to medium canisters for households and small enterprises use) is a better and cleaner fuel than wood and charcoal used for the same purposes.

Several electricity companies that have been unable to invest and keep up with growth in the demand within the localities they serve, or that have suffered conflict-related damages, now find themselves with inadequate or obsolete production and transport facilities. In the best-case scenarios, private sector companies that provide a good level of service are not able to be the driving force behind hydropower investments, because of the high investment per unit of capacity, the long-term return on the investment, and the lower rate of return of the investment.

Peri-urban electrification is, in most cases, below standard and, with the exception of Cameroon and Gabon, rural electrification has not been pursued on a significant scale. No power company has developed a pro-poor commercial culture. The overall rate of household electrification in CEMAC is less than 15%, according to Africa Development Indicators (World Bank Group, 2011).

23.6.3 The Energy Dimension in the Poverty-reduction Strategies

In general terms, a sectoral approach has been used to include the energy dimension in poverty-reduction strategy papers (PRSPs).[29] Energy has been treated as a stand-alone sector and from a supply-side perspective (power-generation systems, biomass energy production and management, electricity-grid extension, petroleum exploration), mainly under the aspect related to the macroeconomic framework enhancement or infrastructure development.

The articulation of the energy dimension with the other main axes dedicated to poverty alleviation (social and income-generating activities, human development, access to basic social services for poor and vulnerable groups, rural development, and gender equity) was not seen as very significant.

However, an awareness of this gap in considering energy for poverty alleviation as arisen and the second generation of the PRSPs engaged an interactive multistakeholders dialogue to integrate the energy dimension into the poverty-alleviation options.

Table 23.8 summarizes the energy options as considered in the PRSPs documents elaborated by selected countries in Africa (Benin, Burkina Faso, Guinea RD, Mali, Niger, Rwanda, and Senegal).

28 Own estimation based on information from UNDP/WHO (2009), UNDP Human Development Report (2010) and Niez (2009).

29 PRSPs: country-driven approaches to tackling poverty, which have been developed through nationwide consultations with stakeholders.

23.6.4 Assessment of National Energy Policies/strategies in Selected African Countries

23.6.4.1 West and Central Africa

The assessed policies[30] relate to those of selected countries such as Burkina Faso, Cote d'Ivoire, Central Africa Republic, Ghana, Liberia, Mali, Niger, Senegal, Sierra Leone, and Togo. Nearly all of these identify access to energy as an objective or a priority in their energy policies. Table 23.9 summarizes the objectives and priorities and provides common threads of the energy policies in some of the selected countries. But rarely were objectives and expected results accompanied by a set of strategies, measures, and actions to achieve the targets.

Access to energy, energy security, and regional cooperation are the key energy priorities in all the reviewed national policy papers. In some countries, efforts have been made to speed up access to clean energy forms through dedicated programs and projects. A successful initiative from Senegal in West Africa is given in Box 23.5.

23.6.4.2 East and Southern Africa

In East and Southern Africa access to energy services varies more widely than that in West and Central Africa (see Chapter 19). Countries in East and Southern Africa can be divided into three groups. The first are those that have achieved or have definite policies and targets for universal access (e.g., Mauritius, South Africa). The second group consists of countries well on their way to having and implementing policies, and actively pursuing targets for greater access (e.g., Botswana, Kenya, and Zimbabwe). The third group includes countries with very low access rates and policies that do not seem to promise greater access rates in the near future (e.g., Burundi, Malawi).

Access to finance is a major barrier to extending energy services. In East Africa, Kenya addressed the problem and successfully raised finance to improve electricity generation. In 2006 the Kenya Electricity Company raised substantial investments through a public offer (PO) on the Nairobi Stock Exchange. The PO was an unexpected success and the electricity company exceeded the targeted amount (over US$112 million) and the share offer was oversubscribed by nearly double this amount (Bhagavan, 1999).

South Africa had the political will, the financial resources, and the capacity to implement the National Electrification Programme and increase electricity access from 36% in 1995 to 75% in 2007 (Niez, 2009). The connections to poor households are very highly subsidized, which makes access affordable for poor people. Every household in an area is provided with electricity supply, not only those customers who apply and pay, which significantly reduces cost. Other measures, such as prepayment meters, further reduced cost. Many people could not benefit from the huge investments in electricity supply because they could not afford to use it. The government then introduced a lifeline tariff of 50 kWh free of charge for poor customers. The Free Basic Alternative Energy Tariff subsidizes energy sources such as kerosene, LPG, and renewable energy, particularly in areas not connected to the grid, but this tariff is not or is poorly implemented (Box 23.6).

In Botswana, the Rural Electrification Collective Scheme (RCS) started in 1988 is an example of adjusting conditions of supply when the initial policy does not achieve its objective. The government extends the grid to the village and customers pay for the extension to their houses. Initially uptake was very slow and it took over ten years to adapt the scheme by gradually easing payment conditions, but not the total amount, until potential customers were able to afford the smaller installments over a longer period and then electricity access substantially increased at full cost recovery.

In Zimbabwe, low take-up rates threatened the minimal returns on investment in rural electrification. The Rural Electrification Agency (REA) established in 2002 supports income-generating activities for small and medium enterprises (SMEs) in order to increase electricity demand in rural areas and stimulate small-scale commercial and industrial development. REA provides loans and delivers electrical machinery ordered by SMEs. The Rural Electrification Programme is funded by a levy on all electricity bills of 6% (in 2007) as well as government fiscal allocations. Once small enterprises had access to electricity demand went up, and the variety and use of electric machinery increased and, at the same time, the use of stand-alone generators declined.

The third group is made up of low-income countries that cannot afford the necessary additional investments to accelerate greatly their energy access rates and will have to raise more finance from external sources, move their access targets from 10 to 20 or 30 years, or use alternative low-cost technologies serving more people in the short to medium term.

In the GEA solid biomass, and in particular woodfuels, are not considered as a modern energy form. However, 80% of the population still depends on woodfuels for their energy needs in Africa. To bridge the energy gap until modern energy forms are available and affordable, there is a need to relook at the traditional woodfuels sector with a view to modernize access, use, and supply. The wood and charcoal sector must be re-evaluated because it is an economic resource from which millions of people derive jobs and income. In Malawi and Burundi – two landlocked countries – the woodfuel market contributes about 2% to GDP. Community-based woodfuel production (CBWP) has been introduced in some African countries (Madagascar, Mali, Senegal) and has proved to be a successful strategy to decentralize forest management from exclusive government control to the local level, empowering communities to

30 The national energy policies/strategies are reviewed based on the existing/available policy papers or other available documents that mention the principles of national energy policies.

Box 23.5 | Senegal LPG National Program

A national program to promote LPG use in Senegalese households was implemented in 1974. This program was developed to attenuate the effects of drought and deforestation. The program's goal was to increase LPG consumption and decrease the reliance on biomass by the most vulnerable populations. Initially, a cooking stove with an attached 2.7 kg LPG cylinder was promoted. Then, in 1983, a more solid cooking stove with a 6 kg LPG cylinder better adapted to the cooking habits and income levels was also subsidized. In addition, the Senegalese government exempted all LPG-related equipment from customs duty, and eventually subsidized the LPG itself in 1976. This program, which focused on the distribution of 2.7 and 6 kg LPG bottles (called popular gas), resulted in an annual increase in LPG consumption from 3000 tons in 1974 to nearly 140,000 tons in 2005. This represents an average annual growth rate of 10–12%. The transition from biomass to LPG was achieved gradually, particularly in urban areas. It resulted in a new domestic fuel consumption profile in urban areas characterized by the use of LPG and charcoal. The key lesson learned from the Senegalese LPG program is that the political will and adequately targeted measures are necessary to achieve large-scale access to modern forms of energy.

Box 23.6 | Electricity Access for Poor People: a Study of South Africa and Zimbabwe, Key Findings

In both countries examined, primary data on the electrification of poor people are almost non-existent – and this forms a key limitation of this study. Although, for instance, the National Electricity Regulator in South Africa keeps track of rural electrification levels, the data are not categorized by poor and non-poor users. Because of these data limitations, the findings and conclusions of this study should not be regarded as fully conclusive.

The comparisons between South Africa and Zimbabwe indicate that the policy environment to encourage and enable the provision of energy services for poor people needs to be designed for the specific needs of the country. The reforms undertaken to enhance access to electricity realized positive outcomes, particularly under the grid-based electrification programs. In South Africa, national electrification levels more than doubled from 34% to 70% between 1994 and 2001, as they also did in Zimbabwe, growing from 20% to 42% between 1980 and 2001. The Government-funded electrification program in South Africa took a shorter time and reached a much larger proportion of the population than the program in Zimbabwe.

In an attempt to reach poor people in remote locations, both countries focused on the establishment of off-grid programs which were mostly centered on SHS powered by solar PV technology. Even if all the operational and financial problems are resolved, off-grid programs based on solar PV home systems require an urgent review as they are focused on lighting, which is not the highest priority for poor people (Davidson and Sokona, 2002). Designing energy programs for poor people must address household-cooking and water-heating needs as a priority over lighting, which would, for example, reduce dependence on fuelwood. Similar priority would need to be attached to the provision of electricity for motive power, which would support small-scale rural industries for income-generating activities, and other services such as water pumping.

In both countries, the reforms have attempted to make electricity affordable to poor people. South Africa has introduced special subsidies on electricity consumption, including some free electricity. Zimbabwe has established a rural electrification fund to subsidize rural electrification schemes.

The electricity basic services support tariff (EBSST) subsidy in South Africa, which supplies 20–50 kWh of free electricity to poor people in selected areas, seems to have realized direct benefits for poor people. It had some positive impact on poverty alleviation as it reduced electricity expenditure. The reforms in both countries have ensured the protection of funds for financing the electrification of poor people by requiring transparency and accountability, albeit in different ways. In South Africa, the National Electricity Regulator (NER) aggressively monitors and makes public the progress of the National Electrification Programme through the NER's annual reports. In

Zimbabwe, the Performance Improvement Programme includes explicit rural and urban electrification targets that the utility is obliged to meet.

In order to meet the electrification challenge in rural areas, a diverse set of technical and institutional approaches will be needed – covering large-scale grid-connected extensions and new developments, together with smaller-scale distributed energy systems using both conventional and renewable energy sources.

Strong institutions are the backbone of an efficient and effective energy sector. National policies that create the right enabling environment for investment and business-led market growth are going to be essential.

The paper recommends the following for further investigations:

- Income-differentiated electrification, both current and trend data.
- More detailed understanding, through participatory approaches, of the associated social and economic characteristics of energy-consumption patterns of poor people.
- Innovative technological approaches to reduce connection fees and distribution costs, and so reduce the overall cost of increasing access to electricity to poor people.
- Further assessment and review of the use of renewable energy, especially SHS, as a poverty-alleviation tool in off-grid electricity supply.
- Exploration of public–private management schemes that could benefit poor people. This should include an assessment of the role of independent power producers and energy service providers.

Source: Davidson and Mwakasonda, 2004.

manage their forest resources sustainably (de Miranda et al., 2010). The CBWP approach has also been successful in promoting forest rehabilitation and reducing deforestation rates, creating long-term ecological benefits. In countries where the dependence on woodfuels is very high CBWP could be part of national energy policy.

At least as a transition phase, there is an urgent need to disseminate modern woodfuel technologies more widely as part of the access to energy services agenda. Traditionally, people use woodfuels in open fires with major negative impacts on health. Modern woodfuel technologies, including gasification, save woodfuels, minimize harmful emissions, and can make sustainable use of Africa's forest resources. In addition, efficient modern charcoal kilns should be strongly supported and disseminated to improve productivity and reduce waste of forest resources.

23.6.5 Energy Strategies of Africa and Sub-regional Bodies

The New Partnership for Africa's Development (NEPAD), adopted at the Organization of African Union in Lusaka, Zambia, in July 2001, recognizes the important role that energy plays in the development process of African countries, not only as a domestic necessity, but also as a factor of production whose cost directly affects prices of goods and services, and the competitiveness of enterprises (Zhou, 2003). In this regard, NEPAD has identified actions that need to be taken to address the critical barriers to universal access to modern energy in Africa.

NEPAD set a target for providing access to electricity for 35% of the population of Africa by 2015 and modern forms of energy for cooking, such as improved stoves or fuels like LPG, to half the population. Since then, all regional organizations have developed strategies or action plans.[31]

31 In 2002, NEPAD proposed that regional organizations, such as ECOWAS, CEMAC, or the EAC, play a key role in increasing the access to modern forms of services. NEPAD set a target for providing access to electricity for 35% of the population of Africa by 2015 and modern forms of for cooking, such as improved stoves or fuels like LPG to half the population. Since then, most of these regional organizations have developed strategies or action plans, such as the ECOWAS/UEMOA White Paper on Energy Access, the EAC Energy Access Strategy, and the CEMAC Action Plan for Promotion of Energy Access (all adopted in 2006) (Holland and Mayer-Tasch, 2007).

23.6.5.1 West and Central Africa

In West Africa, ECOWAS and the West African Power Pool (ECOWAS/UEMOA, 2006) formulated policies to enable at least half of the rural and peri-urban population to gain access to energy services by 2015. This would give access to 36 million additional households and over 49,000 additional localities. The specific objectives are to provide access to:

- 100% of urban and peri-urban areas; in rough terms, this means doubling the current access rate.
- 36% of rural populations – where the rate in the least densely populated countries is just 1%, and for the more advanced countries is 10%.
- Moreover, 60% of the rural population will live in a locality equipped with modern basic social services – healthcare, education, drinking water, communication, and lighting. This will be achieved through either decentralized electrical facilities or grid extensions. The objective entails increasing current levels threefold.

In Central Africa the CEMAC Action Plan (CEMAC, 2006) is geared primarily to rural and peri-urban zones, and energy access development will be balanced through:

- Strong LPG dissemination in peri-urban areas (70%), increased usage in secondary towns (50%), with use rates decreasing from 35–10% depending on the size of the inhabited area.[32]
- Usage by other households of improved stoves with chimneys (proportion of households increases from urban to rural areas).
- Supplying 50% of the peri-urban population with electricity through the power grid.
- Providing 35% of rural households with grid electricity or solar kits.
- Installing a corresponding infrastructure in non-electrified villages, giving 56% of rural inhabitants access to power supplies.

A set of 11 strategic activities are included and consist of:

- coordinated development of hydropower;
- rational use of surplus biomass;
- waste from agroindustrial units and peri-urban areas;
- rural energy service projects in promotion zones;
- intensive peri-urban electrification project;
- promotion of PVs;
- optimizing the domestic fuel market;
- support for the coordinated development of the hydrocarbon market;
- elaboration of an energy charter;
- establishment of an energy access observatory; and
- technology transfer and strengthening of national value added.

23.6.5.2 East and Southern Africa

As in West Africa, in 1995 the Southern African Power Pool was created to develop electricity trade, reduce energy costs, and promote greater supply stability for the region's 12 national utilities.

The Southern African Development Community (SADC) countries signed an energy protocol which came into force in April 1998 (SADC, 1998). Key objectives of the protocol are:

- to harmonize national and regional energy policies, strategies, and programs;
- to cooperate in the development and utilization of energy and energy pooling to enhance security and reliability;
- to develop jointly the human and institutional capacity of the energy sector; and
- to promote standardization where appropriate in the energy sector.

23.6.5.3 Summary of Regional MDG-related Energy Target

Regional organizations for sub-Saharan Africa have also proposed targets for countries in their regions to adopt, as follows for 2015 as specified in the MDGs objectives.[33]

The Forum of Energy Ministers of Africa Position Paper (FEMA, 2006):

32 We assume a combination of measures, including substitution between sources. This means that in some areas the LPG share will increase, but in others another energy source will replace it.

33 The majority of summary is drawn from a publication by UNDP/WHO in 2009, "*The Energy Access Situation in Developing Countries: A Review Focusing on the Least Developed Countries and Sub-Saharan Africa*".

- 50% of Africans who live in rural areas and use traditional biomass for cooking would need to have access to energy services, such as improved cooking stoves, which reduce indoor air pollution, as well as efficient kerosene and gas stoves.
- 50% of urban and peri-urban poor should have access to reliable and affordable energy services for their basic energy needs, such as cooking and lighting, and productive uses such as agrocultural processing and general value addition.
- 50% of schools, clinics, and community centers should have access to modern electricity services for the provision of lighting, refrigeration, information, and communication technology.

The ECOWAS White Paper (ECOWAS/UEMOA, 2006):

- 100% of the total populations (325 million people) will have access to a modern cooking fuel.
- At least 60% of people who live in rural areas will have access to productive energy services in villages, in particular motive power to boost the productivity of economic activities.
- 66% of the population (214 million people) will have access to an individual electricity supply, or 100% of urban and peri-urban areas, 36% of rural populations, and, moreover, 60% of the rural population will live in localities with:
  - modernized basic social services – healthcare, drinking water, communication, etc.
  - access to lighting, audiovisual, and telecommunication service, etc.
  - coverage of isolated populations with decentralized approaches.

The CEMAC Action Plan for the Promotion of Energy Access (CEMAC, 2006):

- 50% of the population to have electricity access, with at least 35% of the rural population having access.
- 80% of the peri-urban and rural population to have improved access to modern fuels for cooking and heating.

The EAC Energy Access Strategy (East African Community, 2006):

- 55% of the total population in the region will have access to LPG or improved stoves and to sustained biomass supply. This is the equivalent of an additional 50% of the population that currently does not have access to modern cooking practices.
- 100% of urban and peri-urban households will be provided with an electricity service.
- 100% of the rural population will live in a locality where social service centers are equipped with energy services.
- 100% of administrative headquarters and localities with more than 3500 inhabitants will be equipped with mechanical power and heating technology.

The SADC Regional Indicative Strategic Development Plan (undated):

- 70% of rural communities will have access to electricity (by 2018), or
- 70% of rural communities will have access to modern forms of energy supplies (by 2018).

23.6.6 Key Conclusions on Policies at a Regional Level

It is evident that Africa has sufficient energy resources to fuel its own development, but so far most of the resources are undeveloped or exported. This is particularly so with oil that is sold in crude form and imported back as refined products, and yet the continent could build additional refinery capacity that can supply the bulk of Africa's needs. The energy industry is oriented to export (in oil-producing countries) and there is a lack of investment to mobilize the hydropower resources, large and small, and natural gas resources are unexploited. The hydropower resources in the DR Congo are barely exploited and are far from demand centers. There are few economies of scale in Africa, which makes the development of large energy resources unaffordable for individual countries and requires joint investments. Increasing the trade of energy, especially of oil, gas, and electricity, among African countries can significantly improve the uneven distribution of energy resources in the continent. To achieve this, capacity development and reinforcement in areas of governance, financing, and energy are necessary. Such capacity should be created at individual, institutional (individual capacity integrated with the institutions to afford its objectives), and systemic level (adequate coordination among the institutions).

Recently, regional bodies have developed a growing interest in promoting policies to improve energy access for poverty alleviation in addition to their natural regional priorities geared toward regional cooperation, infrastructure development for electricity and gas interconnections, and capacity development.

As cited above, ECOWAS, CEMAC, and SADC have developed time-bound objectives for access to modern forms of energy in their subregions in line with the MDGs horizon. This regional political will needs to be pursued and completed by action plans for the implementation and mobilization of funds.

The African Development Bank et al. (2003) has developed a strategic plan that takes poverty alleviation as one of its priorities. The Bank is

updating its energy sector policy (enacted since 1994). An appropriate updated policy has to comply with national priorities and support energy security at both the macroeconomic and local levels.

South Africa, Botswana, Ghana, and Zimbabwe have implemented policies and strategies to give poor households greater access to electricity and to make the use of electricity more affordable. Emphasis on access was, in three cases, the primary focus and in their different ways the policies and strategies have achieved their objectives. When it was found that the programs started in these countries did not fully achieve their objectives, adjustments were made over time. In South Africa the Free Basic Electricity tariff was introduced, in Botswana up-front cost and the repayment rates were reduced, and in Zimbabwe the cross-subsidy was raised from 1% to 6% to pay for the program.

23.6.7 Lessons Learned

- Sub-Saharan Africa has adequate energy resources (hydropower, oil, gas, coal) to fuel its development, but they are largely unexploited. Greater regional cooperation and trade offer the least-cost option for energy development.
- The experiences of West African countries show that social tariff, social electrification, moderate residential tariffs, and subsidized connections were key instruments for their success.
- National and subregional energy policies and strategies would need to be harmonized with other relevant policies for efficient implementation and development.
- Energy policies should aim at creating conditions to support subregional and regional energy industry and market development for renewable and non-renewable energy resources.
- There are many successful African examples of addressing barriers to energy development. Learning from and upscaling these best practices will avoid costly mistakes and increase access to energy services.
- Sub-Saharan African's utilities have implemented some reforms, but more needs to be done to increase the efficiency of the power sector. Tariffs are often not cost reflective, and subsidize the affluent sector of society who could afford a connection anyway. Charging full cost to this group would save the government subsidies which might be better used to extend the grid to a poorer part of the population and advance development.
- Energy issues should be well integrated into PRSPs and other national and regional development issues. In particular, energization of rural areas achieves greater results when integrated into multisectoral rural development strategies, and programs.
- All options of energy supply, grid, minigrid, and off-grid, are valuable in their appropriate context.

23.7 Asia Review: Successes, Failures, and Proposals

23.7.1 Introduction

One-fifth of the population (some 800 million people) of the Asia-Pacific region still lack reliable access to electricity, and more than half (near two billion people) still lack access to clean cooking facilities. According to a recent report by the International Energy Agency (Niez, 2009), around 1.3 billion people globally lack access to electricity, and more than half of these are in the Asia-Pacific region. This has severe socio-economic costs, particularly for the 641 million people in this region who live on less than US$1/day as they tend to spend a higher proportion of their income on energy.[34]

Although in some Asian and Pacific subregions the proportion of the population with access to electricity improved overall between 1990 and 2005, this growth was much less than the GDP growth rate over the same period. Growth in access to electricity and in GDP has also been much greater than the global averages (see Chapter 19). In southeast and northeast Asia, this growth was also much greater between 1990 and 2000 than that in more recent years.

By 2005, more than two million households in the region were generating electricity from stand-alone SHS.[35] However, assuming an average household size of five persons across these countries, this only equates to roughly 10 million people or only 1% of the population without access to electricity.

23.7.2 Energy Access Programs and Success Stories in Some Selected Countries

This section highlights the roles of factors that enhance access to electricity supply through successful rural electrification programs in Asia. In grid-based rural electrification programs, these factors include:

- dedicated public institutions and community organizations for rural electrification;
- self-sustainable revenue generation;

34 See UNESCAP, 2007 from which this section draws heavily.

35 However, they receive very limited access to electricity, as the SHS have a supply very low capacity, and supply very few energy services.

- strong non-residential customer base to cross-subsidize electricity to residential customers;
- sufficient public investment in rural electrification prior to reforms that allow private participation in electricity supply;
- economic growth;
- sound financial performance of rural electrification institutions and an ability to expand generation capacity adequately;
- involvement of stakeholders in planning and implementing rural electrification schemes;
- in some cases, the removal of regulatory barriers, e.g., house registration identity documents in Thailand.

In rural electrification programs not based on grids, the key factors to increase electricity access include innovative financing schemes to overcome the barrier of high up-front costs of isolated or decentralized electricity-generation systems (e.g., *Grameen Shakti*, see Box 23.7), SHS, and technology support.

While the figures in the next paragraphs serve as a common denominator to the problem, there exists wide disparity in rural electrification in South Asia. Sri Lanka has a rural electrification rate higher than the global average, while only 12% of the rural population in Afghanistan is connected to the grid. India, Pakistan, and Bangladesh alone constitute more than 90% of the region's population without access to electricity, with the remaining 10% in other South Asian countries.

India, Nepal, Sri Lanka, and Bangladesh have taken the lead in using off-grid technologies to create access to electrification in rural areas through a range of schemes and models. Of the region's 614 million rural people without electricity, many live in isolated communities, far from the national electricity network. These off-grid communities are generally small and dispersed, consisting of low-income households with characteristics that are economically unattractive to potential private sector energy providers, or even to government electrification programs that usually prioritize the allocation of scarce resources.

In 2008, the national electrification rate in Nepal was 64.5% with a very uneven urban–rural distribution. In urban areas, where less than 20% of the population lives, the household electrification rate is 93.1%, while the rate in rural areas is only 52.5%. It is highest in the accessible lowland regions and lowest in the mountain regions. The per capita electricity consumption is only 81 kWh/yr, one of the lowest in the world (Palit and Chaurey, 2010). In 2001, only 27% of the total population had access to grid electricity. In 1996, the Government of Nepal started a pilot electrification project under the Rural Energy Development Program (REDP) to promote modern forms of energy. Its objective was to alleviate poverty, improve livelihoods, and preserve the environment in remote and rural parts of the country, where grid-based electrification was not expected to materialize in the near future. After the successful implementation of the pilot projects in five districts, it was extended to a further 25 districts.[36]

The REDP concept is heavily based on the decentralized and participatory decision-making process and a holistic development approach. A salient feature is its strong community mobilization process, focusing on (i) organizational development, (ii) skills enhancement, (iii) capital formation, (iv) technology promotion, (v) environmental management, and (vi) vulnerable community empowerment. Participation, transparency, consensus decision making, and inclusion of all households in the community, irrespective of class, color, creed, or gender, are the four pillars of good governance for ensuring equal ownership and equitable sharing of benefits accrued from MH systems.

By 2007, the REDP had installed 185 MH plants, with a total capacity of 2.47 MW. Together, these plants provide electricity access to more than 120,000 people for lighting and mechanical power for agroprocessing and other productive applications (Rijal et al. 2007). The main reason for REDP's success is its effective resource investment in capacity development of local stakeholders, effective community mobilization, and affordable tariff structure (GNESD, 2004).

The Energy Sector Assistance Programme (ESAP) has also been instrumental in supporting the Alternative Energy Promotion Centre to promote MH schemes of up to 100 kW. Besides loan financing available through commercial banks, there was also the provision of financial subsidies for these projects. Also, a total of 69,411 SHS were installed in the country, bettering the program target of 40,000 systems under the ESAP's first phase. The program was also successful in establishing guidelines for administering solar energy subsidies and putting in place quality assurance and monitoring systems for the solar energy projects.

Sri Lanka stands out in South Asia for its high rate of household electrification. Between 1986 and 2005, the national electrification rate improved substantially from 10.9% to 76.7%. Almost 75% of Sri Lanka's rural households are connected to the electricity grid, while another 2% are provided with basic off-grid electricity connections. In the off-grid sector, small hydropower has been the preferred option, with the first off-grid village hydropower scheme commissioned in 1992. The program resulted in a dramatic increase in the development of grid-connected and off-grid renewable energy projects, prepared and implemented by the private sector and village communities. Studies have concluded that the large-scale penetration of SHS in Sri Lanka has helped rural communities to improve their socioeconomic conditions and reduce adverse environmental impacts.

36 In Nepal, almost 30% of electricity supplied in the rural areas is through the off-grid route. The use of alternative energy sources for rural electrification took place because of the early realization by the Government of Nepal that the central electricity grid may not reach most rural populations (Palit and Chaurey, 2010).

With a view to enhancing rural electrification, the Energy Service Delivery Project (ESDP) was jointly initiated by the World Bank and the Government of Sri Lanka in July 1997 for a five-year period. The project aimed to create nationally coordinated programs to introduce, popularize, and consolidate alternative energy sources including village MH system. The project provides financing, including a grant portion from Global Environmental Facility, for both grid-connected schemes and off-grid connected schemes for rural electrification.

The project facilitated an accelerated development of village MH schemes in Sri Lanka, with technical backstopping from the Intermediate Technology Development Group (ITDG), a NGO. As ITDG had been promoting grid-connected small hydropower plants, off-grid MH systems, biogas systems, and small wind systems for 15 years in Sri Lanka, its expertise was helpful during the dissemination program.

The successful lessons from the ESDP are now being replicated on a larger scale under a successor program, Renewable Energy for Rural Economic Development Project, funded by the World Bank (World Bank, 2003).

In Thailand, the Provincial Electricity Authority (PEA) formulated a 25-year National Plan for accelerated rural electrification in 1977. This served as the master plan for the country's rural electrification. The PEA was able to increase electricity access to rural populations from 7% in the 1970s to 99% by 2007. The key factors behind the rapid growth in Thailand's rural electrification include the creation of a dedicated entity, the Office of Rural Electrification, by the PEA, with specific responsibilities to implement the rural electrification program, self-sustainable revenue generation, involvement of end users in planning, financing of development of distribution network, and subsidies to residential customers (Shrestha et al., 2004b). High levels of electrification were achieved in Thailand by the early 1990s. As a result, subsequent reforms in the power sector, such as private participation in power generation and tariff reform, do not seem to have affected the rural electrification in Thailand.

Bangladesh's rural electrification program was launched in 1977 at around the same time as that of Thailand. The program in Bangladesh was implemented through two-tiered institutional arrangements involving the Rural Electricity Board and rural electricity cooperatives known as *Palli Biddut Samities* (PBSs). Each consumer is a member of the PBS that serves them. The Rural Electrification Board is responsible for planning and developing the distribution network. The PBS is responsible for preparing a master plan on electrification of its members and for forecasting load growth. The PBS also manages financial and operational activities. The 70 PBSs established provide electricity to more than 40 million people living in 38,000 villages (GNESD, 2007).

Rural electrification has helped generate local employment and promoted local non-farming economic activities in Bangladesh (Barkat, 2005). This has helped to make electricity more affordable for people. PBS has been successful in reducing system losses by 50% and improving billing collection, which stands at more than 95%, compared to national utilities (Rijal et al., 2007). According to GNESD (2007), PBS is a model to be followed by highly centralized national electricity utilities. Its success lies in effective decentralized actions, facilitation of cooperatives with subsidized finance, a revolving fund for loss-making cooperatives, subsidized power from the Bangladesh Power Development Board, performance target agreement of cooperatives with the Rural Electrification Board, and intersectoral cross subsidy provision for customers (Rijal et al., 2007; GNESD, 2007).

The rural electrification programs in Bangladesh and Thailand have a number of things in common. These include (Shrestha et al., 2004b):

- the creation of an entity with specific responsibilities to implement the rural electrification program;
- involvement of end users in the distribution network planning process;
- financing of distribution network development, the creation of the distribution networks, is funded through grants and low-interest loans from the government, as well as bilateral/multilateral agencies; and
- provision of subsidies to residential consumers of electricity.

Despite the similarities in approach, the achievements were more significant in Thailand. Only 19% of Bangladeshi households were electrified by 2000. Although the Rural Electrification Board and PBSs covered 90% of the area in Bangladesh with a basic distribution infrastructure, household connectivity is still very low. According to the IEA, the overall electrification rate in Bangladesh was 41% in 2008, with 76% of the urban population and only 28% of the rural population having access to electricity. Although the rural household electrification rate is poor, Bangladesh has recorded an impressive rural electrification performance with the help of solar PV technology, particularly SHS (Box 23.7). The solar PV program was developed by the Infrastructure Development Company Limited, Bangladesh, with the help of the World Bank.

Three factors that appear to have influenced the divergence in achievements of the rural electrification programs in Bangladesh and Thailand are financial resources, electricity generation capacity, and level of economic growth:

- Financial resources: The PEA in Thailand was able to cover its operational cost through revenue generation from the sale of electricity. This enabled the PEA to use new resources allocated for rural electrification to expand the distribution network. However, unlike the PEA, the PBSs in Bangladesh were not able to meet their operational costs. Both, however, received power from a national electricity-generating

Box 23.7 | *Grameen Shakti* Microfinance Scheme in Bangladesh

Grameen Shakti was incorporated in 1996 as part of the *Grameen* family of companies. It specialized in renewable energy, such as SHS, wind, and biogas. The main objective was to produce electricity to provide the minimum needs of electricity for lighting after dusk to enable income- generation activities to continue at night. *Grameen Shakti's* board of directors and top management had extensive experience of microcredit financing and many were founding members of the Grameen Bank. Their experience in microcredit was essential in the design of *Grameen Shakti* programs.

Grameen Shakti has various financing models (Barua, 2005).

- Mode 1: The customer has to pay 15% of the total price as a down payment during installation and the remaining 85% of the cost is paid by monthly installation within 36 months, including a 12% service charge.
- Mode 2: The customer has to pay 25% of the total price as a down payment during installation and the remaining 75% of the cost is paid by monthly installation within 24 months, with an 8% service charge.
- Mode 3: The customer has to pay 15% of the total price as a down payment during installation and the remaining 85% of the cost, including a 10% service charge, is made by 36 post-dated checks.
- Mode 4: 4% discount is given for cash purchase.
- Mode 5 (microutility): The customer has to pay 10% of the total price as a down payment during installation and the remaining cost is paid by installments within 42 months, with no service charge. Here the customer sets the system up on his/her premises, and other shop owners receive the facility of SHS in exchange for payment.

Grameen Shakti developed one of the most successful market-based programs with a social objective of popularizing SHS, as well as other renewable-energy technologies, to millions of rural villagers. *Grameen Shakti* used its Grameen Bank concept of microcredit to evolve a financial package suitable for rural people, which helped, in particular, to bring down costs. The customized pricing system based on installments helped *Grameen Shakti* to reach economies of scale with the increase in sales. Their business is centered on customer-service excellence. *Grameen Shakti* engineers pay monthly visits to households and offer their services for a small fee upon the signing of an annual maintenance agreement by clients. *Grameen Shakti* also undertakes several other activities, such as educational loans and gift schemes, which go well beyond the energy service itself and help develop trust between it and the local communities. By the end of December 2009, the total number of installations had reached 113,736 SHS.

authority at subsidized rates. But the ultimate financer of these subsidies in Bangladesh was the government, as the Bangladesh Power Development Board had been losing money and was unable to generate its own resources to pay for its operations. This was caused by combination of factors, including that the average Bangladesh Power Development Board tariff was set below the long-run marginal cost, there were high system losses (38%), and a low rate of bill recovery. The losses in Bangladesh also adversely affected the availability of financial resources from multilateral institutions, as between 1990 and 1995 they withdrew from financing the power sector in Bangladesh.

- Generation capacity: Lack of adequate supply, because the power-generation capacity expanded more slowly than the projected increase in demand. Unlike Bangladesh, generation capacity was not a barrier to expanding rural electrification in Thailand.
- Economic growth: High economic growth also implies expansion of commercial and industrial activities and therefore increased demands for electricity. The rise in the number of non-residential customers and the level of their electricity consumption provide a greater resource base for subsidizing residential consumers. The smaller, non-residential resource base was a factor that seems to have inhibited the electrification rate in Bangladesh. The per capita income growth during the rural electrification program was much faster in Thailand than in Bangladesh. At less than 2%, the poverty levels[37] in Thailand were very low, compared to 36% in Bangladesh in 2000. Bangladesh's high poverty levels imply that the consumer base with very low paying capacity is much larger in Bangladesh than in Thailand.

37 Population earning less than US1$ a day (UNDP Human Development Report, 2003).

In 1997, Indonesia promoted a household electrification program based on off-grid, stand-alone SHSs. This electrified rural areas where there were no plans to extend the government-owned utility's grid network. The Indonesian government has established a revolving fund, or grant, to implement these systems.

Users made down payments to cooperatives, and then paid monthly fees until the cost was covered. The program emphasized the formation of representative community groups (involving men and women in all stages of the electrification process), which helped to manage the electrification projects successfully.

The program promotes the use of locally made system components, which makes it cheaper and technically sustainable. This has been a success story for the off-grid electrification process, particularly for countries that lack the financial resources for grid extension in remote areas (UNEP/GNESD, 2002). The credit for this success goes to the effective management of cooperatives and the development of local manufacturing capability, which have reduced the system costs. However, as this scheme is based on a bottom-up approach, with users bearing all costs, it is limited to high-income groups only.

23.7.3 The Experience of India in Rural Electricity Access

With the largest rural population in the world, India is facing a huge electrification challenge. About 60% of rural households have access to electricity. Electricity consumption per capita is low at 543 kWh/yr/capita (Niez, 2009). There is also wide disparity in access to electricity between urban and rural populations, and also between states.

In the power generation sector, although India has considerably improved its generating capacity over the years, with installed capacity growing from 1362 MW in 1947 to 159,648 MW[38] by 2008 (Palit and Chaurey, 2010), the supply of electricity across the country currently lacks both quality and quantity. There is an extensive shortfall in supply, a poor record for outages, and high levels of technical and non-technical losses.

A number of specifically targeted schemes were launched in India to facilitate electricity access for poor people (Box 23.8). Most of these schemes were implemented by the state electricity utilities with central financial assistance disbursed through the Rural Electrification Corporation (REC).

The grid connection is the most favored approach to rural electrification for most rural households. But renewable off-grid technologies, such as solar PV, mini-/microhydropower, biomass gasifiers, biofuel-powered generators, and small wind aerogenerators in hybrid mode are also disseminated to areas that are inaccessible to the grid, such as remote, hilly, and forested villages, islands, or hamlets that are not recognized as villages by national census records.

Off-grid technologies have been used either through the creation of local minigrids, or by disseminating household-level technology, such as solar PV, for lighting and other low-consumption activities. It is reported that off-grid capacity in India is around 13 GW, of which 10 GW is diesel and 3 GW is renewable energy (Banerjee, 2006). Off-grid power plants based on renewable energy are typically in the range 1–500 kW, and are located in independent distribution network (minigrids). Most off-grid systems have been promoted by Government of India schemes.

23.7.3.1 Rural Electrification Policy

Rural electrification is a key factor in accelerating rural development. The provision of electricity is essential for the requirements of agriculture and other important activities, including small and medium industries, *khadi* (indigenous) and village industries, cold chains, healthcare, education, and information technology. Where a grid extension is not feasible in rural areas, the policy recommends distributed generation, through either conventional or non-conventional means, as the preferred option. District committees would coordinate and review the extension of electrification in the district, review the quality of power supply and consumer satisfaction, and promote energy efficiency and conservation. The policy stresses that the state governments should actively raise awareness of electricity issues, including generation, distribution, energy conservation, and the energy efficiency and energy-water nexus.

The policy says that it is essential for energy efficiency to be promoted in rural areas through mass campaigns. It also notes that the use of inefficient and energy intensive equipment by the agricultural sector distorts the consumption pattern and results in non-optimal utilization of tariff subsidies. It recommends the use of economically viable, energy efficient farm equipment, especially irrigation-pump sets.

The main vehicle chosen to implement the policy's universal access objectives is the *Rajiv Gandhi Grameen Vidhyutikaran Yojana* (RGGVY). This was launched in April 2005 with the goal of electrifying all villages and hamlets that were without electricity, and providing access to electricity to all households within five years. The RGGVY's basic objective is to create a rural electricity infrastructure in the country in order to provide all rural households with access to electricity within a given timeframe. The RGGVY emphasizes not just village electrification, but the facilitation of rural development, employment generation, and poverty alleviation through access to electricity. This includes below-the-poverty line (BPL) households, and also caters to the needs of agriculture, small and microenterprises, cold chains, healthcare, information technology, and education.

38 Thermal power (coal, gas, and diesel) accounted for about 64% of total installed capacity with 102,704 MW, large hydropower for 23% with 36,863 MW, grid-connected renewables for about 10% with 15,521 MW, and the rest from nuclear power.

Box 23.8 | Policy Regimes for Rural Electrification in India

In 2002, the Gokak Committee recommended that a choice between grid connection and decentralized generation should be made on the basis of technical, managerial, and economic issues. These included distance from existing grid, load density, system losses, and load management.

The Electricity Act 2003 was enacted in June 2003. Its overall objective was to develop the electricity industry and provide electricity access to all areas. Sections 4 and 5 of the Act specifically require the Government of India to formulate appropriate and adequate policies for the supply of electricity in rural areas.

The aims of the National Electricity Policy, introduced in 2005, include:

- Access to electricity: available to all households in five years.
- Availability of power: demand to be fully met by 2012; energy and peaking shortages to be overcome and adequate spinning reserve to be made available.
- Supply of reliable and quality power to specified standards, efficiently, and at reasonable rates.
- Per capita availability of electricity to be increased to over 1000 kWh by 2012.
- Minimum lifeline consumption of 1 kWh/household per day by 2012.
- Financial turnaround and commercial viability of electricity sector.
- Protection of consumers' interests.

The National Electricity Policy also states that wherever grid-based electrification is not feasible, decentralized distributed generation facilities (either conventional or non-conventional methods of electricity generation, whichever is more suitable and economical) together with local distribution networks will be provided, so that every household can access electricity.

The scheme's scope includes the provision of a rural electricity distribution backbone (i.e., 33/11 kV substations with adequate capacity and lines in blocks), creation of a village electrification infrastructure (i.e., electrification of unelectrified villages and settlements), provision of distribution transformers of appropriate capacity in electrified villages/settlements, decentralized distributed generation and supply, and electrification of rural households below the poverty line.

The RGGVY provides a capital subsidy of up to 90%. This is disbursed through REC Limited, a nodal agency for the scheme's implementation. The other 10% is to be arranged by the project developer. It is planned to involve private developers in the program, with the subsidy to be released on an annuities basis depending on the system's performance over five years. However, electrification of BPL households is financed with a 100% capital subsidy. The guidelines say that priority shall be given to villages where grid connectivity is not foreseen in the next five years.

The remote village electrification (RVE) program of the Ministry of New and Renewable Energy (MNRE) started in 2001. It aims to provide basic lighting facilities in unelectrified census villages, regardless of whether these villages were likely to receive grid connectivity. But the scheme was subsequently modified to cover only those unelectrified census villages that are not likely to receive grid connectivity. In addition to domestic use, the scheme has the option to provide energy services for community facilities, for pumping for drinking water or irrigation, and for economic and income generating activities in the village. Like the RGGVY, central financial assistance of up to 90% of the projects' costs is provided as a grant with specific benchmarks. The balance of 10% is financed through other decentralized governmental institutions.

The Village Energy Security Programme (VESP) was conceptualized as a step toward the RVE program. It also addresses a village's total energy requirements for cooking, electricity, and motive power, and it aims to transform the largely unsustainable use of locally available biomass to

Box 23.9 | A Good Example to Follow: Village Energy Security Programme in India

Launched in 2004, the Village Energy Security Programme (VESP) is a community-based initiative that aims to provide clean, affordable energy in rural areas – home to around 70% of India's population. The focus has been on finding ways for villages – particularly those located in remote rural areas that are unlikely to be provided grid electricity in the near future – to achieve energy security based on locally available renewable energy sources (preferably biomass). The program goes beyond rural electrification to village energization. It therefore places additional emphasis on cleaner options of cooking through improved cook stoves and biogas, productive use of energy for livelihood generation, and sustaining the energy systems through captive plantation. As of December 2009, 79 test projects have been sanctioned, of which 55 were commissioned in eight different states. These test projects were undertaken in non-electrified remote villages and hamlets that are not likely to be electrified through conventional means in the immediate future. Based on a community centric approach, a one-time grant (up to 90% of the project cost) was provided to the village community for installation of energy systems capable of meeting the village community's energy demands. The community, in some cases, also provided an equity contribution (either in cash or kind) to bring in the much needed ownership required for the success of any community centric projects. Based on an assessment conducted to review the performance, impacts, and lessons of the VESP test phase, it was found that the VESP projects emerged as a vehicle to motivate the community, especially the youth, to attempt develop their skills. Local youths enhanced their skill to operate the installed power-generation systems in almost all the VESP subprojects. Innovations adopted by select Project Implementation Agencies for capacity development of the technology operators helped to improve project performance. There are mixed results for social mobilization and leadership of the Village Energy Council (VEC), with mobilization and leadership relatively better in the test projects implemented by NGOs as compared to those implemented by state departments. Revenue management is comparatively better in projects where villagers have cash income because of either existing income-generation activities or newly introduced activities after being electrified under VESP. Active involvement of Gram Panchayats in some projects helped to develop the required synergy in getting village-development funds for VESP, both toward project cost and operational expenses.

However, along with the above-mentioned best practices some shortcomings were also reported. The uptime of the projects, considering their remoteness and various other inherent technical and institutional problems, is satisfactory in some of the projects, but it is poor in most of the projects. Some of the challenges for sustainability were found to arise from less-concentrated electricity demand in the villages, low economic activity (implying a lower electricity demand), less ability to pay by the consumers, difficulty in O&M, limited technical knowledge within the VECs, and weak fuel-supply chain linkages. One or a combination of these factors leads to a low load factor and fewer hours of operation, and thereby a low capacity-utilization factor. The potential of income generation activities and productive load was also not fully exploited because of the absence of proper guidance to the VECs to initiate and execute such possibilities.

Source: Palit and Chaurey, 2010.

innovative, sustainable modern biomass energy. The objectives of the VESP are:

- To meet village energy requirements through biomass material and biomass-based conversion technology, or other renewable technologies where necessary.
- To go beyond electrification by addressing the total energy requirements, such as those required for household cooking.
- These projects would involve the installation of energy production systems: biomass gasifiers, biogas plants, plantation activities, and improved cooking stoves (*chulhas*).

23.7.3.2 Institutional and Financial Viability of Electrification

Electricity is in the concurrent list of the Indian constitution, and therefore both state and central governments have jurisdiction over it. The state governments' jurisdiction includes generation, intrastate transmission, distribution, and intrastate trading of electricity. The central government's purview includes policy formulation, generation plants catering to more than one state, interstate transmission, and interstate trading of electricity. In the rural electrification sector, the principal actors have traditionally been the state electricity utilities, because they were responsible for the distribution of electricity in the states.

Table 23.10 | Subsidies for rural electrification schemes in India.

Scheme	Target under the scheme	Subsidy vehicle	Amount of central financial assistance
RGGVY	100% household electricity access throughout India by 2012	Capital subsidy	90% grant is provided by the Government of India 10% as loan by REC to the state governments Total subsidy disbursed by September 01, 2009: INR256,790,000,000
VESP	1000 villages to be electrified within the current five-year plan	Capital subsidy Operational subsidy for first two years	90% of the total project cost Maximum CFA per household is INR20,000 10% of the total project cost
RVE	Electrification of villages and hamlets that are not likely to receive grid connectivity	Capital subsidy subject to upper limits	90% of total costs of electricity generation systems

Source: TERI, 2007.

The total costs of RGGVY schemes were estimated recently as US$13.64 billion. The Ministry of Power funds 90% of RGGVY project costs, with state governments funding the remaining 10% through either long-term loans from the REC or other financial institutions, or from their own budgets. Household-connection charges are borne by individual households. However, for unelectrified households below the poverty line, the household connections are financed wholly by capital subsidies.

The total implementation costs for the RVE program and the VESP are estimated to be US$377 million. As with the RGGVY, subsidies from MNRE cover up to 90% of the project implementation costs (Table 23.10).

23.7.3.3 India Programs: Key Lessons

- Government support is essential to the development of a successful rural electrification plan. Laws and reforms have shaped the institutional and legal framework, but without firm implementation of policies and goals, enforced through legislation, the electrification process is difficult to achieve.
- The creation of franchises for the management of local power distribution in rural settings is reported to have brought efficient billing and revenue collection, and thereby ensure stable delivery of electricity. Studies by The Energy and Resources Institute (TERI) indicate that franchises are particularly effective in managing electricity provision and cost recovery, because they are in close contact with the targeted communities. This has led to a stronger sense of ownership of the electrification process.
- The three-tier quality-monitoring mechanism established the RGGVY is reported to be ensuring proper implementation of projects, thus contributing to their efficiency and long-term sustainability. Similarly, the five-year performance warranty and annual maintenance contracts for all systems installed by the RVE program is securing proper and sustained energy supply services.
- Involving rural communities in the decision-making process has contributed substantially to the effectiveness of the off-grid electrification program, adding value to the planning process and giving communities a sense of ownership of the process.
- A study by TERI in 2008–2009 to review the off-grid and grid-connected distributed generation projects produced a number of interesting observations. Lessons learned from the study include:
  - Grid-connected projects have advantages in terms of reliability and quality of supply, as the grid acts as a balancing sink or source, and also supplements power in the local area during periods of plant shutdown. The productive load, irrigation pumps, and agroprocessing can be served on demand, which is particularly significant for small, off-grid projects that are otherwise not being served at all. There also seems to be a greater community demand for grid-connected power, because of the limited hours of supply that off-grid projects provide.
  - Off-grid projects encounter many sustainability challenges, because most of these projects are located in remote villages. These challenges lead to the system's lower plant load factor and low uptime. This leads to a higher generation cost, which users may not be able to afford. Users also become reluctant to pay when the plant doesn't function. Lack of payment then makes it hard for the operators to continue to run the service, creating a vicious cycle in the system that can be difficult to break out of.

23.7.4 China

China is the largest developing country and makes poverty reduction a top priority policy. Since the late 1970s, when China started opening up to the world, it has made immense progress, both economically and socially. This has been the case particularly since the early 1990s, when the country moved from a planning-based to a market-based society. Over the past 10 years, the major energy programs have been rural power-grid development, a national biogas program, a rural hydropower-based electrification program, and electrification in remote areas.

23.7.4.1 Energy Access for the Urban Poor

In general, there are no significant barriers for urban residents to access energy for any purpose. Cities of all sizes have the infrastructure to provide basic services, for example electricity, safe water, and

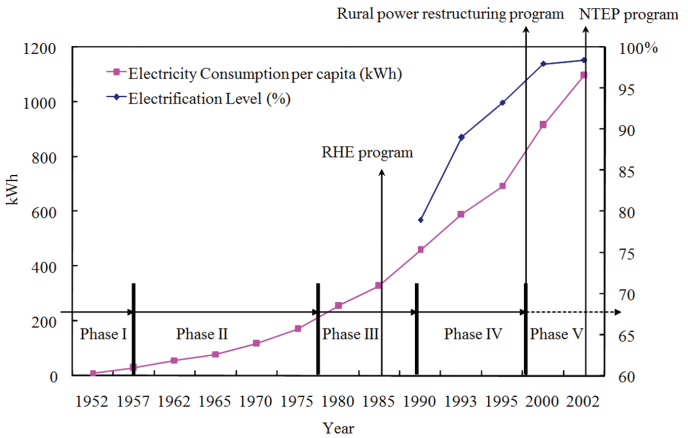

Figure 23.3 | Results of NTEP Program.

telecommunications. The household electrification level[39] in China exceeded 98.4% in 2002, and all townships[40] in China have had access to electricity since the National Township Electrification Program (NTEP) in 2005. The power-grid extension is not determined by affordability, but by the requirements of families. The Chinese government allocates a special subsidy that allows the poorest urban households to afford their basic needs, including energy.

23.7.4.2 Energy Access for Rural Populations

Energy system construction is a key part of China's development of its rural infrastructure. Rural energy should be understood in two ways. One focuses on the general idea of rural areas, while the other concentrates on hard to reach, remote, or mountainous regions. As a large country, the difference in approaches to 'general rural' and 'special rural' is highly significant.

'General rural' requires a universal energy service system. This involves the government promoting development of the energy system in line with the urban standards. This helps to improve livelihoods and the quality of life in rural areas. For 'special rural', remote areas or mountainous regions where infrastructure is difficult to access or construct, China uses local resources, such as small hydropower, wind, or solar energy, to provide clean and relatively cheap energy (in comparison to other approaches, such as grid extension). These are included in the NTEP, which uses wind turbine, solar PV panels, and other advanced technologies.

Electricity is the most difficult infrastructure to develop in rural areas. China has moved rural electrification forward through five main stages (Figure 23.3):

1. The first stage was the initial development period for rural power, from 1949 to 1957. Rural electricity generation depended largely on local resources, but local communities also developed small-scale power stations.

2. The second stage was a stable period of rural power development that lasted from 1958 to 1977. This aimed to meet the demands of agricultural production and irrigation.

3. The third stage, from 1978 to 1989, saw the rural power infrastructure develop rapidly, driven by small hydropower-based primary electrification.

4. The fourth stage, from 1989 to 1998, began as a planned development period from 1989 to 1998. From 1989 the government introduced standardized management to rural electrification construction to ensure effective development.

5. The fifth stage, which has been underway since 1998, highlights management reform of rural power and restructuring of rural grids.

23.7.5 Lessons Learned

- Energy access needs to be closely linked with the creation of social equity, rather than taken in isolation. Energy programs for poverty reduction need to be always integrated into a wider social program, along with access to clean water, roads, and education.

- In general, the experiences were related to social goals, meaning access to modern forms of energy for final use to improve welfare. Energy as a production input in poor and isolated rural areas in combination with other factors and opportunities could create income opportunities. For this, more and deeper analysis is needed.

- Governments need to play an important role in achieving equity. They should, therefore, take responsibility for planning, organization, and social mobilization aimed at fulfilling social targets.

- Developing countries seem to have no unified approaches to addressing poverty reduction and energy access. Speeding up urbanization, under an umbrella of national economic development, would help increase long-term access to energy.

- A universal energy service demands a range of approaches, with specific services for the extreme poor. A universal energy service should not only be oriented to the consumers who can afford the cost, but actually realize a general infrastructure for all the populations.

- Successes in disseminating solar technologies, such as those that Bangladesh, Sri Lanka, Nepal, and India have achieved, demonstrate

39 Household electrification level indicates the percentage of electrified households of all national households.

40 Administrative regions in China are separated by province (autonomous region), city, county, township, and village.

that off-grid programs, in association with the private sector and rural microfinance institutions, are realistic. Projects can be scaled up appropriately, with improved access to capital, development of effective and reliable after-sales service, customer-focused market development, and routine stakeholder participation.

- The Thai and Bangladesh experiences in rural electrification show that, besides the creation of a dedicated entity to implement rural electrification programs, involvement of end users in the distribution-network planning process, and a policy to subsidize low-income residential users, the electricity pricing policy would need to be such that the electricity revenue at least meets the operating costs of rural electrification. Furthermore, the economic growth of the country could provide a sound base for cross-subsidizing the residential users under rural electrification and the generation capacity of the grid system should not be a barrier to expand rural electrification.

- The Indian experience in rural electrification shows the key roles of commitment to targets, enforced through legislation, involvement of the rural communities in the decision-making process (which adds value and gives communities a sense of ownership of the process), and local management to have brought efficient billing and revenue collection, and thereby ensure the stable delivery of electricity.

- Off-grid projects encounter many sustainability challenges because most of these projects are located in remote villages. These challenges lead to the system's lower plant-load factor and low uptime. This leads to a higher generation cost, which users may not be able to afford.

23.8 Latin America Review

23.8.1 Introduction

In many Latin American and Caribbean countries the relationship between energy and poverty is either lacking or treated superficially in national development plans, energy policies, or poverty-reduction strategies. There is also little research on the linkages between access to energy services and national development goals, poverty alleviation and reduction, and environmental issues.

Despite high rates of urbanization, around 30 million people, of which 21.4 million are poor, still do not have access to electricity. Access to modern fuels for cooking is another major problem: either families do not have access to modern fuels or, if they have, it accounts for a disproportionate share of their income (ECLAC, 2009).

It is important to increase our knowledge of the relationships between poverty and energy. It is also important to show that if the goal is to provide access to modern forms of energy, energy policies cannot be approached from a macro view of the energy industry, nor should they be merely part of other issues, such as energy security, geopolitical issues, or climate-change impacts. Energy access policies should not be considered in isolation, but integrated into development policies, regional policies, and other general policies such as health and education.

It is remarkable that several LAC countries do not have policies oriented to reducing poverty and inequity, with the exception of social assistance (from fiscal funds) to alleviate poverty. Such assistance alleviates and reduces the pressures on poor populations, but do not create conditions to reduce or eliminate poverty. Although access to modern forms of energy, like electricity, is relatively high, poverty levels and inequity also remain significant.

23.8.2 Poverty and Energy Access

Approximately 200 million people currently live below the poverty line in LAC, of which some 133 million live in urban areas and 67 million in rural areas.[41] In this region, poverty is more an urban than a rural reality, but the share of urban and rural poverty differs widely across countries and subregions. In South America, about 70% of poor people live in urban areas, whereas only 48% of poor people are urban[42] in Central America (Table 23.11)[43].

Key qualitative differences exist between policy approaches aimed at improving access to energy by poorer populations in rural and urban areas. It is an issue that would need to be considered in the rural and urban contexts, as well as in the context of poverty in general.

Approximately 21.5 million poor people have no access to electricity in the region's 14 most populated countries (excluding Mexico). The region is characterized by highly heterogeneous energy resource endowments, levels of economic development, and Human Development Index across countries, and by very large socioeconomic asymmetries between the top and bottom income groups of the population within each country (see Chapter 19).

Available data show that poor households pay a much larger share of their income for energy services. The bottom income quintile of the population pays between 5% and 16% of their median monthly income for energy, while the top income quintile pays between 0.5% and 3% of their income (Figure 23.4).

The same situation is evident in the sample of Central American countries (see Chapter 19). The difference in energy use and energy expenditure

41 During a decade of reforms (1990–2000), the number of poor people increased by14% as a result of structural reforms (from nearly 210 million to 240 million).

42 Brazil alone accounts for approximately 50% and 40% of the total urban and rural poverty, respectively, in South America. In Central America, El Salvador, Guatemala, Honduras, and Nicaragua account for more than 70% of the total urban poverty, and more than 81% of the total rural poverty in that subregion.

43 See ECLAC, 2009 from where this section draws heavily.

of the top income quintile is as much as three to six times that of the bottom quintile.

Despite the high level of urbanization and electricity coverage achieved by LAC countries, energy accessibility still remains very much an unresolved development challenge for many countries in the region. Lack of access to modern forms of energy sources disproportionately affects low-income groups in most countries, aggravating the large socio-economic asymmetries that remain a major development hurdle for the region.

A general lack of appropriate policies is the principle bottleneck that now impedes access to modern energies in LAC. In the power market, many countries have converted their state-owned monopolies into privatized systems over the past three decades. Many are unbundled competitive markets. These competitive markets place great emphasis on short-term demand with the capacity to pay, and place a premium on existing generation and new-generation investment that have very short construction lead times and low capital intensity. In such markets, the state has largely removed itself from the electricity business. The model does not tend to encourage aggressive electrification programs in rural areas, where profits are hard to generate (Organization of American States, 2004).

Energy affordability and the need to increase energy access for poor people still features as a low priority in the political agenda of most countries. Neither is part of the regional policy agenda, which has tended to focus on the issues of energy security in the face of higher oil prices, reducing the investment gap in energy infrastructure, and addressing the regulatory gaps and barriers that persist after the energy sector reform process of the 1990s.

23.8.3 Energy Access Policies in Rural and Urban Areas

The policy challenges for rural and urban areas are different in terms of alternative models, technology options, management opportunities, energy portfolios, financial transfers, and guaranteed utilities investments. The barriers that public policies must overcome are different in nature, dimension, level, and magnitude for rural and urban areas (Box 23.10).

In both areas, there is a deficit of information to address the energy-poverty-economy-environment linkage effectively. This is a serious obstacle to policy formulation, as it restricts clear characterization of the problems (lack of systematic information and diagnosis).

In remote rural areas of Latin America, the high cost of providing a grid electricity service and LPG for cooking combined with the low payment capacity

and constraints on equipment availability, presents a major challenge.[44] Successful interventions are characterized by multiple policies, including:

- capacity development and technical support;
- subsidized payment and credit for equipment for off-grid solutions at both the household and community levels;
- subsidized monthly energy service bills to match the ability to pay;
- promotion of sustainable firewood use and improved stove/household ventilation programs;
- promotion of women's education and health programs; and
- promotion of community participation and integration into broader national poverty reduction.

Experience in Peru with programs that provide decentralized energy access solutions, such as single-household PV panels and batteries, shows better rates of success when families purchase the equipment and take responsibility for its maintenance through schemes adjusted to their ability to pay. Programs in which the same type of equipment was installed for free by public agencies, without transfer of property, show higher failure rates, with the equipment often non-operational after only a few years because of lack of maintenance. This experience highlights the importance of engaging active participation and financial responsibility of the target communities, adjusted to their ability to pay, to ensure the sustainability of decentralized energy access interventions.

In poor urban settlements, insufficient income and absence of credit combine with illegal occupation of lands, inadequate equipment, clandestine connections to electric power services, and difficult access to regular fuel distribution channels for cooking, heating, and water-heating purposes (e.g., LPG service, gas networks). All these factors prevent access through regular channels, which results in low-quality, informal services and/or deprivation of basic energy needs, with strong impacts on the education and labor prospects that are critical for successful integration into the urban economy. In urban contexts, energy deprivation in combination with inadequate access to sanitary and water services might also have a disproportionate impact on women's and children's health.

Paradoxically, in urban environments, high energy use levels may be found in poor families because they often use second-hand, low-efficiency equipment acquired at low cost in informal markets. This situation highlights the importance of incorporating equipment replacement and efficient use of energy into urban energy access programs. This should

44 The supply of electric power through local solutions, such as small hydropower stations or PV systems through solar panels, could be an alternative to grid extension.

Box 23.10 | Barriers Faced by Energy-access Policies in Rural and Urban Contexts

Problems and barriers in urban areas

- Insufficient or irregular cash income prevents paid access to available energy services and adequate equipment.
- Clandestine connections to electricity grids – associated with accidents, fire hazard, precarious connections, and equipment failures.
- Low-efficiency, second-hand household equipment creates high consumption and waste.
- Precarious or non-existing titling of housing and land properties prevents access to public services and credit through regular channels.
- Social marginalization and insecurity discourage private and public investments to extend existing grids into informal settlements.
- Failure to apply targeted public subsidies to extend service infrastructure that addresses poor settlements.
- Failure to apply cross-subsidies and block-tariff schemes to facilitate access by low-income clients.
- Failure to integrate energy-access projects into urban poverty-reduction programs.
- Resistance to using public subsidies for infrastructure investment.

Problems and barriers in rural areas

- Geographic isolation can render uneconomic the extension of electricity-grid coverage (>$1000–1500 per additional connection).
- Limited distribution of modern fuels (e.g., LPG) for caloric uses because of geographic isolation, distance to markets, and absence of distributing enterprises.
- Insufficient income/lack of credit prevents purchase of decentralized technology equipment (e.g., PV household systems, biomass and minihydropower systems for isolated municipalities).
- Failure of public investment to build the infrastructure required for energization.
- Failure to apply targeted public subsidies to induce the purchase of decentralized energy technologies by households and communities.
- Illiteracy and low levels of education and participation in programs.
- Failure to integrate energy access into rural development and poverty- reduction programs.
- Lack of political will and low priority of disenfranchised rural communities with weak political representation.

include mechanisms for financing new and more efficient equipment, as well as destruction of the inefficient equipment replaced.[45, 46]

Table 23.12 lists the most common types of energy access policies found in rural and urban contexts in LAC countries. Policies used in both contexts, such as subsidization of electric tariffs and household fuels (e.g., LPG, kerosene), are listed under general policies.

23.8.4 Selected Energy Access Policy Experiences in LAC

23.8.4.1 General Fuel Subsidies

Fuel subsidies as part of an energy policy are nominally justified as a means to provide energy access to populations that are otherwise unable to afford it. However, in reality, fuel-price subsidies in LAC are driven by political decisions, and are largely appropriated by affluent sectors of the population who are the largest fuel consumers. The available evidence does not point to any discernible positive impact of these generic fuel subsidies on improving energy access for the poorer population. Despite that, it is estimated that total public expenditure on fossil fuel subsidies in LAC countries amounted to US$25 billion in 2005, of which approximately 8%, or US$2.14 billion, was for LPG. Venezuela, Ecuador, and Argentina spend the largest amount in LPG subsidies[47] (Table 23.13). Uruguay, Brazil, Peru, Jamaica, Honduras, and Chile do not use this type of subsidy. A major opportunity exists in the region to reorient public expenditure away from these highly regressive subsidies, and toward more carefully designed subsidy schemes that specifically target only the poor beneficiaries.

45 Equipment replacement and rational use of energy are the focus of recent proposals in Argentina, Brazil, Colombia, and Cuba, and includes new labeling for refrigerators and the retirement of older, inefficient equipment (ECLAC, 2008).

46 For a more in-depth analysis, see ECLAC, 2009.

47 Transport fuels: diesel oil is subsidized in Venezuela, Mexico, Argentina, Ecuador, and Colombia. Fuel oil is subsidized in Mexico, Venezuela, Ecuador, and Argentina.

23.8.4.2 Brazil: Targeted LPG and Electricity Subsidies for Poor Families

In Brazil, LPG is the main fuel used for cooking. In the late 1990s, as part of a general revision of public expenditure, the government proceeded with the removal of general LPG subsidies. To mitigate the price impact on low-income families from the withdrawal of LPG subsidies, the government created a new scheme in 2001, *Vale Gas*, to subsidize energy supply for low-income families. A gas voucher was introduced for LPG, which provided financial assistance to consumers with a per capita income of up to half the minimum wage. This program was intended to assist approximately nine million people, more than half of whom resided in the northeastern region.

To be eligible for this subsidy, families had to prove income shortage and enlist with the government's registry of poor families. From 2003, the Lula government maintained this program, incorporating it as part of other social support mechanisms, known today as *Bolsa Familia*. It has reached some 12 million families (almost 25% of all families in Brazil) at a cost of US$5.5 billion in 2008 (ESMAP/WEC, 2006).

Targeted electricity subsidies have been used to reduce electricity costs for poor consumers. Progressive rates (low rates for lower levels of consumption) were targeted at consumers who could provide evidence of financial need. In this case, the eligibility of families for subsidized rates was delegated to the utility companies, under the supervision of the National Electric Energy Agency, the regulatory entity of the Brazilian electrical system. In the Amazon region, targeted fuel subsidies are fundamental to increasing energy access. Since 1993, diesel oil has been subsidized through the *Conta de Consumo de Combustíveis* fund (Fuel Consumption Account) with resources collected from special taxes on all electricity bills for households in the interlinked system. This is an example of a cross-subsidization scheme between grid-serviced electricity consumers and off-grid diesel generator users in remote areas.

Incorporation of energy access into poverty-alleviation programs in Brazil

The lowest levels of energy access[48] are found in the north and northeast regions of Brazil, together with the lowest Human Development Indexes in Brazil. The 2000 National Census (Instituto Brasileiro de Geografia e Estatística, 2001) shows that 64% of households without access to electric lighting have a family income below two minimum wages. This figure increases to 89% for households below these minimum wage units. Since the 1960s, the Government of Brazil has invested in rural electrification programs, recognizing that energy access in isolated areas is central to reducing poverty and hunger, improving health, literacy, and education, and improving the living conditions of women and children. The federal Program for Energy Development in State and Municipalities began in December 1994 with the explicit goal to reach isolated regions that do not have grid coverage, mainly through PV systems and locally available renewable sources. The major focus was the electrification of about 50,000 schools without electricity and of water pumps in areas vulnerable to drought. This program was later incorporated by the Cardoso government (1995–2002) into the *Luz no Campo* program, run by *Eletrobras*, the state-owned electric utility. Its objective was to finance the electrification of one million new rural consumers over a period of three years through grid extension. In turn, the Lula government (2003–2010) maintained this program under the name of *Luz para Todos* as an integral part of the government poverty-alleviation policy *Bolsa Familia*. Official data show that as a result of the program 1,877,362 additional households gained access to electricity during the past five years.[49]

The major features in the success of the Brazilian programs include:

- political priority and government commitment to rural electrification programs since the 1960s;
- continued public investment and strengthening of program budgets through various administrations from 1995 to 2009;
- effective mechanisms for targeting the available subsidies exclusively to poor families in need, thus ensuring highly efficient public expenditure; and
- integration of the energy access program into the government's broader policy of social support for poverty alleviation.

48 Habitants without access (%): Brazil = 5.5, north = 17.6, northeast = 11.1, middle-west = 3.9, south = 3.1, and southeast = 1.9 (Ministero de Minas y Energía, 2003).

49 This section draws heavily from a paper elaborated by Suani Teixeira Coelho, Patricia Guardabassi, Beatriz Lora, and José Goldemberg.

Box 23.11 | Colombia's Act 142 (Régimen Legal de Bogotá D.C., 1994)

Colombia's Act 142 of June 11th 1994 established a regime for the provision of household public services. It sets out explicit social equity criteria, such as:

- continued expansion of public services coverage through systems that offset the insufficient payment capacity of users;
- proportional tariff rates for low-income sectors according to principles of equity and solidarity;
- subsidies to people demonstrating insufficient income;
- stratification of individual households according to a common national methodology and criteria, and clear identification of the households to be provided public services at the municipality level;
- public investment support, and use of other incentive instruments, to promote utility companies in departments and at the national level.

23.8.4.3 Colombia: Massive Gas-application Program 1997–2009

The use of cross-subsidy schemes helps lower income users to pay for services and covers their basic needs.[50] In practice, higher income households, commercial, and industrial users pay a surplus on the full cost of the public service. This is defined by the Solidarity and Redistribution Fund. These funds are used to subsidize the public service cost for the lower income users. Intermediate income groups pay the full price.

These principles have guided Colombia's massive gas application program since the mid-1990s. The program started by connecting lower income users, providing natural gas for household caloric uses. The plan increased the number of households using gas from 0.5 million in 1991 to 4.3 million by July 2007, and the number of municipalities covered from 191 in 2000 to 415 in 2007. Available data show that the program has continued to target low-income users as the primary beneficiaries. Of these 4.3 million households, 53% are in low income categories (strata 1–2) and receive subsidized rates, and 85% are in the lower half of income categories (strata 1–3). Only 15% of households fall into the upper income categories (strata 4–6). It is difficult to quantify the amount of state contributions to this plan, but it is widely known that the highest cost did not derive from the subsidies to poor people, but from an income transfer made by the state company *Ecopetrol* (producer of the natural gas) to another state company, Ecogas (distributor and transporter of the natural gas, which was privatized in 2007). It is difficult to assess if this model could be replicated in other countries, as it depended on the particular institutional framework in Colombia at that time. The main lesson from this policy experience is that when there is sufficient political will and state backing, it is possible to find formulae to achieve massive gains in bringing energy services to the lower income population (ECLAC, 2009).

50 Official Journal: Santafé de Bogotá, D.C., Monday, July 11, 1994. CXXX N° 41.433.

23.8.4.4 The Argentine Off-grid Electrification: an Example for a Medium Developing Country

Argentina has made significant progress in its efforts to reform the power sector. While it has a relatively high overall rate of electrification (over 95%), substantial numbers of the rural population still remain without electricity services (over 25%). The Renewable Energy for Rural Markets Project (PERMER) aims to provide about 35,000 remote rural households, 1750 public services (rural schools, health posts), and 500 productive uses with electricity through provincial 'off-grid concessions' that are negotiated or bid out for minimum subsidy and regulated by independent provincial regulating agencies. The concessionaire is free to choose the least-cost technologies applied to meet its obligation to provide universal service.

This project subsidy is about 50–60% and paid partly at the time of procurement of a new lot of systems and partly against met installation targets, to balance the advantage of a direct control of outputs with manageable working-capital costs to the concessionaire. Installations, service quality, and customer satisfaction are verified *ex post* by the regulator. The monthly fees paid by the user are for O&M costs and for recovering the concessionaire's share of investment costs.

To ensure that energy services meet the local demand, as well as to attract private sector interest, market studies were conducted for all interested provinces. The existence of such a market study is one of three preconditions for becoming a PERMER participating province entitled to subsidies from the bank loan.

The business model is changing 'from grid to off-grid.' The management and technical personal of the utility involved in the project is linked to the utility in charge of the grid-connected market. Various lessons have

been learned and the utility way of doing business has changed. Most of these changes are aimed at lowering the extremely high costs of operating and maintaining the very remote and dispersed systems. One common underlying element to most of these changes is an increased attention to the responsibility of local users, microenterprises, and subcontractors for O&M, fee collection, and new installations. This approach is a promising way to improve concession models and combine a variety of important advantages:

- Reductions on O&M cost as they can replace costly field visits by visits of the subcontractor.
- The subcontractors are closer to the market, both in geographic and social terms, and can hence react directly and in a more flexible way to individual customer needs.
- The majority of users are indigenous – and so are the subcontractors. This improves communication.
- Being present locally, the subcontractor has a better grip on potential reasons for payment default.
- This local social control works both ways because subcontractors feel responsible toward 'their users' for the overall service quality.
- Some of the users pay the subcontractor with goods instead of money, which reduces default rates and increases local market efficiency.
- Additional high-value employment and income is created in local microenterprises.
- One of the subcontractors has started to offer a variety of additional services in response to local demand.

The user is the central part of any off grid system; therefore borders blur between user and utility. One of the most interesting findings of a recent study on the emerging issues of service quality is that both the perception of responsibilities and the specific O&M arrangements for the individual off-grid systems have evolved over time, depending on the specific users and technicians.

Training is crucial. A full-time sociologist has been hired to improve user training and demonstration material for SHS. A training session is given to each user during system installation. The aim is to:

- improve battery treatment so as to decrease life-cycle cost and increase user satisfaction (fewer failures);
- avoid misuse of components (e.g., short-cutting fuses and charge controllers, use of inadequate loads) so as to reduce system failures (and the related costly repair visits!);
- improve the users' understanding of their systems and energy efficiency measures (i.e., to increase 'energy culture') and the roles and responsibilities of each player so as to improve overall user satisfaction; and
- ultimately to lower the default rates.

Regarding the regulator, two important ways for cost reduction were identified:

- Adopt adequate 'off-grid service standards.' Specific regulations for rural service have to be adopted to allow for the different service levels provided by off-grid systems. Regulations were simplified to consider the off-grid situation.
- The driving force behind all of the utility's improvements to its business model is the aim to decrease the high costs of visiting remote, decentralized systems. In any remote off-grid system, the user is by definition the only one who is always at hand. User behavior therefore decides about the ultimate quality of service, and interventions from the utility side should be avoided where possible. The most interesting improvement is the integration of independent local microenterprises as 'subcontractors' in the downstream part of the rural service-delivery chain.

23.8.4.5 Bolivia and Peru: Rural Electrification in Remote Areas

In Peru, electricity coverage in rural areas has made steady gains, increasing from approximately 8% in 1993 to 30% in 2007. The Government of Peru has announced plans to further extend electricity coverage to 5.6 million people through public investments of US$1.33 billion between 2008 and 2017 (Ministerio de Energía y Minas, Republic of Perú, 2008). In Bolivia, electricity coverage of rural areas rose from 6.8% in 1976 to 28.3% in 2001 (Espinoza, 2005). Through its latest 2002–2007 rural electrification plan (*Plan Bolivia de Electrificación Rural,* PLABER, 2003) the Government of Bolivia expected to expand this coverage to 45% by 2008, investing some US$170 million to connect 200,000 additional families. The estimated cost per additional rural connection in both countries runs slightly above US$1000 per household, increasing for more remote communities.

The experience of both countries clearly shows that gains in rural electricity coverage require a strong commitment of public resources to infrastructure investments over extended periods. It also shows that the support of international cooperation agencies and regional development banks[51] has played a key role in supplementing scarce national funds to tackle successfully the large social investments demanded by rural electrification.

51 Such as Corporación Andina de Fomento, InterAmerican Development Bank, etc.

The development of a market for decentralized energy technologies in rural areas requires large investments in pilot projects, technical assistance, technology transfer and diffusion programs, capacity development, and the engagement of local communities. Many of these extension activities have been funded through international cooperation projects. Bolivia has made steady gains in rural electricity coverage from about 12% in 1992 to over 30% in 2005.

In both countries, rural communities show a positive willingness to pay for energy services, with many installing diesel generators despite their relative higher tariffs. Around 25% of households in remote rural areas actively seek to install PV systems, through both private and international cooperation projects. Low rural incomes severely limit the ability to pay the full cost, so a key factor in the success of these programs is the design of appropriate financing schemes. Financing schemes generally take the form of a combination of a monthly service tariff (to be paid by the user) and a one-time subsidy paid by the government to install the equipment. Depending on the scheme and the ability to pay, a portion of the equipment might also be paid by the user through a combination of microcredit, tariff payments, or other means. Ideally, a project should catalyze the development of a self-financed local system, with paying users and service providers organized through a private or local community enterprise.

Financing schemes in successful projects are generally characterized by the following features:

- Rural households assume ownership and financial responsibility for part of the cost of the equipment that is transferred to them. This creates incentives to care for and maintain the equipment owned by the household (e.g., in-house equipment, such as batteries and lights).
- Sufficient public funds are assigned to the project to subsidize the capital and installation costs of the technology as required by the rural household's ability to pay. The public agency must also ensure thorough testing and certification of the technology prior to installation.
- Monthly service tariffs paid by rural households must be set at a level that reflects both the ability to pay and the coverage of local costs. Both are necessary to ensure the system's longer term sustainability.
- A private or community enterprise is established to collect tariffs, provide maintenance and technical support, and ensure the whole system's quality of service.

23.8.5 Lessons Learned

- Results depend on a proactive role by government in the energy sector, and in many cases through its own public utilities, to accelerate universal access to modern forms of energy.
- Definition of feasible and attainable targets for sectors without access, as well as possible resource availability, along with the target group's economic, social, and environmental condition.
- Specific support, particularly in rural areas, to facilitate the mobilization of local funds to contribute to closing the funding gap. The mobilization of these resources requires appropriate mechanisms and enabling institutional and legal frameworks, not only at national, but also at local levels.
- Adequate management models are needed to guarantee long-term sustainability for rural access to electricity and modern fuels. Examples of failure were related to the absence of or inadequate management of projects for off-grid or remote settlements energization.
- A specific pro-poor regulatory framework to protect poor communities and promote access to modern forms of energy at an affordable price and tariff.
- Scale-up investments targeted to decentralized energy systems. Successful examples and expertise around the world should be leveraged.
- The scope of energy use and investment subsidies in both rural and urban areas should be defined clearly.
- Allocate funding and resources to create local capacities and promote energy literacy to ensure the effective involvement of local actors and their organizations in the energy planning and decision-making processes. Capacity and knowledge are the key elements to empower poor people to participate in the energy debate – and in the production, implementation, operation, maintenance, and use of the local energy infrastructure.
- Energy for poor people would need to included, as a specific chapter, in an integrated framework of energy projections.
- Reasonable supply horizons would need to be guaranteed by means of callable investment plans.
- Capacity development and reinforcement would also need to go hand by hand in the development of pro-poor policies.
- Deeper integration and cooperation at the regional level could facilitate access to modern forms of energy at the same time as reducing energy costs, expanding the market, increasing possibilities for projects that are not feasible at national level, sharing energy resources, and promoting technological development.

23.9 Concluding Remarks and Suggestions

A substantial amount of analytical work has been carried out on the main ways to address the challenge of access to modern forms of energy. Some recent accomplishments include:

Table 23.14 | Examples of energy access – direct and indirect assistance.

Access investment type	Investments or grants in:	Objective
Direct	Modern fuels for cooking Rural, urban, and peri-urban electricity Productive uses of energy in homes and small businesses Energy efficiency for households, communities, or small businesses Institutional development and reinforcement	modern forms of energy for households and communities modern forms of energy for new or improved productive uses and small enterprise development Development of new institutions to support energy access Improvements in energy efficiency (household or building efficiency for residential energy)
Indirect	Development of information systems and data records Improvements in policies, strategies, and technical assistance Sector studies of energy-access issues Power plants, transmission, and other infrastructure that support the development of greater energy access	Facilitate improved investment for energy access Investments in supporting infrastructure necessary to extend new or improve quality to existing households Promote economic development that can help poor people in more indirect ways Generate information on energy services for poor people Development of policies and strategies to enhance energy access

- identifying and documenting best practices in rural electrification;
- mobilizing expanded investment from both the public and private sector;
- developing frameworks to regulate new institutional arrangements for modern forms of energy provision, including private electricity distributors that serve rural and peri-urban populations;
- developing methodologies and case studies that demonstrate the benefits of targeted energy service investments for poor people;
- improved understanding through surveys and other research on how poor people meet their energy needs in the rural and peri-urban context; and
- regional strategies for scaling-up energy access, focusing mainly on electricity.

The main areas identified as a priority for addressing energy access include the expansion of rural electrification programs in many developing countries through grid or off-grid programs, a greater attention to the policy reforms necessary to address energy for the urban and peri-urban poor, and a refocusing on the problems involved in the use of traditional fuels for cooking.[52] It is also important to address the more upstream investments necessary to expand energy access to poor people. These are issues highlighted as important in the transition to higher quality fuels and appliances for poor households in developing countries.

This development of knowledge, experiences, and proposals is an important contribution to the design and implementation of policy strategies and concrete actions. However, the figures show that major efforts are still needed to make universal access a reality.

International development agencies are committed to promoting affordable energy access in developing countries, but sometimes retain many of the old biases of previous strategies and policies. An energy strategy must start from a deep analysis of the need for energy by poor people. Energy access and affordability are multidimensional and context dependent, and the appropriate responses to these are equally diverse. In several cases 'energy' is essentially taken as synonymous with 'electricity,' which does not demonstrate an understanding of the full range of energy needs, and so cannot fully address energy access.

Past investments in programs such as rural electrification and renewable energy for rural areas have yielded significant achievements in terms of progress in countries that are committed to such programs, along with new intervention models that are also replicable elsewhere. In most countries, these investments must, of course, be complemented by the development of supporting infrastructure (Table 23.14).

Current priorities demand greater strategic direction, such as:

- Direct assistance to poor people to facilitate access to modern fuels and electricity through various measures and incentives.
- Reduce costs and increase efficiency in upstream infrastructure for urban, peri-urban, and rural populations.
- Improve, promote, and implement energy efficient programs oriented to poor people.
- Promote good governance, including transparent and pro-poor regulatory mechanisms.
- Removal of other key barriers, such as up-front costs.
- Develop specific institutional frameworks with fixed targets and adequate resources, both human and financial.
- Implement international financing mechanisms, based on soft loans, oriented to develop and subsidize the necessary infrastructure to facilitate access to modern forms of energy.

52 For reasons that need deeper analysis, the majority of the efforts are oriented to electricity and much less so to fuels for caloric uses.

Case-specific analyses are necessary to develop appropriate solutions. Some countries face major difficulties in addressing the problem because of the low level of development and weakness of the economic system.

23.10 Key findings and lessons learned

This chapter's discussions and analyses offer a range of lessons and insights:

- Although efforts have been made to improve access to electricity and modern fuels, the energy gap – both between developed and developing countries, and between wealthier and poorer people in many countries – persists, and is even widening.
- Governments and international organizations recognize the positive effects of access to energy services. However, very few countries have yet developed a comprehensive approach to improving access with a specific focus on poor people.
- There are significant gaps in our knowledge of energy services, as well as a poor understanding of the main reasons for, and barriers to, access to modern forms of energy.
- The structural reforms implemented during the 1980s and 1990s emphasize efficiency, but ignore social issues. This has helped create a non-friendly environment for energy access.
- Priorities could include the following:
  - Increase energy coverage for households and productive uses.
  - Enhance generation capacity by including regional projects and regional cooperation.
  - Address energy services for key public facilities, such as schools and clinics.
  - Push for better achievement of basic human needs, represented by energy services, such as provision of electricity for lighting, health, education, and community services, and modern fuels and technologies for cooking, heating, and sanitary uses.
  - Solutions would need to be tailored to individual country contexts, especially in relation to institutions, capacity, and energy resource availability. A mix of actions for each country would be driven by the availability of resources, plus the legal, regulatory, and policy environment, the institutional and technical capacity, the relative cost of implementation of the different solutions, and/or the sociocultural contexts.
  - Capacities should be developed and reinforced at individual, institutional, and systemic levels to enable feasible and affordable policies to be designed and implemented.
- The significant gains achieved in electricity coverage, for example in India, China, and Latin America, were mainly the result of strong political commitment and public investment programs executed through public utilities with clear development mandates.
- The transference of resources between the oil productive chain and the natural gas productive chain has financed infrastructure development and expansion in several Latin American countries.
- Levels of poverty, particularly in rural areas of LDCs, require that infrastructure investments be either subsidized or wholly executed through public funds, because the low income capacity of the target users prevents full cost recovery.
- Governments must acknowledge that extending energy access further to poor people will only result from a political decision that establishes clear mandates, targets to be achieved, and commitment of the required public funds over extended periods of time (decades). There is sufficient evidence that important changes will only be possible through political will at the highest level.
- International cooperation and development banks have played a key role in providing concessionary financing and grants to supplement national funds, making the undertaking of these large investments possible. This would hopefully continue.
- Investment and O&M expenditure on modern forms of energy represent a significant proportion of total investment and GDP in LDCs. Achieving universal access in these countries by 2030 will require international support, political compromise in sustainable development, and reduction of inequality.
- Effective targeting of direct and indirect subsidies has been a key to all the successful experiences of expanding access to electricity, modern fuels, and associated technologies to poor populations. It will not be possible to avoid subsidies if the targets are to be achieved. In many countries, significant opportunities exist to apply cross-subsidization and differentiated/block-tariff schemes in energy services across income groups, to enable adequate access and regularization of services to the poorest populations.
- Facilitating access to appliances was a key component for households and, in successful programs, allowed them to benefit from increased energy use. Energy services provision should include access to modern forms of energy and access to appliances.

The main lesson learned from past experiences on the implementation of strategies and actions for access to modern forms of energy and technologies is that there is some room for original or innovative proposals.

Key basic principles or enabling conditions that appear repeatedly in documents or proposals include:

- Providing universal access to modern forms of energy is a necessity, not a luxury.
- The need for good understanding of the energy services to be addressed, along with reliable analysis.
- It is imperative to transform the paradigm. Energy activities are not just another industry, but a system with strong socioeconomic and environmental dimensions, with direct impacts on the sustainable development of any country. Energy is not a commodity, but a strategic good. It is essential for economic, social, and environmental sustainability.
- Governments must make long-term commitments, with explicit and clear public policies oriented toward poor people.
- Several good practices can be replicated elsewhere in places that experience similar circumstances (policies and regulation, capacity development, technical standards, best-available technologies, financing and implementation approach, coordinated research and development).
- The need for soft funds and financing mechanism to develop infrastructure and to provide up-front costs for the potential consumers.
- Direct government involvement in implementation, through public utilities or private or non-profit organizations (e.g., NGOs, cooperatives) or adequate public-private cooperation.
- The oriented subsidies (direct or indirect) to create enabling economic conditions.
- Access to modern forms of energy for poor people should not only be conditioned to clean energy forms but also to clean appliances.

23.11 Policy Options and Some Recommendations

To achieve the overall goal of economic growth and poverty alleviation but avoid the pitfalls of poor planning and inappropriate targets is a daunting challenge in any context. Providing universal access to modern forms of energy poses its own set of additional institutional and policy challenges, which have historically hindered efforts to increase energy affordability and are a major reason why so many people remain without access to better energy services. Policy recommendations can take the form of general ideas or guidelines. Regional and national contexts should be considered in defining strategies, instruments, and measures.

23.11.1 Diagnosis and Information

A better understanding and a clearer diagnosis of the structure and functioning of energy systems, along with the needs (energy services) to be supplied, is needed. It has often been absent in the discussion of proposals and the role of public policies.

An information system on energy use will help to identify problems and barriers, and will promote understanding of local conditions, sociocultural behavior, and a system's ability to implement actions.

Section 23.3 remarks, adequate information on needs to be satisfied and priority energy services to be provided are the necessary initial step. Identification of barriers and problems to address energy affordability is a key issue to identify, design, and implement adequate strategies and measures.

Good policies and strategies need good diagnosis. Wrong or absent diagnosis could mean inadequate proposals. Support and funds to diagnosis and information would need to be part of the strategies.

23.11.2 Reform of the Tariff, Tariff Structure, and the Subsidy Systems

Subsidies are generally justified as a response to inequality and social expectations in energy provision (Barnes and Halpern, 2000; UNEP, 2002). However, their net effect can be positive or negative depending on the intended goals of the subsidy, and the way a subsidy is implemented.

An effective tariff and subsidy regime has to be transparent and minimize administrative costs to avoid gaming of the system and to maximize the benefits that accrue to the intended recipients (UNEP, 2002). The subsidies themselves would need to have some of the following characteristics:

- **Clear mandates**. Subsidies would need to have clear mandates and be appropriately financed to ensure that the financial burden is acceptable and properly allocated, and that the opportunity costs are not too high.
- **Targeted**. Subsidies could be designed so as to reach those most in need and to ensure that resources are not wasted. Lifeline tariffs can be tied to other aid programs to ensure they are meeting the recipients' needs.
- **Phased**. Subsidies would need to be established with clear guidelines for their phasing out, such as a sunset clause or performance-based milestones.
- **Market enhancing**. Subsidies that help develop and nurture a market early in its development can be very effective, while subsidies that can undercut a growing market should be avoided.

- **Flexible**. Subsidy programs would also need to incorporate flexibility to deal with the uncertainties that are an inevitable part of making changes to institutions and markets.

- **Complemented**. It needs to be complemented with funds toward solving the first cost capital financing problem (Barnes and Halpern, 2000). Up-front costs of equipment are, usually, the key barrier.

Generally speaking, social tariff and social prices are the instruments with which to address poor people. Two conditions are key elements in the definition and application of such social tariff and prices: to be sure that all the poor people that need the subsidy are included (guarantee of inclusion) and to be sure that people that do not need the subsidy are not included (guarantee of exclusion).

Finally, for economic sustainability of the system it is necessary that average costs of the total energy provided be covered by the average tariff or by the price recovered by the provider.

23.11.3 Innovation and Guarantee of Financing Mechanisms

Financing mechanisms are needed for every scale of energy intervention. Mobilizing affordable and genuine international, regional, national, and local funds is crucial. Sustainable energy access will not be achieved by occasional or intermittent donors and actions.

Existing and new financing mechanisms could be oriented so that they have a real impact in addressing energy access for poor people. This review process needs to be inclusive, and result in the modification of procedures and mechanisms to enable small and non-conventional energy programs targeted to poor people to receive adequate funding. Likewise, the proportion of pro-poor energy investments would need to increase consistently with the magnitude of the challenge at hand. This is urgent if the funding gap is to be bridged.

The mobilization of local funds should also be considered. International financial institutions and donors can play a facilitating role. The mobilization of these resources requires appropriate mechanisms and enabling institutional and legal frameworks not just at the national level, but locally too.

23.11.4 Changes in Regulatory Structure

Current regulations often act at cross-purposes to the efficient delivery of services through new and innovative technology and institutional options, such as the use of distributed generation (ESMAP, 2001; Morgan and Zerriffi, 2002). This is the result of both regulatory structure and regulatory practice in systems that have generally been put in place with centralized utilities in mind. It is difficult for such centralized regulatory systems to monitor effectively a large number of smaller operators. Similarly, the regulatory burdens on the smaller operators of a system designed for large utilities can be prohibitive. These regulatory problems can be handled in a variety of ways, including the creation of standardized licenses, the delegation of regulatory responsibility, flexible power quality and reliability standards, and tailoring regulations to different types of entities (Reiche et al., 2006).

23.11.5 Capacity Development and Strengthening

Capacity development can be understood as the processes of creating, mobilizing, enhancing (or upgrading), and converting the skills and expertise of institutions in the contexts required to achieve the specifically desired socioeconomic outcomes. Capacity development must be achieved through activities at the individual, institutional, and systemic levels. Capacity-development efforts at each of these levels are discrete elements of the capacity-development process (Bouille and McDade, 2002).

No single institution can have the capacity to resolve the complex governance, energy, and capacity-development challenges and their linkages to issues of equity, environmental sustainability, economic efficiency, and public sector management. The challenges are not static, but change in dimension, location, priority, and costs as the energy system evolves.

An interdisciplinary perspective and a multistakeholder approach are needed to address the multiple dimensions of access to modern forms of energy.

Resources would need to be allocated to develop local capacities and promote better knowledge of local energy. Local populations would need to be involved in energy planning and decision-making processes. Better understanding of the role of energy can contribute to the sustainability of systems and improve relations between the energy provider and the energy user. Target actors for capacity development should include government, the private productive sector, civil society, academia, consultant institutions, and the media.

23.11.6 Policy Alignment

Energy policy is part of a wider development policy and would need to be aligned with other sector policies and objectives. If these policies are misaligned, they can reduce the effectiveness of any given policy. Policy misalignments can occur when different energy policies work at cross-purposes or when government priorities that could benefit from an effective energy policy are not aligned.

While individual technology choices are made at the microlevel (that is, by an individual or small group of decision makers), these decisions

are influenced by policies at the macrolevel, generally, the government (Stewart, 1987). The impact of macropolicies on technology choice is the result of changing "firm objectives, resource availability and cost, markets, and technology" (Stewart, 1987). For example, high import tariffs on technology components can significantly drive up the price of distributed systems and so act as a barrier to access. Taxes can also change the relative pricing of traditional versus modern fuels, creating price pressures even on those without access.

At a broader level, there is a need to link rural and peri-urban energy supply more closely with rural development. This would shift the focus from minimal household supply to a more comprehensive approach to energy that includes productive activities and other welfare-enhancing uses of electricity. Ideally, the linkages between energy and other policy priorities, such as health, education, and poverty alleviation, should be recognized explicitly and local solutions that address these needs be encouraged and supported. By taking a more comprehensive approach, revenues can be increased because of the higher ability and willingness to pay by productive users, and the effectiveness of investments should be higher because of the link with welfare-enhancement goals. The new mix of customers and demand allows for natural market segmentation, which improves the viability of energy supply efforts.

To be effective, policies and programs within the energy sector geared toward low-income energy services also need to be aligned with other poverty-alleviation efforts. Provision of infrastructural services, including modern forms of energy, does not change the poverty equation. When development efforts fail, improvements to electricity supplies alone have little effect on local welfare. Work done in Peru found that providing a combination of services – electricity, water, sanitation, and telephones – had a greater impact on poverty reduction than that provided by a single service. Adding a fourth service resulted in welfare improvements that were seven times greater than those delivered by the second service.

Many populations experience an inability to pay for energy services. In some cases, such as in Lao People's Democratic Republic, villages have been connected to electricity for 15–20 years, but around a quarter of households remain unconnected (Independent Evaluation Group, 2008). Where purchasing power is the underlying problem, it is critical that provision of modern forms of energy be evaluated alongside other development options. Overall, given the low returns on investment in energy services, and in particular electrification, it is essential that public resources be concentrated on the investments that have the greatest impact on development. Poor people are more likely to benefit from an access to modern forms of energy approach that creates jobs and raises income, as opposed to a simple household connection.

23.11.7 Regional Integration and Cooperation

The traditional approach of limiting energy planning and service provision to the political frontiers could be a barrier for access to modern forms of energy. There are several reasons why nation-based planning is suboptimal:

- The geography of energy supply options does not necessarily correspond to political boundaries – the cleanest and cheapest energy source may lie across national borders.
- National energy markets are often too small to justify the investments needed for particular energy supply options.
- Cross-border energy supply often provides diversification of energy source – a key component in energy security and cost reduction.

Latin America offers several examples in which integration and cooperation among countries reduce energy costs and, indirectly, facilitate access to energy.[53] Africa, for example, has very good potential for such integration based on projects or interconnection. An integrated energy market, such as in the European Union, is not necessary. An expanded regional market could offer feasible technical options to reduce costs and still maintain the integrity of national markets. Bilateral or multilateral agreement on energy projects that share costs and benefits could be an enabling action to expand markets to low-income populations. The development of energy markets on a regional basis offers significant benefits, as the linking of national petroleum and electricity industries can help mobilize private and domestic investments by expanding market size.

Major benefits are associated with regional energy integrations: improved security of supply, better resource allocation, enhanced environmental quality, and wider deployment of renewable energy resources, all of which contribute to access to modern forms of energy and sustainable energy systems.

Africa has a regional diversity that offers substantial opportunities for integration. Regional integration is increasingly being seen as a way for individual countries that suffer from structural and economic weaknesses to join the global economy. Better macroeconomic conditions will facilitate access to energy.

23.11.8 Final Remarks

Overall, and on the basis of successful experiences of increasing access to modern forms of energy, no single approach can be recommended

53 Close to 100% of Paraguay's population has access to electricity. This was made possible by South America's two largest binational hydroelectric power plants: Itaipú, made and financed by Brazil, and Yacyretá, implemented by Argentina. As both countries need the energy and have the capacity to implement the project, they could afford the project. Paraguay provided 50% of the river and paid 50% of the investment in energy. Both projects enabled Paraguay to have full access to electricity, a very difficult task for the country to achieve alone. A similar situation exists in Central America and in the Caribbean, where the major oil-producing countries (Venezuela and Mexico) are cooperating with small, oil-importing countries in the Caribbean. For example, Venezuela and Cuba exchange oil for medical assistance.

above the others. What is clear, however, is that the current institutional arrangements and policies have met with mixed success, at best. Reforms are needed, at global and country level, to strengthen the feasibility of energy projects for poor people, expand the range of actors involved, open up the regulatory system, and allow for innovation. Several examples demonstrate that some of the main factors for success include:

- Political will and government priority;
- Continuing support, both financial and administrative;
- Effective mechanisms for effective targeting of policy interventions; and
- Integration of energy policies with other sectoral policies, particularly those dealing with poverty alleviation where these exist.

Success depends on regional, national, and local circumstances. In some instances, such as Nepal's Rural Energy Development Program (REDP), a decentralized and participatory decision-making process and a holistic development approach is very important. This goes together with a strong community-mobilization process that focuses on:

- organizational development,
- skills enhancement,
- capital formation,
- promotion of technology,
- environmental management, and
- empowerment of vulnerable communities.

Participation, transparency, consensus decision making, and inclusion of all households in the community, irrespective of class, color, creed, or sex, are the four pillars of good governance to ensure equal ownership and equitable sharing of benefits accrued from MH systems.

Challenges and economic, sociocultural, and political barriers require more elaborated strategies and a higher global compromise to satisfy GEA objectives. The key catalyst to improving access to energy in some Latin American and Asian developing countries is political will. The examples of India, China, Argentina, Chile, or Brazil all demonstrate that if a political decision is made, the results are positive. However, this has not been the case in many sub-Saharan Africa countries, in LDCs, and in those with a very low Human Development Index. In these countries, universal access to modern forms of energy by 2030 will not be achieved with microactions and isolated measures, unless they are integrated into a long-term national program with clear targets, dedicated and guarantee funds, adequate institutional frameworks, and robust strategies. An approach based on providing a few thousand solar lamps to rural settlements, or a PV with capacity of just a few watts, will improve the quality of life for poor rural inhabitants, but are not capable of real improvement in welfare and securing the inclusion of marginalized populations. They can be seen as intermediate actions, but should not be considered as a solution for access to modern forms of energy.

Reforming the way in which energy is financed and sustainably operated has a major potential to reduce inequality. Lifeline subsidies are needed, at the very least. There are conditions under which cross-subsidies can be effective, but this may require a different role for both higher level government agencies and the international system. Some principles, such as supporting energy planning, making investment capital available, creating incentives for commercial lending, promotional campaigns, and technical assistance, have already been identified for certain markets. Centralized agencies can also aid in coordination, in eliminating conflicts in mandates and programs, and in helping to build much needed local institutional and organization capacity.

The circumstances in developing countries militate that the energy path, especially for rural and peri-urban areas, be dissimilar to that followed by developed countries. This will require innovation and experimentation on both the technological and institutional levels. Lack of appreciation of such approaches at the policy level is curtailing progress, because many policymakers tend to follow conventional approaches without taking account of contextual differences.

We know that universal access to modern forms of energy at the household level depends on various factors, such as prioritizing energy access, long-term policy commitments by national governments to create strong institutional, regulatory, and legal frameworks, and financing from all available sources. It is important that governments facilitate support from national and international development organizations on the research, design, and development of appropriate technologies. Collecting, compiling, and sharing knowledge is equally important.

It is expected that governments will report on the progress they have made on addressing the energy access agenda in all its dimensions, including funding for small decentralized solutions, community capacity development, leverage of local indigenous financing, and achievement of national energy access targets, among others.

Last, but not least, the wide range of material analyzed shows that abundant ideas and proposals are available to address many different situations. What is absent are political decisions to implement them.

Dedication

We dedicate this work to our families for their understanding and support for our long, collaborative journey that led to this chapter and which included both sad and joyful moments.

In loving memory to Maria, Georg, and Gerth, who departed us while we were working on this chapter.

With a warm welcome to Heidi Marie, Estelle, Henry Ian, Inés, and Alfred Victor who joined us in our collective travel towards a sustainable future.

Executive Summary

Innovation and technological change are integral to the energy system transformations described in the Global Energy Assessment (GEA) pathways. Energy technology innovations range from incremental improvements to radical breakthroughs and from technologies and infrastructure to social institutions and individual behaviors. This Executive Summary synthesizes the main policy-relevant findings of Chapter 24. Specific positive policy examples or key take-home messages are highlighted in italics.

The innovation process involves many stages – from research through to incubation, demonstration, (niche) market creation, and ultimately, widespread diffusion. Feedbacks between these stages influence progress and likely success, yet innovation outcomes are unavoidably uncertain. Innovations do not happen in isolation; interdependence and complexity are the rule under an increasingly globalized innovation system. Any emphasis on particular technologies or parts of the energy system, or technology policy that emphasizes only particular innovation stages or processes (e.g., an exclusive focus on energy supply from renewables, or an exclusive focus on Research and Development [R&D], or feed-in tariffs) is inadequate given the magnitude and multitude of challenges represented by the GEA objectives.

A first, even if incomplete, assessment of the entire global resource mobilization (investments) in both energy supply and demand-side technologies and across different innovation stages suggests current annual Research, Development & Demonstration (RD&D) investments of some US$50 billion, market formation investments (which rely on directed public policy support) of some US$150 billion, and an estimated US$1 trillion to US$5 trillion investments in mature energy supply and end-use technologies (technology diffusion). *Major developing economies like Brazil, India and above all China, have become significant players in global energy technology RD&D, with public- and private-sector investments approaching US$20 billion, or almost half of global innovation investments, which is significantly above the Organisation for Economic Co-operation and Development (OECD) countries' public-sector energy RD&D investments (US$13 billion). Important data and information gaps exist for all stages of the energy technology innovation investments outside public sector R&D funding in OECD countries, particularly in the areas of recent technology-specific private sector and non-OECD R&D expenditures, and energy end-use diffusion investments.*

Analysis of investment flows into different stages of the innovation process reveals an apparent mismatch of resource allocation and resource needs.

Early in the innovation process, public expenditure on R&D is heavily weighted toward large-scale supply-side technologies. Of an estimated US$50 billion in annual investment globally, less than US$10 billion are allocated to energy end-use technologies and energy efficiency.

Later in the innovation process, annual market (diffusion) investment in supply-side plant and infrastructure total roughly $US_{2005}$$0.8 trillion, compared with a conservative estimate of some US$1–4 trillion spent on demand-side technologies. These relative proportions are, however, insufficiently reflected in market deployment investment incentives of technologies, which almost exclusively focus on supply-side options, to the detriment of energy end use in general and energy efficiency in particular foregoing also important employment and economic growth stimuli effects from end-use investments that are critical in improving energy efficiency. *The need for investment to support the widespread diffusion of efficient end-use technologies is also clearly shown in the GEA pathway analyses. The demand side generally tends to contribute more than the supply-side options to realizing the GEA goals. This apparent mismatch suggests the necessity of rebalancing public innovation expenditure and policy incentives to include smaller-scale demand-side technologies within innovation portfolios*.

Given persistent barriers to the adoption of energy-efficient technologies even when they are cost competitive on a life cycle basis, technology policies need to move toward a more integrated approach, simultaneously stimulating the *development* as well as the *adoption* of energy efficiency technologies and measures. *R&D initiatives that fail to incentivize consumers to adopt the outcomes of innovation efforts (e.g., promoting energy-efficient building designs without strengthened building codes, or Carbon Capture and Storage [CCS] development without a price on carbon) risk*

not only being ineffective but also precluding the market feedback and learning that are critical for continued improvements in technologies.

Little systematic data are available for private-sector innovation inputs (including investments), particularly in developing countries. Information is patchy on innovation spillovers or transfers between technologies, between sectors, and between countries. It is also not clearly understood how fast knowledge generated by innovation investments may depreciate, although policy and investment volatility are recognized as critical factors. Technical performance and economic characteristics for technologies in the lab, in testing, and in the field are not routinely available. Innovation successes are more widely documented than innovation failures. Although some of the data constraints reflect legitimate concerns to protect intellectual property, most do not. Standardized mechanisms to collect, compile, and make data on energy technology innovation publicly available are urgently needed. The benefits of coupling these information needs to public policy support have been clearly demonstrated. *A positive policy example is provided by the early US Solar Thermal Electricity Program, which required formal, non-proprietary documentation of cost improvements resulting from public R&D support for the technology.*

The energy technology innovation system is founded on knowledge generation and flows. These are increasingly global, but this global knowledge needs to be adapted, modified, and applied to local conditions. The generation of knowledge requires independent and stable institutions to balance the competing needs and interests of the market, policy makers, and the R&D community. *The technology roadmaps and the policy regime that characterize innovation in end-use technologies in the Japanese Top Runner program are a good example of the actor coordination and knowledge exchange needed to stimulate technological innovation.*

Generated knowledge needs to spread through the innovation system. Knowledge flows and feedbacks create and strengthen links between different actors. This can take place formally or informally. Policies that are overly focused on the development of technological "hardware" should be rebalanced to support interactions and learning between actors. *The provision of test facilities in the early years of the Danish wind industry is a good example of how policy can support knowledge flows and the strengthening of collaborative links within networks of actors in an innovation system (energy companies, turbine manufacturers, local owners).*

Long-term, consistent, and credible institutions underpin investments in knowledge generation, particularly from the private sector, and consistency does not preclude learning. Knowledge institutions must be responsive to experience and adaptive to changing conditions. Although knowledge flows through international cooperation and experience sharing cannot presently be analyzed in detail, the scale of the innovation challenge emphasizes their importance alongside efforts to develop the capacity to absorb and adapt knowledge to local needs and conditions. *The current global cooperation in energy technology innovation is well illustrated by the International Energy Agency (IEA) technology cooperation programs reviewed in Section 4.4; all invariably show a sparse involvement from developing countries.*

Clear, stable, and consistent expectations about the direction and shape of the innovation system are necessary for innovation actors to commit time, money, and effort with only the uncertain promise of distant returns. To date, policy support for the innovation system has been characterized by volatility, changes in emphasis, and a lack of clarity. *The debilitating consequences on innovation outcomes of stop-go policies are well illustrated by the wind and solar water heater programs in the United States through the 1980s, as well as the large-scale (but fickle) US efforts to develop alternative liquid fuels (Synfuels). The legacy of such innovation policy failures can be long lasting. The creation of a viable and successful Brazilian ethanol industry through consistent policy support over several decades, including agricultural R&D, guaranteed ethanol purchase prices, and fuel distribution infrastructures, as well as vehicle manufacturing (flex fuel cars), is a good example of a stable, aligned, and systemic technology policy framework. It is worth noting that even in this highly successful policy example, it has taken some three decades for domestic renewable ethanol to become directly cost competitive with imported gasoline.*

Policies need also to be *aligned*. Innovation support through early research and development is undermined by an absence of support for their demonstration to potential investors and their subsequent deployment in potential markets. Policies to support innovations in low-carbon technologies are undermined by subsidies to support carbon-intensive technologies. *Fuel efficiency standards that set minimum (static) efficiency floors fail to stimulate continuous technological advances, meaning innovations in efficiency stagnate once standards are reached. As a further example of misalignment, the lack of effective policies to limit the demand for mobility mean efficiency improvements can be swamped by rising activity levels.*

Policies should support a wide range of technologies. However seductive they seem, "silver bullets" do not exist without the benefit of hindsight. Innovation policies should use a portfolio approach under a risk-hedging and "insurance policy" decision-making paradigm. Portfolios need to recognize also that innovation is inherently risky. Failures vastly outnumber successes. *Experimentation, often for prolonged periods (decades rather than years), is critical to generate the applied knowledge necessary to support the scaling up of innovations to the mass market.*

The whole energy system should be represented in innovation portfolios, not only particular groups or types of technologies; the entire suite of innovation processes should be included, not just particular stages or individual mechanisms. Less capital-intensive, smaller-scale (i.e., *granular*) technologies or projects are less of a drain on scarce resources, and failure has less serious consequences. *Granular projects and technologies with smaller scales (MW rather than GW) therefore should figure prominently in any innovation portfolio.*

Finally, public technology policy should not be beholden to incumbent interests that favor support for particular technologies that either perpetuate the lock-in of currently dominant technologies or transfer all high innovation risks of novel concepts to the public sector.

24.1 Introduction

24.1.1 Welcome to Chapter 24

Unlike resources found in nature, technological and social innovations are human-made resources that can be generated and expanded as a matter of social choice but come with costs and with uncertain outcomes. Energy-technology innovations not only encompass new inventions and improvements in the performance or attributes of technologies like coal gasification, solar thermal electricity, batteries, or energy-efficient windows or light bulbs, but also in how firms develop and markets and users relate to and utilize such technologies. Social innovations that result in changes in behavior of technology suppliers as well as users can therefore be just as important as improvements in technological efficiency or emissions performances of individual technological artifacts.

Innovations do not fall like manna from heaven; they need to be created through a multistage process. The stages include research, development, demonstration, market formation, and finally, the culminating pervasive diffusion of successful innovations. In the most general definition, energy technology change is the capital-embodied result of institutionalized R&D and collective learning processes[1] between developers/suppliers and users of technologies, operating within specific innovation and adoption environments that are strongly shaped by policies. This chapter therefore adopts a systemic view of an Energy Technology Innovation System (ETIS) and focuses on the particular role of policy in the energy innovation process and the functioning of ETIS.

Chapter 24 is both theoretical and deeply empirical: it provides the first ever quantitative estimate of global investments in energy-technology innovation (Appendix I), as well as a rich set of new case studies (summarized in Appendix II). These case studies trace the evolution of individual energy technologies, describe often neglected aspects of energy technology innovation, and assess the role of policies in influencing energy technology innovation. Throughout, this chapter emphasizes the importance of understanding the energy-technology innovation system in its entirety, including its many feedbacks. Because the energy-technology innovation system is complex and remains incompletely understood, readers are advised to use caution when seeking precise mathematical formulations for models or simple policy recipes. Nonetheless, despite its limitations, a systems perspective on energy technology innovation – particularly one that integrates supply and demand aspects – offers new insights that complement and improve upon traditional views and resulting fragmented technology policy approaches.

Chapter 24 provides guidance to policy makers about how to positively influence energy innovation, as well as how policy can be harmful and counterproductive. Common myths are explicitly examined. Refraining from being overly prescriptive about particular individual policy instruments, Chapter 24 instead offers broad guidelines drawn from the case studies for improved innovation policies that recognize both the inevitable uncertainty in the innovation process and its systemic nature. The chapter concludes with research and information/data needs and summary findings. Space limitations preclude a full presentation of the 20 case studies drawn upon in Chapter 24. They are presented in one-page summaries as an appendix to this text and are available upon request.[2]

24.1.2 Roadmap of Chapter 24

Figure 24.1 shows a roadmap of Chapter 24. After the introduction (Section 24.1), Chapter 24 moves to the assessment of ETIS, which consists of three main parts.

Section 24.2 characterizes ETIS. The review is necessarily selective, but identifies key components and themes. Features of ETIS are organized around knowledge and learning (Section 24.2.2); attributes of energy technologies and their industries and drivers of changing technology characteristics, such as economies of scale and scope (Section 24.2.3); and the functions of actors and associated institutions (Section 24.2.4). These are the distinct mechanisms of innovation described in the engineering, economics, management, and sociological literature and include knowledge accumulation (and depreciation), economies of scale and scope, and various learning processes. This part concludes with an integrative representation of ETIS and its components according to the "functions of innovation systems" literature. This emphasizes the dynamic, evolving nature of an ETIS over time (Section 24.2.5).

Section 24.3 identifies ways of assessing ETIS. The breadth of assessment metrics are reviewed in detail in the *Assessment Metric* case study

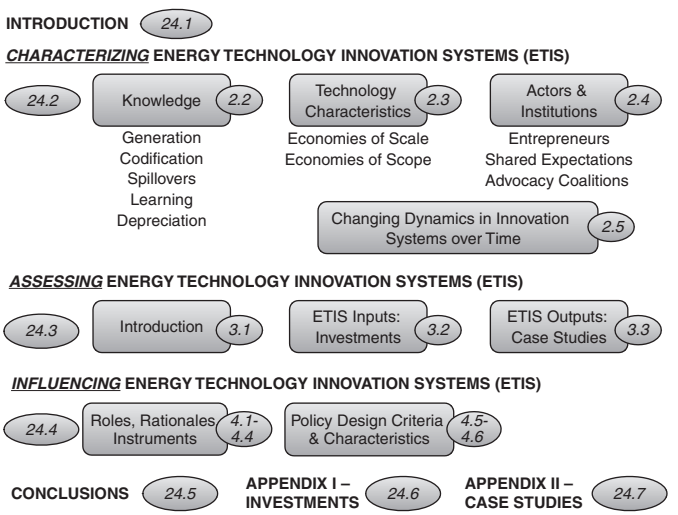

Figure 24.1 | Roadmap of Chapter 24

1 Excellent historical studies on oil-refining (Enos, 1962) and gas turbines (Watson, 2004) illustrate these processes.

2 Available at www.globalenergyassessment.org.

(see summary in Appendix II). The discussion then proceeds to a quantitative commensurate assessment of current investment inputs into ETIS, as summarized in Section 24.3.2. In order to assess ETIS in terms of outcomes (Section 24.3.3), Chapter 24 draws upon 20 case studies, which are summarized in Appendix II. Section 24.3.3 provides an overview of the case studies, their rationale, and selected illustrative examples of ETIS outputs across a variety of energy technologies.

Section 24.4 then examines the question of how to influence the direction and effective functioning of the ETIS. The policy community is a key constituency for the findings in Chapter 24. The ETIS framework presented is an integrative conceptual framework that neither can nor should be used to generate policy prescriptions. Therefore, after an overview of actors and rationales for technology policy (Sections 24.4.1 and 24.4.2), policy models and instruments (Section 24.4.3) and their increasingly international dimension (Section 24.4.4) are outlined. Chapter 24 abstracts generalizable *policy design* guidelines and criteria that should support innovation success and mitigate against innovation failure (Section 24.4.6).

Chapter 24 culminates in a discussion of the research, data, and information needs identified in this assessment (Section 24.5.1), as well as overall conclusions (Section 24.5.2).

As noted, this chapter is written to provide a practical guide for policy makers concerned with supporting the effective functioning of the ETIS in the context of the GEA objectives on climate, access, security, and health. To develop policy guidance, Chapter 24 also reviews some key characteristics and metrics of ETIS. These sections (24.2.2 to 24.2.5) are written with greater technical depth and language, and are aimed also at those in the research and business communities interested in understanding the fundamentals and mechanisms of innovation in an energy context. Readers more interested in policy aspects can move on to Section 24.3, revisiting the more technical material of Section 24.2 at a later stage. Given the range of potential audiences, considerable effort has been made to define key terms (see Table 24.1 and also the GEA Glossary), use consistent terminology, and support conceptual arguments with empirical details from the case studies.

24.1.3 Technological Change in Energy Systems

Technological and congruent institutional and social changes have been widely recognized as main drivers for long-run economic growth ever since Solow (1957), and for broader societal development as well (Freeman and Perez, 1988). In terms of causality, caution is advised as technology and institutional/social setting co-evolve, mutually depending on and cross-enhancing each other. Technological change in energy systems to a large degree determines how efficiently energy services can be provided, at what costs, and with which associated externalities. Scholars agree on the importance of technological change in past and future energy transitions (e.g., Smil, 1994; Grubler, 1998; Nakicenovic et al., 2000; Grubler, 2008; and the literature review in Halsnæs et al., 2007).

The *Grand Designs* case study (summarized in Appendix II, see also Wilson and Grubler, 2011) provides a synthesis of major patterns driving historical energy transitions and contrasts this historical perspective by examining also the scenario literature on the importance and patterns of technological change in alternative futures. The transformative power of technology arises from: (1) combinations of interrelated individual technologies (clustering) and applications of technologies outside their

Table 24.1 | List of key terms

Key Term	Definition as Used in Chapter 24
ETIS	Energy Technology Innovation System: the innovation systems approach applied to the energy system. In this approach, innovation is understood as an interactive process involving a network of firms and other economic agents that, together with the institutions and policies that influence their innovative behavior and performance, bring new products, processes, and forms of organization into economic use
Invention	origination of an idea as a technological solution to a perceived problem or need (usually codified via a patent)
Innovation	putting ideas into practice through an (iterative) process of design, testing, and improvement, including small-scale demonstration or commercial pilot projects, and culminating in the establishment of an industrial capability to manufacture a given technological innovation
Diffusion	widespread uptake of a technological innovation throughout the market of potential adopters
R&D (Research and Development)	knowledge generation by directed activities (e.g., evaluation, screening, research) aimed at developing new or improving on existing technological knowledge
Demonstration	construction of technology prototypes or pilots demonstrating technological feasibility
RD&D (Research, Development and Demonstration)	integration of the required upfront stages in a technology life cycle (invention-innovation) related terms: RDD&D (i.e., RD&D + deployment)
Market Formation	application of a technology in a specific limited market setting (or niche) by harnessing either a specific comparative advantage (e.g., PV electricity in remote areas without grid connections) or via public early deployment incentives (e.g., feed-in tariffs) related terms: market creation, niche markets, deployment, early commercialization
Learning	improved (technological) knowledge derived from production experience (learning-by-doing) and/or user experience (learning-by-using) that leads to performance improvements, including cost reductions
Knowledge Spillovers	knowledge transfer between different innovation actors and technology application fields through mechanisms such as imitation, trade, licensing, foreign direct investment, and/or movement of people

initial sector/use (spillovers); (2) the continued improvements of technology performance and costs as a result of innovation efforts and market growth (learning and economies of scale effects, among others); (3) energy end-use and technology users/consumers are particularly critical; and (4) generally, rates of capital turnover and technological change in the energy systems remain slow. These four "grand" patterns of energy technological change are addressed in more detail below.

(1) No individual technology, as important it may be, is able to transform whole energy systems that are large and complex. The importance of technology arises in particular through *clustering* (combinations of interrelated individual technologies) and *spillover* (applications outside the initial sector/use for which a technology was initially devised) effects. The concept of general purpose technologies (GPT) (e.g., Lipsey et al., 2006) captures this notion that some technologies, like steam power or electricity, find multiple applications across many sectors, industries, and energy end-uses. Technologies operate more effectively as families or as "gangs" rather than as individuals. Strong interrelatedness conditions major innovations in the energy sector to a multitude of complementary changes, including also new business and financing models, as demonstrated in the history of electric light and power (Hughes, 1983) or the emergence of oil-based individual motorized mobility with automobiles (Freeman and Perez, 1988). Once a technology is adopted, a number of related technologies, derived products, and business models become established. Improvements and knowledge about possibilities and applications accumulate, generating further learning economies as the application range grows (Watson, 2004). Combined, these processes create powerful self-reinforcing mechanisms that make it very difficult to dislodge a dominant technological regime, a fact referred to in the technology literature as "path dependency" or "technology lock-in" (e.g., Frankel, 1955; Arthur, 1988a; 1988b; 1989; Unruh, 2000). As a result, new technologies, even when economically feasible, face higher short-term adoption costs compared to established technologies (Cowan and Hulten, 1996; Unruh, 2000).

(2) Generally, when new technologies are introduced, they are initially crude, imperfect, and very expensive (Rosenberg, 1994). Incumbent technologies are generally more advanced in their respective technology life cycle and thus enjoy an associated learning and deployment advantage (Cowan, 1990). Therefore, performance (the ability to perform a particular task or deliver a novel energy service) of a new energy technology initially dominates economics as a driver of technological change and diffusion. Only after an extended period of experimentation, learning, and improvements, and the establishment of a corresponding industrial base (in many cases, profiting from standardization, mass production, and scale economies of a growing industry) do new technologies become capable of competing with existing ones on a pure cost basis. In other words, *attractive beats cheap*, at least initially. Policy intervention can short-cut this evolutionary pattern and are justified when "attractiveness" is defined by lower externalities (e.g., emissions, energy security, etc.). However, such policy interventions come at a price: either costly direct public subsidies or changed economic incentives (via levies, fees, taxes imposed on incumbent, undesirable technologies – and paid for by consumers). There is also a risk of policy-induced premature "lock-in" in technologies that ultimately turn out to be either socially undesirable, too expensive, or risky for unregulated markets (cf. the *French Nuclear* case study in Appendix II), or pose unanticipated social/environmental challenges, e.g., land competition with food production or greenhouse gas emissions associated with fertilizer use and land-use changes in the case of first generation biofuels (Plevin et al., 2010).

(3) The history of past energy transitions highlights the critical importance of end-use services (i.e., consumers, energy *demand*). Historically, energy supply has *followed* energy demand in technology applications, and energy end-use markets have been the most important market outlets for new energy technologies (as quantified in the *Grand Designs* case study. See also Appendix I for a quantification of current energy end-use versus energy supply investments). In other words, new energy technologies generally need to find consumers (users), preferably many. This holds important implications for both modeling future energy transition scenarios and technology innovation and diffusion policies alike, where energy end-use technologies are often underrepresented.

(4) The process of technological change (from innovation to widespread diffusion) takes considerable time, usually many decades. In addition, rates of change become slower the larger the energy system or its components, and when consequences of those changes are more disruptive. A novel approach that quantifies the historical scaling dynamics of energy technologies and illustrates this conclusion is reported in the *Scaling Dynamics* case study. The historically slow rates of change of energy technologies and systems, which span from several decades up to a century (for a review, see Grubler et al., 1999), arise from four phenomena:

- Capital intensiveness: investments in energy technologies are among the most capital-intensive across industries, characterized by high upfront costs, a high degree of specificity of infrastructure, long payback periods, and strong exposure to financial risk (IEA, 2003). Capital intensiveness, therefore, ceteris paribus slows technology diffusion.

- Longevity of capital stock: the lifetime of the capital stock of energy systems in many end-use applications (buildings), conversion technologies (refineries, power plants), and above all, infrastructures (railway networks, electricity grids), is generally long compared to other industrial equipment or consumer products (Smekens et al., 2003; Worrell and Biermans, 2005). Longevity of capital stock tends to slow capital turnover and thus the diffusion speed of new technologies.

- Learning/experimentation time: extended time is required for experimentation, learning, and technology development from invention to innovation, to initial specialized niche market applications, and finally, in case of success, to pervasive adoption across many sectors, markets, and countries.

- Lastly, considerable time is also required for technology clustering and spillover effects to emerge.

Only in exceptional cases does the diffusion of new technologies proceed via a premature retiring of existing capital stock, as is the case in current cell phone markets or with information and communication technologies (ICT) in general. In view of the generally slow rates of change in large technology systems like energy, pervasive technological transformations require a long-term view, and it is better for transition initiatives to start sooner rather than later.

The above characteristics of technological change in energy systems are important for policy, as they suggest that approaches must be systemic, long-term, and cognizant of inevitable innovation uncertainties. Short-term, piecemeal efforts to stimulate innovation and speed technology diffusion are unlikely to result in the kind of major technological transformations needed to achieve more sustainable energy systems as called for throughout the GEA.

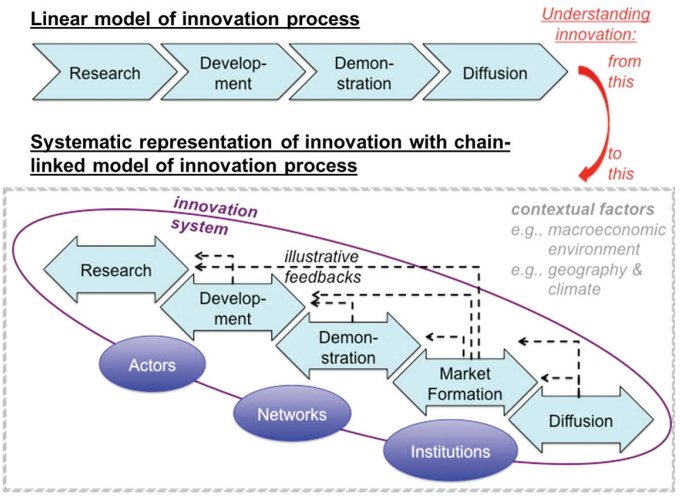

Figure 24.2 | The Evolution of Thinking on Innovation Processes.

24.2 Characterizing Energy Technology Innovation Systems

24.2.1 Introduction to the Energy Technology Innovation System

24.2.1.1 From Linear Models to Innovation Systems

The evolution of technology is often conceptualized through a life cycle model that proceeds sequentially from birth (invention, innovation), to adolescence (growth), maturity (saturation), and ultimately senescence (decline due to competition by more recent innovations). Models of innovation describe the drivers and mechanisms behind this technology life cycle. These have evolved substantially and continue to evolve further. The intellectual history of innovation concepts reaches back into the nineteenth century (e.g., Marxist economic theories and their conceptualization of technological innovation). Still influential today are the theories of Joseph A. Schumpeter (1942), who emphasized the importance of radical or disruptive technological and organizational changes, the role of entrepreneurship, and competition. In contrast to Schumpeter's emphasis on radical "breakthrough" innovations, the importance of the compounded effects of numerous, smaller (incremental) innovations is also now widely recognized. Concepts formulated by Vannevar Bush in his 1945 report to the US president, *Science the Endless Frontier*, were influential on early models of innovation (Bush, 1945). These are often referred to as "linear" models. These models emphasize the role of basic,[3] largely publicly funded science in a linear innovation process from basic research to applied development, demonstration, and concluding with the diffusion process (see the upper part of Figure 24.2).

In truth, it is well understood that the innovation process is neither linear nor unidirectional (Mowery and Rosenberg, 1979; Landau and Rosenberg, 1986; Freeman, 1994). Rather, the stages of the innovation process are linked, with feedbacks between each stage, giving rise to the term "chain-linked" model (Kline and Rosenberg, 1986; Brooks, 1995). This is illustrated in the lower part of Figure 24.2. The linear knowledge flow direction from basic science to applied technology as implied by the old "linear" model is now recognized to be more complex because it can also go in the opposite direction, with applied technologies enabling breakthroughs in basic science.[4] Likewise, research has identified the importance of knowledge spillovers and networks in collective learning processes, as there is no quasi-automatic "trickle down" from basic scientific knowledge to industrial applications of that knowledge.

Figure 24.2 represents the main modifications and additions to this "chain-linked" model of the innovation process. In this improved model there are multiple feedbacks among the different stages and their interaction, combining elements of "supply push" (forces affecting the *generation* of new knowledge) and "demand pull" (forces affecting the *demand* for innovations) (see the review in Halsnæs et al., 2007). Indeed, the stages often overlap with one another and the more interaction among the various stages, the more efficient the innovation process as offering more possibilities for learning, and knowledge and technology spillovers. And, of course, some technologies are successful without proceeding through each step in the innovation process (Grubler, 1998).

The distinction between supply-push and demand-pull has traditionally been important, especially as they imply different technology policy instruments – e.g., public R&D expenditures or incentives for private R&D as classical technology "supply" instruments versus government purchase programs, mandated quantitative portfolio standards, regulated feed-in tariffs, or subsidies as classical technology "demand"

3 The term "basic research" refers to study and research in pure science that aims to increase the scientific knowledge base. This type of research is often purely theoretical and has the intent of increasing the basic understanding of certain phenomena or behaviors; it does not seek to identify concrete applications of phenomena studied or to solve particular applied problems.

4 For example, satellite measurements leading to the discovery and subsequent explanation of previously unrecognized environmental problems such as stratospheric ozone depletion.

policy instruments. As argued here, from the perspective of a systemic innovation model characterized by multiple feedbacks, this technology supply-demand dichotomy is artificial to a degree. Transformative technological change generally requires the simultaneous leveraging of all innovation stages, processes, and feedbacks, and thus a combination of both supply- and demand-side technology policy instruments.

In an additional improvement over previous models, a market formation stage[5] has been added in explicit recognition of the so-called "valley of death"[6] observed in this innovation process between technology demonstration and diffusion. Many technologies fail at this or a similar hurdle between development and demonstration if they are too expensive, otherwise uncompetitive, too difficult to scale up, or lack perceived market demand. Market formation activities support new technologies that can struggle to compete with incumbent technologies that enjoy economies of scale and the learning advantages resulting from their more mature technology life cycle. In some cases, natural market niches exist that value the relative advantages of the new technology and offer a price premium. In other cases, it is important to create new niches (Kemp et al., 1998).[7]

The importance of the institutional context in which innovation occurs is also increasingly emphasized (Nelson, 1993; Geels, 2004). This points to the need for a more systemic approach to innovation, extending beyond the technology-focused "hardware" innovation process to also include analysis of actors, networks, and institutions.

Finally, the broader context of the innovation system matters. Technological, national or geographical factors affect the relative importance, roles, and relationships between components of the innovation system or the specific incentives structures in place. The concept of "national systems of innovation" (Nelson, 1993; Lundvall, 2009) describes this specificity. As a result, innovation systems for specific energy technologies vary substantively in their details, involving different sets of actors (e.g., incumbents or new entrants), interacting in different ways (e.g., research or market development), focusing on different problems (e.g., problem solving or learning by doing), and acting at different spatial scales (e.g., national or global) (Jacobsson and Lauber, 2006; Hekkert et al., 2007).

24.2.1.2 The Innovation Systems Approach

Taken together, the different elements described in the preceding section comprise the innovation systems approach used as the conceptual framework for this chapter. This is represented in the lower part of Figure 24.2. The different traditions of innovation and energy technology research outlined above (from linear to systemic) are drawn upon to support this chapter's integrative perspective. The innovation systems approach centers on the set of factors that drive and direct innovation *processes.* From a systemic perspective, innovation is understood as an interactive process involving a network of firms and other economic agents (most notably users) who, together with the institutions and policies that influence their innovation and adoption behavior and performance, bring new products, processes, and forms of organization into economic use (Nelson and Winter, 1982; Freeman and Perez, 1988; Lundvall, 1992).

The innovation systems approach emphasizes that the life cycle of a particular technology must develop in tandem with its corresponding innovation system (Jacobsson and Johnson, 2000). For new technologies that are incremental improvements to existing ones, innovation systems are already in place. For example, the development of a more efficient gas turbine occurs within a mature innovation system comprised of large firms with high R&D spending, strong networks between suppliers and users of the technology, established markets and well-aligned institutional infrastructures. In contrast, innovation systems need to be built up for radically new or disruptive innovations that strongly deviate from existing technologies and practices (van De Ven, 1993). Current examples of radical innovations in the energy domain are solar photovoltaic (PV) and electric vehicles. Innovation systems emerging around such technologies may be characterized by poorly developed markets, misaligned institutional settings, poorly structured knowledge networks, and small firms with limited resources to develop and market the new technology (Alkemade et al., 2007).

It takes time to build up an innovation system, particularly for radical innovations whose initial development typically takes place over decades (see the *Scaling Dynamics* case study). Weak or immature innovation systems may delay the progress of an innovation, or decrease the likelihood of its success (van De Ven, 1993). In the initial stages of the innovation process, only a few actors are involved in developing a new technology. Over time, other actors enter, the knowledge base starts to grow, often the legitimacy of the new technology increases, and more financial resources become available (although sometimes creating exuberant expectations that can lead to investment bubbles). Through this "formative phase," the innovation system around a new technology is built up (Jacobsson and Lauber, 2006). At a certain point, the innovation

5 Traditionally, market formation policies have been used in the defense (e.g., jet engines) and space sectors (e.g., photovoltaic [PV] technology) to kick-start a minimum level of technology demand for a nascent industry or technology.

6 The "valley of death" describes a situation where a successful R&D project either cannot attract funding for further development, or, once developed, cannot attract funding for large-scale demonstration of the new technology. It can also occur when the capital intensiveness of a project exceeds the financial resources of an otherwise willing investor (e.g., venture capital) or when promised public support does not materialize. For instance, the US FutureGen "clean coal" (advanced coal gasification, combined cycle, electricity generation plant combined with CCS) demonstration project was discontinued mid-stream after the US Department of Energy stopped funding due to substantial cost overruns (Rapier, 2008).

7 Examples of "natural" market niches include the first applications of PV in instruments (calculators) and toys in the Japanese electronics industry that did not need any public policy support and incentives, see the *Solar PV* case study in Appendix II. For an example of "created" niche markets, consider the case of Switzerland, where regulation requires electricity back-up systems for all public and technological infrastructures. This has created niche markets for microturbines and fuel cell applications for onsite electricity generation in hospitals, supermarkets, or cell phone towers.

system becomes large and developed enough for technology diffusion to take place during a "growth phase" (Jacobsson and Lauber, 2006).

24.2.1.3 The Energy Technology Innovation System (ETIS): What is it? Why is it needed?

ETIS is the application of this systemic perspective on innovation to energy technologies. In terms of the innovation system, this means the synthesis and analysis of data on the various stages of the innovation process; on different inputs, outputs and outcomes; on actors and institutions; and on the key innovation processes. In terms of the energy system, this means the synthesis and analysis of data on both the energy supply side and the energy demand side; on different energy technologies; and on both developed and developing countries. ETIS is thus an integrative approach that aims to comprehensively cover all the components of energy technology innovation systems, in terms of innovations, mechanisms of change and supporting policies, and energy technologies (supply and end-use), as well as in terms of geographical and actor network coverage.

Why is such a systemic approach needed? The GEA sets out clearly the magnitude of the challenge facing the global energy system. The GEA transition pathways – described in Chapter 17 – illustrate that a substantive and pervasive technological transformation in energy systems towards vastly improved efficiency and decarbonization is needed. This holds regardless of the ongoing debate over whether it is possible to improve existing technologies incrementally, with the primary challenge one of diffusion (Pacala and Socolow, 2004), or whether breakthroughs with radically new technologies are needed with the main challenge being basic and applied research (Hoffert et al., 2002; Hoffert, 2010).

It is the magnitude of the challenge that most clearly points to the need for a systemic perspective rather than a piecemeal approach focused on particular technologies (e.g., PV or CCS) or particular drivers (R&D or feed-in tariffs). This is fully supported by the accumulating body of knowledge on innovation processes and innovation histories, both successful and failed. New research carried out for this chapter adds to these findings. All point to the interrelationships and dependencies within effectively functioning innovation systems. This too necessitates a systemic approach.

ETIS has certain key characteristics which emerge repeatedly through the literature and are worth emphasizing. These include interdependence, uncertainty, complexity, and inertia. Interdependence means that different components of ETIS influence one another; moreover, the strength and direction of these influences may change. The outcomes of the innovation process are irreducibly uncertain, and it is *not* possible to ensure *ex ante* success for technology A if recipe B is followed. Complexity arises inevitably from the number and variety of innovation system components and their shifting interdependencies. This is further exacerbated by context-dependence in the application of the ETIS framework to specific energy technologies. Inertia also arises from interdependencies, and is exacerbated by the long-lived capital stock and infrastructures in the energy system, as discussed above.

From these characteristics follow certain key implications for efforts to intervene in ETIS to support its effective functioning. Again, these emerge repeatedly in the literature and include coherence, alignment, consistency, stability, and integration. "Effective functioning" is used here in a qualitative sense. ETIS that demonstrate the full complement of drivers, mechanisms, actors, and institutions described in this chapter are more likely to be successful than ETIS that are lacking in one or more areas. Failure and success are not defined in absolute terms. Innovation system success could be interpreted most simply as widespread diffusion of new technologies and practices and when innovation benefits outweigh costs (in a large societal context). This is the ultimate outcome of interest for innovation processes in the context of energy system transformation required by the GEA objectives. Conversely, innovation system failure can be dramatic, as in a technology which fails in the "valley of death," or relative, as in a technology which diffuses slowly, to a low extent, or in a stop-start manner.

24.2.1.4 Strengths and Weaknesses of the ETIS Perspective

A systemic approach to innovation in an energy context is largely novel and challenges some established wisdoms. This is a recurring theme throughout Chapter 24 and is explicitly noted in the final policy guidance section, which directly questions certain policy myths, and in the quantitative assessment of financial inputs into ETIS presented in Appendix I. The systemic perspective necessitates an integrative analysis: from large-scale supply-side technologies to dispersed end-use technologies within the energy system and from early stage R&D through market formation to diffusion activities. Conventional data collection and analysis (as well as the formation of public and commercial institutions) has tended to focus on one piece of this puzzle. This chapter's comparative assessment makes (within the limitations of available data) commensurate what have to date largely been apples, oranges, pears, and peaches. Certain patterns emerge from this commensuration that have direct implications for the ETIS and its effective functioning. An example is an apparent mismatch between the target of innovation investments and the need for diffusion investments. This is explained and discussed at length below. Here, it suffices to note that the implications of the systemic perspective offer a challenge to prevailing practice and thinking. One example is the question of whether the technological, market, and institutional differences between the supply side and demand side of the energy system mean an integrative comparison is worthwhile or even meaningful. The ETIS perspective contends that it is, as the resulting insights are both important and potentially transformative.

Despite the strengths of the systemic perspective, its weaknesses and limitations should also be acknowledged. Though rich and detailed in certain areas, ETIS research is weaker in others, such as feedbacks

between components of innovation systems. Studying innovation from a systemic perspective in the energy domain is a relatively young endeavor, with an empirical bias toward national, sustainable, and supply-side energy technologies. Policy experiments and field experience are largely still ongoing, particularly in a Northern European context that, together with Japan, provides many of the innovation histories from which the ETIS framework has been inductively derived. Studies in developing countries are particularly lacking, although this assessment begins to fill the gap with specific case studies on R&D expenditures in emerging economies, energy technology innovation in China, and lessons from solar PV market deployment in rural Kenya. Data are partial, incommensurate, or otherwise limited, as discussed below in the context of assessing ETIS (see Section 24.5.1 on data and information needs identified in this assessment). The understanding of mechanisms and linkages is incomplete. As a result, the ETIS perspective should not be interpreted as a full systemic dynamics model that can support quantitative modeling, simulation, or optimization. Rather, ETIS as developed in this chapter is a conceptual framework with the necessary generality to apply across the entire energy domain.

24.2.1.5 Empirical Basis of the ETIS Perspective

ETIS integrates current understanding of innovation processes within the energy system, their interlinkages, and the roles and influence of different actors and institutions including public policy. This systemic perspective is founded upon empirical work on technology histories such as wind power, processes such as learning, actor networks such as advocacy coalitions, social institutions such as expectations, and so on. This empirical work is covered in extensive literatures, which are referenced throughout the text. In addition, this chapter contributes a series of new empirical studies that are summarized in Appendix II, published in full in a companion volume, and referenced throughout the text. These are also summarized in Tables 24.2, 24.3, and 24.4 below and discussed further in the *Assessment Metrics* case study, summarized in Appendix II.

It is important to emphasize this empirical basis for the ETIS perspective. The various components of the ETIS described here characterize what is understood about successful innovation, as well as what may be missing

Table 24.2 | Chapter 24 case studies (innovation histories): demand-side technologies.

Short Name	Summary Description	Example of Relevance for ETIS	Chapter Section
Hybrid Cars	Development of hybrid electric vehicles in Japan, United States, and China, emphasizing the role of public policy.	Importance of policy alignment and consistency. Role of market demand and end-user preferences.	24.7.9
Solar Water Heaters	Early success and later failure of the solar water heater industry, particularly in the United States.	Lasting legacies of industry failure, including knowledge depreciation. Alignment of innovation system actors.	24.7.10
Heat Pumps	Different stages of heat pump diffusion in Sweden and Switzerland, emphasizing the role of public policy.	Interactions between supply of, and demand for, innovation. Importance of policy stability and consistency.	24.7.11
US Vehicle Efficiency	The "CAFE" standard for vehicle efficiency in the United States, and its influence on technological change.	Interaction between policy standards and changing market characteristics, including prices.	24.7.12
Japanese Efficiency	The "Top Runner" program to improve end-use efficiencies in Japan, and the role of dynamic incentives.	Flexible policies creating dynamic incentives within a clear overall strategic direction.	24.7.13

Table 24.3 | Case studies (innovation histories): supply-side technologies.

Short Name	Summary Description	Example of Relevance for ETIS	Chapter Section
Wind Power	Evolution of innovation stages and strategies in different wind power markets worldwide.	Need to integrate RD&D support with market formation. Interaction and feedback between innovation actors.	24.7.14
Solar PV	Development of solar PV in different markets worldwide, focusing on drivers of cost reduction.	Long-term R&D support complemented by market formation activities to stimulate commercial learning.	24.7.15
Kenyan PV	Market dynamics in the solar PV market in Kenya, emphasizing product quality issues.	Local institutions to set and enforce standards for quality control and assurance.	24.7.16
Solar Thermal	Early experience of solar thermal electricity in the US, and spillovers to later stage production.	Codification of knowledge. Interaction between R&D and learning to support cost reductions.	24.7.17
US Synfuels	History of US government investment in synthetic fuel production as oil substitute, and ultimate innovation system "failure."	Over-exuberant expectations in the context of changing market conditions. Public/private roles in innovation system.	24.7.18
French Nuclear	Review of pressurized water reactor (PWR) program in France, including cost escalation.	Interaction between learning effects and institutions, including standards and regulatory stability. Limitations of learning paradigm in technology cost reductions.	24.7.19
Brazilian Ethanol	History of ethanol production and developments in automotive technologies in Brazil, focusing on supporting role of policy.	Coalitions and shared expectations among innovation system actors, and interactions between related technologies.	24.7.20

Table 24.4 | Case studies (innovation processes and metrics).

Short Name	Summary Description	Example of Relevance for ETIS	Chapter Section
Grand Designs	Review of patterns, drivers, and dynamics of energy systems, both historically and in future scenarios.	Knowledge spillovers and inter-dependence between innovations creating inertia and path dependence.	24.7.1
Scaling Dynamics	Comparison of rates and extents of growth in 8 energy technologies historically.	Experimentation with small-scale units takes place during extended early formative phase.	24.7.2
Technology Portfolios	Tools to guide the selection of innovation portfolios under conditions of uncertainty.	Formal tools to support portfolio selection and diversification. Historical under-representation of end use technologies.	24.7.3
Knowledge Depreciation	Loss or obsolescence of knowledge, with examples in the context of energy innovation.	Importance of stable, sustained inputs to knowledge generation. High potential rates of knowledge depreciation.	24.7.4
Assessment Metrics	Quantitative metrics and qualitative approaches for assessing innovation.	Assessment of inputs, outputs, or outcomes, but not typically innovation systems as a whole. Data limitations.	24.7.5
Chinese R&D	Overview of R&D investments in China, with relevant institutions and mechanisms.	Substantive and growing R&D, dominated by industry but with strong government role. Supply-side technology emphasis.	24.7.6
Emerging Economies R&D	Review of RD&D investments in 6 major emerging economies, by technology type and source.	Increasing importance of emerging economies in global energy technology innovation system. Supply-side technology emphasis.	24.7.7
Venture Capital	Trends and targets of venture capital investments in energy technology innovation.	Rapidly growing venture capital investments in energy innovation. Non-fossil supply-side emphasis.	24.7.8

in cases of failed innovation. In this way, it should be treated as descriptive, induced, and interpreted *ex post* from available evidence; it should not be treated as normative. Partly for this reason, we use the ETIS perspective in the concluding section to abstract some general guidance for policy makers rather than offering more specific, universal prescriptions. As noted, the ETIS perspective is not sufficiently developed nor detailed to support a quantified system dynamics model. Nor is it necessarily appropriate to generate formalized, testable hypotheses which are replicable in both form and method across different technologies and contexts. Clearly, further work is needed in this direction. Testing, critiquing, and improving the ETIS perspective is of critical importance, given the magnitude of transformation needed in the energy system as captured by the GEA.

24.2.2 Characteristics of ETIS (I): Knowledge

24.2.2.1 Sources and Generation of Knowledge

"The most fundamental resource in the modern economy is knowledge and, accordingly, the most important process is learning" (Lundvall, 1998). Knowledge is a ubiquitous and powerful driver of technological change. Technological knowledge can be basic ("know-why") or applied ("know-how"), as well as publicly available (e.g., through scientific or engineering journals) or entirely tacit (e.g., resting with accumulated experience of a production engineer in manufacturing). Understanding the process of generation, reproduction, and diffusion of knowledge and the constraints to knowledge flows is therefore critical for innovation policy.

Knowledge is generally largely a public good. Once produced and disclosed, it is difficult to control or restrict its use. For activities organized around reward systems based on reputation and primacy of discovery, like science, this poses less of a problem (Dasgupta and David, 1994). As more basic knowledge becomes integrated into technological solutions and into the realm of private production, the public aspect of knowledge which makes it expensive to generate, but cheap to reproduce, is generally classified as a source of market failure. This results in underinvestment in knowledge production (Arrow, 1962a). This is the traditional argument for encouraging public sector support for the generation of basic knowledge and allowing knowledge appropriability of private R&D through systems of property right protection.

Knowledge is generated at several different levels of innovation systems, through several distinct processes of knowledge exchange and transformation within and between agents and institutions. It is, therefore, a powerful source of feedback, correction, and advance in innovation systems. Basic science is, of course, a strong component of innovation in energy systems (Ausubel and Marchetti, 1997) and the disciplines that support it are numerous. However, technical change in energy systems tends to be based dominantly in engineering practices and disciplines, and the origins of major innovations have often come from outside basic energy science proper. (The best historical example is the development and application of steam engines much before the discovery of the Laws of Thermodynamics.) These specialized sources of knowledge outside classical basic science are crucial for energy technology innovation. Technology knowledge is also spawned during productive experience and a result of producer-user collaborations in technology development and of producer-producer collaborations in technology production at the manufacturing stages (von Hippel, 1988; Lundvall, 1992; see also Fridlund, 2000 for a case study on user-producer learning in the electric power sector in Sweden). Experience in production and use, as well as knowledge exchange between different types of producers and users, are important sources of specific knowledge that cannot be generated by scientific research (i.e., cannot be predicted from general principles or comparable technologies). This feedback process from

application experience to redesign and engineering has been particularly important in energy technologies (see the *Wind Power*, *Solar PV*, and *Kenyan PV* case studies summarized in Appendix II) and highlights the importance of market applications as main knowledge and learning feedbacks enhancing R&D efforts that require appropriate incentives beyond R&D.

Applied energy research and development on the supply side has been oriented and guided by four main sets of goals, or "focusing devices" (Rosenberg, 1982):

- harnessing new energy sources and carriers with special qualities like energy density, abundance, transportability, but also flexibility, convertibility, and modularity;
- increasing efficiency, both in thermodynamic as well as in economic terms (cost reductions);
- improving control, security, and stability of energy conversion and delivery infrastructures; and
- improving adverse social and environmental impacts of energy systems.

Whereas the first three goals can be considered endogenous for the energy system, the goal of improved social and environmental performance has historically been triggered by regulation. R&D intensity (R&D expenditures per unit of value added) in the energy sector is strongly differentiated between energy supply (e.g., electric utilities) and energy demand (e.g., manufacturing of electricity using equipment such as TVs or computers) industries. At least in developed countries, energy supply industries have lower R&D intensity levels than the manufacturing average, similarly low as in the textile industry (see Figure 24.3). Conversely, electrical machinery, transport equipment and motor vehicles exhibit higher than average R&D intensities, although no information is available to differentiate their R&D into energy- and non-energy-related components (e.g., more fuel efficient engines versus safety improvements in motor vehicles).

24.2.2.2 Characteristics of Knowledge: Codification and Spillovers

Knowledge possesses a number of unique characteristics. It is *nonrival* (the use of knowledge by someone does not preclude its uses by someone else); *nonexhaustible* (can be used/reproduced without paying for an additional copy); *combinatorial* (knowledge is combined from different specific knowledge bases); and *cumulative* (builds on pre-existing knowledge). These features of knowledge can generate very high social rates of return and call for minimizing or even eliminating access costs to knowledge if social welfare is to be maximized (Foray, 2004). Indeed, much knowledge relevant in an industry is routinely shared and used by private actors through nonmarket mechanisms, a phenomenon referred to as knowledge "spillover."

Knowledge spillovers across sectors and across countries have been considered key engines of technological development and economic growth. The most salient sources of knowledge spillovers explored (e.g., Falvey et al., 2004) are universities and R&D centers; personnel training; scientific publications and patents; personnel movements, interfirm turnover; formal and informal networks of scientists, engineers, and technicians; licensing and technology transfer agreements; foreign direct investment; international research collaboration and research; reverse engineering, and international trade in final, intermediate, and capital goods.

The literature is vast and not free of controversies. In general, it has been shown that knowledge spillovers positively impact growth and productivity (Coe and Helpman, 1995; Coe et al., 2009), with highly localized

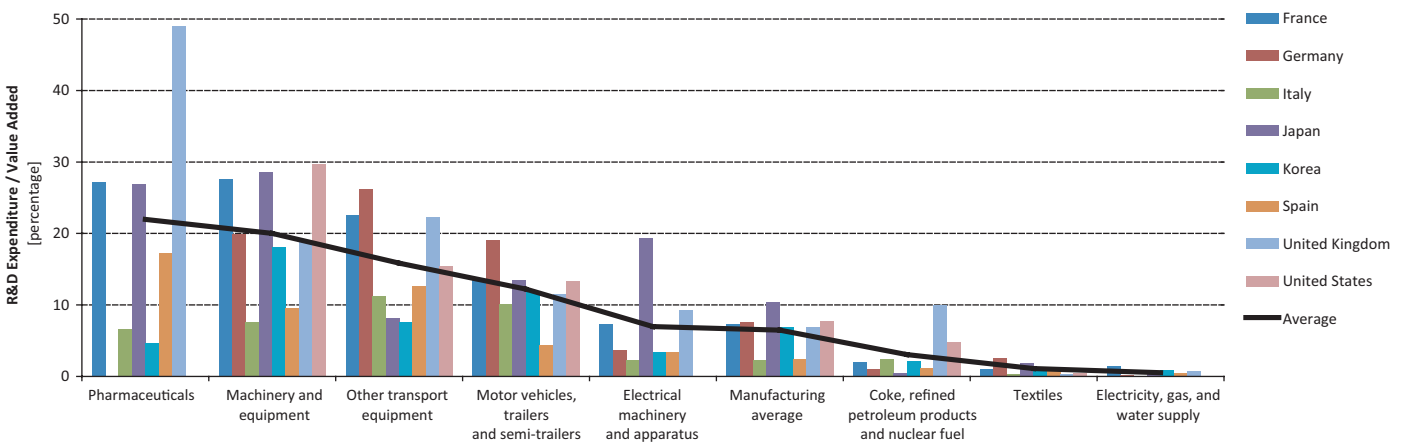

Figure 24.3 | R&D intensity (expenditures per value added, in percent) for selected sectors and OECD countries in 2002. Source: The OECD Research and Development Expenditure in Industry database and STAN Database.

geographical effects (Jaffe and Trajtenberg, 1999). It has also been shown that the extent of international knowledge spillovers depends on national R&D efforts (Mancusi, 2008; Unel, 2008). Thus, knowledge spillovers depend critically on the assimilative capacity of the recipient country. There are very few studies focusing specifically on knowledge spillovers in the energy sector (an exception being Bosetti et al., 2008). Measuring knowledge spillovers poses many challenges, for knowledge is highly heterogeneous, unobservable, and difficult to define in quantitative terms (Mohnen, 1997; van Pottelsberghe de la Potterie, 1997).

However, there are other important barriers to learning and knowledge advancement through spillovers, which are more relevant for innovation policy design. Knowledge implies more than simply information such as data and formulas; it also implies the cognitive capability to interpret, process, and articulate information. Similarly, in order to understand a problem and make sense of knowledge produced elsewhere, firms require a minimum threshold of accumulated knowledge or absorptive capacity, derived from their direct involvement in R&D, production experience, or training (Cohen and Levinthal, 1990). In many cases, it has been shown that firms engage in R&D not only to produce new knowledge, but to be able to learn knowledge produced elsewhere (Cohen and Levinthal, 1989). In other words, enforcing knowledge appropriability (i.e., knowledge access) is insufficient for knowledge generation and learning (Foray, 2004). Policies are therefore also needed to further absorptive (assimilative) capacity to facilitate learning in firms, but also in the public sector and society at large. For energy technology innovation policy, this implies that an exclusive focus on technology transfer (knowledge appropriability) is entirely insufficient to guarantee technology diffusion, as the latter critically depends on sufficient local knowledge or assimilative capacity. Local knowledge is needed to first decide which globally available technologies offer local diffusion potentials, which requires capacity building for technology assessment both in the public and private sectors. Local knowledge is also needed to import/manufacture, adapt, install, and above all *use* a new energy technology effectively (see e.g., the *French Nuclear* case study, which illustrates the importance of local technological capability in the successful scaling up of imported reactor designs, or the *Kenyan PV* case study as an illustration of the problems arising if local capacity for testing and evaluating technical characteristics [and defects] of imported PV cells are unavailable).

It also important to note that not all technological knowledge is embodied in artifacts or codified in blueprints, manuals, and sets of instructions; much knowledge remains tacit (uncodified) in the form of personal or institutional knowledge and skills. In this case, knowledge generation implies practicing and accumulation of experience (Nelson and Winter, 1982), which needs to be achieved locally and cannot be substituted by "imports." Generally, new knowledge tends to be less codified and articulated, which makes it more difficult to reproduce, memorize, recombine, and learn, which in turn makes it costly to transfer in a usable form (von Hippel, 1994). For new energy technologies, this implies above all a need to develop a local industrial base (either in manufacturing or in using/marketing a new technology) and to promote partnerships that can further the transfer of tacit knowledge. For example, the *Wind Power* case study illustrates the importance of public testing facilities for new wind turbine designs that furthered localized learning and tacit knowledge transfer among firms.

Knowledge is also highly dependent on local conditions and environments and on market structures, and therefore tends to be dispersed by the division of labor and specialization, which raises difficult coordination and communication problems (Machlup, 1984; Smith, 2002). The public sector therefore has an important role to play in furthering formal or informal coordination mechanisms, e.g., technology development "roadmaps,"[8] and setting dynamic technology performance standards (see the Top Runner program described in the *Japanese Efficiency* case study).

Lastly, knowledge can depreciate rapidly if it is not continuously replenished. This depreciation occurs through personnel turnover and retirement, technological obsolescence, and institutional inertia (see Section 24.2.2.4).

For all these reasons, knowledge cannot simply be assumed to generate automatic "spillover" effects. A (local) enabling learning environment is as important, as is the generation of knowledge (elsewhere) in the first place.

The nature of spillovers also depends on the type of knowledge, on the type of industry, and, finally, on the life cycle stage of a technology. In the early phases of the technology life cycle, disembodied knowledge tends to be predominant. As learning experience accumulates,[9] underlying phenomena are better understood and measured, practices and procedures become increasingly codified, and hardware is adapted and developed. The more codified and embodied (in artifacts) technological knowledge is, the easier it is to capture spillovers.

Empirical studies have shown evidence on the importance of knowledge spillovers in new energy technologies, particularly in the cases of PV (Watanabe et al., 2002) and wind energy (Kamp et al., 2004; Lako, 2004).

In Watanabe et al. (2002), a virtuous cycle between R&D, knowledge spillovers, market growth, and price reduction is thoroughly illustrated for the case of the Japanese PV industry. By stimulating public and private R&D on a broad base of industrial sectors and by simultaneously creating incentives for niche market deployment,

8 Successful examples of technology roadmaps can be found especially in the semiconductor industry.

9 The concept of learning via knowledge spillovers is sometimes referred to as "learning-by-interacting" (Lundvall, 1992).

the Japanese Sunshine Program triggered a range of mutually enhancing positive feedback mechanisms. The technology knowledge stock increased rapidly both from proprietary R&D and knowledge spillover effects among Japanese PV R&D and manufacturing firms (even after accounting for knowledge depreciation). Next to innovation, learning contributed to important cost reductions in PV cells, which further induced increases in demand and production; market growth in turn further increased R&D expenditures, closing a positive feedback loop between knowledge generation and market development. As shown in the *Solar PV* case study, PVs also benefited importantly from inter-industry learning spillovers and scale economies, among other factors. The *Wind Power* case study confirms this conclusion: knowledge spillovers have been important sources of innovation and design improvements, including knowledge spillovers between industries (materials, aerodynamic simulations, and designs) and between manufacturers nationally (facilitated by testing stations), as well as internationally. Denmark's success involved not just R&D, but also the facilitation of feedback between users and producers of wind turbines (Garud and Karnoe, 2003). This positive feedback process, based upon inter- and intra-firm knowledge spillovers in which learning and absorptive capacity production are mutually reinforced, can potentially augment an industry's capability of knowledge production (Foray, 2004). The *Solar Thermal* case study shows how interactions between researchers and firms commercializing technologies create feedbacks so that real world problems can stimulate improvements in design. This "learning-by-doing" can be more important for technology development than R&D, and is discussed further below. The *Kenyan PV* case study shows how interactions between firms and users are important to communicate how users adapt technologies into their daily practices, thereby revealing potential quality and technology problems that in turn form the basis for further design improvements.

24.2.2.3 Knowledge Creation through Learning-by-Doing and Learning-by-Using

Processes of learning are essential for the development and introduction of new technologies and comprise a complex set of actors (*who*) and processes (*what* and *how*). Learning results in improved and standardized production processes and products, which in turn can often result in cost reductions. In order to highlight that learning processes require dedicated efforts rather than just the passage of time, resulting cost reductions are often illustrated by so-called "learning curves," i.e., curves that describe the cost development as a function of cumulative production (as a proxy for learning).[10] In reality however, it is not the act of production per se that provides a source of learning but rather a complex set of interrelated processes that include learning at the individual and organizational scale, classical economies of scale in manufacturing, knowledge spillovers, market conditions and structure (e.g., raw material prices, degree of competition), etc. Common to all is that they exercise their impact on costs and cost reductions via accumulated production/market deployment and/or growing industry size.

The learning curve originates from observations that workers in manufacturing plants became more efficient as they produced more units (Wright, 1936; Alchian, 1963; Rapping, 1965). The roots of these microlevel observations can be traced back to early economic theories about the importance of the relationship between specialization and trade, which were based in part on individuals developing expertise over time (Smith, 1776). Drawing on the concept of learning in psychological theory, Arrow (1962b) formalized a model explaining technical change as a function of learning derived from the accumulation of experiences in production: Arrow's "learning by doing" (LbD) model. Accumulating experience in the early stages of an innovation's life cycle can be a powerful strategy both for maximizing the profitability of firms (BCG, 1972) and for the societal benefits of technology-related public policy.

In its original conception, the learning curve referred to the changes in the productivity of labor that were enabled by the experience of cumulative production within a manufacturing plant. It has since been refined. For example, Bahk and Gort (1993) make the distinction between "labor learning," "capital learning," and "organizational learning." Subsequently, the Arrow model was complemented by an analogous concept, that of "learning by using" (LbU), referring to learning effects from the perspective of technology users (e.g., plant and equipment operators or consumers as opposed to technology producers).

Often, the term "experience curve" is used in the literature to provide a more general formulation of the learning concept, including not just labor but all manufacturing costs (Conley, 1970) and aggregating entire industries rather than single plants (Dutton and Thomas, 1984) or entire technological "trajectories" rather than individual technology generations. Though somewhat different in scope, each of these concepts is based on Arrow's explanation that "learning-by-doing" provides

10 In the functional form of: $C_t = C_0 * X^{-\varepsilon}$ where the costs at ***t*** are a function of the costs at ***0*** multiplied by the cumulative production volume X to the exponent of the so-called learning rate ε. Thus a learning rate ε=0.2 indicates a cost reduction by 20% per doubling of cumulative production. A related concept used in the literature is the so-called progress ratio $PR = [P_0 * (2X)^{-\varepsilon}]/[P_0 * X^{-\varepsilon}]=2-\varepsilon$. Hence a progress ratio of 0.8 (1-ε) indicates that costs are at 0.8 of their original value after a doubling of cumulative production. A specific characteristic of learning curves is that costs are reduced by a constant percentage with each doubling of output. As the doubling of cumulative production is more rapid in the early phases of an industry compared to mature ones, cost reductions invariably are steeper in early industries and tend to decline with increasing maturity as the doubling of cumulative production volume requires ever longer time. The observed cost reduction for different technologies analyzed in the literature covers a range up to 40% cost reductions for each doubling of the total number of units produced (e.g., Argote and Epple, 1990). There are also well-documented cases in the aircraft and nuclear reactor industries that exhibit "negative" learning, i.e., costs increase rather than decrease with accumulated production volumes. (See the *French Nuclear* case study in Appendix II.)

opportunities for cost reductions and quality improvements and the following discussion will therefore refer to this phenomenon simply as "learning"[11] or "learning curve."

There have been a number of misconceptions about how to use and interpret learning curves (see Neij, 2004; Nemet, 2006) that have resulted in certain pitfalls in communicating with policy makers. For instance, a popular misinterpretation of learning (or experience) curves is that policies can simply "buy down" (e.g., Brennand, 2001) technology costs through, for example, one-sided demand-pull policies without due regard to the equally needed supply-side technology innovation policy aspects. A second pitfall of cost "buy down" policy approaches is the assumption that the extent of possible "learning" can be *ex ante* anticipated (i.e., "forecasted"), which evidently is not possible. Evidence from the descriptive case studies performed within Chapter 24 is used to inform the general insights for policy design covered in Section 24.4.

Learning phenomena and curves are frequently evoked in cost trend analysis of nonstandardized products produced globally or nationally. The resulting uncertainties and variation in estimates/projections need, however, to be assessed critically (van der Zwaan and Seebregts, 2004). Variations in calculated learning (or experience) curve parameters as a function of different levels of spatial aggregation, observational period, or the use of price data as a proxy for cost information are examples of important uncertainties. Future prices may not only be reduced as a function of "learning," but may also increase as a result of escalating input prices, quality improvements of the product, or lack of competition in quasi monopoly markets, especially under rapid demand growth. The example of wind turbines illustrates this point nicely. Whereas prices fell in line with the "learning curve concept" until the late 1990s, prices have risen since the early 2000s. A recent study reviewed cost estimates in offshore wind projects in the United Kingdom and found a real-term cost escalation of a factor of two since 2000 to some £3000/kW, or US$5000/kW (UKERC, 2010). Similar trends have been observed in the VS as well (Bolinger and Wiser, 2012). The reasons for such cost escalation are varied and include rising material prices, much larger wind turbines, and component supply bottlenecks, among others. It also appears that policy (favorable feed-in tariffs) stimulated rapidly increasing demand growth for wind turbines and enabled opportunistic pricing strategies of wind turbine manufacturers. The rapidly growing demand led to significant supply bottlenecks, further reducing competition in this oligopolistic industry.

Secondly, the driving forces of the cost reductions remain unexplained by such aggregate analyses. In order to develop scenarios of possible future technology cost trends as a guide for policy, the sources of cost reduction must be identified and analyzed separately – be they characteristics of innovations (radical or incremental), knowledge generation and spillovers, the importance of economies of scale effects, or other factors. Such detailed analyses are increasingly becoming available (see, e.g., Krawiec et al., 1980; Hall and Howell, 1985; Nemet, 2006; van den Wall Bake et al., 2009; see also the *Solar PV* and the *Brazilian Ethanol* case studies).

R&D investments or other sources of knowledge generation are now increasingly recognized as not being simple substitutes for the accumulation of actual production experience (see the discussion in Halsnæs et al., 2007). These two sources of technological learning are therefore more usefully conceptualized as complementary to each other.

24.2.2.4 Knowledge Depreciation

It is important to recognize that technological knowledge – like all knowledge – can be accumulated (learned) but equally lost (unlearned). Knowledge depreciation particularly affects settings in which knowledge remains largely tacit, residing in individuals or organizational entities (e.g., managers) and needs to be acquired again in case of staff turnover or stop-and-go production schedules. A second type of depreciation occurs as old knowledge becomes obsolete. Knowledge can depreciate because of an insufficient "recharge" (Evenson, 2002) of knowledge in cases where innovation proceeds rapidly such that old technological knowledge is no longer relevant for updated processes/techniques, but new learning cannot proceed quickly enough because of financial constraints. It is the latter type of unlearning that is of particular concern in energy technology innovation systems – when rapid rates of innovations coincide with erratic funding and policy support, for which history provides ample examples.

Both knowledge gained from experience through market deployment and knowledge gained from R&D depreciate. The *Knowledge Depreciation* case study (Appendix II) discusses the case of R&D knowledge depreciation of nuclear power (and energy efficiency) R&D in the member countries of the International Energy Agency (IEA), but there is also evidence of nuclear knowledge depreciation beyond R&D, such as in the ability to construct nuclear power plants illustrated in the recent disappointing experiences (substantial costs and construction time overruns) at the two construction sites of the European Pressurized Water Reactor (EPR). (See also the *French Nuclear* case study.)

The particular vulnerability of tacit knowledge to depreciation implies that learning by doing is prone to especially high rates of knowledge depreciation, since experience in production is less likely to be codified than research and development activities and may thus be "unlearned" rather quickly.

11 Often the literature refers to "experience curves" to describe cost reductions in aggregate costs over entire industries and across a whole series of technological generations and thus includes the effects of product design changes and improvements as well as manufacturing economies of scale in cost reductions, which were initially excluded in "learning curve" analyses (for a discussion of these two concepts see Nemet, 2009b). However, this terminological distinction has not become standardized and aggregate cost reductions over entire industries continue to be referred as "learning curves" as well. To add to the confusion, the ensuing cost reductions of learning processes are also defined differently in the literature, either as percent cost reductions per doubling of cumulative output (or manufactured units), or as the percent original costs remaining after a doubling of cumulative output (cf. the discussion in footnote 10).

As an example of the first source of knowledge depreciation, it has long been recognized in the management literature that in service industries (e.g., pizza franchises) organizational and production knowledge can be lost quickly, especially under high rates of staff turnover (that may be up to 300%/year). Argote et al. (1990) and Darr et al. (1995) report knowledge depreciation rates of between 25–50% month in service industries. Such high rates of knowledge depreciation basically imply that after a year only between 0–5% of the original knowledge of an organization remains. Kim and Seo (2009) arrive at similarly high depreciation rates of some 26%/month in their analysis of Liberty ships manufacture during World War II, even if earlier studies on the same case (e.g., Thompson, 2007) estimate much lower rates of 4–6%/month.

A classic technological un-learning case discussed in the literature is that of the Lockheed L1011 Tri-Star aircraft (Argote and Epple, 1990). The experience in aircraft industries suggests a significant reduction in manufacturing costs as more production experience (output volumes) is accumulated (learning by doing). The only exception seems to be the Lockheed Tri-Star aircraft. When production resumed after an extended production halt, manufacturing costs were much higher and also did not decline, reflecting lost experience or unlearning. The reason for this knowledge depreciation was basically the same as for pizza franchises. During the production halt, the entire staff of the manufacturing plant was fired, including managers who, according to Michina (1992; 1999), are the main locus of organizational learning and knowledge accumulation in aircraft manufacturing. Benkard (2000) reports corresponding knowledge depreciation rates of typically 40%/year in aircraft manufacturing.

In innovation-intensive industries, estimates of knowledge depreciation are extremely limited. Hall (2007) provides one of the few comprehensive efforts to estimate knowledge depreciation across various industry sectors, relating the market value of firms to patent data to estimate the R&D knowledge depreciation in six US industry sectors. Hall finds knowledge depreciation to vary significantly over time and across industries, with median R&D knowledge depreciation rates of between 15%/year (drugs and instruments) to 36%/year (electrical). Watanabe et al. (2002) provide one of the few estimates for energy technologies. By constructing a knowledge stock model for the Japanese PV industry that includes both R&D by firms and knowledge spillovers from other firms (measured via patent citations), he estimates a mean PV knowledge depreciation rate of some 30%/year (Watanabe et al., 2002). This implies that without continuous recharge (R&D), an existing technology knowledge stock is reduced to some 25% of the original value after five years and to less than 5% after 10 years. Nemet (2009a) provides an illustration for the US wind turbine industry by analyzing a set of "highly cited" wind energy patents. He finds that 40% of all (cumulative) citations occur during the first five years, after which citations decline to basically zero after 25 years. This declining trend in patent citations after year five reflects their decreasing significance and can be used as a proxy for R&D knowledge depreciation, which corresponds to a rate of approximately 10%/year after the fifth year.

The available literature thus suggests typical knowledge depreciation rates of 10–40%/year in industries comparable to energy (i.e., where innovation and R&D play a significant role). Given such high rates of obsolescence of technological innovation knowledge, continuous knowledge recharge becomes extremely important. In case of erratic stop-and-go policy support for knowledge generation, e.g., through R&D, knowledge depreciation rates can outweigh knowledge recharge rates, as discussed in the *Knowledge Depreciation* case study for nuclear. The nature of knowledge generation support (stable versus erratic) is thus as important as the absolute levels of resources made available, which provides an important argument for stability and gradual expansion of inputs to ETIS over "crash" programs that may not be sustained over any significant time periods.

In their study of knowledge depreciation of professional services, Boone et al. (2008) conclude that the extremely low rates of knowledge depreciation found in engineering design firms are explained by comprehensive knowledge documentation (earlier designs are documented and kept for subsequent use), as well as much lower staff turnover rates (3%), particularly among senior engineers. As such, the study provides valuable lessons for improved knowledge management in ETIS, highlighting the importance of documentation, codification, and preservation of knowledge, as well as the need for a minimum degree of continuity in senior staff that are the living memory of organizations.[12]

24.2.3 Characteristics of ETIS (II): Economies of Scale and Scope

A discussion of the sources of technological advance is not complete without reference to the rich body of literature on sources for cost improvements beyond product and process innovation and new knowledge application discussed above, including in particular economies of scale and economies of scope. While economies of scale are recognized as particularly powerful drivers in the historical evolution of energy industries such as electric power (e.g., Lee and Loftness, 1987) or petroleum refining (Enos, 1962), economies of scope merit discussion here for their potential impact on future energy systems.

24.2.3.1 Economies of Scale

What are Economies of Scale?

Economies of scale describe reductions in average unit costs as output or production increase over the long run, assuming all factors of

12 It is significant that private firms practicing comprehensive reassignment (job-rotation) policies frequently lack any institutional memory of earlier corporate strategies and corresponding innovation successes and failures. For instance, a group of managers at a major oil company attended a workshop with one of this chapter's authors. At the workshop, these managers contemplated possible investment strategies into renewables, entirely unaware that the company had invested previously in solar PV and biofuels and had already sold these activities.

production are variable. They are often conflated with technical returns to scale, which describe a more than proportional increase in output for a given increase in inputs. For examples, see Table 24.5. For further discussion and theory, see Chapter 4 of Rosegger (1996).

Economies of scale can act at different levels (see Table 24.5). Cost reductions associated with scaling at the unit level of a technology (e.g., size of wind turbines) or at the level of manufacturing plants (size/output of a manufacturing plant producing wind turbines) are all important drivers of change in energy technologies.

Unit and Manufacturing Level Economies of Scale

Figure 24.4 illustrates the increasing unit scales of energy technologies over the twentieth century (for other graphical examples, see Smil, 1994; 2008). The graph on the top shows average unit capacities; the one on the bottom shows unit scale frontiers (maximum size of units produced/installed) with characteristically concentrated periods of scaling up (note the log-scale y-axis on both graphs). Increases in unit scales have been a pervasive phenomenon for energy technologies throughout the twentieth century.

Observed increases in unit capacities of energy technologies are strongly linked to falling costs driven by economies of scale, particularly for large capacity energy supply and conversion technologies. For example, over a 50-year period, beginning with World War II, the average cost/unit output of a performance optimized fluid catalytic cracking unit in a US oil refinery fell by around 4%/year on a compounded basis (close to an absolute cost reduction by a factor of seven). These continuous cost improvements were driven by capital and labor productivity gains associated with an order of magnitude increase in unit capacity from 15,000 to 140,000 barrels/day (Enos, 1962).

Additional examples of unit-level economies of scale are presented in the *Solar PV, Solar Thermal,* and *French Nuclear* case studies. Distributed energy conversion and end-use technologies are more likely to be characterized by manufacturing scale economies. The exemplar is the car, beginning with the Model T Ford produced from 1908–1927. Bywords of Fordist manufacturing include *specialization* of machine tools, *routinization* of labor tasks, *standardization* of output, and sequencing of manufacturing along *assembly lines* (Raff, 1991). These technical, process, and organizational innovations allowed a scaling of manufacturing output from a single plant at Highland Park near Detroit, with remarkable increases in labor productivity. In a 12-month period between 1913 and 1914, the labor requirements for assembly of a single Model T fell from 12.5 to 1.5 man-hours. This, in turn, contributed to the price of a Model T falling by two-thirds over its 20-year production run (Ruttan, 2001).

Further examples and discussion of manufacturing level economies of scale are presented in several of the case studies, including *Solar PV*, *Hybrid Cars*, *Heat Pumps*, and *Brazilian Ethanol*.

Drivers of Economies and Diseconomies of Scale

Table 24.5 summarizes some common drivers of scale economies. The examples given above further emphasize the relationship between scale and technical efficiency (e.g., wind power), labor productivity (e.g., cars), and capital productivity (e.g., refineries). Demand growth and standardization are two other important factors.

Table 24.5 | Economies of scale at different levels, using wind power as an example.

Level of Scale Economy	Example of Scale Economy	Outcome of Scale Economy using Wind Power as an Example
unit level	increases in wind turbine blade length and tower height cf. **technical returns to scale**: outputs increase proportionally more than inputs, e.g., inputs = f(area), outputs = f(volume) fixed balance of system components spread	lower $/MW for larger MW wind turbines higher MWh/MW for larger MW wind turbines (no reference to costs) lower $/MW for
plant level (also facility or installation level)	over larger numbers of units operating	larger MW wind farms
manufacturing level (also production level)	capital productivity improved by spreading fixed input costs over higher output volumes	lower $/turbine for larger turbine manufacturing facilities
organizational level (also firm level)	labor productivity improved by specialization; lower cost volume purchases of capital equipment*	lower $/MW or $/turbine for larger turbine manufacturers or wind farm developers
industry level	political economic influence (rent-seeking) securing, e.g., increased subsidy or price support*	lower cost or higher revenue as contribution of industry to GDP or job increases
inter-industry level (also external or system level)**	development of enabling infrastructure (e.g., distribution networks) and institutions (e.g., forward contracts); development of complementary industries (e.g., materials or equipment suppliers)	lower cost or higher revenue as share of total electricity production increases

*Rosegger (1996) refers to these as "pecuniary" economies of scale, which are nontechnical and associated with input costs or output revenues.
** External economies of scale are one explanation for the potential benefits of both national industry clusters and transnational economic unions e.g., Henriksen et al., 2001a.

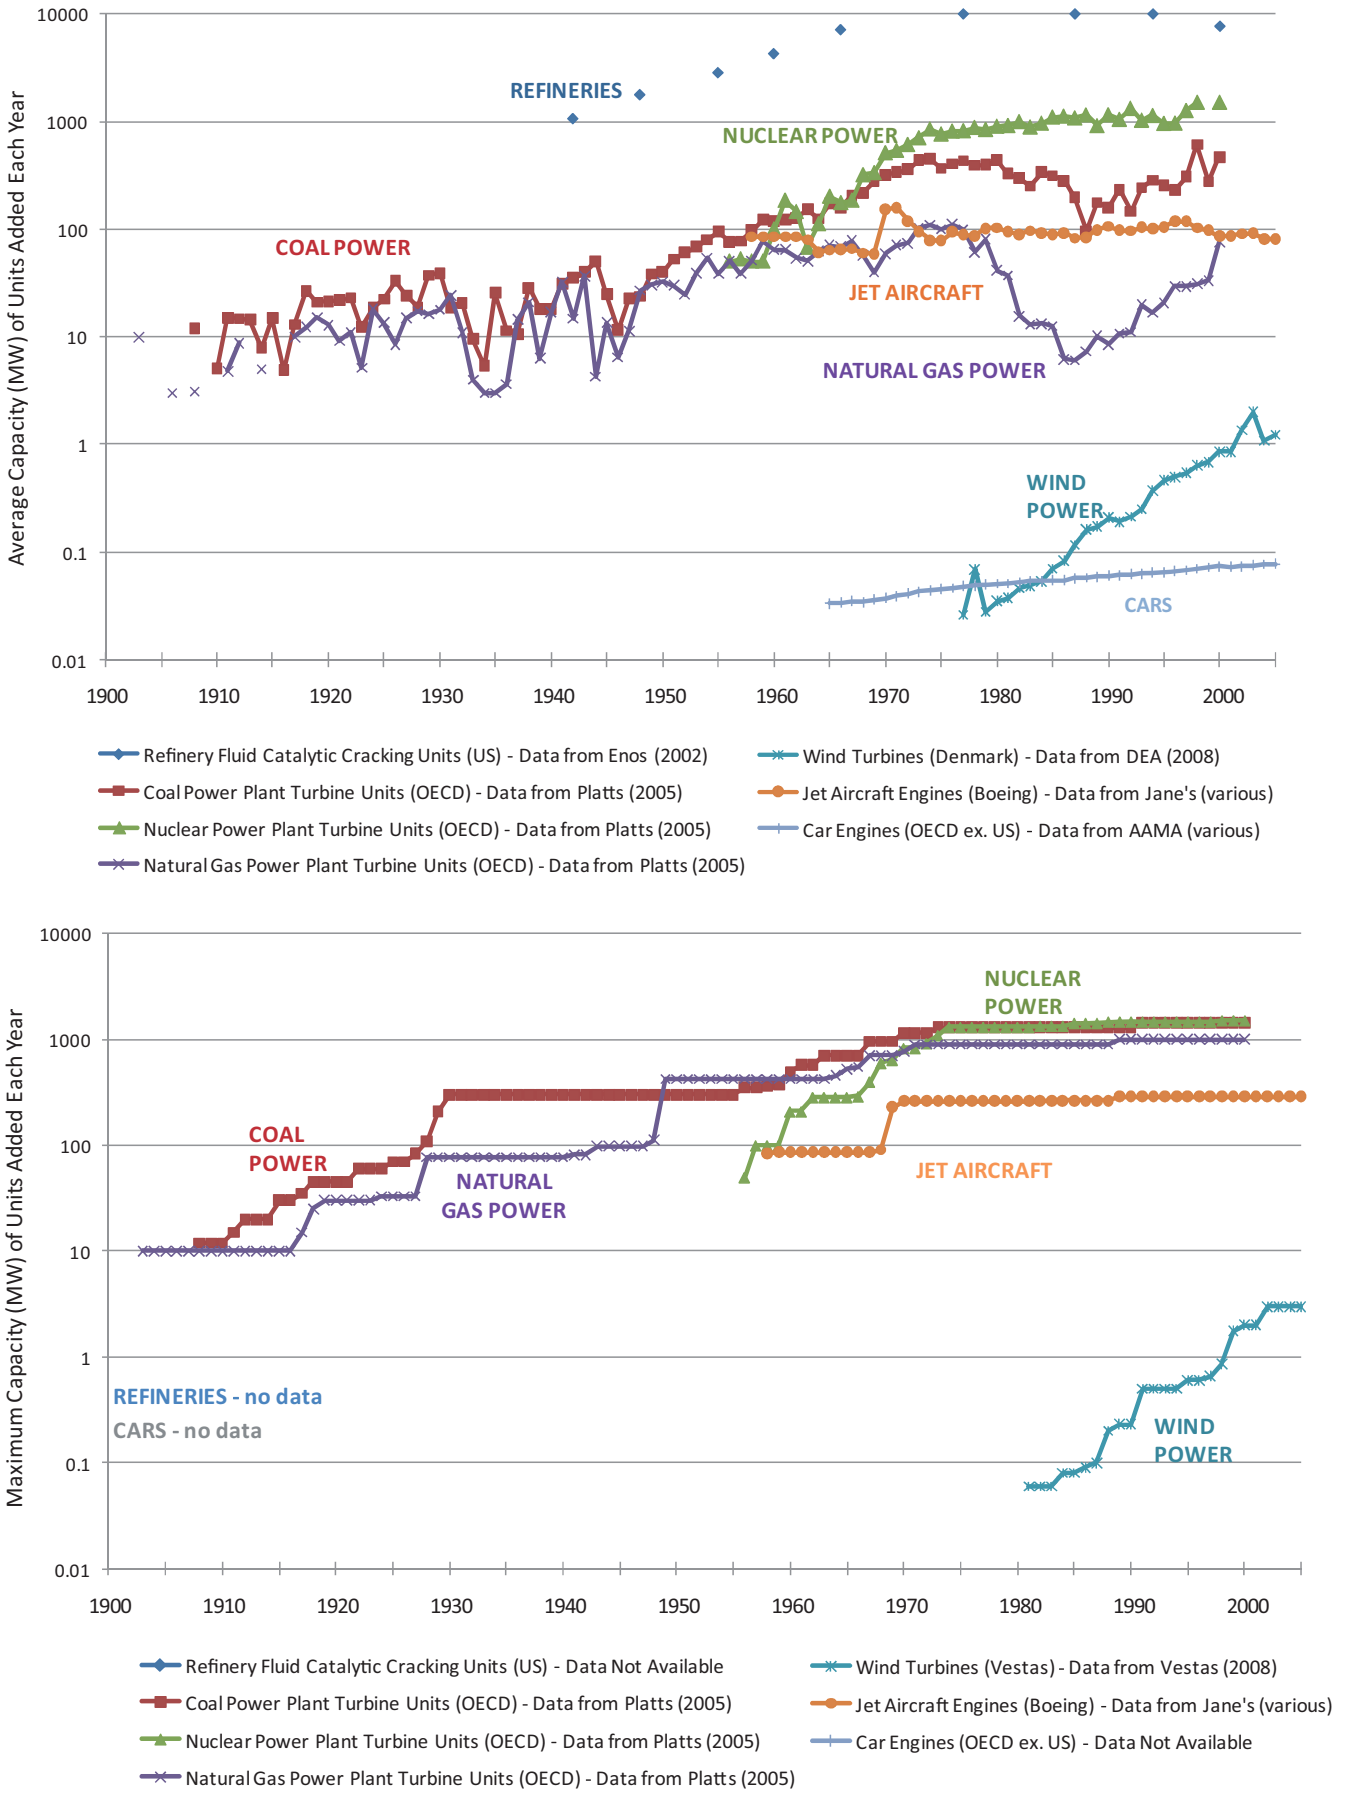

Figure 24.4 | Increasing unit of scale of energy technologies, average (top) and scale frontier (bottom). Unit scales are expressed as MW capacities and plotted on log-scale y-axes. For details, see: Wilson, 2009.

For energy technologies with perceived social benefits, consistent government policies to support market demand are needed to underwrite the scaling up of unit and/or manufacturing capacities. Conversely, stop-start market-based policies undermine manufacturers' confidence, increase the risk of investing in scaling up production, and ultimately can result in market collapse. This is clearly demonstrated in the *Solar Thermal* case study.

Alongside demand growth, technology standardization has proven important for manufacturing scale economies at the unit or plant levels. The more successful growth of nuclear power in France in comparison to the United States can be attributed in part to the standardization of reactor and plant design and to knowledge spillovers, both profiting from a well-tested US Westinghouse reactor design. Later in the French nuclear program, scaling of unit capacities from the standardized 900 MW reactor to more bespoke or "Frenchified" 1300–1500 MW reactors led to marked cost increases (see the *French Nuclear* case study).

These cost increases also demonstrate the possibilities of diseconomies of scale – not lower, but higher $/MW or $/MWh – associated with an increase in the complexity of designing, building, and operating integrated technologies close to the unit scale frontier (Rosegger, 1996). For large-scale power plants in the late 1970s, complexity led to additional borrowing costs during the construction phase due to delays (Koomey and Hultman, 2007) and foregone revenues during the operating phase due to an increase in the frequency and duration of unforced outages (Ruttan, 2001; Lovins et al., 2002). Increasingly stringent health, safety, and environmental regulations also impacted larger scale plants more severely. The transition through the 1980s and 1990s from large-scale coal and nuclear power plants to smaller scale, more flexible and less capital-intensive natural gas-fired units (better suited for increasingly deregulated markets) illustrates well that the availability of economies of scale are contingent on both technical and market factors.

Isolating Economies of Scale as a Source of Cost Reduction

Simple engineering models relate cost to scale in the form:

$$\frac{\$_t}{\$_{t-\square}} = \left(\frac{scale_t}{scale_{t-\square}} \right)^{(scale\ factor)} \quad (1)$$

with a scale factor less than one indicating economies of scale. A study of wind turbines in Germany during the 1990s found that a scale factor of 0.84 described the observed fall in wind turbine investment costs per MW installed capacity by 11% for a doubling of turbine size from 0.3 to 0.6 MW, and by a further 18% for a subsequent unit size increase from 0.6 to 1.5 MW (Grubler, 2010).

However, observed average cost reductions during the development and commercialization of an energy technology commonly conflate unit and manufacturing level scale economies as well as learning effects. Isolating the contribution of economies of scale at different levels, therefore, requires models that disaggregate the various influences on cost.

Econometric approaches typically use a Cobb-Douglas functional form (linear in log-transformed variables) to explain unit cost as a function of scale. Models fitted to data on coal power plants built in the United States from 1960–1980 showed that a doubling of unit scale reduced the cost per unit capacity by 12–24%, controlling for learning effects, compliance with environmental regulation, and changes in productivity and input prices (Joskow and Rose, 1985; McCabe, 1996). It is worth noting that the data period to which these models were fitted describes the rapid growth phase of unit scale during which unit scale economies might be expected to be most evident (see Figure 24.4 above).

More sophisticated engineering models control for the effect of non-scale related drivers of cost reductions over time. A good example is presented in the *Solar PV* case study for the United States. Manufacturing scale economies were found to explain 43% of observed cost reductions in solar PV module cost ($/$W_{peak}$) between 1980 and 2001 (Nemet, 2006). During this period, manufacturing plant output had scaled by two orders of magnitude, from 125 kW/year to 14 MW/year.

24.2.3.2 Economies of Scope

Whereas economies of scale describe the reduction in unit costs with increasing scale of production of a standardized good/commodity, economies of scope describe the reduction in unit costs that can be achieved by producing more products jointly as opposed to individually (see Panzar and Willig, 1975; Teece, 1980, for an exposition).

The traditional manufacturing economic literature draws the following contrast: whereas economies of scale describe production processes where the focus is on quantity and the emphasis is on reducing unit costs, the focus in economies of scope is on product variety. Economies of scope are realized through the effective sharing of knowledge, facilities, equipment, and other inputs such as marketing and design services. In addition, machinery and production processes were designed to facilitate and speed-up the process of change-over between products. Economies of scope can also be realized when there are cost savings arising from byproducts in the production process.

In the energy field, the literature on economies of scope is somewhat limited (examples include Mayo, 1984; Kwon and Yun, 2003; Farsi et al., 2008; Shum and Watanabe, 2008). A concept used to describe energy plants that reap economies of scope from the production of an array of multiple energy carriers is sometimes referred to as energy "combinates." The prime example of economies of scope in energy are, therefore, cogeneration systems, i.e., the joint production of electricity and heat in power plants (combined heat and power [CHP] plants), where the waste heat can be used for heating purposes, e.g., via district heating systems. More recently, such schemes also include district cooling systems, such as using steam generated in electricity plants to drive chillers and the distribution of chilled water for air conditioning purposes.

A necessary condition for the realization of economies of scope in cogeneration systems are either an appropriate co-location of industrial and end-use applications with energy conversion facilities or the possibility to interconnect these diverse users and energy uses through district heating/cooling pipeline systems. Given the usually large scale of electricity generating plants, such schemes are generally only economically viable if generation and demand are not too distantly located (e.g., cogeneration from power plants located within larger cities) or have a sufficiently high energy demand density to justify the high investment costs of heat pipeline systems. Conversely, the advent of decentralized distributed energy systems can increase cogeneration potentials. Examples of applications include natural gas microgeneration (with waste heat recovery for heating of commercial and larger residential buildings and sales of electricity back to the grid),[13] or biomass gasification coupled to gas engines for joint production of electricity and heat.

24.2.4 Characteristics of ETIS (III): Actors and Institutions

24.2.4.1 Introduction

Innovation processes take place within an environment that consists of actors and institutions (Edquist, 2001). Collectively, this makes up the innovation system at the heart of the ETIS perspective. Models of innovation typically highlight the various stages of innovation, and the interactions and feedback loops between these phases (see Figure 24.2 above). The systemic approach emphasizes that innovation is also a collective activity involving many actors, and that innovation processes are influenced by their institutional settings and its corresponding incentive structures (Edquist and Johnson, 1997; Lundvall, 2007).

Institutions are not only organizations and formal structures like rules and regulations, but also established habits, practices, routines, and norms of the various actors within the system. In this sense, institutions can be seen as learned patterns of behavior and interaction, marked by the historical specificities of a particular system and moment in time. As such, their salience and strength may shift as conditions change. Learning and unlearning on the part of actors in the innovation system are thus essential to the evolution of a system in response to new challenges.

There are many different actors and institutions in ETIS. Many have been covered in preceding sections. An example in the section on knowledge feedbacks and spillovers are the networks of interacting and cooperating innovation system actors that enable and mediate this knowledge exchange (Carlsson and Stankiewicz, 1991). Three examples not covered previously are considered below in more detail. These are entrepreneurs and experimentation, shared expectations, and advocacy coalitions.

13 See for example, www.lichtblick.de/h/index.php.

Another key set of actors and institutions influencing the innovation system relate to public policy. Policies can reinforce or support broader institutional change within the innovation system with regard to learning, collaboration, risk taking, consumer preferences, and so on. While some measure of policy stability is necessary, adaptive policy making in response to feedback from policy dynamics (the interaction of policies and the traditional habits and practices of the actors) are important for stimulating innovation under conditions of uncertainty (Mytelka, 2000).

Policies to support market formation have proven important in encouraging renewable energy technologies through their early commercialization. Such policies might involve subsidies, tax incentives, regulated feed-in tariffs, procurement policies, minimum production quotas, and exemptions from regulation, among others (Raven, 2007). The *Wind Power* case study shows the importance of early market creation efforts by the Danish government for small-scale wind turbines. The *Solar Thermal* case study and the *Kenyan PV* case study illustrate the importance of niche markets for building the capacity to construct, operate, maintain, and assure quality control of a new technology.

The roles and importance of different actors and institutions varies between innovation systems, and also changes over the life cycle of an innovation. For example, a wide range of both public and private actors can be involved in mobilizing resources to support ETIS, and in developing their skills and competences as a result of this resource mobilization (Carlsson and Stankiewicz, 1991). Typically, as innovation systems increase in maturity, the importance of private actors increases (Suurs and Hekkert, 2009a). Various case studies profile the changing importance of public and private actors. In the *US Synfuels* case study, for example, a hybrid approach to public-private roles was ultimately undermined by how mobilized resources were used.

24.2.4.2 ETIS Actors and Institutions (I): Entrepreneurs

There is no such thing as an innovation system without entrepreneurs (Carlsson and Stankiewicz, 1991). Entrepreneurial risk-taking is essential to cope with the large uncertainties surrounding new combinations of technological knowledge, applications, and markets (Meijer and Hekkert, 2007). Above all, entrepreneurship is needed for bringing new technologies, products, and practices to markets. Experimentation is integral to the process of knowledge generation and learning described earlier, allowing for the evaluation of the reactions to new applications on the part of consumers, governments, competitors, and suppliers. The role of the entrepreneur is therefore to turn the potential of new knowledge, networks, and markets into concrete actions that both generate and take advantage of new business opportunities. Entrepreneurs can either be new entrants who see new market opportunities (e.g., university spin-offs) or incumbents who diversify their business strategy to take advantage of new developments.

In most innovation processes, a period of variety creation driven by experimentation takes place before a dominant design emerges and is further developed. The *Wind Power* case study shows how entrepreneurial experimentation led to a large variety of wind turbine designs from which the three-blade vertical axis turbine eventually emerged as the dominant design. The *Hybrid Cars* case study shows the importance of entrepreneurial experimentation among Japanese car manufacturers for initiating the buildup of an innovation system. The *Scaling Dynamics* case study emphasizes the importance of experimentation during the formative phases of many different energy technologies, whereas the *French Nuclear* case study illustrates the consequences of "short-cutting" extended experimentation in the interest of rapid upscaling of a dominant technological design.

24.2.4.3 ETIS Actors and Institutions (II): Shared Expectations

Innovation is always characterized by uncertainty. The expected merits of a new technology in terms of performance or costs cannot be known *ex ante* as being shaped by the agency at play in ETIS (R&D strategies and funding levels, niche market developments, extent of possible learning effects, etc.) as well as by exogenous factors (such as oil prices, as illustrated in the *US Synfuels* case study). Strategic decisions on the direction of the innovation process and the more promising technological avenues can be important to sustain innovation system development. Note, however, that trying to force technology development over short timeframes risks disappointing high initial expectations, as is demonstrated in the *US Synfuels* case study.

Shared or collective expectations are an important means of reducing uncertainty and stimulating entrepreneurial activity (van Lente and Rip, 1998; Borup et al., 2006). This is clearly demonstrated by the *Solar PV* case study. Shared expectations help guide the search of actors within the innovation system by selecting technological alternatives from the variety created by knowledge generation activities. As such this function is equivalent to the "visioning" step advanced in the technological transition literature (Smith and Stirling, 2010; see also Chapter 16 for a more detailed discussion).

Guidance functions can be provided by a variety of actors, including individual firms, actor networks, or governments, as has been the case in Japan (see *Japanese Efficiency* case study). Policies can shape changing societal preferences to reflect public policy objectives like greenhouse gas emission reduction. The *Hybrid Cars* case study clearly shows how zero-emission vehicle regulations and large-scale R&D programs affected the research direction of car manufacturers. The *Brazilian Ethanol* case study shows that strong political leadership can be another important means of guiding the search within an innovation system. Long-term technology roadmaps are another important means of establishing shared technological innovation expectations, as are credible long-term policy signals – for instance, in the form of pollution (e.g., carbon) taxes that rise over time at pre-announced, predictable rates.

24.2.4.4 ETIS Actors and Institutions (III): Advocacy Coalitions

New energy technologies face resistance from actors with interests vested in incumbent systems. To build up an innovation system, actors – usually from nongovernmental organizations (NGOs) and industry – must counteract this inertia through, for example, political lobbying and building advocacy coalitions (Sabatier, 1987; Sabatier, 1988). Public institutions may also contribute (Fligstein, 1997), as in the case of planning agencies advising regional or national governments to develop supporting policies for emerging technologies. In all such cases, innovation system actors try to convince other actors to take particular actions that they cannot conduct themselves. Nonetheless, it should be emphasized that incumbent technology systems often have great lobbying power to resist changes.

24.2.5 Changing Dynamics Over Time in Effectively Functioning ETIS

Researchers in the "functions of innovation systems" tradition have identified seven key processes in emerging innovation systems that are needed for a successful maturation through the formative phase (Jacobsson and Lauber, 2006; Bergek et al., 2008). These key processes interact strongly and all can potentially be supported by policy makers. Although networks between actors in an energy innovation system tend to be international, national policies can strongly influence how the formative phase in specific countries occurs. Table 24.6 summarizes the seven key processes and references the earlier sections in which they were discussed.

Positive interactions and feedbacks between the key processes shown in Table 24.6 are integral for the successful build up of an innovation system (Jacobsson and Bergek, 2004; Hillman et al., 2008). These positive feedback loops are referred to as "motors of innovation" (Suurs and Hekkert, 2009b).

In the first phase of innovation system development, a "science and technology push motor" is characterized by knowledge development and the creation of positive expectations about the new technology by scientists and engineers to help guide the search and stimulate funding that supports further knowledge development in and beyond R&D.

The science and technology push motor can turn into an "entrepreneurial motor" if entrepreneurial experimentation leads to knowledge exchange between the entrepreneurs and the research community. Next, a "system building motor" involves a wide range of actors involved in the development and production of a technology lobbying for market formation and an alignment of institutional structures with the needs of the new technology. If successful, this collective activity can overcome the resistance to change of incumbent actors with vested interests.

Table 24.6 | Seven key processes in innovation systems.

#	Key Process	Summary Description	Relevant Sections in Chapter 24
1	Entrepreneurial experimentation	Taking risks, creating variety, "field" testing, developing business opportunities.	Knowledge Generation; Learning; Actors (Entrepreneurs)
2	Knowledge development and exchange in networks	Generating and sharing knowledge to improve performance, learn from experience, etc.	Knowledge Generation; Knowledge Spillovers; Learning; Actors (Exchange)
3	Guidance of the search	Strategic directioning of the innovation process to reduce uncertainty.	Economies of Scale and Scope; Institutions (Expectations)
4	Market formation	Creating, protecting or supporting niches for innovations to enter the market.	Innovation Models;Niche Markets
5	Resource mobilization	Allocating financial, material and human capital to the innovation process.	Economies of Scale and Scope; Metrics and Assessment
6	Counteract resistance to change	Overcoming systemic inertia and vested interests.	Actors (Advocacy)
7	Materialization	Building up production or manufacturing capacity.	Innovation Models; Economies of Scale; Metrics and Assessment

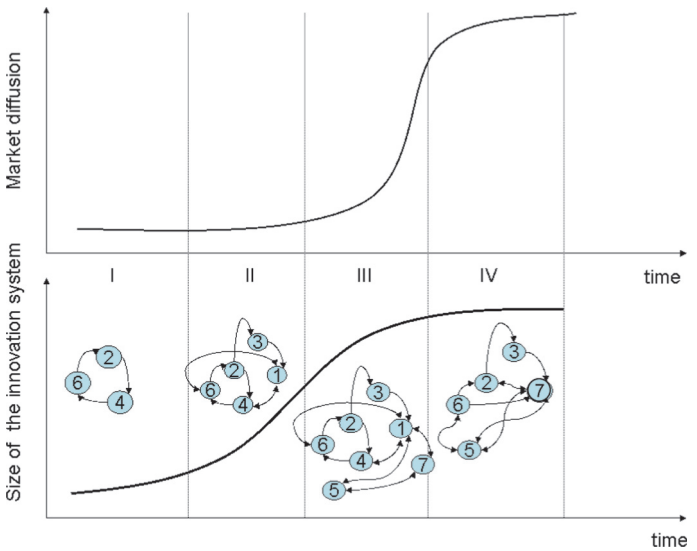

Figure 24.5 | Stylized life cycle of a new technology over time (Phases I to IV, top) and corresponding build up of the technology's innovation system and the seven key processes involved (circles) and their interactions (arrows) (bottom). See Table 24.6 for a definition of the key processes.

Finally, a "market motor" may emerge once market formation has taken place and a technology has started to diffuse with a concomitant build up of production capacity. Overcoming resistance to change and guidance of the search now become less important. The succession of these four motors of innovation is represented stylistically in Figure 24.5 (bottom panel), alongside the S-shaped curve describing a technology's life cycle (top panel). The build up of the innovation system can be measured in terms of the number of actors involved, the extent and complexity of the networks between these actors, and the specific institutions aligned with the innovation. However, such indicators are specific to individual technologies and innovation system contexts and cannot be generalized. Figure 24.5 shows how the innovation processes (represented as circles) and the interactions between them (represented as arrows) increase through the formative phase prior to the technology's diffusion into the market (Phases I-II). As market diffusion accelerates (Phase III), the innovation system grows to its maximum (Phase IV).

24.3 Assessing Energy Technology Innovation Systems

24.3.1 Introduction

There is no uniform simple metric to describe ETIS in terms of commensurate measures of needed inputs and corresponding system outputs. Unlike in macroeconomics, it is not possible to develop a simple production function of ETIS. The *Assessment Metrics* case study reviews in detail the literature on innovation metrics from which Chapter 24 draws to structure this section.

In terms of assessing the inputs to ETIS, Section 24.3.2 (see also Appendix I) provides a comprehensive overview of ETIS in terms of current (as of 2005) investments into energy technologies across the entire life cycle phases of ETIS, from knowledge generation to market formation (niche market investments), to technology diffusion (in both energy supply and end-use technologies). The choice of this metric arises from three considerations:

- *Novelty*: Such an overview assessment has to date been absent in the literature, which invariably has focused only on pieces of the entire system, like public energy R&D expenditures, or investments into renewables.

- *Commensurability*: The metric needs to be comparable across all technologies, across all ETIS activities/processes, and across different sectors and markets (regions); hence the use of the US dollar as a core metric.

- *Centrality*: Investments are a central element of ETIS, constituting a core input to knowledge generation and any embodiment of technological change. They are a key process in ETIS (resource mobilization) and also constitute an important constraint for ETIS in their own right.

The adoption of a single metric to assess current inputs into ETIS does not suggest that readers should ignore the multidimensionality of metrics proposed in the literature on ETIS (see the *Assessment Metrics* case study) but rather to allow to put the relative weight of different stages of ETIS and currently revealed preferences (in terms of resource mobilization) into a quantitative perspective. As such, Section 24.3.2 also provides a baseline against which the needed redirection of ETIS investment flows as described by the GEA transition pathways scenarios (Chapter 17), for which these numbers served as important input, can be assessed (see in particular Section 17.3.5).

The assessment in terms of outputs of ETIS is necessarily more eclectic and illustrative as there is no single common metric for describing technological change (the "output" of ETIS) across all technologies, life cycle stages, and markets. Section 24.3.3 therefore provides salient illustrative examples drawn from Chapter 24's case studies. The focus is on two core dynamic metrics: technology diffusion and costs, which evolve over time to illustrate both their dynamic nature as well as their mutual interdependence. Falling costs drive expanding market applications which, in turn, provide yet further cost reductions, e.g., through economies of scale effects in manufacturing and learning (by doing and using) processes.

24.3.2 Quantitative Assessments of Inputs (Investments)

24.3.2.1 Introduction and Overview

This section attempts a first ever quantitative overview of financial resources that constitute a fundamental input to energy technology innovation in terms of required resource mobilization. Evidently, money is not the only resource that needs to be mobilized: the development of knowledge, skills, supporting institutional settings, etc. is important too. Financial investment data, however, are more readily available than other ETIS input, output, or outcome metrics. In addition, they are a useful tool for policy makers, as budgets are a key policy tool in governments and industry alike. Finally, even if the information provided below is still relatively scarce, investments in innovation give a sense of the scale of the energy innovation enterprise.

The key messages of this section are as follows. First, there are formidable data problems associated with the need to describe energy technology innovation, which highlights important areas of future research and renewed initiatives to provide better technology-specific data for informed policy choices. In addition, consideration of institutions needed to collect and share these data at the national and international levels is badly needed.

Second, this section illustrates the increasing scale of resource mobilization across successive stages of ETIS, from research, development, and demonstration (~50 billion[14]), to market formation investments (~150 billion), and finally to the dominant diffusion investments (>1000 billion). If large-scale technological change is on the agenda, changes in the diffusion environment and associated incentives for technology adoption and diffusion – e.g., through changes in relative prices – are key in addition to developing improved technologies in the upstream stages of ETIS.

Third, this analysis reveals that the structure of current investments in ETIS is highly asymmetrical between the dominance of diffusion investments in energy end-use technologies, and their under-representation in the investments in the earlier stages of ETIS. In other words, this overview helps elucidate the relatively large support for supply-side technologies such as fossil fuels and nuclear energy in RD&D. This is difficult to reconcile with the energy innovation needed to respond to the multitude of challenges of current energy systems, ranging from energy access to energy security and climate change mitigation, all of which call for vastly improved energy end-use efficiency.

Fourth, six major emerging economies – Brazil, the Russian Federation, India, Mexico, China, and South Africa, known collectively as BRIMCS countries – now account for a significant fraction of global ETIS. However, significant regional imbalances, particularly in the support for energy RD&D, persist. The increasing globalization of ETIS in general and of energy technology RD&D in particular suggests that new mechanisms for international technology cooperation and coordination might be called for, which again raises the question of the need of an appropriate institutional (re)design, as existing institutions such as the IEA are limited in scope and membership (mostly oil-importing OECD countries).

Innovation inputs are quantified in this chapter by the associated financial resource mobilization per broad technology class and by stage of the technology life cycle. The definition of the innovation stage is straightforward, as characterized by RD&D expenditures, which are a well-defined expenditure category in macroeconomic and corporate accounts. The subsequent phase of market creation investments is defined by either relying on special funding mechanisms such as venture capital or special (government-induced) market incentives such as feed-in tariffs, production tax credits, and the like, but the definitional boundaries are necessarily more blurred. Finally, diffusion investments are those that represent commercialization of mature technologies and that need no special policy incentives to mobilize the required investment in markets. Evidently, all investments across the entire technology life cycle will always be influenced by the overall incentive environment, as characterized by relative prices, taxes, etc., i.e., by numerous nontechnology-specific policies. What differentiates market creation from diffusion investments is the degree to which investments rely on dedicated technology policy support for their early

14 R&D expenditures represent aggregates of national statistics, which are mostly available only in International $ (i.e., in PPP terms). When expressed in US$ (i.e. at market exchange rates, MER), R&D expenditures would be lower by some $10 billion. As private sector R&D is significantly underreported, a global order of magnitude estimate of $50 billion energy R&D can be considered commensurate with the subsequent niche market and diffusion investment numbers that are expressed in US$ (i.e., MER-based).

Table 24.7 | Summary of current global public and private ETIS investments (in billion US_{2005}) by stage and type of technology application (first order estimates and ranges from the literature).

	Innovation (RD&D)		market formation		diffusion

market deployment. A tentative, albeit incomplete, attempt at a global overview is provided in Table 24.7. Further details are provided at Appendix I.

24.3.3 Case Study Assessments of Innovation Outputs

As part of this assessment, Chapter 24 conducted 20 case studies. This section discusses the rationale for conducting these case studies, as well as the rationale for selecting this particular set of cases. All 20 assess the innovation system and are intended to complement the quantitative overview described above. The implications for understanding energy innovation and for public policy are described in Sections 24.4.5 and 24.4.6 below. Some illustrative results from the assessment of innovation processes that emerge from the case studies are included here as well (see Section 24.3.3.3). Space limitations precluded the full presentation of all case studies in this chapter; they are summarized in Appendix II. The full case studies will be published separately quot are also reported on the GEA Chapter 24 website.[15]

24.3.3.1 Rationale and Logic of Case Studies

The rationale for conducting case studies arises from the need to complement quantitative evaluations with richer descriptive characterizations of innovation systems. This assessment uses evidence from descriptive case studies to further illustrate the general insights for policy design covered in Section 24.4. The complexities of the dynamics of the innovation process are often ignored in quantitative models. While a growing body of work on quantitative evaluation improves understanding, their explanatory power has so far proven limited.

15 For more information, see www.globalenergyassessment.org.

Attempts to econometrically identify the effects of demand-pull and technology-push – e.g., Kouvaritakis et al. (2000); Watanabe et al. (2000); Miketa and Schrattenholzer (2004); Klaassen et al. (2005) – have provided limited claims in the available studies because of their sensitivity to assumptions about the depreciation of R&D knowledge stock and about the lags between policy signals and decisions to innovate. Both of these parameters have proven difficult to estimate empirically. Using the observation that most technologies tend to decline in cost over time, the notion of the "learning (or experience) curve" has been widely used to simulate the cost reductions that can be expected from programs that subsidize demand (Duke and Kammen, 1999; Wene, 2000; IEA, 2008b). However, observed discontinuities in learning rates, perhaps resulting from omitted variable bias, limit their reliability. Moreover, large dispersion in observed learning rates, even including negative rates, complicates choices of which point estimates to apply (Nemet, 2009b).

The relationship between R&D investments and technical change is even more difficult to model, in part due to the inherent stochasticity of the R&D process. One notable approach has been to measure the value of the commercialized projects that emerged from federal R&D programs (NRC, 2001). This cost-benefit valuation approach has been used to evaluate the US Department of Energy's wind and PV R&D investments. Key shortcomings in this approach center on the assumptions needed to construct a counterfactual case in which one must characterize outcomes in the event that the R&D investment was not made. Prospectively, another approach common to R&D management has been employed in which decision analytic techniques are often used to obtain the necessarily subjective judgment of experts who are most familiar with the specific technologies (Peerenboom et al., 1989; Sharpe and Keelin, 1998; Clemen and Kwit, 2001). A report by the National Research Council (NRC, 2007) recommends that the US Department of Energy adopt a process including expert elicitations. They provided prototype elicitations for carbon storage, a vehicle technologies program, and four other programs. Examples of such assessments include studies of PVs and carbon capture (Baker et al., 2009).

More generally, quantitative assessments of innovation systems may be biased toward the selection of cases for which detailed data are available. This may explain the lack of empirical work on energy end-use technologies relative to supply technologies. Also, it may limit comparisons across countries, as there may be insufficient variables for comparing the results of heterogeneous studies across countries. Finally, the reduction of the complex process of innovation to a few factors may omit important aspects of the system and contribute little in mechanistically explaining causality.

The qualitative descriptions in case studies provide an avenue for incorporating explicit considerations of the innovation system's complexities and feedbacks, which would otherwise be ignored. It is important to note that generalizing from case studies is limited by the specifics of context and technical characteristics, which are described. Selection bias is also discussed. Policy conclusions take these limitations into account.

24.3.3.2 Summary of Case Studies

The selection of case studies was based on the following criteria. First, in many cases the focus was on individual technologies. For these technology-focused studies, technologies were selected that had a dynamic aspect – for example, technically, economically, or in terms of deployment. Second, many of the cases included a situation in which public policies played an important role in affecting the process of innovation and diffusion. The case studies were particularly interested in describing the activities of governments. Third, to the extent that data availability allowed, an effort was made to include international diversity and include cross-country comparisons. Fourth, care was taken to also include from the available case studies illustrations of innovation failures or imperfections (e.g., *US Synfuels*, *Solar Thermal*, or *French Nuclear*). Finally, some case studies were conducted because they illustrate specific attributes of the innovation system, as described above. In selecting studies under this criterion, a special effort was made to evaluate ETIS characteristics that are poorly explained in the literature (e.g., *Knowledge Depreciation* or *Scaling Dynamics*).

This chapter's assessment includes 20 case studies, which can be categorized in several ways (Table 24.8). Six of the case studies explicitly address innovation in developing countries. Fifteen include some assessment of government actions affecting the innovation system. At least 12 include a discussion of knowledge feedbacks in the innovation system – or in some cases, the lack of feedbacks. The case studies can also be categorized by whether they were conducted in order to illustrate a particular aspect of the innovation process described above, or whether they were focused on evaluating the innovation system for a particular technology. The latter category was divided into cases that examined end-use technologies and those that examined supply-side technologies. Emphasis was placed on achieving a rough balance between these two technologies to address the exceptionally weak empirical basis for understanding innovation in end-use technologies. Table 24.8 categorizes the 20 case studies as (1) illustrations of specific characteristics of innovation systems; (2) energy end-use technologies; and (3) energy supply technologies.

24.3.3.3 Illustrative Examples of Innovation Outputs from Case Studies

Six examples illustrate the types of work that can be used to evaluate the outcomes of the innovations process, particularly in response

Table 24.8 | Innovation case studies conducted for Chapter 24.

to public policy. Common to all is the adoption of the perspective of technology diffusion, as well as costs. In terms of ETIS outputs, the dynamics of widening market applications, as well as costs and their interdependence, serve as core metrics in these six illustrative examples.

Figure 24.6 illustrates one possible outcome of ETIS in terms of accelerated diffusion of new energy technologies in later adopting regions via spillover and learning effects (*Scaling Dynamics* case study).

Figure 24.7 illustrates the response to policy, in this case the introduction of the Corporate Average Fuel Economy (CAFE) standard in the United States, in terms of diffusion of the induced technological innovations in the automotive sector (*US Vehicle Efficiency* case study).

Figure 24.8 illustrates the components in cost reductions of sugarcane production in the Brazilian ethanol industry as a twin example of an analytical opening up the "black box" of technology cost improvements and an example of technology responsiveness to an exemplary decades-long sustained public policy effort (*Brazilian Ethanol* case study).

Figure 24.9 shows cost reductions and technical improvements in early solar thermal electricity generation in the United States, from 1982–1992. A virtuous cycle (i.e., a positive, self-reinforcing feedback loop) of unfolding of ETIS came abruptly to an end with the discontinuation of policy support, illustrating the pitfalls of erratic policies and the key importance of continuous policy support (*Solar Thermal* case study).

Figure 24.10 shows the declining cost of PV associated with the Japanese subsidy program from 1994–2004 and provides the positive example of the responsiveness of ETIS outputs to a sustained and predictable policy environment (*Solar PV* case study).

Finally, Figure 24.11 summarizes the cost trends of non-fossil energy technologies analyzed in the Chapter 24 case studies. These data have been updated with most recent cost trends (2010) available in the literature for PV Si Modules (IPCC SRREN, 2011) and US onshore wind turbines (Wiser and Bolinger, 2011). Note that the summary illustrates comparative cost trends only and is not suitable for direct economic comparison of different energy technologies due to important differences between the economics of technology components (e.g., PV modules or heat pumps [only]) versus total systems installed, cost versus

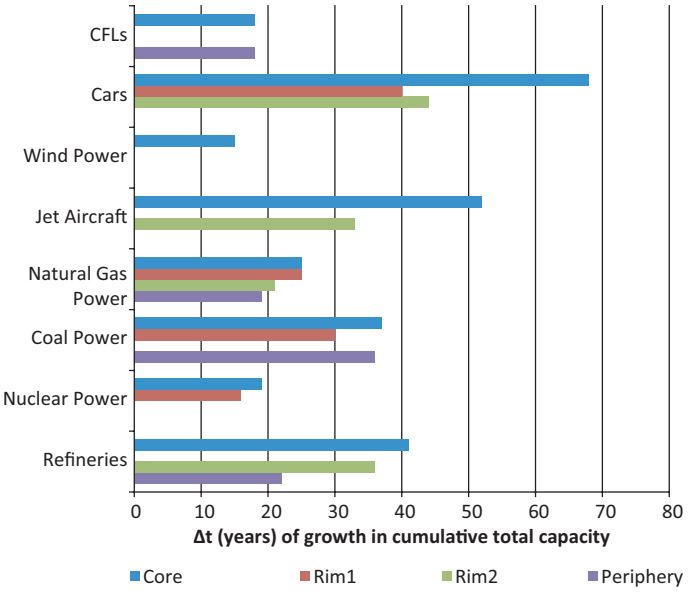

Figure 24.6 | Diffusion rate or Δt – time to grow from 10–90% of installed cumulative capacity – between innovating *Core* regions and later adopting rim (graduated between *Rim1* and *Rim2*) and *Periphery* regions for a range of energy technologies (CFLs denoting compact fluorescent light bulbs). Note that the geographical diffusion categorization is based on technology adoption rates rather than country aggregates. Source: Wilson, 2009.

price data, and also differences in load factors across technologies (e.g., nuclear's electricity output per kW installed is between a factor three to five larger than that of PV or wind turbine systems). Despite a wide range in cost trend experiences across technologies, two important

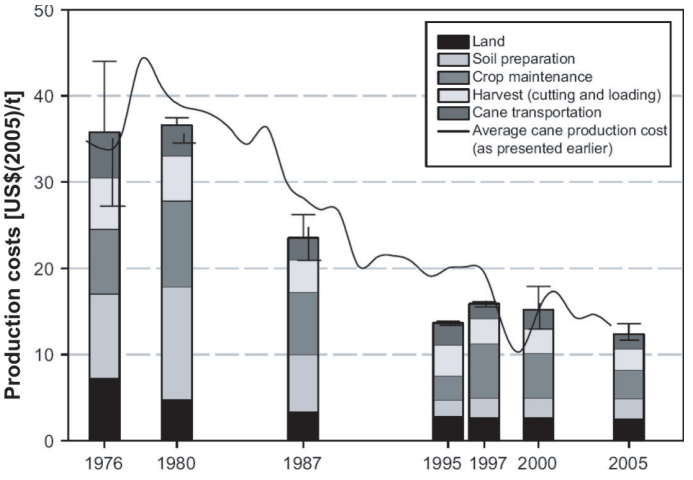

Figure 24.8 | Decomposition of cost components and their improvements for Brazilian ethanol (cane production only). Source: van den Wall Bake et al., 2009.

observations stand out: (1) there is a marked contrast between nuclear showing persistent cost escalation versus the other non-fossil technologies, that generally show declining costs/prices with accumulated market deployment experience. (2) Improvement trends are highly variable across technologies and also over time. For some technologies (e.g. wind in the United States and Europe) historical cost improvements were temporarily reversed after the year 2003/2004 suggesting possible effects of ambitious demand-pull policies in the face of manufacturing capacity constraints and rising profit margins that (along with rising commodity and raw material prices) have led to cost escalations in renewable energy technologies as well.

24.4 Energy Technology Innovation Policy

24.4.1 Public vs. Private Actors: Roles and Differences

There are a multitude of actors involved in ETIS that either can be differentiated with respect to their role in a technology's life cycle (technology research, development, or adoption, i.e., the supply of and the demand for technology innovation) or with respect to their nature as public or private sector institutions (governments, firms, associations), or individuals (entrepreneurs, consumers). Moreover, the innovation actor landscape that has traditionally be defined within a national context is becoming increasingly globalized, considering the increasing role of multinational firms and direct foreign investments as sources of technological change, and the role of multilateral institutions (World Bank, GEF) and NGOs, which are increasingly involved in ETIS.

The role of these actors can vary considerably. A firm can be a developer of a particular technological innovation while at the same time an adopter for another innovation; their respective role as actors over a technology life cycle also changes. Actors are also extremely heterogeneous in terms of their technology knowledge and competence

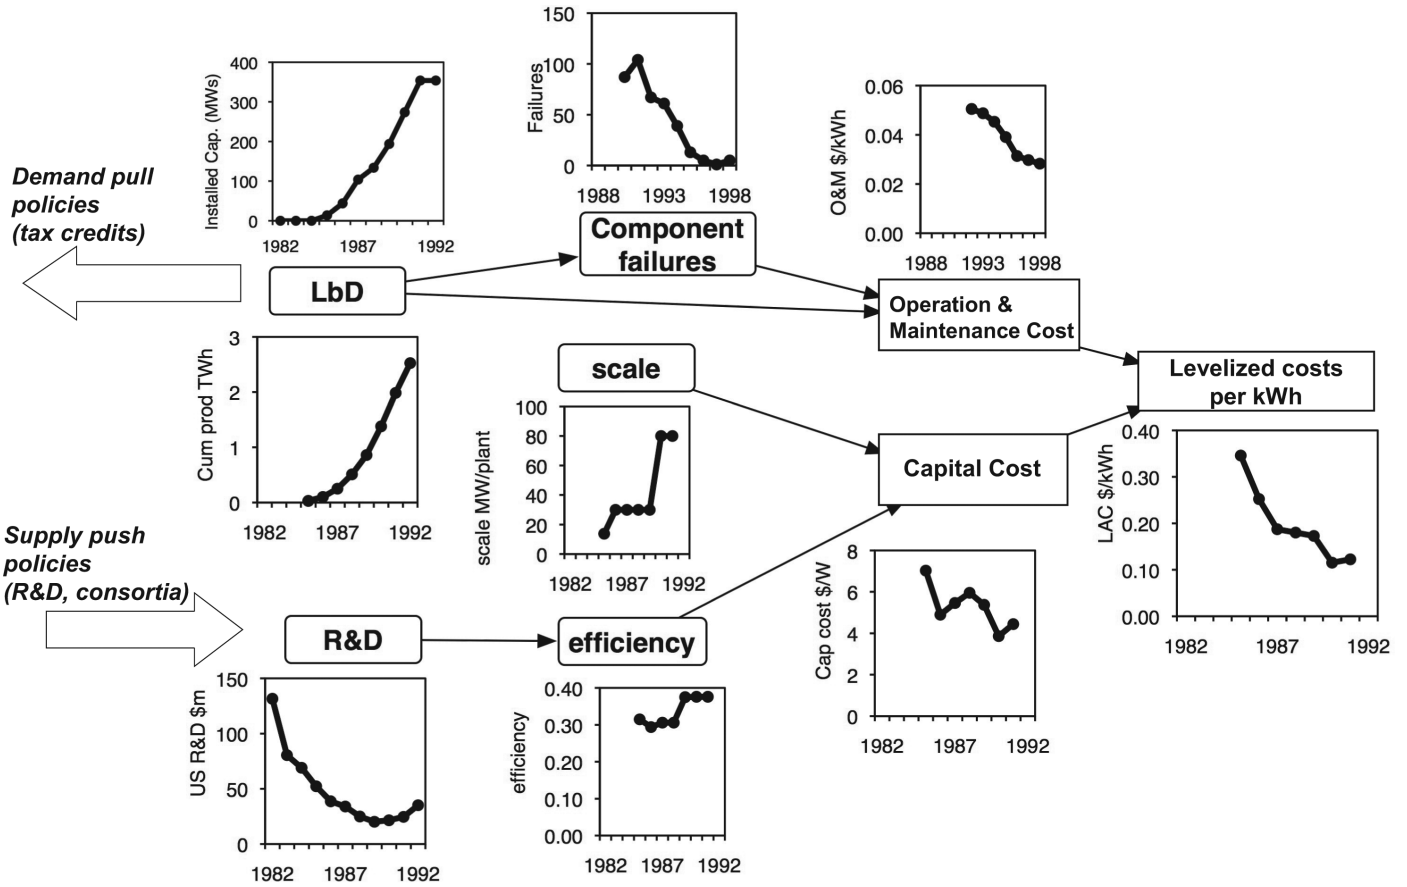

Figure 24.9 | Causal link model diagram for cost reductions and technical improvements in early solar thermal electricity generation in the United States, 1982–1992. Source: *Solar Thermal* case study. Note: R&D = Research & Development, LbD = Learning by Doing.

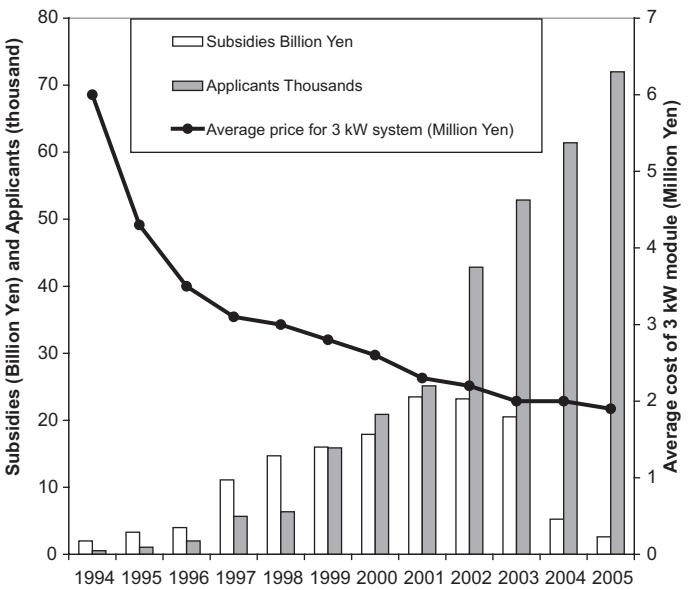

Figure 24.10 | Japan subsidies and applications for rooftop PV systems versus average 3 kW module price. The 2005 data correspond to specific investment costs of US_{2005}5816/kW and the 2.6 billion yen subsidy to US_{2005}23 million. Source: based on Jäger-Waldau, 2006.

base and the resources they can mobilize for innovation (development or adoption), as well as in their characteristics (e.g., different discount rates applied to energy efficiency investments).

For the purpose of this chapter, the differentiation between public and private sector actors is of particular importance. Whereas private sector actors are the main actors of technological innovation in terms of performers of R&D, technology developers, and in manufacturing and marketing of technological innovation, they cannot influence associated (knowledge or environmental) externalities nor the incentive environment in which innovation takes place. This accords a special role to the public sector with respect to technology innovation policy and is reflected in traditional areas of public policy concern (see Section 24.4.2), including public R&D funding, incentives for private R&D, the setting of technology or environmental performance standards, and the general area of economic incentives for technology adoption (e.g., via taxes or subsidies).

Lastly, the literature on institutional innovation (e.g., Ruttan, 1996) is relevant here. Evolving institutional settings can be interpreted by themselves as forms of social "techniques" or innovation that can help to overcome knowledge asymmetries or split incentives that can hinder

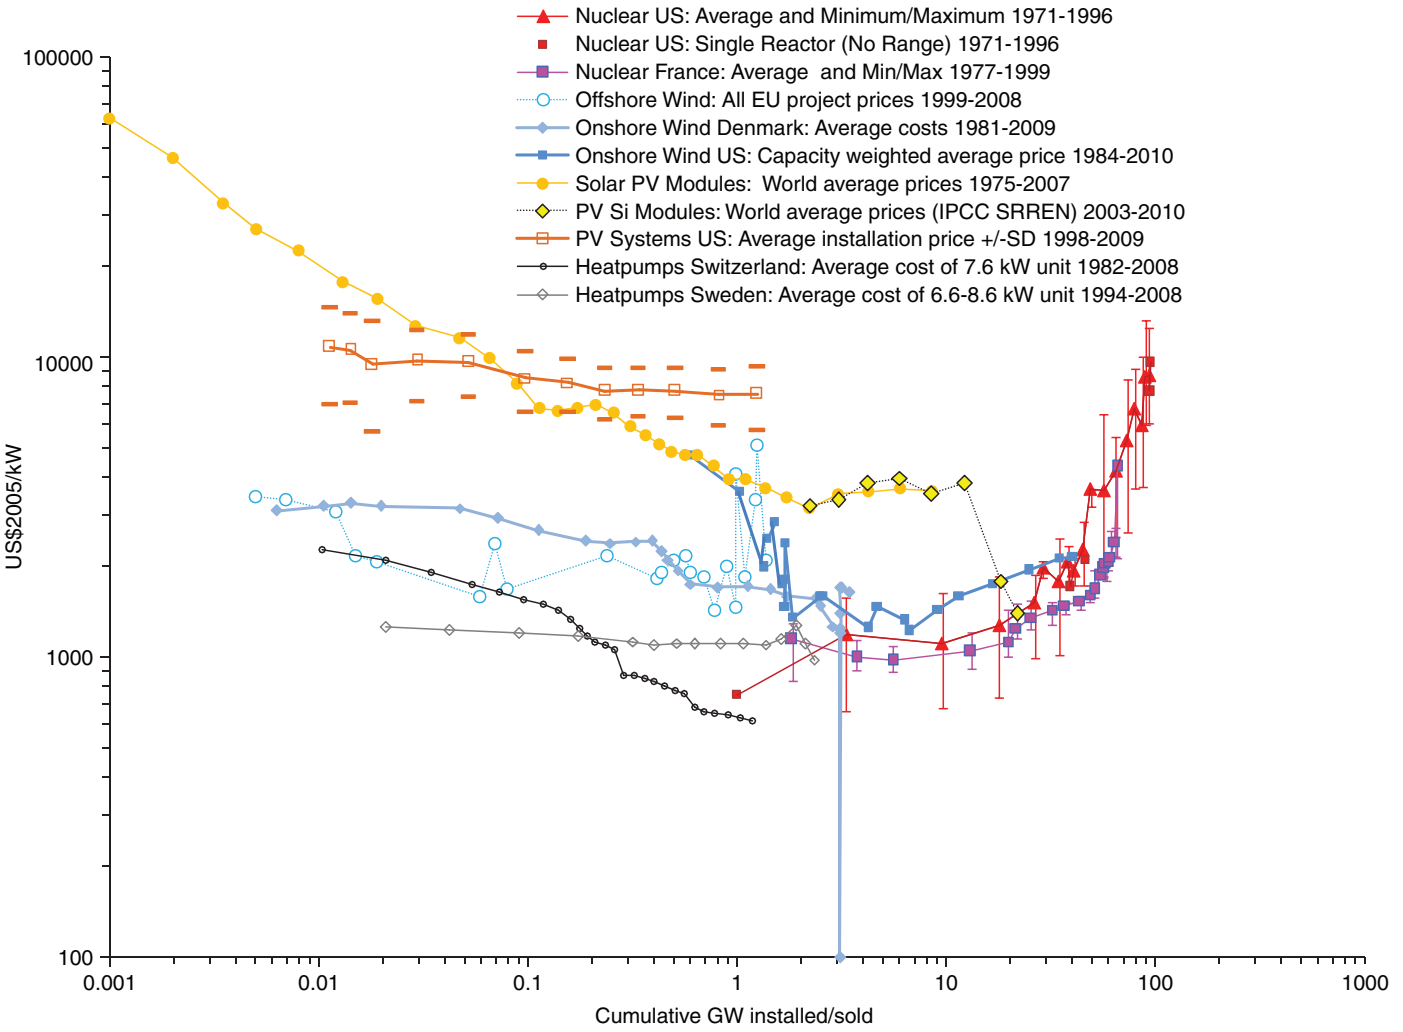

Figure 24.11 | Chapter 24 Case Studies summarized: Cost trends of selected non-fossil energy technologies (US_{2005}/KW installed capacity) versus cumulative deployment (cumulative GW installed). Source: Chapter 24 case studies.

socially desirable technological innovation. For instance, energy service companies (ESCOMs) are an example of an institutional innovation in the form of new actors who can assist households or public sector entities, like schools, in the adoption of energy efficiency innovation.

24.4.2 Rationale for Public Policy

When considering the rationale for investments in energy technology innovation (ETI), there are two main questions to be answered: why should anyone – the government or private companies – engage in ETI? And, what is the particular rationale for government policy and investments in ETI?

A private firm would endeavor to innovate in response to a perceived need in the marketplace or to create a new product to market to the world. Such profit-maximizing behavior is obvious and important because the global energy marketplace is indeed very large. The IEA estimates that investments in energy supply alone will cumulatively total US$22 trillion globally between 2006 and 2030 (IEA, 2007). Thriving businesses in the energy domain translates into economic development, economic growth, the maintenance and creation of jobs, high-technology domestic sales, and perhaps exports. ETI can also reduce the costs of delivering energy services to consumers, freeing them to save or spend money on other goods and services in the economy. An important question is whether or not the private sector invests sufficiently in ETI, and unfortunately the data do not yet exist to answer that question satisfactorily. Companies are not required to disclose information about their investments, and even if they did, it would be difficult to determine what fraction of the private-sector expenditures by automobile companies and other manufacturers of energy-consuming goods can be counted as efforts to improve the energy efficiency of products. It is also hard to define energy technology. Information on private-sector expenditures in the early-deployment phase is more readily available because venture capital (VC) and private equity investments, asset finance projects, and corporate finance deals are announced and tracked (e.g., Anadon et al., 2009; see also Section 24.6.2 in Appendix I).

There are reasons to believe that the private sector probably underinvests in ETI, both in comparison to historical R&D investment levels and in view of the social and environmental challenges related to the energy sector. First, what data exist indicate that investments are declining. According to one analysis of the US private sector using data from the National Science Foundation's annual survey of companies, private sector ETI investments fell approximately 20% during 1994–2004. The US electricity sector's R&D arm, the Electric Power Research Institute (EPRI), saw its budget decline by a factor of three during that time period (Nemet and Kammen, 2007). Also, companies are far more likely to invest in short-term RD&D projects that are likely to bear fruit in the near term than to invest in longer term, more fundamental R&D. This is especially true during times of broader economic turmoil or recession and energy price volatility. Such volatility leads to a "lumpy" pattern of investment on the part of the private sector, where big investments are followed by precipitous declines, and vice versa. Innovation requires sustained and steady "inputs" – people who are able to focus over the longer term on improving or inventing energy technologies, and adequate and stable resources to do so (Gallagher et al., 2006).

Turning to the particular rationales for government involvement in ETI, the first is to support, complement, and encourage the private sector's efforts because a vibrant energy sector in any economy will contribute to economic growth and prosperity. Second, energy services are fundamental human needs, and improvement of those services can better the human condition. If innovation reduces the costs of those services, consumer welfare and human well-being are improved. In poor countries, where millions still lack access to basic modern energy services provided by energy carriers such as like electricity, the government has an especially important role to play in developing appropriate technologies for rural energy users, and devising and implementing demonstration and deployment programs for better cookstoves, heating and building technologies, and so forth.

Government investment in ETI is also justified to make energy supply more reliable and secure; help the energy system emit fewer pollutants; and reduce the negative impacts of energy extraction, conversion, and use of water and land resources. In other words, market failures to protect the environment and enhance the security of a country help justify government involvement in the innovation process.

The last rationale for government policy for ETI is to overcome market barriers. Incumbent energy technologies or systems tend to have institutions, infrastructures, and policies that support them, providing barriers to entry for new technologies (sometimes called lock-in or path-dependence). There is also a famous valley of death between the invention phase of innovation and the deployment phase. This valley is really two valleys, because there are often difficulties moving from R&D to demonstration (which is expensive), and then again difficulties taking a proven technology to the marketplace during the early deployment phase. Governments can erect bridges across these valleys to reduce the barriers and speed the passage of these technologies from the lab to the market. In sum, policy can help push and pull advanced, cleaner, and more efficient technologies into the marketplace.

24.4.3 Models and Instruments of Policy

Policies for innovation can directly target the innovation process, support the innovation system, or unintentionally impact innovation while targeting an unrelated concern.

Direct policies for innovation vary according to their target and their timing during the innovation process. Policy is needed at each stage of this process (see the top of Figure 24.12 for examples). The role of government is typically viewed as being most evident at the earliest stage of basic science and research. However, together with the private sector, governments are also engines of applied energy R&D. But governments must also play an important role in leveraging private sector investment at the early commercialization stages by supporting demonstration activities (to reduce risks) and market formation (to underwrite demand). Finally, through regulations and other policies, including tax and fiscal policies, governments also strongly influence the diffusion of energy technologies.

There is often an intermediate stage between demonstration and diffusion that can be considered a market formation or early deployment stage. Here, government can play a critical role because policies are often needed to create an initial market to ease the passage of new energy technologies into the marketplace. First-of-a-kind technologies are often more expensive, and governments can create niche markets through procurement and other policies (e.g., feed-in tariffs or technology portfolio standards) to create demand for advanced or cleaner

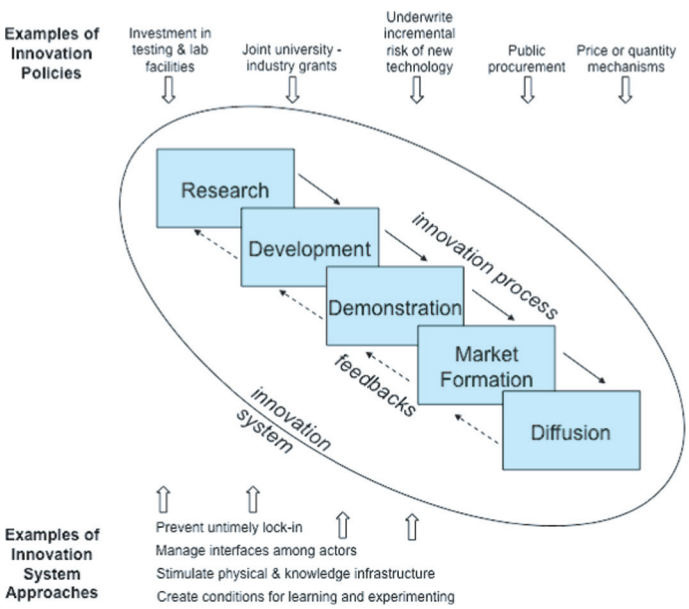

Figure 24.12 | Overview of policies for innovation systems.

energy technologies. With this support, entrepreneurs can experiment and test the market. Technological learning occurs through experience. Even after the niche market has been exploited, policy intervention may be needed to broaden and deepen the market through the elimination of market hurdles, provision of information, tax incentives, or low-interest loans. At some point, a given technology becomes competitive in the marketplace, and the government can exit the market-formation stage. For new, cleaner energy technology to be competitive in the broader market, government policies are also needed to correct for market externalities and define the rules of the game (e.g., through a carbon tax). Because there are so many market distortions, technologies cannot be assumed to freely compete in the global marketplace.

The innovation process is situated within an overarching system comprised of the actors, institutions, and networks involved in developing and commercializing a technology (see Section 24.2 for details). Innovation policies must therefore also target the smooth functioning of the innovation system (see bottom of Figure 24.12). Although government policy affects all stages of innovation, rarely do we see evidence of comprehensive government strategies to optimize the efficiency of the ETIS. Instead, government policies persistently aim at isolated components of the system, such as support for R&D without regard to which policies are needed to maximize feedbacks in the system, or which market-formation policies will be needed if and when the technologies emerge in the demonstration phase.

Policies on issues such as education, taxes and subsidies, and market regulation can exert an important but indirect influence on innovation supply and demand. This reinforces the need for consistency, not just between direct innovation policies but also between the broader regulatory and institutional environments for innovation.

Policies supporting the supply of innovations or the development of technologies include investments in R&D, intellectual property protection, laboratory and testing infrastructure, training and skills development, university-industry collaborations, formal and informal mechanisms of knowledge exchange, technology roadmaps to guide the direction of innovation, and financial incentives such as tax credits for private investments. Not all innovation, however, derives from formal research and development activities. Problem solving and incremental improvements in existing technologies are also of importance and can be stimulated and supported by public sector policies that lead to the creation of outreach, extension, and technical support programs. Policies supporting the demand for innovations as commercialized technologies include demonstration projects, public procurement, market niche creation (e.g., supply obligations), and the creation of appropriate market incentives. Market incentives may be created via changes in relative prices (e.g., environmental taxes or feed-in tariffs), standards, and regulations. These supply-push and demand-pull policies are context-specific complements rather than substitutes. Innovation success stories are typically characterized by comprehensive and consistent policy support through the entire innovation process (see Figure 24.12). Particular innovation policies must account for specific local conditions or be otherwise tailored to the technological or market characteristics of an innovation.

24.4.4 International Dimension to Energy Technology Innovation and Policy

International energy technology spillovers and feedbacks will depend on both local and global factors, and policy at both these levels is crucial. Energy systems and technologies are highly internationalized, and knowledge and learning in the energy sector has an intrinsic international dimension. Moreover, as shown in some of the case studies and the quantitative ETIS investment analysis (Appendix I), non-OECD countries have progressively invested in and developed capabilities in earlier stages of development of new technologies (e.g., China in coal gasification, India in wind turbines, and Brazil in biofuels). The globalization of technology has the potential to significantly increase the rate of energy innovation if international feedback and learning are properly enhanced.

The majority of energy technology is diffused through private means; it routinely flows through foreign investment, licensing agreements, and international trade. Each channel implies different modes of technology transfer and, depending on the effectiveness of local learning investment, different levels of local assimilation (Cohen and Levinthal, 1989). Many of these flows are actually intra-firm technology transfer, since energy firms are counted among the largest multinational corporations in the world, with very high indexes of internationalization (measured as share of affiliate sales on total sales; see UNCTAD, 2002). But this is not exclusive to the fossil energy industries: PV and wind turbine technologies were also developed as a result of experience and learning that crossed borders. But international inter- and intra-firm transfer do not occur without the appropriate systemic incentives, including subsidies, public R&D investment, tariffs, standards, resource mobilization, and the guiding action of policies and institutions.

Incentives for technology diffusion in general include market conditions and government policy, but cleaner energy technologies require normally explicit incentives. While the existence of more advanced and cleaner energy technologies has led many to believe that latecomer countries will leapfrog to such technologies (Goldemberg, 1998), this is by no means an automatic process. Rather, the process is predicated on developing technological capabilities (absorptive capacity) and appropriate market incentives for technology diffusion.

National policy incentives, coupled with either the financial resources to buy and/or the indigenous technological capabilities to make or assimilate advanced technologies, are required in this situation. Local policy incentives and institutions are crucial to overcome adoption hurdles, especially for cleaner technologies. The development of China´s automobile industry is one example. The Chinese government supported its firms to purchase automotive technology through licensing and joint venture

arrangements, but for a long time failed to elicit pollution-control technology adoption due to the lack of pollution control standards until 2000. A lack of leapfrogging was observed with respect to pollution-control technology, but rapid leapfrogging occurred during the 1990s for automotive technology more generally in China (Gallagher, 2006). In the case of ethanol in Brazil, the government employed a comprehensive strategy involving standards, market incentives, RD&D investments, and human resource development to create a sugarcane-based ethanol industry (see the *Brazilian Ethanol* case study). In Mexico, opportunities were missed to cultivate a local wind industry and accompanying capability accumulation. Although the Instituto de Investigaciones Electricas (a public R&D center) had made the first steps toward developing wind turbine technology, the government failed to create incentives at the manufacturing stage, and opted for turn-key plant technology transfer (Borja-Diaz et al., 2005; Aguayo, 2008).

International policy also creates incentive frameworks for the diffusion of energy technologies. This includes treaties (e.g., Kyoto Protocol), norms (e.g., technical standards), and institutions regulating trade, finance, investment, environment, development, security, and health issues (e.g., IEA, World Trade Organization, World Bank, and United Nations Development Programme). However, most of these are not oriented specifically to foster energy technology innovation. A current research gap is the dearth of studies examining the impact of these international policies and institutions on energy innovation. The effectiveness of international schemes like the Clean Development Mechanism and offset markets as energy innovation mechanisms remains unclear.

Adoption of energy innovations tends to proceed faster in late-adopting countries, but achieves lower technological levels than in inventor countries, as shown in the *Scaling Dynamics* case study. This is true also for traditional, carbon-intensive technologies. Most developing countries are currently experiencing a rapid transition into energy- and carbon-intensive modern energy infrastructures and fossil-fuel dependent end-use technologies, most notably the private automobile. Augmenting international spillovers and knowledge flows at early phases of scaling up could enable scope and scale economies in the formative phases of technology, accelerating technology improvement and pulling new technologies from their initial niches of application.

International knowledge spillovers through government-sponsored collaboration efforts seem weak compared to what is needed to foster a significant global energy transition. Perhaps the most prominent example of international energy technology collaboration among governments is the implementing agreements of the IEA. The IEA provides support for numerous international cooperation and collaboration agreements in energy technology R&D, deployment, and information dissemination (IEA, 2010). These agreements cover a broad range of technologies, but they strongly differ in the scope, stage, and level of commitment of the R&D process. Moreover, many are not really R&D collaboration projects, but simply institutional arrangements for information exchange or standardization. While non-member countries and international organizations may participate, OECD members' presence dominates (see Figure 24.13 below). There are other examples of government-supported international collaboration (e.g., the fusion reactor project ITER, or the Carbon Sequestration Leadership Forum), but their effectiveness remains to be assessed.

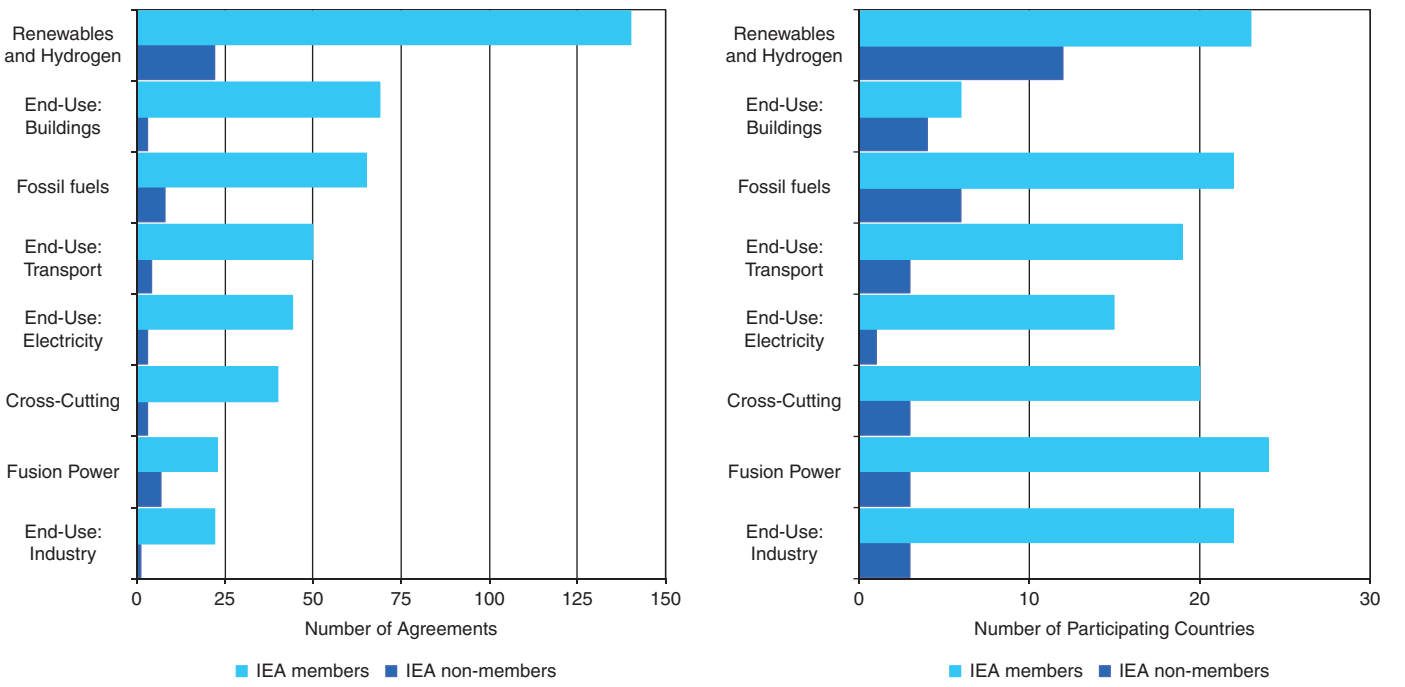

Figure 24.13 | Examples of international technology cooperation via IEA agreements, by participating countries (IEA members and non-members), number of agreements covered (left panel) and number of participating countries (right panel). Note in particular the relative sparse participation from developing countries, which is less surprising considering the exclusive OECD membership of IEA. Source: based on IEA, 2010.

Another potentially important channel for international spillovers and technology transfer is government bilateral agreements. Their real impact on technology spillovers and advancement has not been assessed and will probably remain constrained by national interest issues and disagreement. These bilateral agreements are predominantly North-North, but there are examples of North-South cooperation, and most recently South-South energy technology flows, such as Brazil's set of agreements with 12 African and Caribbean countries for transferring sugar-based ethanol technology. Given their growing importance as both energy consumers and as energy technology providers, India and China have attracted most of the attention, spurring a constellation of binational dialogue and exchange programs such as the new United States-China Clean Energy Research Center, agreed to in November 2009 by President Barack Obama and President Hu Jintao. Again, these programs' effectiveness in fostering innovation and technology transfer remain to be evaluated.

24.4.5 Policy Design Guidelines/Criteria

24.4.5.1 Introduction

The previous sections have outlined the main drivers of technological change embedded in a *systemic* conceptual perspective of the ETIS. The systemic perspective highlights that drivers and policies to stimulate technological change (innovation and diffusion) are closely interrelated. This section summarizes the main findings from the technology policy case studies of Chapter 24 that can guide the design of technology innovation and diffusion policies. In the view of the authors, these guiding principles for policy design carry more weight than the choice of particular policy instruments (including, e.g., externality pricing, preferential feed-in tariffs for emerging technologies, or various forms of subsidies or quantitative regulations such as technology performance standards) that are discussed in the various case studies. In other words, while the policy guidelines outlined below are considered generic and applicable across *all* technology fields and adoption environments, the choice of individual technology-related policy instruments needs to be tailored to technology- and locality-specific circumstances, but are invariably guided by the overarching general policy principles.

Ignoring the systemic characteristics of technological change often leads to a partial view and fragmented (even contradictory) policy frameworks. Although it is well understood that technology is fundamental to solving the energy challenges of our time, including climate change, energy security, and economic growth, what remains less clear is how to most effectively create and deploy new and improved technologies. There are no simple answers; innovation systems are highly complex and interconnected, meaning that decision makers must guard against overly simplistic responses that hide the need for flexible and broad policy approaches to meet energy innovation challenges. Included as boxes within the following sections are several stylized examples of these simplifications – or "policy myths"– and brief explanations of how such simplification might lead policy makers to actions that will not achieve their goals.

24.4.5.2 Create Knowledge! Or: How to Enable Technological Learning while Learning about Technologies Yourself

One cannot influence the creation of technological knowledge in an effective way without knowledge of how the ETIS operates (and its institutions), the inputs it requires, and how to assess the effectiveness of innovation policies (outputs and "outcomes"). A special need in knowledge development relates to data on innovation activities themselves, which for the most part are poor, scattered, and incomplete. Informed innovation policy cannot be created in a knowledge vacuum. It needs to rely on data and appropriate metrics and indicators that can guide adaptive innovation policy design. For instance, our knowledge on technology-specific private sector energy R&D is woefully inadequate, implying that public and private sector innovation priorities risk being misaligned or even contradictory.

Research on energy innovation requires consistent, long-term, comparable, and more detailed data on innovation inputs and outputs, including information disclosure on policy programs. This information is critical for assessing not only the direction and rates of technological change and identifying needs in different areas of the innovation process, but also for evaluating society's response to energy challenges, including policies themselves. Policy makers need to communicate clearly strict quid pro quo conditions for policy support. For instance, direct subsidies on nascent technologies such as demonstration projects and niche market deployment need to be contingent on public disclosure and documentation of successes and failures in the deployment and performance of new technologies, in order to enable learning and the preservation of technology experimentation knowledge.

Decisions and choices that policy aims to influence depend on the structures in which actors are embedded. As technology systems develop, vested interests emerge, not only in the private sector and intermediate institutions but also in the policy-making realm itself. The risk of moral hazard and a poor ability to learn from mistakes can introduce rigidity and biases within the innovation system. This is why societies require reassessment and institutional learning at higher levels of the innovation system, in order to be able to learn and readjust policy objectives, priorities, and instruments. The need for independent and stable institutions that act as intermediaries between the twin vagaries of the policy and market environments, e.g., in the form of technology assessment institutions, cannot be stressed enough. Innovation policy needs institutional capacity for designing, implementing, and monitoring innovation policies, which is lacking in almost all countries, as well as at the international level.

24.4.5.3 Assure Feedbacks! Or: How to Create/Enable Knowledge Flows for Technology Learning and Spillovers

Formal and informal information feedback processes are essential for sustained and successful innovation. This is well known and well cited in the literature, yet it has proven virtually impossible to institutionalize. Even this recommendation has sometimes been seen as an excessive burden on already over-worked public officials, NGOs, and contractors who have little interest in long-term monitoring (PCAST, 1997). Government can support these essential feedbacks in a variety of ways, but can also hinder – or even block – essential information and knowledge flows.

For instance, governments can support knowledge feedback between demonstration projects and niche market applications back to R&D by providing facilities where new technology options are tested and results communicated back to developers/manufacturers. The *Wind Power* case study illustrates the success of test stations in Denmark to support knowledge feedback and quality assurance. The results were widely spread, as networking between actors (i.e., manufactures) was also supported. The test station establishment resulted in essential knowledge and technology development. However, the case study of wind energy also illustrates the negative experience in the Netherlands, where the government supported competitiveness rather than networking. In the Netherland case, the test station environment did not support essential feedbacks and information exchanges between Dutch manufactures.

Niche markets and early market deployment can also provide essential feedbacks. For many new energy technologies, early experience in production and use, including experience in operation and maintenance (O&M), have been essential for successful development because experience is fed back into R&D and design changes. For example, wind turbines developed in the early 1980s were assembled from standard components, and feedback in use and O&M were essential for the development and tailoring of specialized wind turbine components; this in turn supported the development of specialized suppliers. Moreover, high costs related to production and O&M are important drivers for feedback and improvements of products and production processes. Another example for this type of essential market feedback is provided in the *Kenyan PV* case study of PV applications in rural Kenya (see Appendix II). Problems with quality in the PV systems were only revealed through extensive market deployment (and not in earlier demonstration stages or via traditional manufacturing quality control) and led to the subsequent improvement of the technology. Governments or NGOs can assist in this feedback process by providing documentation and public disclosure of market deployment experiences with novel technologies.

Feedback from niche markets and early markets are also important for the formation of the entire innovation system, taking into account not only the technology itself, but also actors and legal and economic frameworks. Essential feedback can be provided by evaluating the process of market formation. By evaluating how the system of innovation is evolving, e.g., the development of knowledge and actor networks, ongoing policy programs can be redesigned to improve in effectiveness and efficiency.

For both technology and market development, extended feedback loops could be achieved through international cooperation and experience sharing. Reporting is essential to overcome any discontinuities (for longer or shorter periods) in the support of technology and market development. Such international knowledge exchange initiatives (e.g., through some IEA programs) remain in their infancy.

24.4.5.4 Globalize! Or: How to Devise Local Policies to Productively Harness the International Flow of Energy Technologies

Energy technologies are intrinsically international. They constantly flow in the private sector through international licensing agreements, joint ventures, direct investment, and trade. Feedbacks in the energy innovation process can and should occur across national borders. To encourage the development and deployment of advanced/new technologies, policies are often needed to create a coherent incentive structure. Local policies are also necessary to foster absorptive capacity to take advantage of technology and knowledge produced abroad.

Protecting intellectual property rights (IPR) is an important aspect of knowledge exchange, but not a sufficient condition – nor even the most important factor – for enabling the transfer of technologies and knowledge (see Box 24.1). Technology diffusion, both across industries as well as across countries, consists fundamentally of adapting existing solutions to new environments through an iterative process of knowledge exchange, revision, reconstruction, and improvement. Setting up the conditions for accessing and assimilating foreign technologies necessarily implies building a local system to produce and reproduce this knowledge.

Developing countries can access new energy technologies through external technology sources like specialized suppliers and multinational firms, or they can support indigenous development of advanced technologies by implementing a comprehensive strategy that includes policy support for human resource development, investments for RD&D, and market formation. Simply buying technologies from abroad is often insufficient because developing countries assimilate these technologies but not the related knowledge about how to adapt, reproduce, and improve upon them.

Naturally, the financial requirements for acquiring hardware, machinery, and equipment are a central aspect of international technology diffusion, especially in capital-intensive, large, and embodied energy technologies. International financial schemes and institutions play a role in the current technological lock-in to the extent that they tend to screen-out investment allocations to cleaner energy sources, local R&D efforts, and knowledge infrastructures. Local and global efforts to mobilize the appropriate financial resources and schemes must be aimed at reducing the valley-of-death transit of clean, advanced, new energy technologies to enable technology and knowledge flows across borders.

Efforts to align national policies toward more effective technology transfer mechanisms must take into account both the predominance of private channels of technology transfer, as well as the role of public investment and incentives needed to provide a level playing field for advanced new clean technologies.

Box 24.1 | How can we ensure that all regions and sectors have access to, and are using, the best technology?

Myths: "*You can just buy (transfer), whatever technology is needed.*"

"*If we just fix IPR issues, technology will transfer seamlessly.*"

"*If developing countries only had strong IPRs, technologies would transfer to their countries.*"

"*If only international IPRs were weaker, developing countries would rapidly adopt new technologies.*"

Technological capabilities and technology levels vary widely across regions. Given that the non-OECD regions will represent an increasing share of the global energy system, effective technology deployment within and to those regions will lay the foundation of growth that is consistent with energy-related objectives.

Patents and other Intellectual Property Rights (IPRs) instruments are not a sufficient condition for innovation or technology transfer. Technology is much more than the "blueprints" of information disclosed in a patent. There are plenty of other conditions and investment needs to be met. Income thresholds set up limits to the scale to which technologies can be applied, limiting their attractiveness. Specialized inputs and infrastructures must be timely and effectively supplied. Skills in operating and integrating complex systems need to be developed. Moreover, many innovations are not patented, and in many industries firms rely on other means for seizing technology advantages (Levin et al., 1987). This means that simply adjusting intellectual property rights will prove far from sufficient to bring about the necessary technology transfer.

The literature discussing the impact of IPR on energy technology transfer is scarce. There is a dearth of empirical or literature evidence that lacking IPR protection is a strong barrier to technology diffusion. In fact, there is emerging evidence to the contrary, i.e., other barriers such as capital costs, lack of infrastructure, lack of local policy incentives like performance standards, feed-in tariffs, and subsidies, and lack of financial resources are more important. In the case of PV and biofuels, for example, the high number of supplier firms and flexibility of sources will most likely reduce the space for monopolist practices in technology contracts. The same seems to be true in the more concentrated wind turbine industry, where developing countries' firms have developed local industries through licensing. However, IPR protections may be a barrier to industry entry for developing countries in the future (Barton, 2009), even when other entry barriers (manufacturing experience) may play a much larger role.

Patents build up incentives for innovation by providing means to control and shape technology transfer. The current global context is already one in which IPRs have been considerably strengthened by prohibiting or restricting compulsory licensing, reversing of burden of proof, and extending of patenting dimensions (Maskus, 2000). Many models on patents show that balancing a patent's dimension can actually reduce the social costs of IPRs, depending on the structure of demand (Nordhaus, 1969; Klemperer, 1990; La Manna, 1992). The resulting trend to maximize all dimensions of patents in TRIPS (Trade Related Intellectual Property Issues) and other trade related IPR frameworks have limited the scope for IPR policies to more rationally foster innovation and transfer by customized IPR systems that properly balance private and social costs.

24.4.5.5 Be Stable! Or: How to Create Policy Stability and Credible Commitments on which Innovation Depends

Governments need to create expectations for actors in the innovation system that are stable and consistent over a multi-year period. Uncertainty in expectations about future policies increases the risk of investing in innovation for energy technologies. Because externalities are pervasive in the clean energy sector – due to both knowledge spillovers and environmental externalities – these distant payoffs rely heavily on policy instruments. However, if expectations about the level or existence of these policy instruments several years in the future are uncertain, firms will discount the value of future policies and under-invest in innovation. Because technology development is in itself a risky endeavor, private sector energy companies will only respond to policies that are credible, last more than a few years, and have a reasonable degree of stability. Moreover, volatility can accelerate knowledge depreciation and loss. Technology policy can be dynamic and flexible to reflect new information, but broad goals must be consistent and funding levels for support of the various stages of the innovation life cycle need to be predictable for the private sector to engage and invest in the creation of new technological knowledge. For energy problems that cannot be solved quickly, patience and predictability are needed.

The case studies make clear the adverse effects of policy volatility and rapidly shifting priorities among policy makers, as well as successes that have resulted from a more recent shift to longer time horizons. R&D budgets have been notoriously volatile. The history of US energy R&D funding is not characterized by stable budgets, but by changes that are much larger than annual changes in economic activity and overall research spending. More than half the time, annual program budgets rose or fell by more than 10% (Nemet, 2007). Wind power, solar thermal electricity, and solar water heaters boomed in the early 1980s and then the industries were devastated by dramatic program cuts in the mid-1980s, even if partially restored soon thereafter. Innovation, job creation, and manufacturing dropped in the United States, and even 25 years later, the focus of activity on these "abandoned" technologies remains outside the country.

A more recent policy innovation has been the shift to policies that ensure stability by including time horizons that set expectations about the intensity of government activity, for example, over ten year periods. The Japanese New Sunshine Program in the 1990s set declining levels of subsidies over ten years. The California Million Solar Roofs Bill set subsidies for 10 years. Renewables obligations in many US states set levels 15–20 years in the future, usually with annual interim targets. An important cautionary note is that long term commitments like these often include clauses that allow loopholes for governments and actors to avoid meeting these commitments should compliance become more difficult than expected, for example through the ability to pay low penalties. A "safety valve" clause in cap and trade has a similar effect if not paired with a symmetric price floor. While the flexibility to change targets may have social benefits, it is important to understand the price paid in terms of reduced incentives for investment for private actors. The shift to longer time horizons for policy making has been an important development, but can also be undermined by implementation details allowing excessive flexibility in cases of nonattainment.

Box 24.2 | How quickly can we move the energy innovation system? How long of a commitment to energy innovation is needed?

Myths: *"If we throw enough money at this, we can make it happen quickly."*

"This is a man-on-the-moon project."

There is no doubt that today's energy challenges call for quick action, and increases in government funding may play a key role in the strategy for solving these problems. In framing the energy challenge, many have evoked the memories of rapid, focused projects to achieve single national goals, such as the Manhattan Project in the United States to develop nuclear weapons, or the US effort to put a man on the moon in less than 10 years.

Although there is a need to pursue energy innovation more aggressively, energy embodies a far broader range of technologies and actors than a Manhattan Project. Virtually every citizen of the globe is an energy user, and therefore has the ability to choose technologies to deploy and fuels to purchase. Energy supplies are produced and provided by a vast range of actors and there is a wide range of supply sources: fossil fuels, bioenergy, nuclear power, solar power, wind power, and others. Each of these involves multiple technology competitions and opportunities for improvements. Historically, accelerated technology deployment programs relied on "selected" single-mission driven technology winners. Meeting future energy needs likely benefits by bringing multiple, competing technology options to the market.

Further, the challenges that face the energy system over the coming century will not be met within a decade. For example, climate change research indicates that the carbon dioxide (CO_2) emissions reductions required to stabilize CO_2 concentrations will be more stringent in the longer-term than in the shorter-term and reductions must continue indefinitely. The challenge for decision makers is to develop the support for a sustained, long-term effort to enhance energy innovation.

24.4.5.6 Align Incentive Structures! Or: How to Avoid Confusing the Market

To maximize the effectiveness of ETIS, it is essential to align incentive structures and employ consistent policy signals. These alignments should be durable so that there is predictability over time for the ETIS. When there is inconsistency or lack of alignment, the efficiency and effectiveness of the system is undermined.

There are two types of alignment that must be considered: (1) alignment of incentives within a given innovation system; and (2) alignment of incentives for different innovation systems to encourage spillovers. To illustrate how to align a particular system, we can utilize the model of the growth phase of the technology life cycle. Aligned policies would include the development of an explicit strategy for supporting technologies that are invented through demonstration and testing, and formation of larger-than-niche markets to facilitate the transition of technologies across both "valleys of death" (from R&D to demonstration, and demonstration to early deployment). Government often must also establish policies that create incentives for technologies to be pulled into the marketplace. Throughout the growth phase of a technology (or set of technologies), governments need to elicit information from actors and devise mechanisms for feeding that information to other actors and other stages of the innovation process. In other words, government often must facilitate the integration of supply and demand and overcome barriers to sharing information essential to the good functioning of energy markets.

When government fails to align the incentive structures for achieving desired outcomes, contradictions emerge and perverse outcomes flourish. Three examples are helpful to illustrate these contradictions.

The *US Vehicle Efficiency* case study on the CAFE standard and the *Hybrid Cars* case studies (see Appendix II) show that the main policy incentive for the development and deployment of energy-efficient vehicle technologies in the United States is the CAFE standard. However, the United States does not impose significant fuel taxes or any fees on the purchase of inefficient vehicles (though it provides a subsidy in the form of an income tax credit for the purchase of certain advanced technology vehicles like plug-in hybrids). As a result, manufacturers are encouraged to innovate only as much as the standard implies, and consumers have virtually no incentive to drive less or to purchase more efficient vehicles. The CAFE standard thus creates a floor for minimum levels of innovation, which implies that the policy mix is incomplete. As one would expect, vehicle miles traveled have steadily grown in the United States (especially because the cost per mile of driving is lower with the fuel efficiency standards), and there was an explosion in the purchases of large passenger cars and light trucks, which had a weaker standard. If the US government added a tax to the price of gasoline, it would help create consumer demand for more fuel-efficient vehicles, thereby facilitating the integration of supply and demand.

The large government investments into RD&D of fossil, fission, fusion, efficiency, and renewable energy technologies can be charitably labeled uncoordinated, and possibly characterized as completely at odds with the much larger government subsidization of the deployment of fossil-fuel technologies. In 2008, IEA member countries invested US$14 billion in energy RD&D, and US$1.6 billion in total for fossil energy technologies (IEA, 2009b). While fossil fuel subsidies may support the fossil fuel RD&D investments, they strongly distort the market for nonfossil energy technologies. US fossil fuel subsidies alone are at the level of approximately US$10 billion/year for traditional fossil fuels, according to a recent report (Adeyeye et al., 2009). Fossil fuel subsidies in the non-OECD countries are estimated to be approximately US$170 billion/year (IEA, 2006). Globally, subsidies to fossil fuels may be on the order of US$500 billion/year, of which about US$100 billion is estimated to be provided to producers (GSI, 2009).

For an example of the lack of policy coordination, consider the United States. There is little evidence in the United States of bureaucratic coordination at the federal level. R&D strategies and decisions are largely made by the Department of Energy in the Federal Executive Branch (although appropriation decisions for R&D are made by Congress, often in contradiction to the R&D strategies set forth by the Department of Energy). Congress, however, establishes the market formation policies – the subsidies, loan guarantees, tax credits, carbon taxes, and cap-and-trade systems. Sometimes the Environmental Protection Agency establishes the market formation or deployment policies (e.g., sulfur dioxide emission trading system; performance standards for power plants), but Congress usually confers this authority. In this system, it is difficult to map out and implement an efficient innovation strategy, much less insure that feedback loops are established and maximized.

Alignment of incentives for ETI probably cannot be achieved without an explicitly designed and implemented innovation strategy for energy technologies. Even with such a strategy, multiple objectives in a country's energy policy can cause a misalignment of incentives. A common misalignment is government making RD&D investments in energy efficiency while simultaneously subsidizing the price of retail fuels. Another example of misalignment is the government encouraging RD&D investments in wind energy when local planning and zoning laws prohibit the installation of wind turbines.

24.4.5.7 Be Systemic! Or: How to Address Innovation in a Comprehensive Way

Innovation policies tend to focus on specific technologies. A narrow technology focus runs counter to the systemic view of energy technology innovation developed throughout this chapter. As well as technology-specific innovation processes, the innovation system is comprised of actors, organizations, infrastructure, and institutions. Relationships and feedbacks between these various components of the innovation system underpin the drivers and mechanisms of innovation discussed in

Box 24.3 | What mix of policy instruments would most effectively spur innovation?

Myths: *"The solution is a massive ramp up of R&D expenditures."*

"If prices are right, innovation will take care of itself."

It is well established that innovation takes place through a system of complementary actors and processes. Each or any of these processes may prove to be a choke point in the innovation system. Government-supported R&D is a core element of the innovation system, and many argue that government R&D expenditures should be increased in the face of our current energy challenges. However, government R&D is far from the only component of the energy innovation system.

Internalizing the costs associated with climate change and energy security to the feasible extent would provide more appropriate signals for technology deployment and private-sector innovation and investment activities. However, a wide range of market failures exist that prevent the private sector from investing in innovation in ways that are consistent with social needs, even if prices are right. Effective pricing is far from sufficient for a robust energy innovation system.

Decision makers find themselves in a situation where there is no single policy mechanism that will support a robust energy innovation system. The system must include a well-functioning and well-targeted government R&D program, but appropriate incentives through the pricing of externalities is also critical for producing demand signals that will induce learning and create incentives for private-sector R&D. A wide range of policy challenges remain regarding other core elements of a robust innovation system, including intellectual property rights and institutional structures to support widespread deployment of new technologies.

Section 24.2. Taken together, these components comprise the selection environment that shapes the outcomes of the innovation process.

A systemic approach to innovation policy requires a package of policy instruments that should adapt to changes and be geared toward triggering changes over time in the innovation systems. Policy packages may also differ from one innovation system to the next. Within these packages, policies must be aligned and consistent in their targets and objectives, as discussed above. Policy packages must also be broad in their coverage, supporting the successful functioning of the whole innovation system. A good example is the cooperation and knowledge feedbacks between different actors and institutions furthered by incentives for collaboration and mandates of information disclosures. Overall, the policy package needs to support knowledge development, feedback processes, and learning for the entire – or at least for the essential parts – of the innovation system. The *Wind Power* case study discusses the development of wind energy in Denmark and shows the success of a systemic approach that includes several actors (energy companies, wind turbine producers, smaller wind turbine owners) and the relationships between those actors, as well as essential institutional features (connection to the grid, spatial planning and permitting process). The *Japanese Efficiency* case study also illustrates this point nicely.

In the case of end-use technologies, actor-networks within innovation systems are often more complex, involving end-users, local authorities, wholesalers, retailers, branch organizations, consultants, installers, energy companies, architects, etc., as well as socially constructed norms, habits, routines, and values. Although these social institutions may play an important part in the success or failure of innovation processes, innovation policies tend to focus on technologies. The broader dynamic between technological change and social change is either sidelined or framed as a simple push-pull relationship with technologies driving responses in social institutions. As a result, social innovation, referring explicitly to changes in the adoption, use, and adaptation of technologies in a social and institutional context, is marginalized as a target for innovation policy. This can be attributed in part to the deep ideological, conceptual, and analytical differences between social innovation and technological innovation, which extend into the policy domain.

Myriad forms of social innovations include participatory planning processes, community-based initiatives, social learning, normative messaging on utility bills, information provision (to change attitudes), educative initiatives (to change values), supply chain alliances and pressures, new business models, and reporting and disclosure requirements. The package of instruments developed to support innovation systems should include policies targeting social innovation as well.

The interdependence of innovation outcomes with social change also highlights the limitations of innovation policy, even when designed within this systemic perspective. Even comprehensive, aligned, and stable policy packages can never guarantee successful innovation outcomes due to irreducible uncertainties.

Box 24.4 | Is innovation policy exclusively concerned with technologies?

Myths: *"The problem is technological. If we solve that, social change will follow."*

"Technological change only arises in response to social needs."

Technological and social change are interdependent. The success of technology-focused innovation processes, as well as the effectiveness of these policies, is conditional on supportive and adaptive social institutions. Participatory planning processes to foster the scaling-up and diffusion of wind power, and community-based organizations that promote energy efficient behaviors and technology adoption, are two current examples. Policies to support social innovations should be considered an integral part of an innovation system approach.

24.4.5.8 Experiment! Or: How to Stop Worrying about Failure

The formative phase of a technology's life cycle concerns the transition from development to diffusion. The dynamics of energy technologies that have successfully diffused historically indicate the importance of building out large numbers of units as a key feature of this formative phase. (A unit refers to a steam turbine in a coal or nuclear plant, a wind turbine, a photovoltaic module, and so on.) From the perspective of governments, experimentation, debugging, improvements and learning possibilities are all proportional to the number of units built during the formative phases of a technology's life cycle. Granularity is therefore a key variable determining innovation and investment risks, as well as the extent of possible experimentation, improvements, and learning favoring smaller, unit-scale, MW-scale projects over larger, "lumpy" GW-scale projects.

The demonstration and early deployment of many units is a natural feature of modular, distributed technologies like residential solar hot water or PV systems, with relatively low capital requirements per unit (even if costs per unit of energy output/capacity might be high). The unit costs of modular technologies may be driven down during the early deployment and diffusion phases by manufacturing scale economies in addition to learning effects. However, the same tendency to focus initially on building out unit numbers is also observed in the histories of large, centralized supply-side technologies. Despite the apparent availability of unit scale economies (i.e., falling unit costs at larger unit capacities), formative phases were historically characterized by only incremental increases in unit capacity over an extended, decadal period. Considerable experience was gained with smaller scale units before significant jumps in unit scale were successfully attempted (e.g., coal power, jet aircraft, and wind turbines).

The consistency of this pattern points to the importance of experimentation with many different units as a precursor both to widespread diffusion and to up-scaling (i.e., pushing technologies up the unit scale frontier). The hallmark of this approach to innovation is granularity: individual eggs in many small baskets. Note that granularity here refers to the formative phases of a given technology; design criteria for portfolios of technologies are addressed below.

Promoting substantial one-off increases in unit scale prior to numerous formative experiments in both precommercial (demonstration) and commercial contexts should therefore be considered a high-risk strategy. The comparative histories of wind power in Denmark and Germany support this cautionary note. Experimentation to generate knowledge on a technology's performance, efficiency, reliability, and other service attributes enhances the required capacity for capturing unit-scale economies. The design, construction, and operation of many different smaller scale units not only leads to incremental improvements and learning-related cost reductions, but also would appear to underpin the success of subsequent larger-scale units.

The importance of these formative experiments helps explain why the time period over which unit scale economies are captured does not appear to accelerate from early to late markets. Although large scale units may be transferable from early to late stage markets, the late stage markets need time to form the requisite institutional capacity to support these increases in unit scale. A context of international cooperation and knowledge transfer would, of course, support the aggregation of learning from experimentation processes running concurrently around the world.

Experimentation can and also perhaps should be multifarious, involving an array of different actors, forms, and stages of the technology's life cycle. In practice, many smaller scale variants of a technology may be pursued on parallel tracks by competing and heterogeneous commercial interests. This granular approach to innovation policy diversifies risk and reduces the consequence of failure.

Government's role should be to fill in the gaps by, for example:

- underwriting small-scale demonstration projects for socially robust innovations with less immediate or higher risk private returns;
- supporting variety in the early deployment phase by creating and protecting differentiated niches;
- reducing upfront capital barriers;

- managing the natural commercial tendency to rapidly confirm a dominant design that confers market advantages and potential cost benefits through scale economies; and
- avoiding over-emphasis on rapid unit scaling.

Failure is an inherent feature of a multifarious and granular portfolio of innovation experiments. Venture capitalists may build energy technology portfolios with an expected nine-in-ten failure rate, knowing that the one in 10 breakthrough will support returns for the portfolio as a whole. Accountability for taxpayer dollars and the associated political risks of funding failures (among other things) makes public innovation policies less tolerant. A shift in mindset is needed to recognize that perfect foresight and innovation are awkward bedfellows, not just in the early R&D phase, but also during the early deployment phase of experimentation with many unit numbers. Learning what does not work supports learning about what does work, and this in turn supports both diffusion and unit scaling. Building diverse portfolios of modular or smaller-scale technologies helps spread this risk of failure. Conversely, concentrating public resources on the scaling up of a particular technology (be it fusion power or GW-scale CCS projects) reduces portfolio diversity and magnifies the risk of failure.

24.4.5.9 Focus on Technology Portfolios! Or: How to Not Pick a Winner, but to be Picky on your Picks

The broad range of necessary ETIs combined with inevitable innovation uncertainty suggests that innovation policies must consider not a random collection of innovations, but rather a wide portfolio of technologies.

Innovation portfolios reflect the combination of technology options pursued within the innovation system that reflects both their respective option value (i.e., societal/ environmental/ economic benefits in the case of successful development and diffusion) as well as their associated risks (e.g., innovation failure or investment risks).

In designing innovation portfolios, a number of basic criteria need to be taken into account:

1. The portfolio needs to reflect a blend of options comprising the entire energy system and spread the investments across many technologies and projects.
2. The innovation portfolio should encompass all salient elements of the technology development cycle and all different channels of technology knowledge creation, such as R&D. demonstration, niche market deployment incentives, and market creation measures.
3. Given inevitable resource constraints, the design of diversified portfolios is more feasible when focusing on granular, less capital-intensive technologies such as end-use innovations and smaller-scale supply options. Conversely, large-scale, capital-intensive, high-risk innovations can meaningfully only be considered in global innovation portfolios. A common thread in case studies on both historical as well as current energy technologies (compare the studies on *Hybrid Cars, Solar Water Heaters, Heat Pumps, Japanese Efficiency, Wind Power,*

Box 24.5 | Are the technologies available that would be necessary to take action today?

Myths: *"No innovation is needed; all that's required is political will."*

"We can't take action now because the needed technologies are not available."

The full suite of technologies that will ultimately be deployed to address the energy challenges in the coming century is not currently available. Technology continues to advance and redoubled efforts to spur innovation will certainly lead to improvements in technologies over the coming decades. At the same time, there are numerous reasons to take action to deploy currently available technologies today: innovation systems are most effective when there is communication between technology users and developers; a range of non-technology factors are associated with the broad deployment of many technologies, and these can take years to develop; capital investments today may preclude effective action in the future; and in many applications, there exist technologies that could have dramatic near-term effects, such as end-use technologies.

Decision makers find themselves in a situation where a wide range of beneficial actions are possible today to deploy existing technology, yet not all technologies are ready for deployment. The challenge for decision makers is to implement policies that will allow some technologies to develop further before moving from the laboratory to the field, and experimentation and feedback with other technologies at a small scale. These policies should support the private sector's role in deploying still other technologies at a large scale if they are clearly proven at smaller scales.

Solar PV, and *Kenyan PV* with the *US Synfuels* and *French Nuclear* case studies) is the importance of granularity. Smaller unit scales of energy technologies (e.g., the size of a one MW wind turbine compared to 1000 times larger typical size of a one GW nuclear reactor) not only result in lower innovation failure risk[16] for a given project, but also in lower barriers to innovation adoption in case of successful demonstration. Technology policy can also profit from granularity, as enabling the spreading of innovation risks across a broader range of a multitude of smaller-scale innovations without requiring the premature selection of few capital intensive innovation projects, preemptying decentralized market-based decision processes. It is not coincidental that granular, smaller-scale innovations in energy end-use technologies have been the dominant source of technological advance in energy systems historically and will likely remain so in the future.

4. In portfolio design, the inherent tension between the desirable goal of maintaining technological diversity and the equally desirable goal of improved economics through standardization and technology focus needs to be considered.

5. The core element of a broad-based innovation portfolio is that policy makers need to be pickier with their technology picks. On one side, innovation policies need to avoid preempting the outcome of decentralized market-based technology innovation, experimentation, and early market deployment decisions that are key in technology development. On the other side, public sector innovation policy legitimately needs to complement private market technology innovation biases against large-scale, investment-intensive technologies that might be crucial in addressing broader social and environmental goals. While resource limitations inevitably require focus on a few strategic technologies, there is a downside: decision makers need to be aware of the pressures to concentrate capital-intensive, high-risk innovation projects (potential innovation "lemons") in the domain of public sector innovation portfolios, implying higher risks that the public sector disproportionally shoulders. The result is an invitation for public support for high-risk innovations or bad business practices (e.g., according a quasi-monopoly to private sector-advanced technology options that capitalize on the economic rents from lavish public subsidies, without "delivering" in terms of much needed technology innovation, such as persistent cost improvements of new energy technologies).

6. Innovation portfolio design ideally includes a blend of the respective options values of technologies, both from a demand-pull and a supply-push perspective. Policy makers also need to be explicit on their underlying risk measures and criteria that enter innovation portfolio design to enhance the legitimacy and transparency of the resulting resource allocation across options and measures.

7. The importance and complexity of these portfolio decisions will require more expertise within governments, as not all technology decisions can (or should) be made by the private sector. Fortunately, formal scientific tools for innovation portfolio design and analysis are becoming increasingly available (cf. the *Technology Portfolio*s case study). These tools can help move the discussion on innovation portfolios to more rational ground, but the further development of these tools requires continued policy and funding support much like energy technologies themselves, as well as an institutional locus for their application.

24.4.6 Conclusions: Generic Characteristics for Energy Technology Innovation Policies

Energy systems consist of interconnected technologies, knowledge bases, and practices that are interdependent and operate in dynamic ways. They are simultaneously embedded into prevailing economic incentive structures and broader social contexts. To be effective, innovation policy must be conscious of these interdependencies across time, space, and actors, and act coherently. Isolated policies acting in only one realm of the market (for example, by stimulating niche markets through tariff policies under a cost buy down paradigm) will not yield strong innovation if not accompanied by coordinated and aligned support for R&D and demonstration projects. Likewise, an isolated technology push focused on R&D without regard to the economic and institutional incentive structures and barriers prevailing in energy markets will be counterproductive for innovation, effectively curtailing the essential feedback and learning from market deployment on which R&D so critically depends.

The changing nature of technology should also be reflected in policy design. Instruments and incentives have to be adapted to the particular problems, tensions, and bottlenecks that characterize each stage of a technology's innovation life cycle. Resource and financial hurdles are, for example, of a very different type in R&D phases than in demonstration and early deployment stages; as market formation advances, the need for agents' coordination also changes in nature and degree. Policies for preserving variety or accelerating standardization are extremely sensitive to the state of development of the technology.

The dynamics of technology over time require the attention of innovation policy to development times and feedback processes. Technology research and development is a time-consuming activity that requires patient funding and active networking. Policy design must therefore be sensitive to the timing of investments and returns. Since knowledge development on suitable solutions and technology improvement takes a long time – and knowledge rapidly depreciates under erratic policy signals – early and persistent policy actions are very important. Long-term planning and policies that persist before being able to reap economic,

16 Given equal probability of failure of two innovation projects, the one with smaller unit scale and hence lower total costs (millions as opposed to billions of dollars) results in lower innovation risk (defined as failure probability times [economic] consequences, i.e., loss of investment).

Box 24.6 | How should policy focus and resources be allocated across technologies?

Myths: *"All technological options will be needed everywhere."*

"We need a balanced portfolio."

"Technological failures are a sign that mistakes have been made."

"We'll need as much diversity as possible."

"Technology X is the answer."

There is a strong tendency for decision makers and technology advocates to focus on a single technology as being the key to meeting energy challenges – the "silver bullet" approach. This single technology focus is a result of both a lack of understanding of the complexity of the global energy system and the tendency of technology experts to support the continued expenditures on single technologies. However, research has consistently indicated that a broad and diversified portfolio is critical to provide options throughout the energy system, to allow for experimentation, and because history has shown that technological expectations are often wrong. A necessary condition for a successful innovation system is the exposure of nonproductive avenues for innovation and the ability to drop these avenues from the portfolio.

At the same time, a diversified portfolio is not necessarily an effective portfolio. There exist a wide array of possible diversified portfolios, and the need for diversity does not obviate the need for decision makers to identify avenues that are most promising and or lacking in effort and adjust the portfolio appropriately. Further, there are many avenues of investment for which increased effort is an obvious need.

The challenge for decision makers is the management of diversified portfolios. This requires institutional structures that are capable of effectively collecting and synthesizing information, robust in the face of necessary technological failures, and capable of adjusting as information changes.

social, and environmental returns are key to ETI. To be consistent in time, policies should be adaptive, flexible, and patient during the early phases of technology development to preserve technological variety, with efficiency assessments and selection of programs/projects in later stages.

The inherent, strong uncertainty that characterizes early phases of innovation calls for flexible institutional mechanisms that are able to actualize expectations regularly. However, as the technology life cycle advances and uncertainty about technical features decreases, capital-intensive investments demand long-term policy stability. Institutional design aimed at accelerating innovation must be aware of this trade-off between maintaining experimentation and technological variety and the economic drive towards standardization, and be able to switch policy priorities over time, but in a predictable, consistent manner.

Knowledge is a crucial factor in innovation, and its nature critically influences policy outcomes. Systemic approaches particularly emphasize the fact that learning processes in innovation occur at many different levels and flow in multiple directions. Knowledge develops and accumulates through a range of complementary processes and activities, which in turn condition the future absorptive capacity for new technological knowledge. Supporting and facilitating these complementary learning processes is a crucial complement for innovation policy, unfortunately too often ignored. The quasi-public and distributed nature of knowledge, together with the strong positive feedbacks between different knowledge bases, call for adequate, timely policy support to these activities, which are easily screened out by market processes. At the same time, policy design should reflect the understanding that knowledge can become obsolete and experience can be lost. Innovation policy is incomplete if it does not adequately address the conservation of memory and a continuous renewal of the knowledge base, which is particularly threatened by stop-and-go erratic policy support.

24.5 Conclusions

24.5.1 Research, Data, and Information Needs

A number of important gaps in data, information and research were identified in the above assessment. Addressing these issues is not only of academic interest but equally critical for improved technology innovation policies, and hence is of greater societal relevance. Ten important

areas are summarized here, regrouped into two broad categories: data and information, and research needs. A central theme is the need to develop better indicators and quantitative data as well as operational models and criteria to answer the core questions of technology innovation policy regarding effectiveness, i.e., what is the most appropriate policy instrument for a particular purpose, what resources are required, and what are the likely response times of the innovation system to policy interventions?

24.5.1.1 Data Needs

In terms of data, four areas stand out where the gap between data needs and availability is particularly large:

- data on innovative activities (R&D) pursued by private firms;
- data on technology specific investments, particularly in end-use technologies;
- data on knowledge spillovers across different innovation fields and at the international level including, in particular, technology-specific trade data and on joint technology development collaborations; and
- systematic and up-to-date data on performance and economic characteristics for energy technologies that are internationally comparable and widely available for technology studies and policy assessments.

24.5.1.2 Information Needs

Information needs include the following areas:

- identification of a limited set of appropriate and manageable criteria and metrics for the assessment of innovation systems in terms of inputs, outputs, and outcomes that can be matched with available or to be developed data sets;
- operational measurement models that describe knowledge depreciation in R&D and LbD processes; and
- criteria for the selection of technology specific case studies especially in a comparative context across countries and across technologies.

24.5.1.3 Research Needs

In terms of research, this assessment has identified the following areas:

- the development of conceptual models that answer the question of how measurable inputs and outputs of innovation systems relate to each other;
- the development of a "meta-theory" of technological change that enables to establish appropriate *ceteris paribus* conditions to be able to compare and assess the dynamics of change and of policy effectiveness across different technologies and development/adoption environments; and
- comparative assessments of the effectiveness of alternative policy instruments aiming at influencing individual components or the entirety of ETIS.

24.5.2 Conclusions on Energy Technology Innovation

Substantial and accelerated innovation is essential to respond to the sustainability challenges of energy systems at all levels, including the local, national, regional, all the way up to the globe scale. Further, a coordinated approach is needed that works within and between industrialized and developing nations.

Such innovations will comprise a combination of both incremental, cumulative changes and radical, discontinuous changes that can only emerge if the various innovation dimensions are nurtured simultaneously. Innovation entails technological, social, and institutional, as well as economic, driving and embedding factors that need to work hand in hand in the development, testing, and ultimate selection and adoption of new innovations.

A core message of this chapter is that the drivers of innovation, as well as the policies that support it, are complementary rather than substitutable for each other. This requires attention to fundamental innovation, or technology push, which needs to be coordinated with efforts to facilitate the expansion of the market opportunities – demand pull – that move innovations from laboratory to cost-effective deployment. As such, the energy sustainability challenge requires changes in whole innovation *systems* rather than simply more independent, individual innovations.

The synthesis of the available literature and case studies suggests that successful innovation systems and their supporting policies are characterized by three main features: alignment, consistency, and patience.

Alignment (i.e., comprehensive and contradiction-free) means that the various forces and policies that drive innovation are considered holistically and not from the perspective that any single driver can substitute for the (lack of) other drivers. Accelerated R&D in new energy technologies without economic incentives for ultimate adoption of the innovations will not yield the much needed change to redirect energy systems toward sustainability.

Likewise, consistency of policies and drivers is key. Incentive structures need to remain stable and not at odds with each other. All innovation actors (researchers, industry suppliers, and customers, the end consumers) rely on predictability and consistency of the innovation environment; otherwise the costs of taking the inevitable innovation risks become prohibitive. An important task for research is to provide a framework that can be used to examine energy and carbon outcomes of innovation policies, including the relative benefits and costs of policy tools aimed at the expansion of the low-carbon energy sector.

Finally, patience is needed. The time lags between basic and applied research, development and testing, market introduction, and ultimate diffusion and the required feedbacks to earlier innovation stages in the process are substantial. Joint expectations (or visions) need time to emerge and accommodating social and institutional settings need time to develop. The international dimension in the development and diffusion of innovations also requires patience.

Innovation and technology policies also can no longer remain fragmented, *ad hoc*, and concentrated on individual technological options. A much more strategic and long-term approach is required to harness the potentials of well-functioning ETIS. Goals and objectives, weighting of different (sometimes conflicting) objectives, strategies and implementation plans to be followed, evaluation criteria for continued reassessment, etc., all need to be formulated to involve relevant stakeholders and take account of international developments. Above all, this requires institutional innovations as, at present, corresponding institutional frameworks and learning capabilities are insufficiently developed. Successful examples such as the Japanese national system of innovation can provide inspiration, but institutional solutions need to be custom-tailored to their specific national or regional circumstances.

A paradigm for a strategic and long-term approach to ETIS is the concept of adaptive/policy learning. Strategies and policies need built-in mechanisms to assure flexibility and the ability to adjust courses of actions and policies to reflect new developments, in order to be able to react to and correct for unanticipated outcomes and surprises. There is an inherent tension between the desired criteria of flexibility/adaptability on one hand, and the equally desirable criteria of alignment, consistency, and patience on the other. These seemingly contradictory objectives can and should be reconciled, but it will involve an open institutional and policy architecture that can mobilize collective learning processes and widely shared strategic goals.

Openness implies increased sharing of data and experience and non-exclusive networks of actors, nationally as well as internationally. In short, much higher levels of cooperation and knowledge exchange are needed to address the potential tensions between national policies and an increasingly globalized ETIS landscape via formal and informal information sharing, cooperation, and coordination agreements. Existing institutional solutions such as the IEA or the International Renewable Energy Agency can serve as useful entry points, but must be expanded to become both truly international and comprehensive in terms of their energy systems perspective, in particular in moving away from the traditional energy-supply bias to include energy efficiency and conservation in a more integrated way.

As daunting as the agenda for a systemic, consistent, and aligned long-term technology policy framework may appear, improvements can be implemented gradually. An illustrative roadmap for action over time consistent with the dynamics of capital stock turnover rates in energy systems is given in Table 24.9.

Table 24.9 | Illustrative roadmap for the development of a systemic, aligned, and consistent policy framework for energy technology innovation and diffusion matching policy approaches to realistic timescales of outcomes.

Timescale of Policy Outcome	Examples of Policy Approaches
short term (e.g., to 2020) capital stock additions (some)	create, stimulate and protect market niches around performance advantages of new technologies deploy market-ready, clean technologies through credible and stable incentive mechanisms develop long-term technology innovation and market deployment strategies in a consultative process, creating "joint expectations" reduce/eliminate direct or indirect subsidies for technologies not aligned to long-term technology strategy and portfolios use "sunset" clauses for planned retirement of depreciated, inefficient, or polluting capital vintages
medium term (e.g., to 2050) capital stock additions (all), capital stock turnover (some)	expand public and private R&D investments stably in diversified portfolios designed to manage risks and corresponding with end-use needs underwrite many granular and multifarious technology demonstration and learning cycles support disclosure, interaction, and feedback between innovation system actors engage in multiple international collaborative projects to further knowledge dissemination and technology spillovers align innovation and market deployment incentives (e.g., recycling externality pricing revenues back to R&D and market deployment incentives)
long term (e.g., to 2100) capital stock additions (all), capital stock turnover (all)	set long-term targets with appropriate monitoring and enforcement mechanisms to sustain shared technology expectations maintain portfolio diversity to prevent premature lock-in or standardization set technology standards for the gradual phase out of "bridging" technologies
throughout (present-2100)	create and nurture formal and informal institutional settings for technology assessment, evaluation, portfolio design, and knowledge sharing

24.5.3 What is New?

At the end of any assessment, it is legitimate to ask: what's new? Readers will undoubtedly form their own opinions, but the (subjective) perspective of this chapter's writing team is summarized below.

As a first, the chapter provides a synthetic overview of the resource requirements (in terms of investments) of the entire energy technology innovation and diffusion process. This assessment thus includes new data, including R&D expenditures in emerging economies, a summary synthesis of diffusion investments, and novel first-order estimates of end-use technology investments for which information has been lacking to date. Notwithstanding the key role of innovation in the front end of the technology life cycle, the numbers nonetheless confirm the predominance of assuring an appropriate incentive environment for the adoption of innovations, where typically 80–90% of financial resources need to be mobilized. The numbers also confirm the critical importance of energy end-use and related technologies in ETIS that need to be better reflected in R&D and market deployment incentives and new business models.

The chapter also contains a rich set of new case studies on energy technological change, which are both novel in their scope and constitute a useful resource for research as well as policy learning. The case studies represent new, original research and are unusual for a major international assessment such as the GEA. However, the fact that they could be conducted even under extreme resource constraints points to the wide interest and collaborative spirit of the technology community, which can be harnessed further to improve knowledge exchange and learning for successes and failures, moving technology policy forward.

The chapter also opens the "black box" of technological innovation and change. It analyzes the "finer grain" underlying the change in the multitude of attributes and drivers of innovation: new knowledge, but also knowledge depreciation, economies of scale, linkages and spillovers to other sectors, phenomena of increasing returns inherent in knowledge generation and in infrastructure-intensive interconnected systems such as energy, as well as resource constraints and (relative) input prices. The new findings, while tentative, again confirm the importance of alignment and consistency under the overall umbrella of the complementarity of policies/measures/incentives rather than their substitutability. These findings add a new dimension to naive perceptions of the prevalence of either supply push (e.g., accelerated, stepped-up R&D programs) or demand pull (e.g., "cost buy down" in new technologies) that have characterized much of the literature and policy debates to date.

Finally, this chapter introduces the novel concept of "granularity." Historically, successful innovations are characterized by a prevalence of a multitude and a diversity of "small" (locally adapted) solutions to problems that occur even at a global scale, as opposed to singular, large-scale, planetary solutions (be it geo-engineering, solar power satellites, or a single design for a nuclear fusion reactor). "Granular," small scale innovations offer the potential of multiple and repeated experimentations, learning, and adaptation to diverse adoption environments. An example is the dramatic difference in industrial and managerial experience that stems from building and operating a million wind turbines, as opposed to some 1000 nuclear reactors. From that perspective, the critical innovations paving the way to energy sustainability will reside in energy end-use (e.g., efficiency) and locally adapted supply options (e.g., in smaller-scale renewables) that are in stark contrast to the prevalence of a uniform, global technology landscape that has characterized the fossil fuel age.

24.6 Appendix I: Investments into ETIS

24.6.1 RD&D Investments

R&D expenditures at the macroeconomic level are routinely collected by national and international statistical agencies (see OECD, 2007). The data usually differentiate by funding source (public versus private sectors); by R&D performing institution (government laboratories, universities, or by private firms); and, finally, by broad economic sector. Methodologies, data collection, and compilations are well established (OECD, 2002).

Energy-related or technology-specific RD&D data are not reported separately in these macroeconomic statistical frameworks, creating formidable data challenges. For a concise review of data sources, methodological issues, and limitations of energy RD&D data, see Dooley (2000). Energy- and technology-specific RD&D data are available for public sector expenditures in member countries of the IEA (IEA, 2009b), but information on non-IEA countries (Brazil, China, and India, or Russia, to name the most important ones) and especially for private sector energy RD&D are extremely fragmented and sparse. Evidence suggests that the IEA public sector energy RD&D statistics may cover only about a quarter of all energy-related RD&D globally, where private sector RD&D and increasingly non-IEA countries substantially contribute to energy RD&D. This assessment therefore includes an effort to compile national energy RD&D data on the emerging economies of BRIMCS (Brazil, Russia, India, Mexico, China, and South Africa), conducted by a team of researchers at Harvard University (Kempener et al., 2010b; see the *Emerging Economies R&D* case study summarized in Section 24.7.8) that also includes (albeit incomplete) coverage of private sector RD&D in these countries. For private sector energy RD&D in OECD countries, this chapter could only draw on the survey conducted by the World Energy Council in 2001 (WEC, 2001) for a sample of OECD countries. More recent international comparative data are simply unavailable.

24.6.1.1 Public Sector Energy RD&D

Figure 24.14 summarizes the trends in public sector energy RD&D since 1974 in IEA member countries and contrasts it with total public RD&D

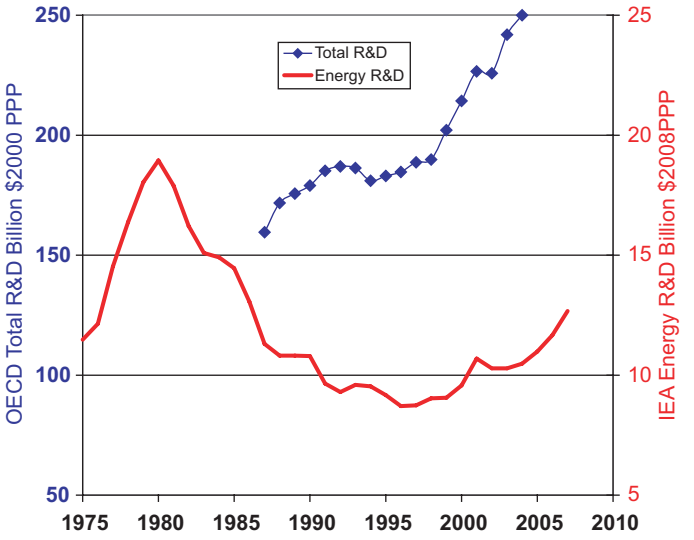

Figure 24.14 | OECD public R&D expenditures ($US_{2000}$$ PPP) versus public sector energy R&DD in IEA countries ($us_{2008}$$ PPP). Note the factor of 10 difference in the scale of the two expenditure categories and the opposing time trends since 1985. Source: Doornbosch and Upton, 2006 (in $US_{2000}$$ PPP); IEA, 2009a (in $US_{2008}$$ PPP).

expenditures. While total reported energy technology RD&D expenditures by definition include demonstration investments in addition to R&D expenditures, little detailed data are available. IEA (2009b) reports a total of some $550 million[17] at purchasing power parities (PPP) for seven countries for which such data are available. The United States represents the bulk of this figure, with approximately $444 million development expenditures, corresponding to some 4% of total public energy technology RD&D in all the IEA member countries in 2008. Hence, it is fair to say that public energy RD&D expenditures are in fact mostly R&D expenditures with little expenditure on technology demonstration proper.

A defining characteristic of energy RD&D is both its comparably small magnitude (5% of total government RD&D), as well as its boom and bust cyclical nature, characterized by rapid expansion in the wake of the oil crises of the 1970s, its subsequent collapse (with corresponding impacts on knowledge depreciation), and only gradual recovery after the year 2000. This is in stark contrast to the continually expanding overall R&D budget in IEA member countries. These trends are extensively discussed in the literature (Dooley and Runci, 2000; Doornbosch and Upton, 2006) and have been referred to repeatedly as "R&D under-investment" by researchers (e.g., Nemet and Kammen, 2007) and business executives (e.g., AEIC, 2010).

Figure 24.15 summarizes the historical evolution of IEA member country energy RD&D by broad technology class, illustrating a third area of concern: asymmetries in public energy RD&D portfolios (see Box 24.7 on RD&D Portfolios). Total public sector RD&D in IEA member countries in 2008 amounted to some $12.7 billion (PPP). Close to $5 billion was spent on nuclear (fission and fusion), $3 billion on "other" energy technologies (hydrogen; electric power outside renewables, fossils, and nuclear; electricity transport and distribution; as well as basic energy research), and about $1.5 billion on fossil fuels and energy efficiency, respectively (for a tabular overview for IEA countries see Box 24.7. For BRIMCS countries, see overview in Section 24.7.7).

As discussed above, comparable internationally comprehensive energy RD&D statistics for non-IEA member countries are lacking. This results in the (incorrect) perception that energy RD&D and technology development is primarily performed in OECD countries. Given that this is no longer the case, enlarging global energy RD&D reporting systems remains a critical task. The Kempener et al. (2010b) energy RD&D survey on BRIMCs countries, suggests that public energy RD&D in the six BRIMCS countries amounted to some $2.7 billion dollars[18] in aggregating national data sources, compared with US$4.4 billion public energy R&D in the United States in 2008 (IEA, 2009b). The case of BRIMCS countries also illustrates the fact that the traditional distinction between public (i.e., government) and private (privately-owned companies) sectors as sources of RD&D funding becomes increasingly blurred. Whole or partially state-owned enterprises (e.g., national oil and gas companies, utilities) constitute an important part of the energy sector in developing and emerging economies and also in many OECD countries. The RD&D expenditures in state-owned enterprises are strongly determined by national governmental policies. Combining public and semi-private energy RD&D, BRIMCS countries have a total current energy RD&D budget of some $15 billion (PPP), about equal to the entire public sector energy RD&D expenditures in IEA member countries ($13 billion, PPP) and still about half of the combined public and private energy RD&D in OECD countries (estimated here at approximately $25 billion). A commonality in the energy RD&D budgets of IEA member countries and BRIMCS countries is the dominance of fossil fuel and nuclear technologies, which currently receive some $11 billion (PPP) in total RD&D funding, or some 75% of total energy RD&D in BRIMCS countries. IEA member countries invest close to 50% of their public energy RD&D investments in these technologies (>$6 billion; $10 billion when private RD&D investments are included).

24.6.1.2 Private Sector Energy RD&D

The situation with respect to data availability of private R&D expenditures is dire. The Directorate General for Research of the European Commission states, "Despite the growing need, statistics on energy R&D expenditures in the private sector remain a problem" (EC, 2005).

17 2008 International $. The R&D expenditure data in this section are expressed throughout in terms of purchasing power parity (PPP) in order to improve comparability across very different economies. One drawback of PPP is, however, that simple ex post adjustments to a common base year (2005 in GEA) are not possible for international, cross-country statistics. Differences to 2005$ PPP should however be minor. PPP values are denoted here simply as "$" to differentiate them from the US$.

18 Data limitations preclude a comparison for an identical base year. Instead, the totals reported aggregate national statistical data for reporting years that vary between 2004 (China) to 2008 (Brazil, Russia, India, and South Africa). Numbers are expressed in terms of PPP.

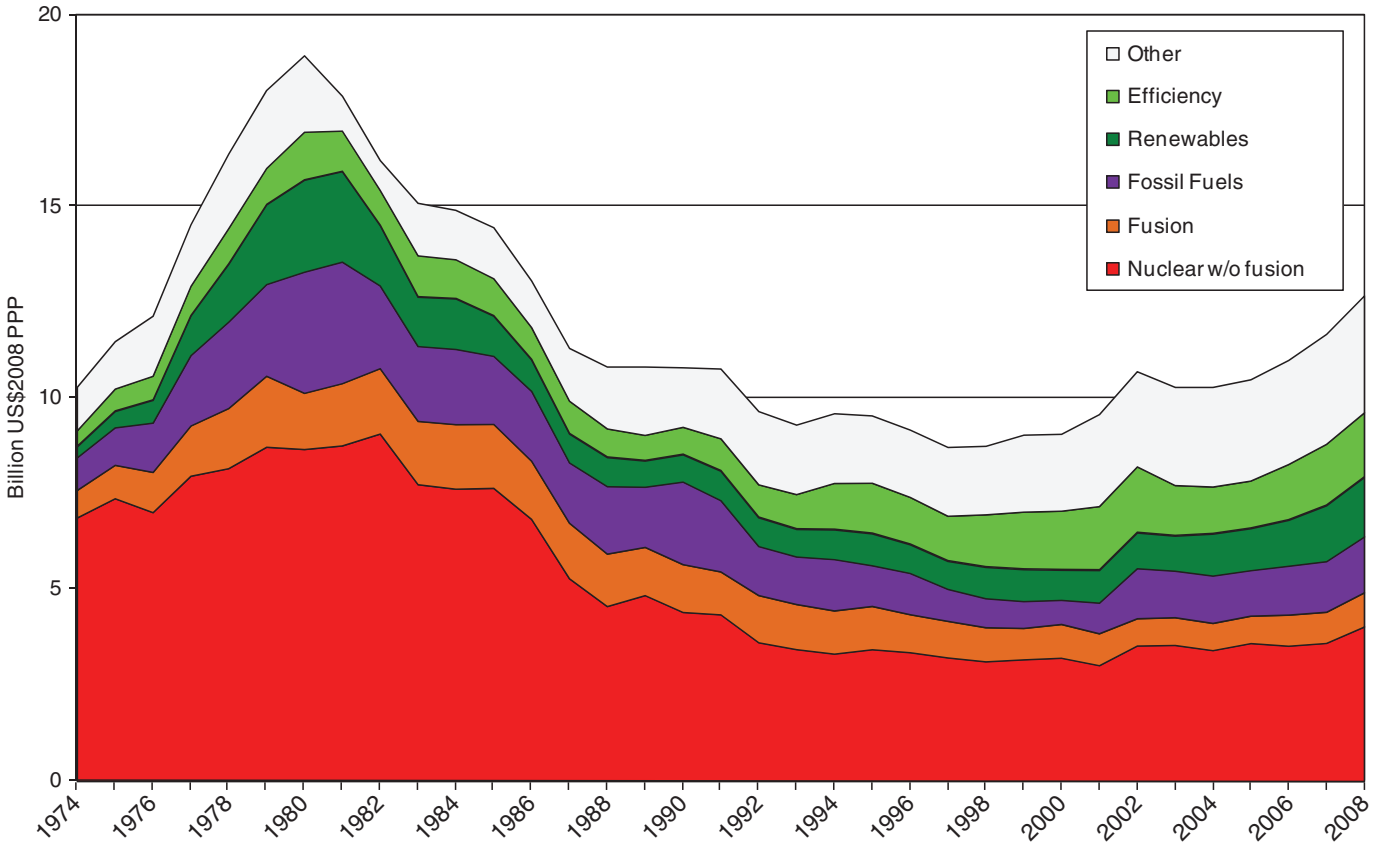

Figure 24.15 | Public sector energy RD&D in IEA member countries by major technology group 1974–2008 (in $US_{2000}$$ million PPP). Source: data based on IEA, 2009a.

Macroeconomic RD&D statistics by broad economic sector are available for a sample of 19 OECD countries in the OECD Structural Analysis database (OECD, 2009). However, the latest year reported is 2002. Data for other countries are not collected and available in any internationally comparable form. In 2002, business enterprises excluding extractive industries (coal mining; oil and gas extraction) performed R&D equivalent to $433 billion (PPP in 2000$) in the sample of 19 OECD countries provided. The only sectorial breakdown available that bears directly on the energy sector are "coke, refined petroleum products and nuclear fuel" ($2.7 billion) and "electricity, gas, and water supply" ($2 billion), with an OECD total of energy-related private sector RD&D of less than $5 billion (PPP). Of course, RD&D performed in the manufacturing sector has a bearing on energy use, e.g., such as in electrical machinery ($13 billion), motor vehicles[19] ($50 billion), or aircraft ($20 billion; see NSF, 2010). How much of the RD&D performed in these sectors is energy-related remains unknown.

19 The six automobile manufacturers listed among the top 25 global corporations in 2006, performed between US$4.6 billion (Honda) to US$7.5 billion (Toyota) in R&D, with a total of some US$39 billion. Other corporations, whose R&D is likely to include an important energy component are Siemens (US$6.6 billion), Samsung (US$5.9 billion) Matsushita (US$4.9 billion), Sony (US$4.6 billion), and Bosch (US$4.4 billion) (NSF, 2010). This listing alone suggests that in terms of private energy-related RD&D, energy end-use technologies are most likely to be of much greater importance than energy supply.

The only available survey of private sector RD&D specific to the energy sector is the study conducted by the World Energy Council (WEC, 2001), covering the period 1997–2000 for a sample of seven OECD countries, which are summarized in Table 24.10. In addition to the WEC survey, the most recent private sector RD&D data for the United States for 2004 (NSF, 2009) are listed for comparison.

The information available on total OECD private sector energy RD&D from 1993–2000 amounted to some $12 billion annually. The technology-specific breakdown is too incomplete and the data too old to warrant a detailed discussion. However, it is noteworthy that with the exception of Japan, private sector R&D on energy efficiency appears either to be unrecorded or, when subsumed under the "other" (or unaccounted for) category, remains extremely small outside Japan. Thus, the sparse available data suggest that also private sector energy R&D seems to follow the supply side (fossil and nuclear) over-emphasis apparent in public sector R&D in OECD countries.

For non-OECD countries, the Kempener et al. (2010b) survey on BRIMCS puts the OECD numbers in perspective (for a detailed breakdown, see the table in Section 24.7.7). The information available on investments in energy RD&D in the BRIMCS countries by the private sector and state-owned enterprises also amount to about $12 billion (PPP 2008), albeit based on more recent data (2004–2006).

Box 24.7 | R&D Portfolios

How can we assess current energy technology R&D portfolios, i.e., the technologies we invest in, with the technology investments needed for an energy sustainability transition?

One way is to describe alternative futures through the scenario technique and use models to calculate the future market potential of specific energy technologies. This potential can be contrasted with public sector energy R&D spending (see the *Technology Portfolio* case study based on Grubler and Riahi (2010) and summarized in Appendix II below).

Given that the future is inherently uncertain, one needs to explore a wide range of possibilities, i.e., a reasonable number of scenarios. The results of these scenarios can be analyzed to derive "need-based" technology portfolios that can guide RD&D allocations across technology fields. A large-scale scenario study (Riahi et al., 2007) explicitly addressed the question of how the portfolio of GHG mitigation technologies changes as a function of the representation of salient uncertainties including energy demand, resource constraints, availability and costs of technologies, and the magnitude of GHG emissions constraints. For the quantification of the respective role of individual groups of technologies in the entire GHG emission reduction portfolios, the concept of mitigation "wedges" (Pacala and Socolow, 2004) was used. A mitigation wedge as defined in Riahi et al., 2007 is simply the contribution to the cumulative emissions reduction over the period 2000–2100 that a particular option provides compared to a baseline scenario. First, three baseline scenarios without GHG emissions constraints were compared to corresponding hypothetical baselines that assume a "frozen" state of technology in the year 2000 (i.e., no technological change/improvements). Then, for each baseline scenario a range of increasingly stringent GHG emissions constraint scenarios are calculated (constraints vary from as low as 450 ppm CO_2-equivalent GHG concentration by 2100 all the way up to 1390 ppmv-equivalent). Additional model sensitivity analyses then explored the impacts of the unavailability of particular technological options (e.g., nuclear or CCS). The calculated aggregated technology specific GHG mitigation "wedges" are summarized in Figure 24.16, showing mean as well as minima/maxima across all scenarios explored. The ranking of different mitigation options is quite robust across the scenarios explored, with energy efficiency and conservation being the single most important option with typically >50% contribution and nuclear with a typical 10% contribution to cumulative 2000–2100 emission reduction. The results are representative of other modeling studies, e.g., as reported by the Energy Modeling Forum (EMF-22) where the maximum share of nuclear energy ranges between 11–12% (Calvin et al., 2009) to 9–14% (Gurney et al., 2009) by the end of the 21st century.

It is also instructive to compare the calculated future mitigation potentials of technologies with RD&D expenditures, summarized for the total of all IEA countries above. A *significant mismatch in R&D portfolios* in favor of nuclear and to the detriment of energy efficiency and conservation emerges. Nuclear received well above 50% of all cumulative (1974–2008) R&D expenditures, with energy efficiency receiving less than 10%, whereas their respective role in the GHG mitigation portfolios is exactly the inverse. To put these numbers into an absolute perspective: cumulative public R&D into energy efficiency totaled some 38 billion $\$_{2008}$ (in purchasing power [PPP] terms), which is lower than total cumulative expenditure into fusion energy ($41 billion PPP). Current R&D levels into renewable and CCS (which is subsumed in the "other" category above that includes *inter alia* also hydrogen, fuel cells, and basic energy research) are also much lower than a future "need-based" analysis suggests, albeit the mismatch is less striking than the one comparing energy efficiency to nuclear.

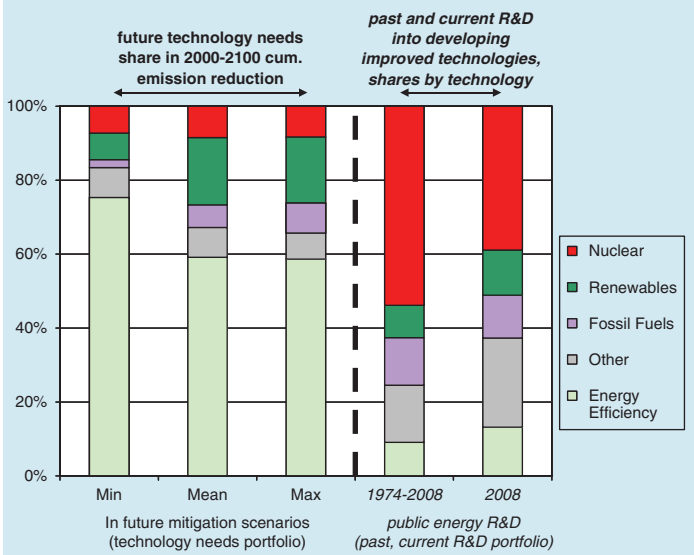

Figure 24.16 | Distribution of past (1974–2008) and current (2008) public sector energy technology R&D portfolios in member countries of the IEA (right) versus portfolios of future GHG mitigation needs (min/mean/max, left) derived from an extensive scenario uncertainty analysis. Source: adapted from Grubler and Riahi, 2010.

Were current energy technology R&D portfolios to represent the respective "option value" of alternative technologies in a climate-constrained world, one would have to increase current R&D into energy efficiency by at least a factor five or by some $6 billion PPP per year (thus not proposing a reduction in nuclear R&D). Given that improved energy efficiency has multiple public benefits beyond climate change (e.g., less energy use, reduced local air pollution, and lessened import dependence) even more ambitious increases in public energy R&D budgets for energy efficiency would be justified.

Table 24.10 | Private sector energy RD&D, selected OECD countries from WEC (2001) survey (in billion US_{2001}^{22}). Also, for the US latest available data for 2004 (NSF, 2009) are shown for comparison.

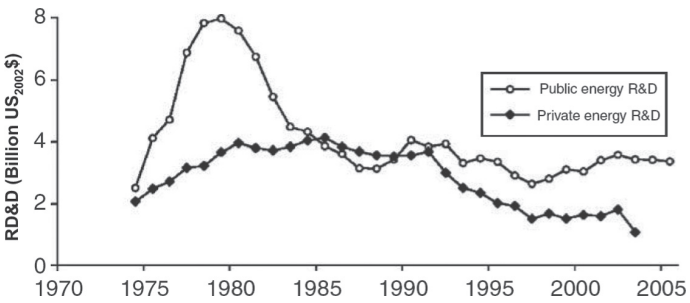

Figure 24.17 | Trends in US public and private energy RD&D (billion us_{2002}^{20}). Source: Nemet and Kammen, 2007.

There is evidence from the United States that private sector energy RD&D appears to follow comparable trends as public R&D (Figure 24.17), as both are influenced by rising and falling oil prices. One interpretation of these joint trends is "that the signal of commitment that a large government initiative sends to private investors outweighs any crowding-out effects associated with competition over funding or retention of scientists and engineers" (Nemet and Kammen, 2007). By analogy, the same influences also appear at work in periods of declining public R&D budgets. The available empirical evidence at present appears insufficient to support the often advanced argument of "crowding-out" effects, i.e., expanded public sector R&D would substitute (crowd-out) private sector R&D (e.g., Popp, 2006).

24.6.1.3 Total Energy RD&D

Based on the limited data available, the order of magnitude estimate of global energy RD&D amounts to some $50 billion (PPP) with some $15 billion in public sector RD&D and up to $35 billion by the private sector. About half of all energy RD&D is spent on fossil fuels and nuclear according to this assessment. The Sustainable Energy Finance Initiative's (SEFI) estimate (UNEP/SEFI/NEF, 2009[21]) of global RD&D into sustainable energy of some $12.4 billion for the year 2005 (including $6.8 billion private and $5.6 billion public sector RD&D) is insufficiently documented to allow a more in-depth comparison, but are likely to represent an optimistic estimate.

24.6.2 Market Formation Investments

Market-formation investments include public and private investments in the early stages of technological diffusion and are sometimes also referred to as "niche market" investments. In the energy domain, these investments include government subsidies for certain technologies (e.g., feed-in tariffs or production tax credits) and public procurement. They also include private investments that may take advantage of markets created by government policies, such as renewable performance standards or price instruments like carbon taxes.

Market-formation investments in the energy sector as a whole are difficult to track, because many transactions are unreported, ways of measuring market-formation investments are not yet harmonized internationally, and efforts to track such investments are only relatively recent.

24.6.2.1 Analysis of Market Formation Sustainable Energy Investments

- Market formation investments in sustainable energy (solar, wind, biofuels, biomass and waste-to-energy, marine and small-hydro, geothermal, efficiency, and other low-carbon technologies/services) can be measured by activity in three main asset classes: venture capital/private equity; new listings on public markets; and asset finance. Figure 24.18 shows the distribution across the three asset classes with total investments across all regions growing

20 To convert to US_{2005} $ multiply by 1.09.

21 The Sustainable Energy Finance Initiative is convened by UNEP, with participation from Bloomberg New Energy Finance (NEF): www.sefi.unep.org/.

22 These rather outdated (but only available) data are presented here mainly for illustrative purposes. In order to avoid confusion, currencies have not been converted to the more recent GEA base year of 2005.

Box 24.8 | How large are the investments in sustainable energy?

It has been reported that over US$200 billion in investments have been made into sustainable energy,[23] and in 2008, this grew to US$223 billion (UNEP/SEFI/NEF, 2009). However, as a leading indicator for the growth of sustainable energy infrastructure, the total US$223 billion is misleading because it includes a number of transactions – a full 30% – that are purely financial, such as mergers and acquisitions (M&A), refinancings, and buyouts. These transactions represent changes in ownership rather than input investments into energy technologies.

Figure 24.18 shows a breakdown of the US$223 billion in investment transactions in 2008 for sustainable energy as tracked by UNEP/SEFI/NEF,[24] and maps them against the categories of RD&D and market formation used in this chapter. By doing so, a clearer picture of the scale of input investments into the sustainable energy technology system emerges. Technology-specific (as opposed to ownership changes represented by some US$67 billion for mergers and acquisitions) investments amounted to a total of some US$$_{2008}$160 billion. RD&D (public and private) made up US$18 billion, with the bulk of the investments (US$141 billion) classified as market formation investments into sustainable energy technologies.

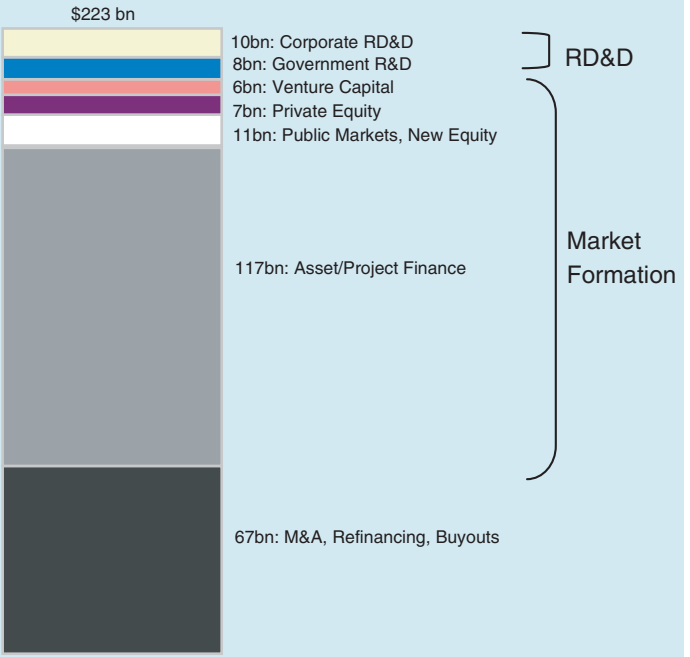

Figure 24.18 | Investments into sustainable energy in 2008. Data source: SEFI/UNEP/NEF, 2009.

at a compound annual growth rate (CAGR) of 63%/year between 2004 and 2008.

- The largest asset class within market formation investments is asset finance, which includes the building of new assets financed via either project finance or balance sheet/syndicated equity. While often investing in quite large and more mature technologies, asset finance investments in sustainable energy are counted here as part of "market formation" because they are highly dependent on governmental subsidies and incentives such as tax equity credits or feed-in tariffs. The amounts also include estimated investments for small-scale and residential installations of sustainable energy technologies such as biodigesters, micro-wind turbines, and solar hot water systems.

- Brazilian ethanol was excluded from market-formation investment totals, as these investments are no longer substantially supported by government subsidies (see the *Brazilian Ethanol* case study). The net effect of doing so was to reduce the total amounts invested by US$17.2 billion for 2004–2008 and US$8 billion in 2008 across all asset classes. (These investments are included in the diffusion investment category in this assessment, summarized in Section 24.6.3 below.)

- The technology sector attracting the most investment for 2004–2008 is wind. Wind-related investments grew at an AGR of 51%/year in this period.

- Investments into energy efficiency are small (~2%).

- The regions that saw the most investment were OECD countries, notably Europe, at 45%, and North America, at 30%, of total investments for the 2004–2008 period.

24.6.2.2 Spotlight on Venture Capital and Private Equity (VC/PE) Energy Investments

While often characterized as investing in highly risky assets, VC/PE investors typically invest after a good deal of technology risk has already

23 "Sustainable energy," according to UNEP/SEFI/NEF, includes: solar, wind, biofuels, biomass and waste to energy, marine and small-hydro, geothermal, efficiency, and other low-carbon technologies/services. It excludes large-scale hydro (>50MW) and all nuclear power.

24 Figure 24.18 includes both project finance for large scale installations and small scale and residential installations as estimated by UNEP/SEFI/NEF.

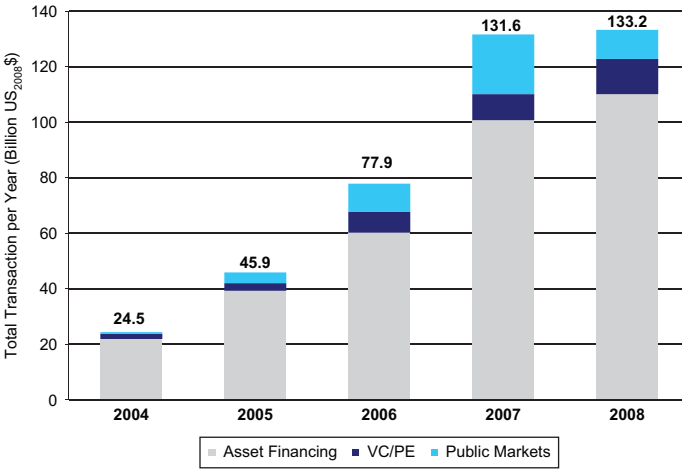

Figure 24.19 | Yearly investments in market-formation for sustainable energy technologies 2004–2008 (total transaction/year in billion $US_{2008}$$). The total market formation investments in 2008 exclude US$8 billion in Brazilian ethanol (classified here as diffusion investments) from the total of US$141 billion reported in Figure 24.18. Source: O'Rourke, 2009; UNEP/SEFI/NEF, 2009; bloomberg new energy finance database (courtesy of ERD3 Project Harvard; NEF/SEFI, 2009).

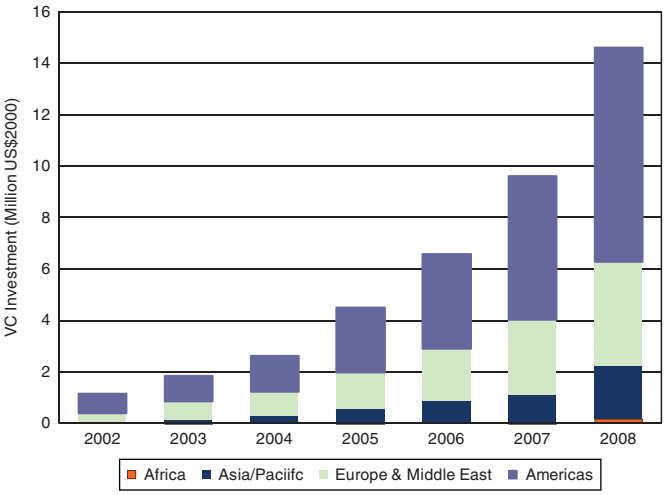

Figure 24.20 | Total amounts of VC/PE in energy by year and region (in 1000 $US_{2008}$$). Sources: O'Rourke, 2009; Bloomberg New Energy Finance database (courtesy of ERD3 project harvard; NEF/SEFI, 2009); Thomson Reuters Venturexpert Database (Thomson Financial, 2009).

been mitigated, when markets for the new technologies are somewhat defined, and when the entrepreneurial company is formed and functioning. VC/PE investors hope to profit from the rapid scaling up of the technology in formative markets, at which point they can sell their equity stake at a high multiple on what they initially invested (see also the *Venture Capital* case study summarized in Section 24.7.8).

Compared to coal, oil and gas, and nuclear energy, sustainable energy technologies are less mature technologies, and VC/PE capital and skill can help accelerate the transition from demonstration to market adoption.

The following investment amounts build upon the UNEP/SEFI/NEF data presented above by adding fossil-fuel technologies and installations with data gathered from the Thomson/Reuter's VentureXpert database (Thomson Financial, 2009). Total amounts and numbers of investments are likely to be higher than what is listed here because investments made by VC/PE funds into energy technology companies forming new markets are often not publicly reported, and investments made by angel (individual) investors are also not reliably reported, even if such investments serve as an important source of capital for both very new and later stage venture companies with energy technologies.

There has been a dramatic growth of investment by VC/PE investors into energy – and specifically into clean energy technologies – since the mid to late 2000s. Figure 24.20 illustrates the recent growth of VC investment into both fossil and non-fossil energy technologies following the regional disaggregation given in the original data source.

- Between 2002 and 2008, at least US$40.88 billion was invested by VC/PE investors into energy technology firms; in some 2,375 transactions.
- In 2008, the total amount of energy (fossil and non-fossil) investments made by professional VC/PE investors worldwide was US$14.6 billion. This grew from some $1.14 billion in 2002.
- The compound annual growth rate (CAGR) for the 2002–2008 period is 53%/year for the total amounts invested and 26%/year for the number of investment rounds ("deals") made.
- The bulk of the investment went into North American and European companies with non-fossil-based energy generation technologies. This uneven distribution reflects both the limited availability of data outside North America and Europe, and the limited availability of professional VC/PE in some regions of the world with other forms of financing more common such as family-firm or investments made by large corporations.

Figure 24.21 shows that the majority of investments made by VC/PE investors are in sustainable/renewable energy generation and end-use efficiency technologies over fossil fuels and power generation technologies. Specifically:

- solar energy-related technology companies have attracted the highest amounts of investments overall, representing some 30% of global energy VC for the whole period. Solar investments grew particularly rapidly between 2005–2008 in terms of numbers of deals and total amounts invested; and
- "end-use efficiency" (such as smart energy metering in buildings, demand response software systems, high efficiency lighting, etc.) also grew in the period, totaling US$5.5 billion for the period.

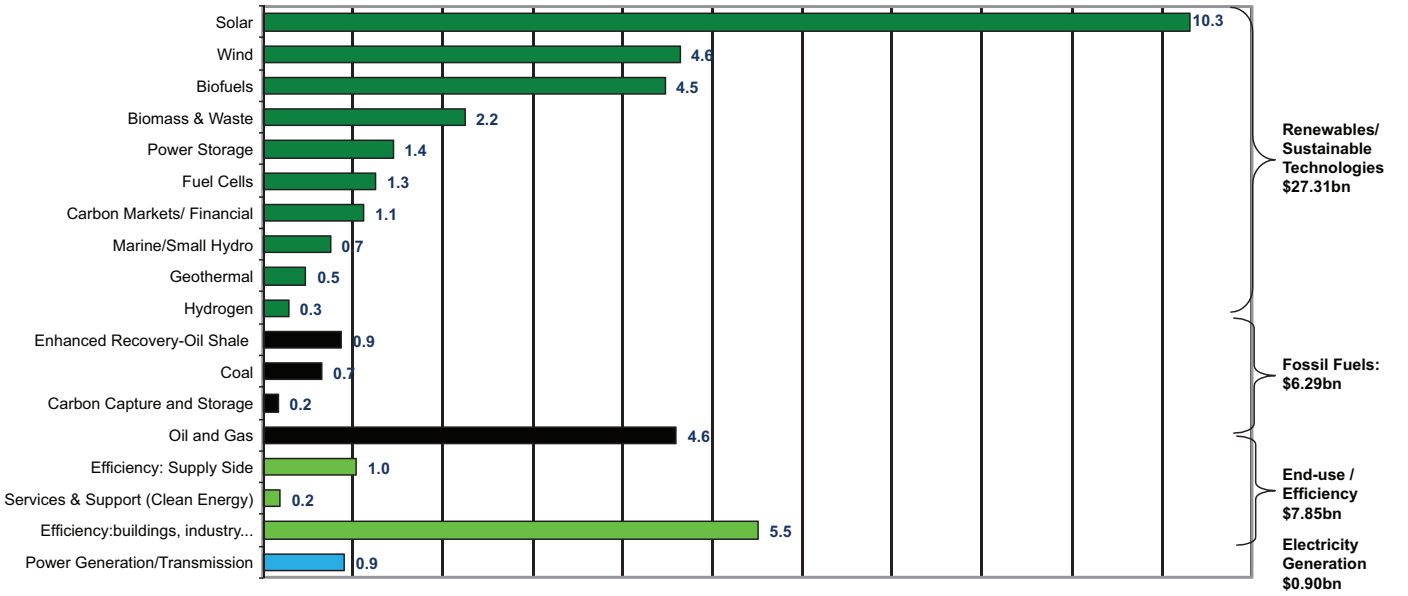

Figure 24.21 | VC/PE investments in energy technologies by technology cluster between 2002–2008 in billion $US_{2008}$$. ("Biofuels" category excludes investments made into Brazilian ethanol companies, accounted for diffusion investments in Section 24.6.3 below.) 24.6.3 Diffusion Investments

Energy sector diffusion investment data are sparse and not collected systematically nationally or internationally. Modeling studies, as well as limited survey data, allow estimates of energy-supply investment levels, but energy end-use investment data are almost entirely lacking. Instead of concluding with the simple statement of data unavailability, this assessment explores some of the reasons for the lack of data and aims to provide at least some plausible estimates of orders of magnitude to provoke discussion and subsequent research in this extremely under-researched and under-reported area.

24.6.3.1 Energy Supply Investments

Data on energy supply investments are extremely limited, so the literature typically relies on model estimates (multiplying statistical data and/or estimates on capacity expansion with average technology-specific investment costs to derive total energy supply investments) or limited surveys. Energy supply modeling studies have become available since the mid-1990s in academia (e.g., Nakicenovic and Rogner, 1996; Nakićenović et al., 1998; Riahi et al., 2007), as well as from the work of the IEA, particularly the World Energy Investment Outlook (IEA, 2003); the Energy Technology Perspectives (IEA, 2006; 2008b); and the recurrent projections of IEA's World Energy Outlook (e.g., IEA, 2006; 2007; 2008a; 2009a), which also contain unique survey data on energy supply investments, particularly in the oil and gas industry. A common feature (and drawback) of all modeling studies is that energy sector investments are not reported for their corresponding base year values, but instead as cumulative totals of the projection horizon of typically 30 years. The absence of published base year input data for energy sector investment projections not only reduces the credibility of the modeling studies, but also makes an assessment of current investment levels and structure and a comparison among the different studies an almost impossible task.[25] In the assessment below, we summarize available information by drawing on the only modeling study that has disclosed its underlying base year energy investment numbers (Riahi et al., 2007)[26] and the surveys reported in IEA's WEO (IEA, 2006; 2008a; 2009a). Because of the significant price escalation observed for energy sector investments (particularly for oil and gas since 2004), the Riahi et al. (2007) estimate (that refers to year 2000 investments and price levels) can be considered a lower bound, assuming recent price escalations will not remain permanent. Conversely, the IEA numbers can be considered as an upper-bound estimate of investments in energy supply (see Table 24.11).

Despite differences in estimated supply-side investments per category, the available data suggest a likely order of magnitude of energy-supply

25 Therefore wherever possible, underlying investment numbers of modeling studies should be made publicly available.

26 Numbers have been published in an interactive web-based database. Base year data refer to capacity additions and price levels for the year 2000 but were expressed in $US_{1990}$$. These were converted to the GEA standard of $US_{2005}$$ using the US GDP deflator multiplier of 1.4. However, despite being expressed in $US_{2005}$$, price levels remain that of the year 2000, as energy sector-specific price deflators are not available internationally.

Table 24.11 | Range of energy supply investments in Billion US_{2005}. (T&D: transport and distribution of electricity).

		LOW[1]	HIGH[2]

side investment of some US_{2005}700 billion/year that could extend to some US$840 billion in 2007/2008, considering the higher ranges reported in the literature. Investments are dominated by electricity generation and transport and distribution (T&D), with some US_{2005}500 billion. Fossil fuel supply, particularly the "upstream" component (i.e., exploration and production), accounts for US$250[27]-400 billion, mostly for oil and gas.

Renewables that figured prominently in market formation investments discussed above are minor players under the market conditions characterizing current diffusion investments. Liquid and gaseous biofuels account for US$20 billion, including US$8 billion for Brazilian ethanol (UNEP/SEFI/NEF, 2009). Large-scale hydropower (<US$100 billion for annual capacity additions of between 25–30 GW) make up a maximum of 17% of current supply-side investments.

Major uncertainties include the accounting for oil and gas exploration activities (at some US$40 billion) that are, strictly speaking, not energy technology investments. When categorized as RD&D activity for future oil/gas reserves – as is the practice by some companies – oil and gas exploration would represent the single largest RD&D spending in the energy technology field. Major differences also exist for electricity transport and distribution infrastructure investments for which only modeling study data are available and estimates differ by about a factor of three. The IEA WEO 2008 projection of average annual electricity T&D infrastructure investments of US$230 billion over the period 2007–2015 appears extremely high, and is comparable to the corresponding electricity generation capacity expansion investments. Lastly, it is interesting to note that no studies available report actual data for current investments in nuclear energy (even though nuclear figures prominently in future projections). According to IEA (2002; 2009a), installed nuclear capacity expanded by 20 GW between 1999 and 2007. IEA (2008a) reports an increase from 358 to 376 GW between 2000 and 2006, which yields an average annual net increase in nuclear capacity of between 2–3 GW, mostly in Asia where investment costs are comparatively modest at an estimated 1500–2500 $/kW (see Chapter 14). This suggests current investments of between US$3–7.5 billion/year for nuclear

27 Taking the Riahi et al. (2007) estimate of US$220 billion, complemented by not reported investment categories, the estimated grand total includes US$230 billion for fossil fuels and US$20 billion for biofuels.

reactors, which makes this the only technology in which RD&D investments *exceed* diffusion investments. (Given its technological maturity of over 40 years since its first market introduction, nuclear can reasonably not be considered a technology in its market formation stage, where such an investment pattern would be both possible and plausible.)

The assessment of the nuclear industry in terms of technological and investment risks by markets, as reflected in actual technology investments, departs markedly from the overemphasis of nuclear in public RD&D portfolios. This misalignment suggests two critical questions for technology policy. First, is the public sector energy RD&D confined to investments in innovations that ultimately find little market appeal? Alternatively, given the heavy emphasis of public RD&D on nuclear, is the public sector providing sufficiently consistent market deployment incentives so the heavily subsidized technology finds market applications?

Evidence regarding the time trend of supply-side energy investments is scarce in the literature. An intriguing empirical finding from the United States, however, shows a significant decline in energy supply-side investments as a share of sector revenues for electricity generation in the second half of the twentieth century (Figure 24.22). The declining investments (as a share of revenues) in the US electricity sector suggest a substantial thinning of resources available for capital turnover and diffusion of new technologies as a twin result of slowing demand growth and energy sector deregulation and liberalization. At present, it remains unclear if this trend is a specific phenomenon of OECD countries or of US electricity supply (an increasingly deregulated sector). However the example supports the conclusion that better current and longitudinal data on energy sector investments are needed for improved decision-making.

This assessment of diffusion investments has focused on the global level for the simple reason that regionally disaggregated investment survey data are lacking. Modeling studies suggest that current (year 2000) energy supply-side investments are distributed about 60:40 between Annex I and non-Annex I countries, as defined by the United Nations Framework Convention on Climate Change (UNFCCC, 1992). Short-term projections (e.g., to 2030 by IEA, 2009a) suggest roughly a 50:50 split between energy supply investment needs between Annex I and non-Annex I countries, for a global total of cumulative energy supply investments 2008–2030 of some US_{2008}25 trillion.

24.6.3.2 Energy End-use Investments

The decentralized nature of these investments by private households (and their corresponding classification as consumer expenditures rather than investments) and by firms (whose energy-specific investments go unrecorded) explains the absence of energy end-use investment numbers in the literature. The small-scale nature and formidable definitional challenges[28] of these numbers also contributes to their absence. This lack of data, even model estimates,[29] introduces a serious challenge in both energy modeling and policy, because the potentially largest source of energy demand (and emissions) reduction is either entirely ignored or assumed to cost nothing. Customary energy and climate policy models deal with energy end-use costs by either "assuming away" missing data by exogenous (and policy independent) autonomous energy efficiency trends or by considering investment costs for the incremental component of energy end-use investments related to improved energy efficiency, which in itself provides a formidable definitional and data challenge.

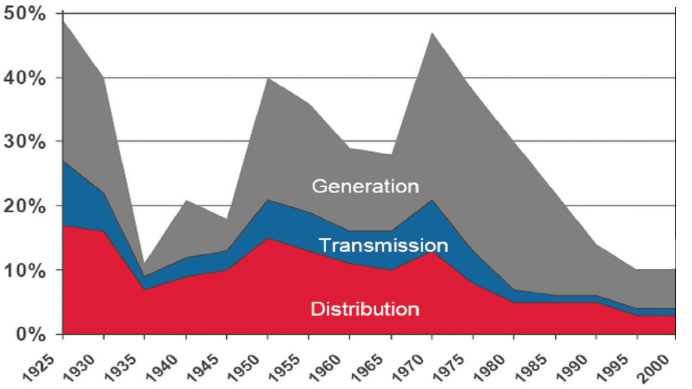

Figure 24.22 | Declining investments (as share of revenues) in the US electricity sector, 1925–2000. Source: modified from EPRI, 2003.

To address this gap, Chapter 24 presents the first global, bottom-up estimate of total investment costs in energy end-use technologies. Volume data (production, delivery, sales, and installations) and cost estimates to approximate total investment costs in 2005 are estimated in both end-use technologies and their specific energy-using components.[30] Low and high sensitivities around central estimates are included, taking into account uncertainties in both volume and cost assumptions. The intention is to provide a first order, educated guess point of comparison with supply-side investments. Supporting data and a discussion text are posted on the GEA Chapter 24 website[31]

28 For instance, it is far from trivial to discern the energy component in the total investments of a new building. Depending on where the systems boundary is drawn, one could look at the heating and air conditioning system, including that part of the building structure that determines its energy use (insulation, windows). Indeed, the entire building structure may be considered.

29 Some studies include incremental energy end-use technology investments associated with additional energy efficiency gains above a typical "business as usual" scenario (e.g., IEA, 2009a). Apart from introducing additional definitional ambiguities (i.e., what constitutes incremental investments), the modeling is usually only done for a few technologies (e.g., transport), which limits its usefulness to inform policy.

30 Available data do not allow a further disaggregation into those subcomponents of investments on energy efficiency improvements, which remains an important future research task.

31 See www.globalenergyassessment.org.

to document the assumptions underlying the estimates below, solicit feedback and comments, and invite further research in this critical area (See also Wilson and Grubler, 2011).

To ensure comparability between supply-side and demand-side investments, a common definition of the unit of analysis is needed. Supply-side investments are quantified at the level of the power plant, refinery, or liquefied natural gas terminal. These are complex, integrated technological systems with energy conversion technologies at their core. These energy-converting components are configured within their corresponding technological system to provide a traded energy carrier to intermediate users (utilities, fuel distributors, pipeline, or shipping companies).

The logical demand-side analogues of these technological systems are the aircraft, vehicle, refrigerator, and home heating system. Although generally less complex, each of these technological systems similarly has an energy conversion technology at their core (i.e., the jet engine, internal combustion engine, compressor, boiler). In addition, each is configured to provide a useful service to final users.

With demand-side technologies, however, this definition of the unit of analysis is problematic. Investments in (and performance of) end-use technologies are dependent on investments in associated infrastructure such as airports, roads, and buildings. Is it meaningful to quantify the investment cost of a home heating system without quantifying the investment cost of a home and the insulation level that determine the dimensioning of the home heating system in the first place? Is the end-use technology to consider a boiler or a building?

Although the same issue exists on the supply-side, it is largely addressed by additionally quantifying investment costs in associated transmission and distribution infrastructures in policy models, as comprehensive statistics are also lacking on the supply side. The problem on the demand side is that the same approach would result in a sum of the total investment costs in all building structures, roads, railways, ports, airports, industrial machinery, equipment, and appliances. Such an exercise would amount to a *reductio ad absurdum.*

A pragmatic pathway out of this system boundary ambiguity is to provide a range of estimates for a range of system boundaries of energy end-use technologies. An initial broader definition and data set describes end-use technologies as the smallest (or cheapest) discrete purchasable units by final consumers. This implies boilers and air conditioning units not houses, and dish washers and ovens not kitchens. A second, narrower definition and data set describes the specific energy-using components of these end-use technologies. This implies engines in cars, and light bulbs in lighting systems. Table 24.12 summarizes these distinctions for the technologies analyzed. In some cases (e.g., industrial motors, mobile heating appliances), a distinct energy-using component was not identified.

The investments in 2005 in end-use technologies are estimated to be on the order of US$1–3.5 trillion; the estimate in 2005 in the energy-using components of these end-use technologies is on the order of US$0.1–0.7 trillion. The breakdowns of these totals by technology are given in Table 24.13 and Table 24.14.

It should be emphasized that these investment cost ranges are rather *underestimates*, as many end-use technologies are omitted from the analysis. Although the principal end-use technologies in terms of the costs of their energy-using components (not the technologies themselves) are captured, investment costs in many technologies cannot be quantified. These include all propeller-based and noncommercial aircraft; helicopters; all military technologies; mass transit systems (whose costs are extremely site specific); heating and cooling systems in commercial and institutional buildings (new build and retrofits); water heaters; information and communication technologies; small appliances; other consumer electronics; and all industrial equipment and processes other than motors (e.g., blast furnaces, pulp mills, cement kilns). With the exception of industrial plants, the inclusion

Table 24.12 | Summary of technologies and components included in estimates of energy end-use technology investments.

End-Use Service	End-Use Technology	Energy-Using Component
mobility	commercial jet **aircraft**	jet **engine**
mobility	**vehicles** (cars and commercial)	internal combustion **engine**
space conditioning	**central heating systems** (boiler/furnace, ducts/pipes, radiators, controls, energy supply infrastructure network connections for new systems)	**boiler** or furnace

of these categories should not substantially increase the investment cost range for energy-using components, as suggested by back-of-the-envelope sensitivity analyses; however, they would substantially increase the investment cost range for end-use technologies in their broader definition.

Given the definitional problems described above, the appropriate point of comparison for estimates of supply-side investment costs is a range spanning the narrow category of "energy-using components" at the lower end, to the broader category of "end-use technologies" at the upper end. Taking also into account the extent of end-use technologies missing from this analysis, *the range of demand-side investment costs is conservatively in the order of US$0.3–4.0 trillion.* This compares with supply-side investment costs on the order of US$0.7 trillion/year.

Although the two ranges span the same orders of magnitude, the upper bound of demand-side investment costs is four times higher than its supply-side equivalent, recalling also that this is likely a (potentially substantial) underestimate. Interestingly, this result aligns with the IEA's estimation that demand-side investment needs exceed supply-side investment needs by a factor of 4 to 5 in the IEA climate policy scenarios (IEA, 2008b). Disaggregating the data by region shows that approximately two-thirds of the end-use investments in 2005 are in Annex I countries; the remaining one-third are in developing economies.

24.7 Appendix II: Summaries of Case Studies of Energy Technology Innovation

24.7.1 Grand Designs: Historical Patterns and Future Scenarios of Energy Technological Change[32]

The case study reviews patterns, drivers, and typical dynamics (rates of change) in energy systems from a historical as well as futures (scenario) perspective. From a historical perspective, two major energy transitions, each of which took up to a century to unfold, can be identified: the phase of growth in coal-fired steam power, and its subsequent displacement by oil and electricity-related end-uses and technologies (Figure 24.23). Similar far-reaching future transitions are also described in the scenario literature as a function of alternative assumptions on rates and direction of inventive activities and performance and cost improvements of new energy technologies.

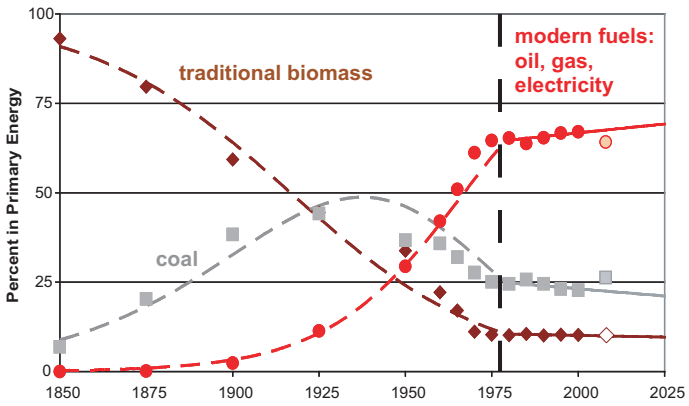

Figure 24.23 | Two "grand" transitions global energy systems measuring market shares in total primary energy use, 1850–2007 (preliminary data) of biofuels, coal, and modern energy carriers (oil, gas, electricity). Note in particular the long period of initial slow market penetration of new technologies and the significant slow-down of historical technology dynamics after 1975.

Summary Points

- Technological and social innovations have been core drivers of historical energy transitions and remain so in future scenarios.
- Energy history and future are characterized by four "grand" patterns of technological change in energy systems:
  - clustering and spillover effects dominate over singular technologies;
  - performance dominates over costs in the early phases of technology development;
  - end-use applications dominate over energy supply; and
  - time constants of change are substantial, spanning from many decades to a century.
- There is evidence that, contrary to the historical evidence and popular conception, rates of systems transitions have substantially slowed since the 1970s.

24.7.2 Historical Scaling Dynamics of Energy Technologies[33]

The twentieth century has witnessed extensive diffusion of many supply-side and end-use energy technologies as part of a wholesale transformation of the energy system. Entire industries have grown, but so too have the size of technologies at the "unit" level (e.g., the rated capacity of a steam turbine or a car engine). Analyzing these historical growth dynamics at both the industry and unit level reveals some general patterns that appear robust across very different energy technologies. First, increases in unit size generally follow a period of experimentation with many smaller-scale units. This is particularly the case for technologies like nuclear or wind power with clear economies of scale at the unit level. Second, the extent to which an energy technology industry grows is consistently positively related to the time duration of that growth. These and other findings have important implications for policy, not least in striking a cautionary note on pushing for significant jumps in technology unit size before a formative phase of experimentation and learning with smaller-scale units has been completed.

Summary Points

- Growth of energy technology industries comprises a *formative* phase, then a *scaling* phase that precedes or is concurrent with an *industry growth* phase.
- The formative phase involves many smaller-scale, granular units with only small increases in unit size. The scaling phase sees large increases in unit sizes, particularly at the scale frontier, and a large increase in numbers of units. The industry growth phase is driven by large numbers of units at larger unit sizes and describes the maturing industry.
- Experimentation with many smaller-scale units tends to precede substantive increases in unit size. The formative phase following an energy technology's introduction into the market is an often lengthy process of testing and experimentation with many small-scale units, which allows technologies to be "debugged" through a process of "designing-by-experience" (Ruttan, 2001). Successful experimentation, improvements, and learning appear to be critically determined

32 Arnulf Grubler.

33 Charlie Wilson.

by the granularity and the associated smaller financial and innovation failure risks of smaller-scale unit projects. Resulting learning effects lead to cost and performance improvements, but also facilitate the subsequent capture of unit scale economies as the industry matures.

- The relationship between the extent and the time duration of an industry's growth is consistent for different energy technologies. It is intuitively obvious that the extent of growth should correlate positively with the time period over which that growth occurs (notwithstanding the many factors that affect diffusion rates). However, the consistency of that relationship for very different energy technologies is surprising. The case study also identifies an important learning externality for later adopting regions that achieve generally faster diffusion compared to leading innovation centers. Compared to historical dynamics, future scenarios reviewed were generally found to be conservative in their technology scaling and market expansion assumptions.

24.7.3 Technology Portfolios[34]

The case study reviews a range of methodologies and model-based applications that can assist policy decisions under (inevitable) technology innovation uncertainty.

One possible approach is based on scenario analysis. As an example of that method, a detailed scenario exercise performed at IIASA explores uncertainties in main scenario drivers of future greenhouse gas (GHG) emissions (energy demand, resource and technology availability, etc.) and extent of future climate constraints (represented through a range of stabilization targets). The study identifies energy efficiency and conservation as the single most important, and also the most robust, technology option across all scenarios. This result is in stark contrast to past and present public sector R&D portfolios, which continue to be dominated by nuclear R&D at the expense of energy efficiency.

A second analytical approach is based on a portfolio theory that helps capture the benefits from (technology) portfolio diversification in the framework of risk-averse decision-making. An example modeling study suggests that risk aversion leads to higher adoption rates of currently higher-cost energy technology options such as modern biomass and renewables, but also CCS. The modeling study also suggests higher short-to-medium term investments into advanced technologies under risk aversion. It is also possible to not only consider variance as a risk measure, but take into account the risk of high impact tail events. For example, a risk premium of only about 1% of total energy expenditures was found to decrease the value of the 99th percentile extreme event by more than a factor of two. Diversification thus not only reduces the mean of risk exposure but drastically lowers the tails of extreme and undesirable outcomes.

Portfolio theory and scenario analysis can also be used in combination, where scenario analysis provides the basis for describing the uncertainty space and portfolio-based approaches then help to identify optimal risk hedging strategies and resulting technology portfolios.

Summary Points

- Formal tools, e.g., scenario analysis and portfolio theory, are increasingly available to move technology policy decisions (e.g., R&D, or early niche market investments) onto a more rational ground.

- A generic pattern from modeling studies that applies these methods to the field of energy technologies involves *portfolio diversification* and *enhanced experimentation* with earlier niche market investments, the extent of which depends on the (user specified) degree of risk aversion in addition to the underlying innovation uncertainty distributions.

- A comparison of technology portfolio scenario studies with past and current energy R&D portfolios reveals that the latter are highly biased, with energy efficiency/conservation underrepresented and nuclear R&D overrepresented in comparison to their respective option values in a climate-constrained world.

24.7.4 Knowledge Depreciation[35]

The case study first reviews the sources of knowledge depreciation that consist of knowledge lost (e.g., due to staff turnover), as well as knowledge made obsolete (e.g., due to rapid innovation). The literature of typical knowledge depreciation rates is reviewed and the limited examples related to energy technologies are discussed in more detail. Illustrative calculations show the implications of knowledge depreciation for two groups of energy technology innovations: nuclear power and energy efficiency based on public energy R&D statistics of IEA member countries (Table 24.15).

Summary Points

- Knowledge depreciation rates – characterized by high staff turnover – can be substantial, reaching 100%/year in service industries. In the energy technology field, knowledge depreciation rates range from 10%/year (wind turbines) to 30%/year (solar PVs) due to technological innovation-induced knowledge obsolescence.

34 Sabine Fuss and Arnulf Grubler.

35 Arnulf Grubler and Gregory Nemet.

Table 24.15 | Current (2007) and cumulative (1974–2007) R&D expenditures of IEA member countries in $US_{2007}$$ billion and estimate of remaining knowledge stock, assuming an average knowledge depreciation rate of 20%/year.

	current R&D		cumulative R&D		remaining knowledge capital stock	
	10^9 $US_{2007}$$	%	10^9 $US_{2007}$$	%	10^9 $US_{2007}$$	as % of cum. R&D
Energy efficiency	1.6	13.1%	38	8.8%	7	**18.4%**
Fossil fuels	1.4	11.5%	55	12.8%	6	**10.9%**
Renewables	1.5	12.3%	37	8.6%	6	**16.2%**
Nuclear fission	3.7	30.3%	194	45.1%	18	**9.3%**
Nuclear fusion	0.9	7.4%	42	9.8%	4	**9.5%**
Others	3.1	25.4%	64	14.9%	13	**20.3%**
Total	12.2	100.0%	430	100.0%	54	**12.6%**

Source: IEA, 2008b and authors' calculation.

- With knowledge depreciation, continuous knowledge recharge through sustained and stable R&D and niche market deployment efforts becomes critical.

- The *pathway* (stable, gradually rising) of policy support is as – if not more – important than the *absolute level* of policy support when characterized by "boom and bust" innovation investment cycles.

- Erratic policy support leads to substantially higher knowledge depreciation, even under otherwise high support levels. Estimates of the energy technology R&D knowledge stock for IEA member countries suggest that nuclear has suffered substantially more from knowledge depreciation than energy efficiency, which is characterized by much lower but more stable R&D expenditures.

24.7.5 Metrics for Assessing Energy Technology Innovation[36]

Assessing the performance of energy technology innovation processes or systems is complex. There are different assessment methods or approaches – both qualitative and quantitative – as well as many different assessment metrics, which are reviewed in more detail in the case study. These metrics are proxies for innovation inputs, outputs, and outcomes that are either intangible (e.g., knowledge stock, practical problems and solutions) or tangible (e.g., scientists, laboratories, installed technologies). *Input* metrics describe financial and labor inputs to the innovation process (e.g., R&D investments). *Output* metrics describe defined products of the innovation process (e.g., cost reductions). *Outcome* metrics describe broader energy sector or economy-wide impacts of the successful diffusion of innovations into the marketplace (e.g., reduction in emissions intensity).

Energy technology innovation is characterized by a mixed, staged involvement of both public and private resources, and an interdependent set of time-lagged processes linking innovation inputs to outputs. In other fields, econometric techniques are commonly used to evaluate outcome metrics such as net social returns on R&D. However, their application to date in the energy field has been limited due to data constraints, as well as the lack of consensus on objectives. Unanswered questions include: does successful energy technology innovation reduce energy or carbon intensity? Reduce unit costs? Reduce the cost of final service provision? Improve security, reliability, and flexibility? Increase option value?

Cross-country comparisons using both quantitative and qualitative approaches are complicated by the absence of standardized data, local specificities in energy technology innovation systems, and confounding factors such as labor cost differentials, intellectual property rights systems, and economic structure.

Summary Points

- Assessments of energy technology innovation can be qualitative, quantitative, or a combination of both. Qualitative assessments often complement the analysis of time series data by adding analytical rigor and depth.

- Assessments typically center on a particular technology within a national context, and/or focus on the effectiveness of innovation policies.

- Metrics of energy technology innovation relate to either *inputs*, *outputs*, or broader *outcomes* of the innovation process. With the partial exception of technological learning rates, there are no metrics that comprehensively link inputs to outputs and outcomes.

- The lack of available and reliable data on innovation inputs and outputs hampers standardized and cross-comparable assessments of energy technology innovation systems across technologies and countries.

24.7.6 China: Energy Technology Innovation Landscape[37]

The case study provides a first-time comprehensive (even if in some aspects, incomplete) overview of the entirety of the energy technology innovation landscape in China. Major programs, institutional actors, funding sources, and R&D allocation by broad technology groupings are outlined and draw on data for the year 2004 (Table 24.16). Mechanisms for setting innovation and R&D priorities as well as strategic and priority areas for China's ETIS are outlined.

Summary Points

- Energy technology R&D in China is both substantial and expanding rapidly. The survey is partially incomplete, as it does not cover R&D in the automotive and other end-use technologies (e.g., appliances) industries. Nevertheless, the survey indicates a total resource mobilization of greater than RMB29 billion in 2004 for energy technology R&D. This translates to either $3.5 or $9.4 billion, based on either market or purchasing power exchange rates, respectively, and compares to a total public energy R&D budget of the United States of US$5.6 billion in the same year.

- Despite its unique feature as a largely centrally planned economy, energy technology R&D in China (not unlike in OECD economies) is dominated by industry, which performs 88% of R&D. Largely government owned enterprises also provide for some 85% of all energy technology R&D funding in China.

- The energy technology portfolio (again, not unlike in OECD countries) is dominated by supply-side options, even considering incomplete data available for end-use technologies such as the automotive sector. Within energy supply technologies, fossil fuel-related technologies account for more than 50% of all energy R&D, followed by electric power and T&D with more than 30% of all energy R&D.

24.7.7 Energy R&D in Emerging Economies (BRIMCS)[38]

This case study provides an overview of energy RD&D expenditures of six major emerging economies referred to as BRIMCS: Brazil, the Russian Federation, India, Mexico, China, and South Africa. For comparison purposes, corresponding US data are also included. The data summarized below synthesizes a wide array of sources that have to date not been compiled in a consistent fashion. RD&D expenditures are differentiated by broad technology group as well as by funding source based on the most recent published data available in each country (Table 24.17). Funding sources include (federal) government or 100% state-owned enterprises (SOE), as well as other sources such as local governments, partially-owned SOEs, private industry investments, or NGOs.

** United States data on industry expenditure is from 2004 (NSF, 2009).

1 Based on PEMEX's fund for Scientific and Technological Research on Energy.

2 Based on total non-governmental investments into PBMR Ltd.

3 Based on 2005 R&D expenditure in car manufacturing industry (CONACYT, 2008).

4 Based on 2005 R&D expenditure in utilities sector (CONACYT, 2008).

> These cumulative values are based on data from only three to four BRIMCS countries, so actual expenditures are likely to be higher.

>> These cumulative values are based on data from two BRIMCS countries or less, so actual expenditures are expected to be much higher.

Source: Chapter 24 case studies and Kempener et al., 2010a.

Summary Points

- Public energy RD&D in BRIMCS countries is substantial and amounts to some $14 billion in PPP terms, slightly above the entirety of the public energy R&D budget of all IEA member countries combined (some $13 billion in PPP terms). Including non-governmental R&D funding sources, total R&D in BRIMCS countries is estimated to total nearly $19 billion.

- The significance of energy RD&D expenditure in BRIMCS countries challenges the traditional view that new energy technologies are predominantly developed within OECD countries and points to the need to include the BRIMCS countries in regular international statistical reporting and in a comprehensive global strategy to promote energy technology innovation.

- BRIMCS countries' energy RD&D data show that fossil fuel and nuclear energy receive the highest level of RD&D support, with renewables and energy efficiency highly underrepresented both in expenditures and statistical reporting.

24.7.8 Venture Capital in the Energy Industry[39]

Access to capital is a major enabler to the scale and speed of technological innovation as produced by entrepreneurs. Entrepreneurial firms face a multitude of risks and barriers. For those working with new technologies, technological, market, and financing risks are paramount. Venture capital (VC) is a source of capital that is willing to finance companies in this risky

39 Anastasia O'Rourke.

stage of the technology life cycle. By investing equity in such risky companies, VC investors are often considered "technology gatekeepers" who have helped to select and create "waves of technological innovation" that have transformed industries (Florida and Smith Jr., 1990).

The case study reviews recent trends in energy VC investments by category and region, drawing on and synthesizing a large body of literature and statistical information that has to date not been available in the public domain. There has been a dramatic growth of VC investment in clean energy technologies since the mid to late 2000s. Detailed statistical trends are presented in the VC case study.

Summary Points

- In 2008, the total amount of energy (fossil and non-fossil) investments made by professional VCs worldwide was US$15.5 billion.
- The compound annual growth rate (CAGR) for the period 2004–2008 is 22%/year of the number of investment rounds (deals) and 45%/year CAGR for the total amounts invested.
- The bulk of the investment went to North American and European companies with non-fossil-based energy generation technologies (solar; biofuels and biomass) and to storage technologies (particularly batteries). Significant investments were also made in end-use energy technologies such as smart energy metering in buildings, demand response software systems, or high-efficiency engines.
- While growth in VC investments has been dramatic, VC makes up only a comparatively small portion of all the capital employed to launch energy technologies into the market worldwide.
- Other niche-market investments in energy are needed as well. These include investments made at a very early stage by private individuals (angel investors); large company internal investments; investments in late-stage growth and private equity (primarily using debt instruments); project finance (also debt, often used to build larger-scale energy production facilities such as wind farms); and finally, investments in energy-technology firms that are listed on various public markets.
- The contribution of VCs to all private investments in energy combined sits at approximately 10%, according to data from New Energy Finance (IEA, 2009a; UNEP/SEFI/NEF, 2009).

24.7.9 Hybrid Cars[40]

This case study reviews the available literature on the development and deployment of hybrid-electric vehicles (HEVs), and particularly examines the role of government in this history. Three country-specific case studies are provided for Japan, the United States, and China. Key factors in the development and deployment of HEVs are identified and discussed.

Some governments are interested in promoting HEVs and other alternatives to conventional internal combustion (IC) engines because of concerns about oil security, air pollution, and global climate change. HEVs achieve greater fuel efficiency than conventional IC vehicles, although the extent of improvement in efficiency depends greatly on the configuration of the specific HEV system.

The three case studies below show that the drivers of invention did not substantially differ among the three countries, but the policy mechanisms and incentives for deployment diverged significantly. In all three countries, the governments originally pushed harder for alternative automotive technologies other than hybrids, such as pure electric vehicles or hydrogen-fuel-cell vehicles. In some cases, private firms made R&D choices that do not appear to have been strongly influenced by public policy, other than to provoke the firms to explore fuel-efficient technologies. In other cases, government policies appear to actually have turned firms away from HEVs. Once HEVs emerged in the marketplace, however, the government response was completely different in the three countries, especially in terms of the extent to which each government was prepared to support their transition through the "early deployment" phase of innovation to facilitate widespread market diffusion.

Summary Points

- Policy for government investments in the RD&D of advanced-vehicle technologies was initially poorly coordinated, with policy for the early deployment of these technologies in all three countries. Japan and the United States reactively established policies to support the early deployment of HEVs once they were introduced to the market, but Japan implemented much more effective policies to support commercialization than the United States.
- Hybrid car consumers are clearly responsive to increased gas prices and other fiscal incentives, including sales tax reductions or exemptions and feebate schemes, and they also appear to buy hybrids out of concern for the environment or energy security.
- Leadership within firms appears to have been a major factor in explaining the relative success among the firms in developing and commercializing HEVs.
- Political and economic factors, most prominently the concern about energy security, were initially the main drivers for government technology policy and investments in advanced vehicle technologies in Japan, the United States, and China.

40 Kelly Sims Gallagher.

24.7.10 Solar Water Heaters[41]

The experience of innovation policy related to solar water heaters in the United States is a story of policy intermittency. A key general finding is that bad outcomes are often not easily forgotten, and can have substantial spillover effects on other technologies. This presents a challenge to the need to support experimentation and intelligent failures.

Solar water heaters (SWH) use a working fluid to absorb sunlight and provide heating and hot water in residential and commercial settings. The technology is currently cost effective, especially in large installations with high demand for hot water. Real-time electricity pricing is considered a potential boost to SWH. China is by far the world's largest market for solar water heaters. An important historical episode for this technology was the programs in the United States in the late-1970s and early 1980s. The biggest technical improvement was the advent in the 1970s of selective coatings, which would absorb more sunlight. Since then, the technology has been rather stable, with some improvements in lifetime and reliability. The key period of R&D investment was in the 1970s at national laboratories and universities. The subsidies in the 1980s were not monitored. There was rampant abuse of subsidies in the 1980s, and many installations leaked and caused extensive damage to structures far in excess of the cost of the water heater itself. The response was to avoid the technology for many years; the US industry went from US$1 billion/year in 1982 to US$30 million/year in the late 2000s. Hundreds of firms went out of business. As a result, much of the learning gained in the period of rapid deployment was lost. The perception of poor reliability persists and has proven difficult to overcome – bad news lasts. An exception to this general policy failure has been a program in Hawaii that makes consumer rebates contingent on an inspection that occurs one year after installation.

Summary Points

- A large, high-profile failure in the early stage of the US SWH industry has proven extremely difficult to overcome.
- For several years after this failure, the technology was not trusted.
- Experience was lost with the collapse of the industry.
- Verification is essential and not expensive.
- Inspection and verification have proven successful in Hawaii.
- Both R&D and incentives placed excessive focus on collector units rather than on system integration.
- Lack of involvement of utilities and builders appears to have hurt the industry.

24.7.11 Heat Pumps – Innovation and Diffusion Policies in Sweden and Switzerland[42]

Innovation and diffusion policies for the development and introduction of heat pumps provide an interesting case study on policy learning. Heat pumps have been supported by several countries since the 1970s as a strategy to improve energy efficiency, support energy security, reduce environmental degradation, and combat climate change. Sweden and Switzerland have been essential to the development and commercialization of heat pumps in Europe. In both counties, numerous policy incentives have lined the path of technology and market development. Early policy initiatives were poorly coordinated but supported technology development, entrepreneurial experimentation, knowledge development, the involvement of important actors, the formation of essential associations and organizations, and early market formation. The market collapse in the mid-1980s could have resulted in a total failure – but did not. The research programs continued in the 1980s, and a new set of stakeholders formed – both publicly and privately funded researchers, authorities, and institutions – and provided an important platform for further development. In the 1990s and 2000s, Sweden and Switzerland introduced more coordinated and strategic policy incentives for the development of heat pumps. The approaches were flexible and adjusted over time. The policy interventions in both counties supported essential learning, successful development and diffusion processes, and cost reductions of the heat pumps. The assessment of innovation and diffusion policies for the heat pump systems can be used to illustrate some general policy conclusions.

Summary Points

- The assessment shows the need for strategic, *long-term*, and *continuous* support. First attempts to introduce a new technology failed, and continuous support was needed to overcome initial shortcomings. Technological change takes considerable time.
- The combination of policy instruments may have to change and the government's approach should be *flexible*. The policy intervention may initially allow uncoordinated intervention to support entrepreneurial testing, but then should be developed into credible, stable, and transparent strategies that allow industry to make long-term investments.
- The policy interventions need to be *system-oriented* and consider both the development of the technology and its emerging market. In

41 Gregory Nemet.

42 Lena Neij, Bernadett Kiss, and Martin Jakob.

other words, R&D is important as a part of the policy strategy, but not enough.

- The assessment indicates a need for *testing and certification* processes to support technical quality and create credibility and legitimacy. R&D initiatives and subsidies require testing and certification to support a stable market development.

- The support of networking to improve strategic integration and the use of learning and to ensure feedback and spillover effects seems essential.

24.7.12 Role of Standards – The US CAFE Standard[43]

In 1975, the US government passed the Federal Automotive Fuel Efficiency Standards, which specified mandatory levels of miles per gallon of gasoline consumed for new vehicles averaged across each manufacturer's vehicle fleet. The required Corporate Average Fuel Efficiency (CAFE) standard increased from 18 miles per gallon (13 liters/100 km) in 1978 to 27.5 miles per gallon (8.6 liters/100 km) in 1985. The standard was effective in meeting its goals; actual fuel efficiency has never fallen below the government requirement. In fact, actual fuel efficiency has almost always exceeded the mandatory level. This over-compliance, combined with the collinear rise in the price of gasoline during the period of escalating standards, suggests that prices have played a role in motivating efforts to improve fuel efficiency, not the CAFE standard alone. The standard for passenger cars has remained the same since 1985, while actual efficiency has improved slightly. The standard will rise to 30 miles per gallon (7.8 liters/100 km) in 2011. Standards also exist in Europe, China, Japan, Australia, and Canada, and are well in excess of US requirements – by nearly 100% in the cases of Japan and the European Union.

The CAFE standard has affected the rate and direction of technological change in vehicles. End-use efficiency has improved almost continuously for the past 30 years. This rise in efficiency was used to accomplish different ends during the period of policy escalation (1975–1985) and after it (1986-present). In the first period, efficiency improvements were directed toward improving miles per gallon. After 1985, almost all of the efficiency improvements were used to increase other attributes, including acceleration, towing capacity, and vehicle size. Energy conversion efficiency has improved in drive trains, engines, drag, and rolling resistance. Drive train and engine energy conversion efficiency improved from 1975–1985; efficiency improved at the rate of 2–3%/year. After 1985, efficiency improvement slowed to about 1%/year, although that rate has increased since 2000. The continuity of this improvement makes it difficult to attribute to CAFE. However, consideration of what end-use characteristics these efficiency gains were used for is revealing; from 1975–1985, vehicle weight dropped by about one-third and acceleration remained the same. After 1985, when CAFE standards stopped rising, efficiency improvements were used to power increasingly heavier vehicles that could accelerate considerably faster. It needs to be noted that the CAFE standards did not apply to all road vehicles, excluding in particular light duty trucks, which incentivized a change in the composition of the road vehicle fleet towards pick-up trucks and, later on, Sport Utility Vehicles (SUVs) with much higher gasoline consumption CAFE regulated passenger cars.

Summary Points

- CAFE standards had a real effect on technological change.

- The improvement in miles per gallon was accomplished not only by a shift to lighter, less-powerful vehicles, but also by the adoption of new energy-efficient technologies.

- Attribution of these changes to the regulations, rather than to gasoline prices, is less clear since the two are so well correlated.

- Standards that apply only to parts of the technological artifacts in use risk behavioral responses from manufacturers and consumers that can go against the original intention of the efficiency regulation.

- The effectiveness of CAFE may actually have been important after 1985 when it served as a fuel economy floor in the face of persistently low gasoline prices.

24.7.13 Role of Standards – The Japanese Top Runner Program[44]

In 1998, Japan initiated a unique program – the Top Runner Approach – to improve the energy efficiency of end-use products and to develop "the world's best energy-efficient products." Under this program, the most energy-efficient product on the market during the standard-setting process sets the Top Runner Standard for all corresponding manufacturers and products.

The Program started with nine products: room air conditioners, fluorescent lighting, television sets, copying machines, computers, magnetic disk units, video cassette recorders, refrigerators, passenger vehicles, and freight vehicles. The scope was reviewed every two to three years and gradually expanded to include 21 products by 2009. It is now considered one of the major pillars of Japanese climate policy. The case study examines 12 years of the program's experience. It first reviews the structure of the Top Runner Approach and then illustrates its impacts. It

43 Gregory Nemet.

44 Osamu Kimura.

also discusses issues associated with the approach, and concludes with some implications.

Summary Points

- Dynamic, continuously adjusted standards have been successful in accelerating the trend of energy efficiency improvement in many end-use products, such as room air conditioners and passenger vehicles. In these cases, the standards provided a clear direction for product development by aiming at higher energy efficiency and eliminating low-efficiency products from the market.

- The case study illustrates that ambitious policies that match market conditions and technological conditions can work well to induce remarkable energy efficiency improvements. Because such conditions depend on the country and the phase of technological development, careful design and adjustment are required for effective policy making.

- Some preconditions may be necessary for success of the Top Runner Approach. One is the Japanese market structure, which is dominated by a limited number of domestic producers. Another precondition is the existence of cost-effective potentials for efficiency improvement. Last, the specifics of the Japanese systems of innovation, in which public and private sectors cooperate largely through informal networks in the dynamic standard setting and implementation process, may be a further precondition for success. When these conditions were met, the Top Runner Approach resulted in a substantial outcome in terms of efficiency gains.

- Although the achievement of the Top Runner Approach is remarkable, there remain some issues for policy consideration. The largest one is the lack of explicit consideration of potential impacts on consumers in the standard setting process. Because the approach is based on the Top Runner products on the market, price increases due to energy efficiency improvements are not explicitly considered. This might lead to product prices too high for consumers to achieve pay back within the lifetime of the product.

24.7.14 Comparative Assessment of Wind Turbine Innovation and Diffusion Policies[45]

Wind turbines have become a mainstream technology – a first choice for many when investing in new electricity generation facilities. This comparative case study addresses how governmental policy has been formulated and formed to support the wind turbine innovation process. Three innovation stages and corresponding innovation strategies are identified. First is the stage of early movers in the 1970s and early 1980s, covering pioneer countries such as Denmark, the United States, Germany, the Netherlands, Great Britain, and Sweden. Second, the stage of booming markets in the 1990s, guided by the successful Danish innovation path of the 1980s, is described. Third is the stage of emerging markets in the 1990s and 2000s, including countries such as India, China, and Korea. Within these different periods, common key elements in governmental policy strategies can be identified as essential for a sustainable and successful innovation process.

Summary Points

- Support for diversity in technology and market formation is essential. The experience of wind turbine policy intervention shows the importance of applying a diversified technology portfolio. Moreover, the study illustrates the difficulties in foreseeing the drivers and trends of any given technology and the need to provide subsidies for implementation to many actors.

- RD&D is fundamental but not enough. In many countries, wind energy innovation was initially supported through RD&D only and the innovation process was envisioned to be linear. However, the RD&D funding alone did not bring about any commercial applications.

- To support technology innovation, quality assurance is essential. An important component of the innovation path of wind turbines was the development of a certification process.

- Support for innovator interaction and networking is essential. However, models for interaction and networking have only gradually developed over time and have been designed differently in different countries.

- Support requires a systemic approach. The case of wind energy shows that governmental policy needs to support the development of the entire innovation system, i.e., the development of the turbines and its infrastructure, but also the involvement of actors, necessary networks, and institutions.

- Support needs to be stable and continuous. The history of wind turbines development is long; it started in the 1880s. Many failures have occurred over time. The continuous support allowed knowledge creation and learning, as well as essential market formation that paved the successful innovation path of onshore wind energy and that now is the basis for the development of offshore wind energy.

24.7.15 Comparative Assessment of Photovoltaics (PV)[46]

A variety of factors, including government activities, have enabled the two order-of-magnitude reductions in the cost of PV over the past five decades. Despite this achievement, the technology remains too expensive

45 Lena Neij and Per Dannemand Andersen.

46 Gregory Nemet.

compared to existing electricity sources in many applications, such that widespread deployment depends on substantial future improvements. No single determinant predominantly explains the improvement to date; R&D, economies of scale, learning-by-doing, and knowledge spillovers from other technologies have all played a role in reducing system costs. Moreover, interactions among factors that enable knowledge feedbacks – for example, between demand subsidies and R&D – have also proven important.

Conversion efficiency, economies of scale, and the emergence of sequential niche markets have been important factors accounting for the impressive cost reductions in PV. Improvements in electrical conversion efficiency have been important to cost reductions, accounting for about one-third of the decline in cost over time. R&D, especially public sector R&D, has been central to this change. Deployment of PV has benefited from a sequence of niche markets where users of the technology were less price sensitive and had strong preferences for characteristics such as reliability and performance, which allowed product differentiation. Governments have played a large role in creating or enhancing these niche markets. Increasing demand for PV has reduced costs by enabling opportunities for economies of scale in manufacturing. Japan's program was especially innovative in that it took not only a long time horizon but also set a declining subsidy such that it fell to zero after the 10 years of the program. This provided not only expectations of demand, but also clear expectations of future levels of subsidy. The Renewable Energy Law in Germany in the 2000s successfully replicated many of the features of Japan's program.

Summary Points

- An array of supporting policy instruments is required: R&D, demand subsidies, etc.
- Timing matters: the question of when to switch from a focus on R&D to deployment is important.
- Much of the success of multiyear demand-side programs (in Japan and Germany) is because these programs created long-term expectations of future demand that enabled large investments in manufacturing facilities, which brought down costs through economies of scale.
- R&D support also needs a long-term commitment, whether through budgets or grants spanning multiple years, or supporting policies. Examples of supporting policies include Japan's Sunshine Program and the United States' Project Independence, which demonstrated commitment by making this area of work a serious national priority.
- Niche markets have been crucial, although they are most effective when not government supported.
- The success of new technological generations may require renewed R&D support even while markets for the existing technology are expanding.

24.7.16 Solar Innovation and Market Feedbacks: Solar PVs in Rural Kenya[47]

The solar PV market in Kenya is among the largest and most dynamic per capita in the world. Over 30,000 systems are sold each year. Much of this activity is related to the unsubsidized, purely free market sale of household solar electric systems, which account for an estimated 75% of solar equipment sales in the country. Solar is the largest source of new electrical connections in rural Kenya.

Despite this undisputed commercial success, product quality has been a significant concern (Jacobson and Kammen, 2007). Quality problems emerged first with the amorphous silicon solar modules that entered the Kenyan market in the early 1990s. This situation created a serious problem in the market, as many potential solar customers were unable to determine which brands performed well and which did not. Through independent testing in 1999, underperforming suppliers and models were identified and consequently withdrawn from the market, but quality problems resurfaced after 2004.

In response, the Kenya Bureau of Standards (KBS) moved to formulate and enforce quality standards for both amorphous and crystalline silicon PV modules. Currently, the KBS requires that import companies secure a certificate that validates their product conforms to the respective Kenyan standards prior to bringing the modules into the country. This certificate of conformity must be issued by an accredited laboratory. No such facility exists in Kenya, so this testing needs to take place in laboratories in Europe, North America, and Asia.

Summary Points

- Product quality assurance and standards constitute an important element for the diffusion of new energy technologies, particularly for decentralized systems like solar PV that are installed at residential sites by local businesses relying on imported modules.
- The recurrent emergence of quality problems in the Kenya PV market confirms that the issue of product quality control cannot be solved decisively by one-time testing efforts or focusing on the improvement of individual low-performing brands. Rather, institutional solutions that persistently require high performance for all brands are needed to ensure quality.

47 Daniel Kammen.

- The formulation, implementation and enforcement of product quality standards requires appropriate local institutional capacity, which needs to be developed and maintained for each market.

- The potential market feedbacks between end-users and suppliers of energy technologies can be weakened when testing stations are only available overseas.

24.7.17 Solar Thermal Electricity[48]

Solar thermal electricity (STE) production technology has improved through a combination of learning-by-doing and R&D investments. Even though R&D levels for this technology were small (even declining) relative to other energy technology programs, these programs played an important role in making full use of the knowledge gained through experience in manufacturing, installation, and operation of these facilities. R&D helped codify and document the often-tacit knowledge that accrued to operators through experience. As a result, this knowledge could be shared across firms and even across countries. It also preserved at least some of the value of the knowledge over time – especially during more than a decade of stagnation in the 1990s, when essentially no large plants were built worldwide. The rebirth of the STE industry during the 2000s indicates that at least some of this knowledge accumulated in the 1980s informs current designs and operation.

Most of our historical knowledge about technical change in STE comes from the 350 MW (mostly troughs) systems that were deployed in California in the 1980s. Since the mid-2000s, a new round of installations has begun, primarily in Spain and the southwestern United States. These installations encompass all three types of STE systems: troughs, concentrators, and dishes. By the end of 2010, total STE capacity neared 1 GW, and several additional GW (>2 in Spain, >3 in the United States) are likely to break ground in 2011. A distinguishing feature of STE, relative to other renewables, is that STE requires big, risky investments. Early investors may have to "eat between one and three US$200 million plants" before improvements enable profitable operation. A policy implication is that the scale of technology requires different types of incentives from smaller-scale renewables such as PV. Two policy instruments are driving a resurgence in STE installations over the past 10 years: (1) California's aggressive renewables obligation, possibly increasing to 33% by 2020; and (2) Spain's feed-in tariff. Complementary policies, such as loan guarantees and tax credits, have driven investment as well.

Summary Points

- Interaction between learning-by-doing and public R&D investment – even if small – was important for the substantial decline in operating costs of STE systems.

- This technology appears to be one for which higher R&D could not have substituted for deployment; learning by doing was essential.

- Initial investments required were large, and chunky, due to scale. Firms knew they would need to absorb losses on the first few plants – a classic valley of death problem that was eventually overcome by the alternative energy bubble on Wall Street in the 1980s. As a result, early plants needed both guaranteed tariffs and capital cost subsidies.

- Part of the value of the R&D investment was the formal documentation of cost improvement efforts, which was publicly available and nonproprietary.

- Technically, the 1980s California (solar energy generating system) plants have been successful. They steadily improved their performances, are still providing power two decades after they were installed, and provide the basis for newly designed plants in Spain and California. The failure of the company that built them was due to falling energy prices and consequent changes in policy rather than technical problems, illustrating the substantial market risks associated with policy intermittency.

24.7.18 The US Synthetic Fuels Program[49]

In response to the drastic oil price increase in the wake of the oil crises in 1979, subsidies for the demonstration and deployment of synfuels – a supply-side technology – received a rare confluence of support from the US government and energy experts (Deutch and Lester, 2004). The policy objective was to ameliorate the energy-security consequences and macroeconomic effects of the US dependence on imported oil by using the country's extensive coal, heavy oil, and oil shale deposits. Given estimates that synfuels would cost only US$60/barrel against the backdrop of (erroneously) projected rapid further increases in oil prices, the demonstration and deployment of synfuels production capability was seen as a major backstop or insurance policy (Deutch, 2005). The US Congress created the Synthetic Fuels Corporation (SFC) in 1980 and gave it the ambitious mandate to achieve production of 0.5 million barrels/day by 1987, and 2 million barrels/day by 1992. The goal of producing 2 million barrels/day in 1992 would have replaced over one-quarter of US crude oil and petroleum product imports, implying a scaling-up to one-quarter of the entire market in only 12 years, which was clearly unrealistic. Five and a half years later, and after expenditures of billions of dollars, the program was terminated without achieving its production goal (Gaskins and Stram, 1991).

Summary Points

- Deterministic cost-benefit analysis should not be the only measure used to make policy decisions when there is deep uncertainty

48 Gregory Nemet.

49 Laura Diaz Anadon, Gregory Nemet, with contributions from Bob Schock.

associated with market conditions (future oil prices) and technical feasibility. Policies aimed at providing insurance against a risk that does not materialize do not necessarily imply a policy failure.

- The mandate to meet ambitious production targets in relatively short timeframes regardless of market conditions and with little technical information was highly risky, partly because of the high expenses involved and partly because it was not accompanied by a long-term vision and corresponding innovation patience.

- Deciding when there is enough technical information to move from applied R&D to demonstration and deployment (or, in the SFC case, production) is difficult, yet crucial. This is especially the case in a situation in which the market and political environments change quickly. In large technology demonstration efforts, a good management and evaluation system is necessary to allow for timely decisions about whether and when to redefine program goals.

- Boom and bust cycles of support should be avoided, as they disrupt the innovation process, result in knowledge depreciation, and deter wider engagement in the enterprise.

- Policy backlash – the risk aversion induced by generalizing the experience of perceived failure of one program to unrelated programs – can have important and long-lasting effects.

24.7.19 The French Pressurized Water Reactor Program[50]

The case study reviews the French nuclear Pressurized Water Reactor (PWR) Program as an example of successful scaling-up of a complex and capital-intensive energy technology. Starting in the early 1970s, France built 58 PWRs with a total gross installed capacity of 66 GWe. On completion in 2000, they produced some 400 TWh/year of electricity, or close to 80% of France's electricity production. The institutional setting is characterized by a number of features. These include a high degree of standardization; external learning via the use of proven US reactor designs under a Westinghouse license; high regulatory stability; the effective absence of any public opposition; and a powerful national utility, ÉDF (Électricité de France), which acted both as *principal* and *agent* in reactor construction. The case study reviews the economics of this successful scale-up of nuclear reactor technology, identifying a significant cost escalation in real-term reactor construction costs, but also a remarkable stability in reactor operation costs. This cost stability is particularly noteworthy considering the need for load modulation in a system relying as heavily on base-load nuclear as in the case in France.

Summary Points

- Even under a most favorable institutional setting, earlier hopes of significant declines in nuclear reactor construction costs did not materialize, illustrating a case of negative learning much like the example of the United States (although cost escalation in France remained substantially below US trends).

- The case study thus demonstrates the limits of the learning paradigm: the assumption that costs invariably decrease with accumulated technology deployment. Not only do nuclear reactors across all countries with significant programs invariably exhibit negative learning (cost increase rather than decline), but the pattern is also quite variable, defying approximations by simple learning-curve models.

- While reactors' real construction costs increased steadily, their *operating* costs remained low and flat in France, as well as for many reactors elsewhere. Perhaps nuclear's "valley of death" is its inherently high investment costs and their tendency to rise beyond economically viable levels. The success of ÉDF in combining principal *and* agent in the construction process, which limited price escalation trends (especially in comparison to the US experience), could be an option worth considering for minimizing cost escalation. Conversely, this logic may suggest that competitive nuclear power is unlikely to be achieved in a private free market, which instead is tending to produce the rapid innovations that now competitively challenge nuclear power.

- The case study also provides valuable lessons for energy technology and climate policy. Cost projections of novel technologies are an inherent element in any climate change policy analysis. The case study confirms the earlier conclusion of Koomey and Hultman (2007) that projections of the future need to be grounded much more firmly within the historical observational space. Climate policy analysis must include a wider variation in cost uncertainties, as revealed by past experiences, than has previously been assumed in policy analysis and models.

24.7.20 Ethanol in Brazil[51]

Brazil's first ethanol program (PROALCOOL), launched in 1975, was a direct response to the dramatic rise in imported petroleum prices in 1973. The military government of the time saw this as a challenge to Brazil's financial stability and energy security, since the country imported 80% of the fuel used by its transport sector. Moreover, Brazil had extensive sugar plantations that were facing increased challenges to their exports from European Union trading preferences with the African, Caribbean,

50 Arnulf Grubler.

51 Paulo Teixeira de Sousa Jr. and Lynn Mytelka.

and Pacific Associated States – ACP countries – and the emergence of corn syrup and other close substitutes for sugar.

PROALCOOL was initially a classic import substitution policy. Subsidies were used to expand ethanol production, then in its infancy, and to induce users to shift to dedicated engines for ethanol that could handle a gasoline blend with more than 5–10% ethanol. When gasoline prices fell a few years later, those who had shifted were left paying the higher costs of ethanol, while the original problem of oil imports remained.

In this changed context, the government decided to invest in the research needed for Brazil to become a more efficient ethanol producer and thus be in a position to eventually eliminate subsidies. At the core of this process was a research partnership that brought together the Brazilian Agricultural Research Corporation and Copersucar, a cooperative of sugar mill and ethanol plant owners. Between 1975 and 2002, ethanol production increased from 0.6 to 12.6 million cubic meters and the price paid to alcohol producers dipped below that of Rotterdam gasoline prices (Goldemberg et al., 2004). By early in the new millennium, increasing yields and reduced processing costs (van den Wall Bake et al., 2009) had eliminated the need for subsidies. The decision to develop flex-fuel engines, in collaboration with foreign-owned automobile producers, strengthened the domestic auto industry and led to a dramatic shift in consumption habits and practices, thus further building the market. Introduced in 2003, flex-fuel vehicles accounted for 81% of the light vehicle registrations by 2008 (ANFAVEA, 2008).

Five policy lessons emerge from the Brazilian ethanol experience:

- First, developing a portfolio of fuel options was important for Brazilian development more broadly.
- Second, domestic research was a major contributor to the positive development outcome over the longer term.
- Third, building coalitions among interested parties helped to sustain long-term development efforts.
- Fourth, sugar cane was grown on large plantations, concentrated heavily in a single state. This left few opportunities for small holders and meant transporting ethanol elsewhere around the country with potentially negative effects on net CO_2 benefits.
- Fifth, ethanol from sugar cane tended to maintain the structure of large-scale, concentrated production. Lessons such as these have been applied in the development of the biodiesel sector. A variety of inputs have been identified for biodiesel and several of these are available in most regions and can be grown by small holders and processed and distributed locally.

Executive Summary

This chapter focuses on capacities and capacity development for energy transitions. The transitions put forward in GEA require a transformation of energy systems that demand significant changes in the way energy is supplied and used today, irrespective of whether the technologies involved are new to the world or to a country, its producers or users.

Energy transitions are, by definition, long-term, socially embedded processes in the course of which capacities at the individual, organizational, and systems levels, as well as the policies for capacity development themselves, will inevitably change. From this perspective, capacity development can no longer be seen as a simple aggregation of individual skills and competences or the introduction of a new "technology." Rather, it is a broad process of change in production and consumption patterns, knowledge, skills, organizational forms, and – most importantly – in the established practices and norms of the actors involved, or what are called informal institutions. In other words, a host of new and enhanced capacities will be needed over time. Informal institutions are reflected in a range of beliefs and boundaries that shape choices about new energy technologies. These can include engineering beliefs about what is feasible or worth attempting and boundaries that shape the processes of choice, such as lines of research to pursue, kinds of products to produce, or practices of consultation and dialogue. They also emerge as "path dependence" in contexts where earlier investments result in high sunk costs, habits and practices are entrenched, and "expert views" are shaped by earlier thinking that narrows the range of choices to established technologies and evaluation techniques.

There is abundant evidence of the slow pace at which new energy technologies are being developed and diffused. Many recent studies have pointed to the continued lack of finance as a serious impediment to the transformation of energy systems in both the North and the South. But finance alone, as this chapter illustrates, does not explain the problems encountered in scaling up projects for energy transitions in developing countries. Nor does it provide a satisfactory answer to the question raised in GEA as to why, if more energy-efficient and carbon-neutral technologies are available, they are not more widely used. Investments that involve innovative changes are by their nature costly, risky, and likely to deliver returns only in the long term. How, then, might pathways to energy transitions be built today that do not compromise change in the future, especially in poor countries that can ill afford to make the same mistakes that industrialized countries have done and then expend the resources to clean up and rebuild in the next generation? A first step is to better understand the challenges posed by informal institutions because of the way they shape choices in the development of new technologies and affect the speed of technology diffusion in both developing and industrialized countries. A second is to develop the capacities to work with and around existing habits and practices in carrying out energy transitions.

Societies and organizations differ in the extent to which established habits, practices, and norms favor interaction and dialogue or more hierarchical patterns of communication. Until recently, dialogues have not featured centrally in project planning and development. Case studies of the implementation of onshore wind power in Europe and the diffusion of solar home systems in Asia and Africa illustrate that dialogues play an important role in developing and institutionalizing capacities for energy transitions. Dialogues may not "solve" problems, but they do open channels for innovative ways to deal with them.

For dialogues to work, confidence-building measures that recognize the legitimacy of local concerns, interests, and needs, as well as take account of the informal institutions shaping the behavior of actors involved in the change process, are essential in gaining broad societal support for an energy transition. And this is the case whether it concerns the choice of renewable energies, the adoption of smart grids or improved cookstoves, a shift from individual mobility to urban public transport, or the decision to construct energy efficient buildings. At the broader national level, a framework for domestic consensus building that involves the wider community in discussions about key issues and choices and their consequences must be developed. One such approach is to create spaces for dialogue about transition pathways, processes and policies that bring together members of the public and private sector, academics, and civil society in what the Dutch have called "transition platforms." As energy transitions are long term processes, spaces for dialogue at the national level also help to legitimize feedback and facilitate adaptive policymaking over time.

The choices made in selecting energy transition pathways and the capacities that will be needed in their pursuit are also inextricably linked to broader development issues and goals. These, too, must become visible as part of a dialogue process and the tradeoffs must be made explicit. The successful implementation of wind power in Germany and Denmark and the targeted bottom-up approaches in the development of small hydro projects in China, Bhutan, Nepal, and Rwanda are examples. The latter illustrate the way mutual interests can be accommodated through dialogues in which local government bodies are brought into the process early in the development of a project and a mechanism for continued dialogue and adaptive policymaking over the life of the project is put in place.

In developing countries, a multi-goal approach can both speed the diffusion of new energy technologies and stimulate the development process. Linking to domestic market building by creating or strengthening capacities for the design, manufacture, distribution, and repair of improved cookstoves and multifunctional energy platforms and the installation of solar home systems have generated multiple benefits such as these. Distributed energy systems based on biofuels are also playing an important role in the broader development process. Developing capacities for making choices about biofuels in technical as well as in economic and financial terms and evaluating these trade-offs are of critical importance in creating such benefits and ensuring their long-term sustainability. Greater attention, for example, needs to be paid to assessing whether, when, and how to scale up the production of biofuels in a given context.

Pursuing a multi-goal approach to energy transitions involves an analysis of local resource availability and the early identification of linkages and support structures that will be needed to build local markets for these new technologies. A multi-goal perspective must then be consciously built into policies, programs, and financing mechanisms. Strengthening the capacities of governments, universities, non-governmental organizations (NGOs), and other organizations in data collection and analysis, research, and problem-solving in the relevant science, engineering and social science disciplines will be essential in supporting such policymaking processes. Developing these capabilities, however, can take many years at a time when decisions about energy transitions that involve biofuels and other clean energy technologies require attention now. This chapter thus explores the role that a variety of different forms of networking for knowledge sharing and collaborative problem solving can play in contributing to the development of domestic capacities for research, analysis, and innovation.

Open innovation practices in industrialized countries are already helping to speed up the pace of problem solving in a growing number of sectors. Users, especially companies, but also government agencies and community organizations, are becoming increasingly aware of these possibilities. The core insight of the open innovation approach is the ability to use the world outside an organization to generate internally useful knowledge in a purposeful manner. This involves the development of networks and the capacities needed to use them. Developing countries are now moving in this direction. In particular, they are strengthening their domestic research sector and linking it to the wider economy through incentives to engage in problem solving, facilitate adaptive changes in the course of energy transitions, and support the process of making choices about energy pathways. Open innovation practices were a critical factor in boosting productivity and reducing costs in the development of ethanol from sugarcane in Brazil, as well as in supporting the growing of jatropha in a multi-cropping environment in Mali and the use of jatropha oil for power and electricity generation.

Designing policies to increase the demand for and supply of clean, energy-efficient technologies, speeding their adoption in sectors such as transport, energy, buildings and building materials, and strengthening their contribution to overall development goals requires the capacity to work from a systems perspective. Bringing key actors together in task forces, panels, and platforms could play an important role here. While not yet widespread, there is evidence that universities in a growing number of countries have created interdisciplinary graduate programs in sustainable engineering that could train a new generation of intermediaries and help change the existing reward structure. But more needs to be done, and more rapidly than in the past, to meet GEA's goals.

25.1 Introduction

"We can't solve problems by using the same kind of thinking we used when we created them." – Albert Einstein

New capacities and new thinking will be needed to take the world to a more sustainable state. This report has outlined the nature and magnitude of the many challenges ahead. Included among these challenges is the need to bring cleaner energy technologies[1] within the reach of users in the developing world, in terms of both access and price (Chapter 19), and to reduce the negative health impacts of the use of traditional lighting implements, cookstoves and fuels (Chapters 2 and 4). Doing so can create new livelihood opportunities that stimulate growth and reduce poverty, a point we develop in this chapter. From a global perspective, current efforts to reduce greenhouse gas emissions are overwhelmed everywhere by the increasing use of fossil fuels. Thus, worldwide a greater emphasis must be placed on the energy end-use sectors (Chapters 8–10), in order to make use of more energy-efficient technologies and systems, as well as on the supply side, in order to dramatically increase the provision of renewable energies (Chapter 11) while modernizing conventional supply systems (Chapters 12 and 13).

There is abundant evidence of the slow pace at which new energy technologies are being developed and diffused (ESMAP, 2008). Many recent studies have pointed to the continued lack of finance as a serious impediment to the transformation of energy systems in both the North and the South. But finance alone does not explain the problems encountered in scaling-up projects for energy transitions in developing countries. Nor does it provide a satisfactory answer to the question raised in previous chapters as to why, if more energy-efficient technologies are available, they are not more widely used (Chapters 8, 9, 10, 18, and 22).[2] In both developing and industrialized countries, lack of knowledge of, and access to – these technologies are major constraints. Meeting the challenges of energy transitions will thus require more comprehensive and integrated approaches to capacity development than those based mainly on building technical and management skills. As one study on capacity and capacity development cautioned, these concepts "are so all-encompassing that practitioners have often found it difficult to make operational sense of them […] It is [thus] important to begin by asking the question, 'capacity for what?'" (DAC, 2006).

This chapter focuses on capacities and capacity development for energy transitions, with particular emphasis on the pathways explored in Chapter 17.[3] Capacity is defined here as the ability of individuals, organizations,[4] societies, and communities to make choices, perform functions, solve problems, and set and achieve objectives in a sustainable manner. Capacity development is understood as the process through which these abilities are obtained, strengthened, adapted, maintained, or changed over time.

Energy transitions are broadly defined as those processes that involve changes to "new," "clean," "sustainable," or "energy-efficient" technologies and the formal and informal institutions required to support them. There is no assumption that energy transitions take place only at the frontier of global knowledge. Moreover, while seemingly very different, energy transitions have much in common. Each involves changes to existing patterns of production and demand that will require new knowledge, skills, organizational forms and habits, practices and norms, whether the process is taking place in a least developed, developing, emerging, or industrialized economy. Because the points of departure for energy transitions are very different across these varied contexts, it is important to develop approaches that enable us to perceive these differences and take them into account in the design of policies, programs, and processes for energy transitions over time.

The transformation of energy systems, irrespective of whether the technologies involved are new to the world or to a country, its producers or users,[5] is a long-term, socially embedded process that involves a host of other changes that extend beyond merely introducing a new technology. Although capacity development has traditionally been seen as a major concern in developing countries, given the nature and magnitude of the changes needed in energy systems around the world, attention to capacity development is now required globally.

Ultimately, the world must shift to renewable, clean, and green energy sources, zero-energy buildings, and more efficient energy supply systems. This shift will involve multiple interrelated transition processes, each of which will give rise to new capacity issues. As a result, capacity development policies and practices will have to change.

This chapter is structured as follows. Section 25.2 conceptualizes energy transitions. It briefly addresses the theoretical tenets of a transition perspective, as well as how and why it is relevant in helping to understand the levels, processes, mechanisms, actors, and institutions that affect and are affected by technological change. It also introduces the policy dimension in energy transitions. Section 25.3 reviews the capacity development literature and then links the energy transition perspective

1 Clean energy technologies are generally defined to include fuels such as natural gas, liquid petroleum gas (LPG), biodiesel, and bioethanol. Some also include carriers such as electricity and end-use devices, e.g., improved cookstoves (Goldemberg et al., 1985; UN AGECC, 2010; see also Chapter 19).

2 This is also the theme of the UNIDO Industrial Development Report (UNIDO, 2011).

3 GEA-Efficiency is a pathway in which energy demand is low and there is a strong emphasis on energy efficiency standards and regulations across all demand sectors. The GEA-Supply pathway focuses on the rapid up-scaling of supply-side options, a necessary condition for achieving a transition where energy demand remains high. New infrastructures and renewables are also important in this pathway. The GEA-Mix pathway is an intermediate transition pathway that emphasizes diversity of the energy supply mix with greater prominence given to local choices and resource endowments and incentives to increase energy efficiency and reduce energy use (see Chapter 17).

4 For example: government agencies, enterprises, universities, farms, and NGOs.

5 This approach to "new" energy technologies is adapted from Ernst et al., 1998.

to the concept of capacity development for energy transitions and the systems-embedded, innovative nature of this process. We argue that models of technology transfer and deployment often fail to appreciate the complexity of change processes, and we introduce the concepts of path dependence[6] and informal institutions[7] as analytical tools.

Having thus set out the conceptual framework, subsequent sections discuss specific aspects of capacity development for energy transitions in developed and developing countries. The sections are organized thematically, paying particular attention to a number of capacity issues raised in the three GEA energy transition pathways. These include energy efficiency; the development of new, clean energy technologies and their diffusion; and the choice of energy supply mix and role of local resource endowments in the development of transition strategies. A range of capacities will be needed to develop and implement these strategies in a manner that will contribute to resolving energy access issues and ensure that they make positive contributions to livelihoods and to sustainable development. The six case studies following the conclusions of this chapter amplify the discussions of these challenges.

Section 25.4 addresses the issue of path dependence and informal institutions as impediments to change. Change processes inevitably face challenges that emerge from established interests, habits, practices, and norms. The case studies in this section illustrate these problems in the adoption of energy-efficient technologies and decentralized energy systems. Section 25.5 addresses the importance of dialogue at the local level among relevant stakeholders, illustrated here in the case of wind power. It also stresses local market development and the role of feedback and flexibility at the project level in supporting the diffusion of new energy technologies. Section 25.6 focuses on distributed energy systems and how they can serve multiple goals and bring about multiple benefits at the local level. Examples include the local production of biofuels and the development of small and micro-hydro stations for lighting and stationary power. Access to knowledge and information is critical in the decision-making processes through which choices about the energy supply mix are made. Section 25.7 discusses some of the capacities that are needed to make such choices and new ways of accessing knowledge, including open and distributed innovation processes and the creation of knowledge networks. The latter are also of interest for the role they can play in reducing the brain drain from developing countries.

The "management" of energy transitions is discussed in Section 25.8, which examines the Dutch energy transition approach as an innovative model for creating strategic intelligence for policy and innovation. The Dutch model is of interest to developed and developing countries because of the potential for creative adaptation of three of its core elements: its focus on transformative change, its reliance on bottom-up processes, and its use of "platforms" to enroll business and other non-state actors in the energy transition process. This section also looks at how oil producers are adapting to the need for change.

Section 25.9 moves to the international level, which has assumed an important role in energy-related negotiations, particularly with regard to trade and technology transfer. The section focuses on strengthening capacities for effective participation in these negotiations. Section 25.10 draws out a number of "lessons" for capacity development and policies that might stimulate and support capacity development processes for energy transitions. These take the form of pointers and issues for consideration rather than a strict list of what actions to take. Capacity development, as we acknowledge throughout, is a complex process that defies a focus on organizations and a simple management approach.

25.2 Energy Transitions: Moving Frontiers

Past energy transitions have been part of broad, systemic processes of change in patterns of production and consumption of goods and services (Smil, 1994; Fouquet and Pearson, 1998; Grubler, 2004). The shift to oil, for example, stemmed from the growing demand for gasoline to power forms of transportation that either did not exist before 1880 (motorized vehicles and airplanes) or relied on the use of wind (ships). The development of automobiles, in turn, owed much to the growing demand for mobility (Geels, 2005).[8]

During each such transition, the old and new energy regimes, based on different technologies, fuels, products, behavior and organizations, co-exist. What is sometimes viewed as a process of technology diffusion is really a more complex transformation process in which a new technological regime grows out of an existing one, with change first occurring in niche markets. The new regime does not emerge in isolation but is connected with the emergence of new technologies, expectations, skills, management systems, supplier-user relationships, ideas, and changes in the regulatory framework (Freeman and Perez, 1988). It sees new fuels and technologies replacing others after a long period of co-existence. Both the technology and social context change in a process that can be seen as co-evolution (Rip and Kemp, 1998). An energy transition thus involves a moving frontier along multiple dimensions. Moreover, these are not deterministic processes, and may fail to emerge or spread, as illustrated in Chapter 19 by the wide gaps in access to modern energy technologies between urban and rural areas of the developing world. Understanding the context in which such transitions occur is critical in bringing about a global energy transformation.

The best theoretical attempt to understand these multilayered processes of systemic change is the transition approach, which is based on a multilevel framework of niches, regimes, and landscapes (Rip and Kemp,

6 Path dependence is the tendency for past practices and decisions to shape present choices.

7 Informal institutions include the traditional habits, practices, and norms of actors in the system.

8 See Chapter 16 for a more extensive discussion of energy transitions in historical perspective.

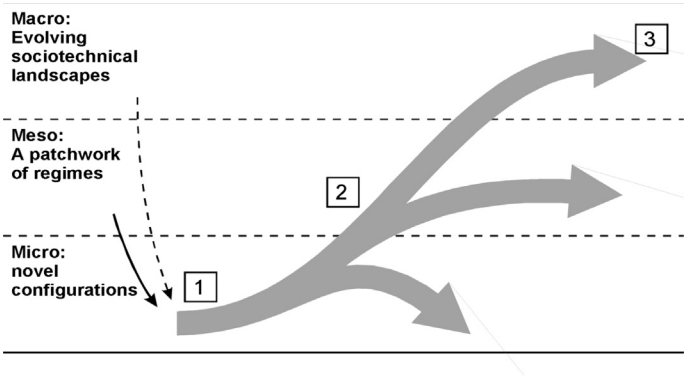

Figure 25.1 | The multilevel transition model. Source: Rip and Kemp, 1996.

1996; 1998; Geels, 2002; 2004; 2005; Geels and Kemp, 2012). Central to the transition framework are regimes, i.e., the dominant practices, search heuristics, outlook or paradigm, and the ensuing logic of appropriateness pertaining in a domain – a sector, policy area, or a field of science and technology – that give it stability and orientation and guide decision making (Kemp, 1994). In the case of automobiles, for example, at a high level of aggregation there is a fossil-fuel energy regime, and at a lower level of aggregation there is an internal combustion engine regime for automotive technology. Users are part of a regime that is a component of what Geels (2004) has called the "socio-technical regime." A regime is an interpretive analytical concept that invites the analyst to investigate the "deep structure" behind activities, e.g., shared beliefs, norms, standardized ways of doing things, heuristics, and rules of thumb (Geels and Kemp, 2012). Policy may be involved in promoting or regulating these socio-technical regimes.

Regimes are part of a broader context – the macro landscape of values, infrastructures, settlements, political associations, prices, lifestyles, aspirations, and concerns of people. The landscape may variously sustain a particular regime or put it under pressure. In the case of automobiles, it does both. At the micro level are niches, novelties, and alternative practices (Figure 25.1). Within this scheme, novelties (new products, technologies, or special institutional arrangements) emerge in niches, particular domains of use, constellations of actors, and a geography, all of which are part of a broader world consisting of regimes and landscapes. What happens in each niche is shaped by the external developments with which it interacts. Each of these levels has its own type of dynamics, but developments are interdependent. The diffusion of niche products is constrained by competition from existing, well-developed products and cultural practices.

Transitions are viewed as the outcome of pressures on socio-technical regimes (e.g., cultural criticism, regulations) and changing conditions, the development of alternative products and systems, elements of which are breaking out of niches because of learning economies, support from various actors (including incumbent companies, politicians, civil society) and processes of alignment (Geels, 2002).

The transition perspective has relevance for transitions to energy systems that meet the GEA goals (see Cluster I). Change may occur within an existing regime. For example, carbon reductions may be achieved through technical fixes that leave the logic of the regime intact. Change may also occur through the transformation or replacement of an existing regime with a new regime of energy carriers involving different technologies, practices, paradigms, and institutions. Here, it is important to note that the knowledge and capacity issues involved in adopting technical fixes and creating new regimes are altogether different. The introduction of the catalytic converter as a technical fix to reduce car emissions, for example, required no changes on the demand side or in the powertrain of vehicles. Neither car manufacturers nor users had to acquire special capabilities. In the case of regime-shifting change, however, such as the move to renewables, a wider range of capacity issues are involved in achieving changes in the lifestyles, habits, and practices of users and producers. Society has to create and sustain a capacity for making choices about options and configurations, skills for installation, and knowledge for product development, load management, defining appropriate policies, and adapting policies to changing circumstances.

In order to pursue a path towards an energy transition, a cluster of new technologies will need to be fostered (Jacobsson and Bergek, 2004; Stern, 2006). Energy transitions therefore involve a moving frontier that advances for different technological options at different rates and in different contexts. This has a bearing on both capacities and capacity development processes. When these new technologies come with risks, as they often do in regime-shifting change, the capacities needed to understand the risks, and to contain and manage them, become important. Special government policies and science and technology programs may be needed to stimulate development of the technologies that underpin a new regime, support their diffusion, and guarantee safety, as well as manage transition processes.

Past energy transitions in the industrialized world have included, for example, the transition from wood to coal, from coal to natural gas for power and heating, from gaslight to electric light, the creation of centralized power systems and nuclear technologies, or more recently, the development and diffusion of renewable and clean energy technologies in both developed and developing countries. In many cases, governments have played a role in encouraging transition processes by increasing public investments in science and technology programs, providing market incentives, and introducing regulations and standardization. But governments alone cannot bring about an energy transition. The following section links the energy transition perspective to the capacity development issues that arise from the systems-embedded and innovative nature of the transition process.

25.3 Capacities and Capacity Development for Energy Transitions

Capacity building and capacity development have mainly been associated with developing countries in the past, but this is no longer the case. Energy transitions involve a broad set of changes in existing patterns of production

and consumption, in the knowledge and skills required, the organizational forms, and the business and governance practices, as well as other social habits, practices and norms, whether the process is taking place in a least developed, developing, emerging or industrialized economy. We thus go beyond the traditional development literature to identify a range of capacities that are of increasing relevance in energy transitions. The section begins with a brief review of the early development and "capacity building" literature, its recent evolution, and the challenges it still faces. It then explores issues of capacity development for energy transitions that emerge from the application of an innovation systems approach.

25.3.1 From Capacity Building to Capacity Development

The early development literature, as Bouille and McDade (2002) noted, referred to capacities in terms of skills, and the process of creating and/or strengthening them, as "capacity building." It assumed that relatively few local capacities existed in specific domains and these would need to be transferred[9] to developing countries mainly through foreign aid and investment. Initially, development agencies focused on providing goods, services, and foreign experts to government ministries in developing countries (UNDP, 2009a), and consequently on ensuring that public sector organizations were capable of managing large public investment programs (Lusthaus et al., 1999).

During the 1990s, a substantial and growing part of the population in developing countries remained without access to energy, although significant investments in energy infrastructure had been realized (WBG, 2003). Donors became increasingly concerned about the effectiveness of foreign aid and this led to major changes in policy, including a rethinking of development assistance practices and the process of capacity building. The policy changes began in 1991, with the publication of a report entitled, *Principles for Evaluation of Development Assistance*, by the Development Assistance Committee (DAC) of the Paris-based Organisation for Economic Co-operation and Development (OECD). Initially a conversation among donor countries about "the role of aid evaluation in the aid management process," the principles went beyond earlier conceptions of donor-recipient relationships to view development assistance as "a co-operative partnership exercise between donors and recipients" (DAC, 1991). The nature of this partnership was not defined, however, nor were prospective partners included in the discussions. In 2005, this changed when developed and developing countries met in Paris and endorsed the view that capacity development was fundamentally an endogenous process that should be led by the recipient countries, with donors playing a supporting role (OECD, 2005/2008).

The Paris Declaration on Aid Effectiveness sought to address issues of sustainable development that went beyond those of finance. This led to the emergence of a new concept, "capacity development." In contrast with "capacity building," capacity development recognized that some capacities existed everywhere upon which one could build.[10] The Paris Declaration also took a broader view of the actors involved, moving beyond individuals to include organizations and society (Fukuda-Parr et al., 2002; Bouille and McDade, 2002). The Economic Community of West African States (ECOWAS), in a white paper for a regional policy on access to energy services, agreed, advocating that "capacity-building [should…] be aimed both at private operators (local operators, investors, donors, etc.) and public actors (ministries, regulatory authorities, rural electrification agencies, etc.)" (ECOWAS, 2006). The white paper also stressed the need for linkages across countries within a region (a point to which we return in Section 25.7.3 on knowledge networks).

The capacity development approach understood capacity as an outcome and capacity development as a process. In contrast with standard assessments of individual performance or project outcomes, some of the capacity development literature came to regard participatory monitoring and evaluation at various points in the life of a project as part of a learning process. From this perspective, feedback is a desired outcome that serves not only as a means for measuring progress, but also as an opportunity for "questioning, reflecting, learning and modifying" (IDRC, 2008). More broadly still, tools for evaluative thinking, such as "outcome mapping," adopted by the International Development Research Centre (IDRC), are more attentive to "changes in the behavior, relationships, activities, or actions of the people, groups, and organizations with whom a program works directly" (Earl et al., 2001). This approach has important implications for the kinds of capacities and capacity development processes that are needed for energy transitions (Young, 2008).

The new conceptual insights notwithstanding, "[i]n recent years about a quarter of donor aid, or more than US$15 billion a year, has gone into technical co-operation, the bulk of which is ostensibly aimed at capacity development. Despite the magnitude of these inputs, evaluation results confirm that development of sustainable capacity remains one of the most difficult areas of international development practice" (DAC, 2006).

The development of sustainable capacity has remained elusive (see Box 25.1), for a number of reasons. One is the persistence of earlier thinking and practices, since "until recently capacity development was viewed mainly as a technical process, involving the simple transfer of knowledge or organizational models from North to South" (DAC, 2006). Such views share with the early development literature a conceptualization of technology as embodied in machinery and equipment, and its transfer and assimilation as automatic and context-free (Bell, 1984; Forbes and Wield, 2002). Development was often seen as a linear process "a sort of race along a fixed track, where catching-up is merely a question of relative speed" (Perez, 1988).

9 In the 1950s, development economists such as W. Arthur Lewis and Raul Prebish argued that developing countries were not capturing an adequate share of the gains from technological change. The solution was to industrialize. But the scarcity of capital, skills, and technology made it imperative for these countries to attract foreign investment (Lewis, 1950; Prebisch, 1959). This view subsequently became entrenched in the development literature (see Bell, 1984; Mytelka, 1989; Forbes and Wield, 2002).

10 Although they differ in their approach to energy transition processes and the capacities needed to support them, the terms capacity building and capacity development are often used interchangeably in the literature.

Box 25.1 | "We are making progress, but not enough"

In its 2003 Human Development Report (HDR), the United Nations Development Programme (UNDP) embraced the capacity development approach and stressed the need for initiative and ownership to reside with and in developing countries. This complemented the evolving view of development assistance as a partnership, but it did not resolve the challenges involved in putting such an approach into practice.

Ways to address the many issues of ownership, inclusive partnerships and the effectiveness of aid raised in Paris in 2005 (OECD, 2005/2008) were still being worked out at a follow up meeting in Accra, Ghana, as the Accra Agenda for Action (2008) illustrated. They included the lack of capacities in developing countries to plan, manage, implement, and account for the results of policies and programs; the need to deal with issues of predictability, conditionality of funds, and the untying of aid on the donor side; and the continued difficulties in scaling up for more effective aid.

Source: Accra Agenda for Action, 2008.

During the 1980s and 1990s, researchers in developing countries began questioning the linearity and passive nature of the catch-up process. Effective absorption and diffusion of new technologies, it was found, mainly took place when accompanied by two broad sets of purposive actions:

- innovative practices, such as adapting imported technologies to suit local conditions, adjusting to new sources of inputs, altering the product mix, and resolving bottlenecks in production (Stewart, 1984; Katz, 1985; Mytelka, 1985; Westphal et al., 1985; Lall, 1992); and
- technological learning, by engaging in a process of intensive technological searching and protracted negotiations with prospective sellers or licensers of technology, by adopting a strategy focused on adaptation and upgrading of the original design and by developing in-house research capabilities (Rosenberg and Frischtak, 1985; Katz, 2004; Ernst et al., 1998; Bell, 2009).

Such purposive actions were not easy or cheap, but were often facilitated by a supportive policy environment (Bell, 1984; Kim, 1997; Nelson, 2004). These lessons were soon forgotten, however, and development practice returned to a focus on more passive approaches to technology transfer through development assistance projects and foreign direct investment, rather than on the learning and technological mastery that drove the process of catching up in the "Asian tigers" (Kim, 2004; Mytelka, 2004).

Another factor contributing to the difficulties encountered in capacity development is the continued donor focus on "skills development and individual training" (Baser and Morgan, 2008), with a particular emphasis on upgrading public sector governance (World Bank and IMF, 2004). As those who have adopted "institutional" or "systems" approaches point out, the way public agencies function is shaped as much by the training individuals receive as by their social and political context (Lusthaus et.al. 1999; Baser and Morgan, 2008; DAC, 2006). Inspired by the work of Douglass North, they define institutions as the "formal and informal rules of the game," which distinguishes institutions from "organizations" (North, 1994). This approach goes beyond a focus on public agencies to include a wider array of organizations whose involvement in energy transition processes is critical. It also acknowledges that these actors cannot be divorced from the "structures of power and influence," or from the informal "institutions" in which they are embedded (DAC, 2006). From this perspective, training programs can go only so far in bringing about change. Instead, as the business and innovation systems literatures have shown, what often impede change in organizations are the habits, practices, routines, and norms of the actors within the organization and in the wider society (Teece, 1988),[11] a point developed in the framework presented in Section 25.3.2.

Lastly, an emerging view, more often heard than put into practice, is that the private sector should take on a more prominent role in the design, financing, and delivery of rural and/or renewables-based technologies (van de Vleuten et al., 2007). Public agencies often lack the capacity and motivation to improve rural energy conditions in developing countries and focus quasi-exclusively on urban energy needs, while expecting private actors to address rural conditions. Private firms, local or international, often lack the in-country capacity to deliver the necessary energy carriers or technologies, in part also because policies and regulation do not favor this type of solution.

25.3.2 An Innovation Systems Approach

The definition of capacity as the ability of individuals, organizations, society, and communities to make choices, perform functions, solve problems and set and achieve objectives, and of capacity development as an endogenous learning process through which these abilities are obtained, strengthened, adapted, maintained, or changed over time, owes much to the work of UNDP (2008a; 2008b; 2009d). It differs from the UNDP definition, however,

11 An example of how these informal institutions can slow the process of change can be found in Section 25.11, Case Study 1, on the introduction of smart grids in the UK.

in three important ways. First, as in the broader institutional and systems literature, this definition distinguishes between organizations, such as industries, farms, government ministries, hospitals, universities, non-governmental organizations (NGOs), and informal institutions. Second, it is rooted in an understanding of energy transitions as processes of innovative change that take place interactively across the multiple levels shown in Figure 25.1. Third, it relates to the growing importance of learning and innovation in the processes of development and change.

During the 1980s and 1990s, changes in production and competition in the industrialized countries drew attention to the role of knowledge and innovation in the competitiveness of firms and, by extension, of nations (OECD, 1992). Over time, the knowledge intensity of production extended beyond the high technology sectors to reshape a broad spectrum of traditional and new industries in both developed and developing countries (Mytelka, 2000). In the developing world, this change placed a premium on learning, capacity development, and innovation in the process of catch-up and keep-up, as case studies in Asia, Latin America, and Africa have shown (Ernst et al., 1998; Muchie et al., 2003; Pietrobelli and Rabellotti, 2006). This would lead to a growing interest in innovation systems thinking as a useful approach to contextualizing learning and innovation processes, first in the industrialized countries and, more recently, in the developing world.[12]

As a set of conceptual tools and frameworks, the innovation system approach is still evolving. Since its appearance in the 1980s, the approach has provided comprehensive and integrated analyses of the processes of learning and innovation in various societies and economies. It is particularly relevant to energy transitions, which are broad processes of innovation and change.

An innovation system can be seen as a network of firms and other economic agents that, together with the institutions and policies that influence their innovative behavior and performance, bring new products, new processes, and new forms of organization into economic use (Lundvall, 1992; Nelson, 1993).[13] The strength of the innovation systems approach lies in its focus on the interactions among these actors and their embeddedness in an institutional and policy context that influences their behavior and performance. Institutions in this sense are not organizations, but "sets of common habits, routines, norms, rules and established practices that regulate the relations and interactions between individuals and groups" (Edquist, 1997) and prescribe behavioral roles, constrain activity and shape expectations, or what we call here informal institutions (Hall and Taylor, 1996; Edquist, 1997; Scharpf, 1997; Storper, 1998; Hukkinen, 1999). These habits and practices are learned behavior patterns marked by the historical specificities of a particular system and moment in time. As such, their relevance may diminish as conditions change. This is particularly likely during the course of energy transitions, which are, by definition, dynamic processes.

From a policy perspective, the strength of the innovation systems approach lies in the attention it draws to policy dynamics and the way these emerge from the interaction between policies and the habits and practices of the actors whose behavior is targeted by policy (Mytelka, 2000). Policies can be designed to reinforce desirable habits and practices, or to induce change, provided that there is some understanding of the habits and practices of local actors, and that a continuous process of feedback provides the inputs for adaptive policymaking. Learning and unlearning on the part of firms, policymakers, and other actors in an emerging or established innovation system are thus at the heart of its ability to respond to new challenges. Continuous flows of knowledge and information provide critical inputs into this process.

These insights have particular relevance for energy transitions that are long-term processes and will require adaptive policymaking to successfully carry out the broad range of interrelated changes, negotiate the multiple pathways, and manage the risks and uncertainties involved. Capacities at the actor and systems levels can be expected to differ both across socioeconomic contexts and over time in energy transition processes. By conceptualizing energy systems as socially embedded and historically shaped by the habits and practices of the actors within them, the innovation systems approach draws attention to the importance of addressing issues that arise out of these informal institutions, in the design of capacity development policies and processes. Among these are the challenges posed by path dependence,[14] i.e., the tendency for past practices and decisions to shape present choices, and lock-in, where complementary technologies or products can very quickly gain dominance in a market even if they are inferior.[15]

Path dependence in energy transitions is reflected in a range of beliefs and boundaries that shape choices about new energy technologies. These can include engineering "beliefs about what is feasible or at least worth attempting," and boundaries that shape processes of choice such as lines of research to pursue, kinds of products to produce, organizational routines and development trajectories (Teece, 1988; Mytelka, 2008).[16] Path dependence also emerges in contexts where earlier investments result in high sunk costs, habits and practices are entrenched (see Box 25.2), and "expert views" are shaped by earlier thinking that narrows the range of choices to established technologies and evaluation techniques.

12 In Brazil and South Africa, an innovation systems approach has been applied in research, in industrial surveys, and in policymaking. It has also been adopted by the European Union, by individual Asian countries, and by New Partnership for Africa's Development (NEPAD) for their innovation surveys.

13 The innovation system approach is introduced in Chapter 24.

14 For more on the concepts of path dependence and lock-in, see Chapter 17.

15 The classic example of lock-in is the QWERTY keyboard used in typewriters and maintained in computers, even though the placement of keys makes it inefficient (David, 1985). For further lock-in examples, see Chapter 19.

16 The business literature has recently begun to focus on "taking the bias out of meeting" and strategic plans by "gathering data, discussing analogies, and stimulating debate that together can diminish the impact of cognitive biases on critical decisions" (Lovallo and Sibony, 2010). However, they do not seem to be aware of the way in which past practices can also affect the selection of data and analogies.

Box 25.2 | Path Dependence

In 2008, the World Bank's International Finance Corporation approved a US$450 million loan for the Tata Mundra project, designed to build five coal-fired power plants in the Indian state of Gujarat. This illustrates the challenge that path dependence can pose for energy transitions. In this case, traditional norms and practices that oppose the use of subsidies and employ short-term, static cost comparisons to evaluate alternative options, provided the rationale for an energy choice that will have negative implications for India's CO_2 emissions in the long term.

The first of the Tata Mundra power plants will be commissioned in mid-2011. It is expected to emit 40% less CO_2 than existing coal-fired power plants in India, but given the lifespan of the new plants, it will contribute "23.4 million tonnes of CO_2 per year" to the environment for the next 25–30 years (IFC, 2009).

IFC vice-president Rashad Kaldany justified this decision on the grounds that, in comparison with other alternatives, "[t]his is by far the least expensive and to try to do something like either wind or solar would cost huge amounts in terms of subsidies" (Wroughton, 2008). While this may be true in the short term, taking longer-term considerations into account, such as the future costs of retrofitting a plant with carbon capture and sequestration technology, or the imposition of a carbon tax on coal-fired power plants, might have altered the choice matrix.

In 2010, the World Bank approved yet another loan for the construction of a coal-fired power plant, this time in South Africa. Once fully operational in 2015, the Medupi power station will emit 26 million tonnes of CO_2/year (Duffy, 2010). Decisions such as these, to support old, polluting technology and to promote new and renewable forms of energy only when they are commercially viable, create further disincentives to change energy demand and supply patterns and make it even more difficult to move down a cleaner energy pathway.

Investments that involve innovative changes are, however, by their nature costly, risky, and likely to deliver returns only in the long term. How, then, might pathways be built today that do not compromise change in the future, especially in poor countries that can ill afford to make the same mistakes that industrialized countries have done and then expend the resources to clean up and rebuild in the next generation? To address this challenge, two complementary approaches are discussed.

One approach involves rethinking the standard economic calculations that have so far failed to take account of social, economic, and environmental costs and their cumulative impacts over time.[17] The other approach recognizes the long time horizons required to develop industrial production capacity in new energy technologies and to build the necessary infrastructure and markets. It therefore favors developing a portfolio of new technologies and associated industries in parallel, and not in sequence (Jacobsson and Bergek, 2004). From this perspective, the most appropriate policy would be not to select the current "best," "off-the-shelf" technology, as neoclassical economists would prefer, but simultaneously to foster a broad range of technologies and associated industries (Sandén and Azar, 2005).[18] This would apply not only to traditional leaders in technology, but also to newcomers such as Brazil, China, and India, and to other countries that today only import their capital goods. In the latter cases, the time needed to build up production capacity would, of course, be shorter than developing entirely new industries. As a major Latin American research program in the 1980s demonstrated, even importing, successfully operating, and reproducing technology requires substantial engineering efforts and may take decades rather than years to develop (Katz, 1983).[19]

A better understanding of informal institutions is also needed because of the way they shape choices in the development of new technologies and affect the speed of technology diffusion in both developing and industrialized countries. Diffusion, as we saw in the previous section, is associated with innovation in organizational routines, new mindsets, practices, and supplier-user relationships. It is thus a context-specific process involving elements of innovation (Kline and Rosenberg, 1986). Much of the literature on energy transformations, especially in

17 Daniel M. Kammen, the World Bank's new "clean-energy czar," reiterated this point in a recent interview (Broydo Vestel, 2010).

18 For example, F-i-T is an instrument for a broad range, while green certificate markets always select the best off the shelf.

19 The introduction, use, and diffusion of imported solar cells, for example, would require the capacities of local engineering firms to design and deliver whole systems; roof and façade manufacturers, electricians, and architects to incorporate the new technology and extend its applications; and changes in formal and informal institutions to align with the new technology. See the cases of Bangladesh and Senegal in Section 25.5.2.

developing countries, retains an earlier language – that of technology transfer – or has adopted a new language – that of "technology deployment" – both of which conceive of the process in contextually neutral and linear terms. In most developing countries, for example, technology transfer through donor-supported projects has been one of the principal ways in which "new" energy technologies have been deployed. But they have rarely led to rapid and sustainable diffusion – a problem that is widely acknowledged and most often attributed to the general lack of absorptive capacity in developing countries.[20] Absorptive capacity is only part of the problem, however. The availability of affordable energy technologies, especially for lighting and power, is important, and the habits, practices, norms, and interests of local actors play a major role.

A recent study of capacity development initiatives based on an analysis of 18 case studies,[21] suggests that donor practices also tend to reinforce path dependence in the project design and implementation phases (Baser and Morgan, 2008), and thus are likely to contribute to the slow diffusion of new energy technologies in developing countries in several ways. Current approaches to capacity analysis are overly focused "on the macro and the aggregate levels such as state building, improved governance and democratization." At the operational level, the experience of managing projects and programs has given rise to an emphasis on "prediction, targeting, control, results and accountability," and an interest primarily in "ideas that are simple, make immediate sense and can be easily integrated into what they are already doing" (Baser and Morgan, 2008).

This section has moved beyond the development literature in its understanding of the range of capacities and the types of capacity development processes that impact on energy transitions. While finance and governance remain major challenges, capacities that will strengthen the flexibility of existing systems to respond to change are critically important in undertaking and sustaining an energy transition. Among these, building the capacity for long-term, dynamic, multi-goal strategic programming and policymaking will be needed. This will not be an easy task in developing countries. It will require vastly increased access to and capacity for the analysis of a continuous stream of domestic and international information and knowledge as inputs to the policy process.

Within the policy process, capacities for individual and organizational learning must be strengthened. In both developing and developed countries, a broader definition for the identification of capacities and capacity development processes to include the learning and unlearning of habits and practices by all actors in the "innovation" system will be needed. "Institutional" capacity development in this sense refers not only to changes in formal rules, legislation, or standards. It also calls for innovation in organizational routines, mindsets, and feedback mechanisms, as well as the creation and strengthening of new networks that enhance interactions and enable learning processes.[22] From this perspective, capacity development for energy transitions aims to embed new practices and the technologies that are part of these practices, within existing social contexts. The next section explores this process in the context of energy efficiency in diverse environments.

25.4 Path Dependence and Informal Institutions

Path dependence and informal institutions have been important contributing factors to the limited acceptance and slow diffusion of a wide variety of new energy and energy-saving technologies. This section illustrates these challenges with reference to the adoption of new and potentially more efficient energy-related practices and energy technologies in urban transport, energy services, buildings, and construction materials. While energy efficiency is often simply a palliative practice within an existing regime,[23] it can – and should – become a pathway towards a regime-altering energy transition. We therefore look at where and how this is being done, and what lessons might be drawn from these experiences for the kinds of capacities and capacity development processes that are needed.

25.4.1 Urban Transport

In the 1960s, major cities in Europe and North America began to develop and implement urban transport policies. These policies were sometimes implemented in collaboration with national governments and the private sector, and then followed decades of fluctuating oil prices and increased traffic congestion and pollution. These policies were not particularly regime-altering. They focused on the creation or extension of metro systems, the reintroduction of the electric trolley, and the development of light rail systems and, more recently, of bus rapid transit (BRT) lanes.[24] To a lesser extent, they have also included partnerships that could significantly alter urban transport technologies by accelerating the adoption of electric and hydrogen fuel-cell

20 For discussions of technology transfer processes and specific cases, see Mytelka, 1985; 1986; Bell and Pavitt, 1997; Kim, 1997; 2003; and Mytelka 2004.

21 Although the study does not deal specifically with new energy technologies, the cases on education, environmental action, local government support, and NGOs are relevant for issues raised in this chapter.

22 See the discussions on open innovation systems and knowledge networking in Section 25.7.

23 A contemporary example is the introduction of energy efficiency standards for automobile engines, not to discourage their use but as a means to deal with energy security issues by reducing consumption of imported gasoline.

24 For an overview of these systems, see Chapter 9.

vehicles, notably in urban bus networks.[25] There are also experiments that might lead to substantial changes in personal mobility practices, such as the Velib self-service, subscription-based, bicycle hire system launched in Paris in 2007 (C40 São Paulo Summit, 2011) and, more recently, the development of similar programs for automobiles. All of these approaches aim to reduce the use of cars in urban environments by working with existing habits of personal mobility, but around the practice of doing so through personal vehicles that clog city streets and collectively generate far more CO_2. European cities are at the forefront of these initiatives.

The first decade of the 21st century also marked an important watershed in human history when, for the first time, more than 50% of the global population are urban dwellers (see Chapter 18). Many of the world's mega-cities are located in developing countries where energy and transport policy and planning are weak and public transport systems do not meet emerging needs. The situation is particularly problematic in Africa (Davison and Sokona, 2001), but it has emerged in the new millennium as a major challenge in cities across the developing world, largely as a result of the continued growth in urban populations and in the use of automobiles.[26]

A number of strategies have been developed to deal with this problem and to attract automobile users to switch to public transport systems. Some of these strategies have emphasized energy efficiency and linked it to a process of ensuring the survival of the public bus systems. In the case of the Bangalore Metropolitan Transport Corporation (BMTC), this required significant changes in government policies and in the management of the corporation (see Box 25.3).

Box 25.3 | Bangalore Metropolitan Transport Corporation

Until August 1997, when it became an independent state-owned corporation, the Bangalore Metropolitan Transport Corporation (BMTC) was typical of India's public bus companies. Its revenues failed to cover costs, and buses were old and inefficient in their use of fuel and polluting. Morale and discipline among workers was low, strikes were frequent, a lack of managerial skills contributed to poor operational efficiency, and there was little scope for introducing changes from the bottom up.

When financial support from the Karnataka State government was not forthcoming and transport services were threatened with privatization, BMTC's management needed to develop a new strategy. They began by bringing the workforce on board. Training, more transparent management practices, and innovative labor welfare measures encouraged workers to be more attentive to maintaining their buses and ensuring compliance with pollution norms. Increasing the number of bus depots from 13 to 29 made it possible to monitor fuel consumption more closely and improve maintenance practices and operational efficiency. As revenues grew, BMTC was able to retire 1700 aged vehicles and purchase 2974 new ones that met European standards.

BMTC also worked hard to change traditional practices in its relationship with the Karnataka government, and in 2003 set up a cell to create an environmental plan for the company and develop closer working relationships with the Karnataka State Pollution Control Board. By 2007, in comparison with Mumbai, Delhi, Chennai, and Ahmedabad, the BMTC had the highest bus to population ratio, the youngest bus fleet, and the best fuel economy ratio. It was also India's only large profit-making state transport corporation. The BMTC has received many awards in the field of affordable public transport, and fuel efficiency in urban services. Perhaps the most important impact, however, was the federal government's decision to diffuse the BMTC model across India's cities.

Source: Torres-Montoya, 2007; Tripathy et al., 2008.

25 These began with the California Fuel Cell Partnership, launched in 1999, and a series of EU programs designed to test hydrogen fuel cell (HFC) buses and refueling stations in some member states (e.g., the CUTE and ECTOS programs). These programs have expanded through collaboration with municipalities, regional governments, and industry in the building of hydrogen refueling infrastructure across Europe and the introduction of HFC and electric HFC buses and other vehicles into commercial use. See the Hydrogen Bus Alliance (www.hydrogenbusalliance.org) and HyRaMP, the European Regions and Municipalities Partnership for Hydrogen and Fuel Cells (www.hy-ramp.eu).

26 The challenge presented by urban population growth and increased automobile use has been particularly acute in Beijing (since the Olympic Games in 2010), in New Delhi (despite the conversion of bus and taxi fleets to less polluting compressed natural gas), Bogota, and Mexico City. Over the past few years, in each of these countries, city and national governments have combined forces to develop transport, urbanization, and related strategies to overcome this problem, sometimes with external funding from, for example, the Clean Development Mechanism in the case of Bogota, and the Clean Technology Fund in the case of Mexico City.

Other strategies have focused on the issue of access to transportation and the role it can play in achieving broader development goals. Several of these initiatives have been supported by local mayors. Curitiba, capital of Brazil's Paraná state, was a pioneer in that respect. Driven by population growth, the city moved away from earlier urban planning efforts based on the automobile, to the design of a master plan, adopted in 1965, for integrated transport and urban planning. As it evolved, the plan focused on the development of a public transport system that was unique at the time – the BRT system (Lindau et al., 2010).

There are now 47 BRT systems worldwide, and more are under construction (see Chapter 9). Among developing countries, 16 cities in Latin America have built BRT systems, and the model has spread to Asia. Africa, however, lags far behind. In sub-Saharan Africa, only Johannesburg, South Africa's largest city, has thus far built the first line of its BRT system, Rea Vaya.[27] Focused on the need to overcome the legacy of apartheid, Rea Vaya links Soweto residents to Johannesburg and is interconnected with the city's other transport networks, Metrorail and the Gautrain. Rea Vaya buses are powered by fuel-efficient diesel engines that meet stringent Euro 4 emissions standards.[28] To the extent that it induces the anticipated 15% of car users to shift to public transport, Rea Vaya is expected to substantially reduce CO_2 emissions.[29]

Despite the attractiveness of these transport systems – more frequent bus services, low fares – the use of private cars continues to grow (see Chapter 9). While access to cleaner and more efficient transport systems potentially influence the behavior of urban and peri-urban residents, more is needed to change established habits and practices with respect to the choice between personal and public transport. On the whole, BRT systems, moreover, have not moved away from standard bus technology and imported petroleum-based diesel fuel. There is some tentative movement in this direction in a few larger cities – for example, in the production of biodiesel and its use in some delivery vans in Cape Town, South Africa, and the development of biodiesel in Brazil.[30] But, of more interest is the spontaneous development in the production and use of biodiesel for the more traditional minibus/matatu/tuk-tuk sector, which plays an important role in urban transport in many developing countries.

Box 25.4 | Biodiesel Initiative in Tanzania

After years in business in the United States, a Tanzanian national returned to his home country and established Mafuta Sasa Biodiesel in 2008. Tanzania consumes over two million liters of petroleum diesel daily, all of which was imported when the company was founded. Mafuta Sasa is positioning itself to replace 2% of Dar es Salaam's diesel market with biodiesel from used cooking oil that has been chemically transformed into biodiesel suitable for use in diesel engines or generators. Matatu owners, the company's principal customers, can now purchase biodiesel at a price 20% lower than that of imported petroleum diesel.

Source: Mwakilasa, 2008; Mafuta Sasa, 2011.

These two examples notwithstanding, given the continued rise in automobile use in growing urban areas, greater efforts will be needed to integrate urban planning and energy policy with other policies that affect the habits and practices of actors on both the demand and the production side (Sinha, 2003; Mutizwa-Mangiza, 2009). Only then can we move away from the car culture of the past and towards more energy-efficient and environmentally sustainable transport systems of the future.

25.4.2 Smart Grids

Problems of path dependence and informal institutions also impact on the speed with which new energy-related technologies diffuse in the industrialized world. Sunk costs in centralized grid systems and the engineering skills that maintain them or, as we show in the next section, traditional cement plants that cannot easily be converted to the production of low-energy/low-carbon cement, for example, explain some of the reluctance in adopting these technologies. In other cases, the costs of conversion and "cost-sharing" formulas may be controversial, also

27 Accra, the capital of Ghana, is beginning construction on its future system, an elevated monorail that will allow maximum use of existing streets and walkways.

28 The first European emissions standards date from a 1970 directive. Each amendment to this directive is numbered consecutively: Euro 1, Euro 2, and so on. Euro 4 dates from 2005.

29 Estimates of expected CO_2 savings from Rea Vaya can be found on the City of Johannesburg website (City of Johannesburg, 2011). Similar estimates exist for Bogota's TransMilenio (ESMAP, 2009) and Mexico City's new BRT lines.

30 In the city of Sao Paulo, a new project is now underway to replace diesel in buses by ethanol from sugarcane and an additive (cenbio.iee.usp.br/projetos/best.htm). The project is funded by the European Union. The city has also launched a hydrogen fuel cell demonstration project.

slowing the process of change. In the United Kingdom, for example, the regulatory formulas that governed distribution network companies until recently did not allow companies to recover the costs of investment in RD&D for network innovation (Sauter and Bauknecht, 2009). What makes these issues so intractable is the way existing habits, practices, and norms interact with the above factors.

A deeper understanding of traditional habits and practices will be required to overcome the problems associated with path dependence and lock-in that slow the processes of change towards low-carbon energy systems. Two types of lock-in are particularly relevant here. First, most energy systems are locked into a high-carbon pathway and are heavily dependent on fossil fuels (Unruh, 2000). Second, in some countries, there has been an historical lock-in to centralized energy supplies and policymaking. This second form of lock-in has its roots in the search for economies of scale in electricity generation (Foresight, 2008). However, this can be problematic if the transition to more sustainable low-carbon energy systems requires some measure of decentralization. As Chapter 15 pointed out, optimized interconnected networks making use of real time information and modern communications technology linking energy supply sub-systems provides redundancy, robustness and flexibility, that can lower overall costs. Critical elements in the new system include distributed generation and microgrids, integrated in digital smart grids that can monitor and heal themselves. Public-private partnerships are important in achieving this vision. Changes such as these will require the development of new habits, as well as interactive practices and skills.

The United Kingdom's energy system provides an apt illustration of these tensions, since it has both a highly centralized architecture and structure, and is subject to ambitious plans for a transition to a low-carbon economy. Two-thirds of the UK heating demand is met by natural gas from a centralized network (DTI, 2007). Less than 10% of heat demand is met by off-grid heat generation – i.e., by sources other than gas or electricity. Furthermore, less than 10% of the United Kingdom's electricity is supplied from renewable energy or combined heat and power (CHP) plants connected to the electricity distribution network. These levels of decentralization are much lower than those in most other northern European countries (WADE, 2006). This centralization of the United Kingdom's energy infrastructure is mirrored in policy frameworks and energy market rules. Local and regional institutions have little say in the shape of energy investment and decision making, except with respect to planning decisions (Foresight, 2008). Only very recently has a legal restriction on the ability of local authorities to sell electricity been lifted (DECC, 2010b).

This centralized approach to energy provision is not necessarily problematic in industrialized countries.[31] An analysis by the UK government shows that there are many ways to meet the United Kingdom's ambitious target of cutting carbon emissions by 80% by 2050 (DECC, 2009). Some of these are technically possible while relying mostly on centralized electricity generation. However, many of the government's policies and plans rely on significant decentralization – including the strategy to meet the UK share of the renewable energy target, the plans for new economic incentives for local renewable heat, and the desire to have smarter grids that balance electricity supply and demand in more complex ways (DECC, 2010a). To facilitate this, some new policies and regulations have been developed and implemented. Grants for householders to install "micro-generation" in their homes, feed-in tariffs for smaller renewable energy installations, and new incentives for electricity distribution companies are just some of these.

It is too early to tell what impact these schemes will have. The experiences of the household micro-generation grants have been mixed. Frequent rule changes and adjustments created significant uncertainty for householders and installers (Bergman and Jardine, 2009). A key aim of many of them is to build new capacity. In the case of micro-generation, the installers, plumbers, and electricians who work in households need new skills, while distribution network companies need to build up capacity and skills in innovation to complement their business-as-usual system maintenance skills (see Case Study 1, Section 25.11 for more details).

25.4.3 Passive Buildings and Building Materials

Similar challenges related to path-dependent choices also confront the speed with which new energy-saving materials and the technologies for passive- or even positive-energy buildings[32] are being taken up, whether in refitting the old or building the new (see Chapter 10). "Novel cements" that use less energy and produce less CO_2 during manufacture have been given tepid reviews in industry fact sheets (Taylor and Collins, 2006). The testing of new building materials, moreover, does not figure prominently on the agenda of voluntary initiatives such as the World Business Council for Sustainable Development's Cement Sustainability Initiative, "Getting the Numbers Right," which focuses on the development of sector-specific CO_2 accounting and reporting protocols (WBCSD, 2009). In 2009, MIT researchers announced that the basic molecular structure of cement has now been decoded, opening up new opportunities for working around entrenched habits and practices. As pointed out by MIT Professor Franz-Josef Ulm, a "validated molecular model" will make it possible to manipulate the chemical structure and design new cement and concrete products for both strength and environmental qualities (Brehm, 2009). To speed these new low-carbon products to market, however, will still require funding for 2–3 years of development and testing to overcome earlier uncertainties among users and producers in the industry. Policies introducing CO_2 as a factor in pricing cement,

31 The centralized approach to energy provision may be more problematic in a number of developing countries, particularly where low population densities and large distances between cities and villages prevent the rolling out of a low-cost infrastructure through the extension of urban energy systems. We discuss a number of alternatives to deal with this problem in Section 25.5.2 on solar home services.

32 Positive-energy buildings could, for example, supply excess energy to the grid.

such as carbon taxes or caps on carbon, as well as new building codes and other energy- and environment-related legislation, would widen the market for low-carbon/low-energy materials.

The building sector has also been slow to encourage the demand for such products, and in many countries has found scant regulatory support for doing so, although a few high-profile positive-energy buildings have been built in the last few years, such as the Elithis Tower in France and the Masdar headquarters building under construction in Abu Dhabi. This is now beginning to change.

Progress is now being made in some niche areas that might point to ways of working around and with existing habits and practices in the building sector. C40 Cities, a voluntary group of mayors from among the world's largest cities, is encouraging the emergence of Mayors as champions in energy-efficient and eco-friendly buildings and urban transportation systems. Since the Mayor of Seoul made a commitment to retrofitting in 2007, 87 buildings – 45 public and 42 private – have been designated for retrofitting, and 62 of these had been completed by the end of 2009 (Oh, 2009). Holistic retrofits "can achieve 50–90% final energy savings in thermal energy use in existing buildings with cost savings typically exceeding investments," but GEA scenario work demonstrates a significant lock-in risk. If building codes are introduced universally and energy retrofits accelerate, but policies do not mandate state-of-the-art efficiency levels, substantial energy use and corresponding greenhouse gas (GHG) emissions will be locked in for many decades (see Chapter 10).

Elsewhere, innovative builders and developers are experimenting with the integration of multiple energy-saving technologies in new building construction. In the United States, with support from federal, state and municipal governments, new housing is being built that combines geothermal heat pumps, energy recovery ventilation systems, and innovative wall insulation technology using solar panels and autoclaved aerated concrete (Colaneri, 2010; McDonough, 2008).

The Leadership in Energy and Environmental Design (LEED), an internationally recognized green building certification system launched in 1998, grew out of the environmental NGO movement in the United States.[33] Hosted by the US Green Building Council in Washington, DC, LEED has brought together a broad coalition of actors including lawyers, scientists, environmentalists, NGOs, business firms, and government agencies, to define green buildings and to establish common, measurable standards. By 2010, some 400 buildings in the United States and 37 in other countries[34] had been awarded LEED certification at the platinum level, which assigns points based on criteria such as sustainable site development, water saving, energy efficiency,[35] materials selection, and indoor environmental quality. LEED certification, especially at the platinum level, is becoming recognized as a mark of quality in green building design, construction, and retrofitting, and is helping to bring about changes in existing norms and practices in the building industry. Developing an appropriate policy and regulatory environment could further encourage this process.

In designing policies to increase interest in energy efficiency solutions on both demand and supply sides of the transport, energy, buildings, and building materials sectors, the capacity to work from a systems perspective is critical. New approaches are required to overcome the reluctance of architects, builders, and engineers to work with new materials or, as we saw in the case of smart grids, to accelerate the introduction of new distributed energy systems. Bringing key actors together on task forces, panels, and platforms[36] could play an important role here. While not yet widespread, there is evidence that universities in a growing number of countries have created interdisciplinary graduate programs in sustainable engineering that could train a new generation of users[37] and potentially help to change existing reward structures in the building profession. But more needs to be done, and more rapidly, in order to develop the capacity to integrate knowledge in new ways by, for example, establishing sustainability certificate programs that will attract current building and materials professionals, bring them up to date, and encourage the processes of networking and knowledge exchange.

Strengthening local capacities to design regulatory policies, support programs, and financial stimulus packages that correspond to domestic conditions will also be needed to accelerate the introduction and rapid diffusion of new energy technologies, as we saw in the case of smart grids. But in a long-term process such as an energy transition, developing capacities for and practices of adaptive policymaking will be essential over time as conditions change. Such adjustments may require legislation introducing mandatory review processes or sunset clauses that provide for the automatic phase-out of existing legislation.

25.5 Dialogue, Market Building, and Diffusion

Societies and organizations differ in the extent to which established habits, practices, and norms favor either interaction and dialogue or more hierarchical patterns of communication. They may be based on

33 This discussion of LEEDS is drawn from the websites of the US Green Building Council (www.usgbc.org), the Natural Resources Defense Council (www.nrdc.org), an environmental NGO whose chief scientist, Robert Watson, was one of the pioneers in the green building movement and founding chairman of the LEED rating system, and M. Landman's list of "LEED Platinum Certified Buildings" based on the database of certified projects (Landman, 2010).

34 These countries include Australia, Brazil, Canada, China, Germany, India, Saudi Arabia, South Korea, Sri Lanka, the United Arab Emirates, and the United Kingdom.

35 A reading of their on-line literature does not make it clear whether certification at the platinum level implies a passive plus building (www.green-buildings.com/content/781911-leed-certification-conspiracy).

36 Platforms are discussed in the Dutch transition approach (Section 25.8.3).

37 These include prestigious institutions such as Kyoto University in Japan; KTH Royal Institute of Technology in Sweden; the Indian Institute of Technology in Mumbai; the University of Cambridge in the United Kingdom; and Stanford, the University of Michigan, and MIT in the United States.

intense interactions or go-it-alone practices, accepting of criticism and the need for change, or see all criticism as negative and build little feedback and few mechanisms for introducing corrective action into project design and implementation. This section explores the importance of dialogue in developing and institutionalizing capacities for energy transitions. It illustrates this with regard to the role of dialogues in the implementation of onshore wind power in Europe and in the diffusion of solar home systems in Asia and Africa. In these cases, links to market building were particularly relevant. Finally, the section reviews the slow pace of diffusion of multifunctional energy platforms and improved cookstoves, and assesses the contributions that dialogue and market building might play in the development of sustainable solutions to these challenges. Understanding dialogues is a first step in this process.

Until recently, dialogues have not featured centrally in project planning and development. Instead, in both developed and developing countries, a common approach has involved a top-down, linear process, in which the flows of information and knowledge are driven by governments or the research or business sectors. Communication consists in the transfer of information and knowledge through the distribution of printed materials, awareness-raising campaigns, the internet, and formal training programs. As the literature now stresses, experts must recognize that they have access to only one of many "forms of knowing and valuing," and often lack sufficient knowledge of the qualities of places, problems, potential solutions, and how to make policies work effectively (Gibbons et al., 1994; Healey, 1998; Renn, 1999; DAC, 2006). Consultations involving focus groups, village-level discussions, and stakeholder meetings can give the impression of being two-way processes, but the boundaries of such consultations are pre-established and often provide limited opportunities for those consulted to express interests, needs, and preferences other than those already on the agenda (Gibbs,1997). The process often fails to reach a broad enough range of potential users to stimulate the adoption of flexible processes at the project design stage, and thus few opportunities for adaptive change are built in once a project is under way. Interpreting the results of consultation processes is also problematic if, as the German physicist Werner Heisenberg noted in relation to his work on quantum mechanics, "what we observe is not nature in itself, but nature exposed to our method of questioning" (Heisenberg, 1962).

An interactive dialogue process, in contrast, offers room for the articulation of a broad range of views, interests, preferences, and needs. Preparing for such a dialogue process involves dealing up front with issues of how to proceed, the content, where the information will come from, the form and frequency of interactions, channels of knowledge and information, and the expected outputs and outcomes of the process. Establishing the legitimacy of interactive dialogue processes also extends to the concepts of "monitoring and evaluation," and the need to transform these somewhat punitive sounding – and thus often ignored – activities so that they provide feedback and flexibility in the course of project implementation (IDRC, 2008).

25.5.1 Dialogue at the Local Level: Wind Turbines

The deployment of onshore wind farms is shaped by a broad array of national policies, but often involves relatively small-scale, decentralized, and location-dependent applications that need planning consent from local authorities. Successful implementation therefore requires numerous local decisions and investments in the wind farm siting process.

In many countries, national policies favoring wind power have come to signify a top-down imposed development model that takes little note of local land-use planning and environmental issues. They often do not encourage project developers to involve local stakeholders in the design and planning of wind projects. In the Netherlands,[38] for example, most project developers are accustomed to building large power stations and have little interaction with local stakeholders. They have failed to recognize local planning concerns, sparking opposition to wind farm project from municipalities and other local stakeholders. Dutch energy companies faced difficulties in getting wind projects built in the 1990s and this contributed to the demise of the turbine manufacturing industry.[39]

In the United Kingdom, the limited development of wind power during the 1990s was due to the lack of experience with small-scale, decentralized, and location-dependent technologies, and the dominance of large, established utilities in wind projects. Some of the first large projects were planned in windy areas, which were ecologically sensitive hilly areas where there was no industrial activity. Public concerns and reluctance among local planning authorities resulted. The tradition of grassroots initiatives to protect the landscape subsequently made local opposition to wind projects very effective.

In Germany, in contrast, national policies were more favorable, enabling the grassroots environmental movement to propose locally based wind projects in collaboration with local communities. In the state of North Rhine-Westphalia, for example, federal and state governments responded to the grassroots movement, and in the early 1990s policy support was tailored to the needs of grassroots wind project initiatives. The German feed-in tariff system guaranteed access to the grid and did not discriminate against small, independent initiatives. Thus a diverse range of actors was able to become involved in both turbine manufacturing and project development.[40] Local ownership has been helpful in mobilizing support from the local level upwards, while the involvement

38 The case studies in Germany, the Netherlands, and the United Kingdom summarized here are drawn from the work of Breukers and Wolsink, 2008; Agterbosch and Breukers, 2009; and Toke et al., 2008.

39 A very different type of project developer, the Dutch wind power cooperatives, adopted a much more collaborative approach, but their impact has remained marginal.

40 In the early 1990s, Denmark also introduced feed-in tariffs. These were not only stable over long periods, allowing investors to plan their projects with confidence, but were also set quite high for the first years. Although the level of subsidies was later reduced, by 2002 almost 2900 MW of generating power had been installed and a strong industry built. Denmark's main focus in the mid-2000s is on re-powering existing onshore wind farms and on developing offshore projects (UNDP/GEF, 2008).

of diverse actors at local, regional, state, and federal levels precluded early resistance, as in the United Kingdom and the Netherlands. The institutionalization of environmental concerns in society and in politics also contributed to the successful development of wind projects as a form of local energy activism. Later, when the turbine and related industries were booming, the support for wind power became broader based – wind power represented not only environmental, but also economic (e.g., employment) and industrial (manufacturing and related services) interests.

Habits and practices are not immutable, but are embedded in the broader social context. In Germany, with the rapid growth of the wind energy sector in the late 1990s and the early 2000s, locally based projects have become less evident, and projects are increasingly developed by outsiders. Although local support has waned and resistance has increased, implementation began to decline when an impressive level of capacity had already been installed. North Rhine-Westphalia has achieved more in a generally less conflicting environment than has been the case in either the United Kingdom or the Netherlands.

While some "unlearning" took place in the German context, there seems to have been some "learning" in the Dutch and British contexts. In the late 1990s, Dutch policies no longer favored energy companies over other project developers. Farmers with access to financial support were responsible for a steady rise in the implementation of locally owned projects. These farmer-led projects provide clear local economic benefits and are developed by people who are part of the local political and social contexts. A further advantage is that the farmers own the land on which the turbines can be sited. Moreover, the farmers are well organized at several levels and so have been able to enter into collective negotiations with national energy distributors, local and provincial authorities, etc.

In the United Kingdom, there have been efforts to reinvigorate a "cooperative" tradition for wind power, stemming from the acknowledgement that the projects proposed and planned by "outside" companies are not always successful in gaining local support. In addition to such "community project initiatives," some commercial project developers have adopted a strategy encouraging the early involvement of local stakeholders.[41] Although there have been successes, the majority of wind turbine projects still meet with opposition from the firmly rooted and increasingly well-organized movement to protect the landscape.

As the case of onshore wind power shows, attempts to speed up implementation of new energy projects without sufficiently addressing local concerns are unlikely to engender societal commitment and acceptance. They may result in stalemate situations where further developments are blocked in a context of conflict and polarization.[42] One lesson is that energy transitions involving decentralized and location-dependent applications need support from the bottom up from a diversity of actors and networks. Such applications need to "fit" into the contexts for which they are proposed. This is not just a matter of compliance with formal procedures, permits and technical standards, but is very much a social-political process involving local stakeholders.

25.5.2 Market Building and the Diffusion of Solar Home Services Systems

For decades, technology transfer through donor-supported projects has been one of the main ways in which new energy technologies have been deployed in developing countries. Although many of these projects were designed to provide energy access for the poor, especially those in rural areas with no access to energy grids, widespread diffusion of these technologies has not followed. This section discusses the problems encountered in the introduction of solar home systems (SHSs) in developing countries, and how they have been addressed.

As early as the 1970s, SHSs were envisaged as off-grid energy services, but the costs and time needed to improve the technology and to build local capacity to produce spare parts and repair the systems drove many away. Although petroleum price hikes temporarily increased interest, efforts to develop SHS technology were not supported by government policies and SHSs were largely abandoned until the mid-1990s.

By this point, the technical performance of SHSs had improved, but producers still faced the challenge of ensuring consistent quality. The absence of quality standards contributed to customer dissatisfaction. Whether treadle pumps, solar water heaters or SHSs, standards and certification are needed "to increase customer confidence […] and reduce the negative perception arising from low equipment quality, unsatisfactory installation and incorrect operation and maintenance procedures" (GNESD, 2007). The prices of these systems had not come down sufficiently for most rural households, as studies in South Africa and elsewhere have shown (ERC, 2007; GNESD, 2007).

With the exception of Kenya, which has one of the most "dynamic commercial photovoltaic markets in Africa with a non-subsidized demand of 1–1.3 MWp per year that has been growing at an annual rate of 15% since the mid-90s" (GTZ, 2009), the diffusion of this technology has remained relatively slow in Africa (Hankins, 2011). Ho (2011) notes, "[i]n 2005, Kenya was home to just over 150,000 solar systems with a median size of 25 watts; coverage has since reached some 300,000

41 In line with this UK experience, but related to micro-hydro power development in developing countries, Rwanda has encouraged dialogues between beneficiary communities and local entrepreneurs in the development of plans for micro-hydro. See Section 25.6.2.

42 This point is not limited to onshore wind power, as is shown by a recent example of the long-term process of litigation that characterized the offshore deployment of wind turbines in the US state of Massachusetts.

households."[43] Sustained market growth in Kenya has been fuelled by a number of factors. On the demand side, these include the "(r)elatively high incomes among farmers (coffee, tea, horticulture), rural teachers, civil servants and businesses with a strong demand for consumer electronics (TVs, radios, cell phones)" (Ho, 2011) and support from NGOs and missions that provide medical and other services in remote areas that require off-grid power. On the supply side, it has been supported by the availability of photovoltaic (PV) modules in a range of sizes, local battery manufacture, an active entrepreneur class with strong connections between Nairobi and rural areas, and growing government interest. The latter was reflected in the Rural Electrification Program which, working with two foreign companies, installed PV systems in over 150 schools in remote off-grid areas between 2005 and 2009 (GTZ, 2009). With regard to capacity development, however, "(o)utside the solar companies themselves, Kenya has no organized solar energy training programs for artisans or engineers. It does have some university-level courses in alternative energy, but these are fairly basic and do not prepare 'solar engineers' per se" (GTZ, 2009).

With a view to removing barriers to the delivery and financing of SHS, the World Bank and the Global Environment Facility (GEF) initiated a series of pilot projects to provide off-grid solar energy services to rural households in 12 developing countries (Martinot et al., 2001).[44] The project tested two approaches for the delivery of SHSs – a dealer-sales approach and an energy service company (ESCO) approach – but it left open the possibility of switching from one to the other, or modifying the chosen approach once the project was underway. This flexibility was critical in developing the capacities for learning and adaptation at the project management and local levels that later proved essential in the diffusion of SHSs in a number of countries.

The range of countries in which these approaches were tested lends robustness to the findings and are supported by evidence from other projects introducing SHSs in Kenya, South Africa, Nepal (Brew-Hammond et al., 2008), and Ethiopia (ERC, 2007; UNDP, 2007). Among the main findings of these studies, three in particular stand out.

First, demonstration projects such as these need to be turned into experiments in learning for all partners, including donors, supplier firms, and clients. From the choice of approach for the delivery of SHSs to the type of financing and the focus on capacity building activities aimed at market development, learning through feedback and continuous dialogue were critical in moving the project ahead. This is particularly relevant where there are small market players who are frequently overlooked when the need for scale or minimum quality prevails. Without learning through feedback, opportunities for upgrading can also be lost as local residents and businesses, which initially adopted solutions that were far from ideal, acquired the means to purchase a better system.

Second, the decision to build flexibility into the project design is critical. This recognizes that different habits, practices, norms, and experiences of government staff, suppliers, and users may require adaptive changes along the way. The Sri Lanka project, for example, adopted both dealer-sales and ESCO models. Early in the project, one dealer decided to shift to the ESCO model but soon found that "the costs of monthly collections among dispersed and remote rural population [were too] high. The firm did not have sufficient rural infrastructure and standing in rural communities to handle collections effectively and efficiently," and so switched back to direct sales, this time facilitated by credit from a microfinance organization (Martinot et al., 2001). The flexibility built into the project design legitimized a process of adaptation that could take place once it became clear that rural practices and norms were hampering the firm's ability to function. Since the communities' experiences with microfinance made this other option possible, the ESCO model has largely been abandoned.

Third, the emphasis on creating and building a market means that projects must focus on those capacities needed to encourage the diffusion of SHS technologies even after a project has ended (Martinot et al., 2005). Taking a broad systems perspective, these include strengthening the capacities of dealers to engage in community outreach and tailor systems to local needs, developing novel financing mechanisms, and encouraging the emergence of local installation, maintenance and repair services. In Ethiopia, for example, the Solar Energy Foundation, which won an Ashden Award in 2009, created a school for young people to train as solar technicians in Rema, Ethiopia, where 2100 SHSs were installed between 2006 and 2008. Graduates of this school have opened Solar Centers in four other areas in Ethiopia, thus stimulating the diffusion of SHS systems across the country (Ashden, 2009). In the World Bank/GEF project, working with standard-setting bodies to ensure product quality and with regulatory bodies to review pricing policies was also important.[45]

Since 1997, Sri Lanka has benefited from three energy projects funded by the World Bank, International Development Association, and the GEF. By 2008, these projects had "created a vibrant local industry of suppliers, developers, financiers, consultants, and trainers," and "some 120,000 households were using solar home systems, with 750 new installations occurring monthly. Nearly 6000 households… [were] obtaining electricity from micro-hydro minigrids that communities own, operate and manage" (World Bank, 2008). It thus appears that Sri Lanka has developed the capacities to sustain the diffusion of SHSs in the near term.

The Bangladesh case shows, perhaps more clearly, how creating a market can drive the diffusion process, as well as promote the development of local manufacturing and value chains. Initially, the government's Rural Electrification and Renewable Energy Development

43 In addition, observations in Kenya also show that a larger number of rural households obtain electricity from car batteries and small PV systems than from the national grid (Jacobson, 2004). This resembles the early automobile industry, where American farmers and rural dwellers used their Model T Fords not only for transport but to run corn shellers, grinders, wood saws, water pumps, and fodder and ensilage cutters (Kline and Pinch, 1996).

44 The 12 pilot projects were implemented in Argentina, Bangladesh, Cape Verde, China, Dominican Republic, India, Indonesia, Kenya, Lao PDR, Morocco, Sri Lanka, and Vietnam.

45 Examples of this can be found in Martinot et al. (2001).

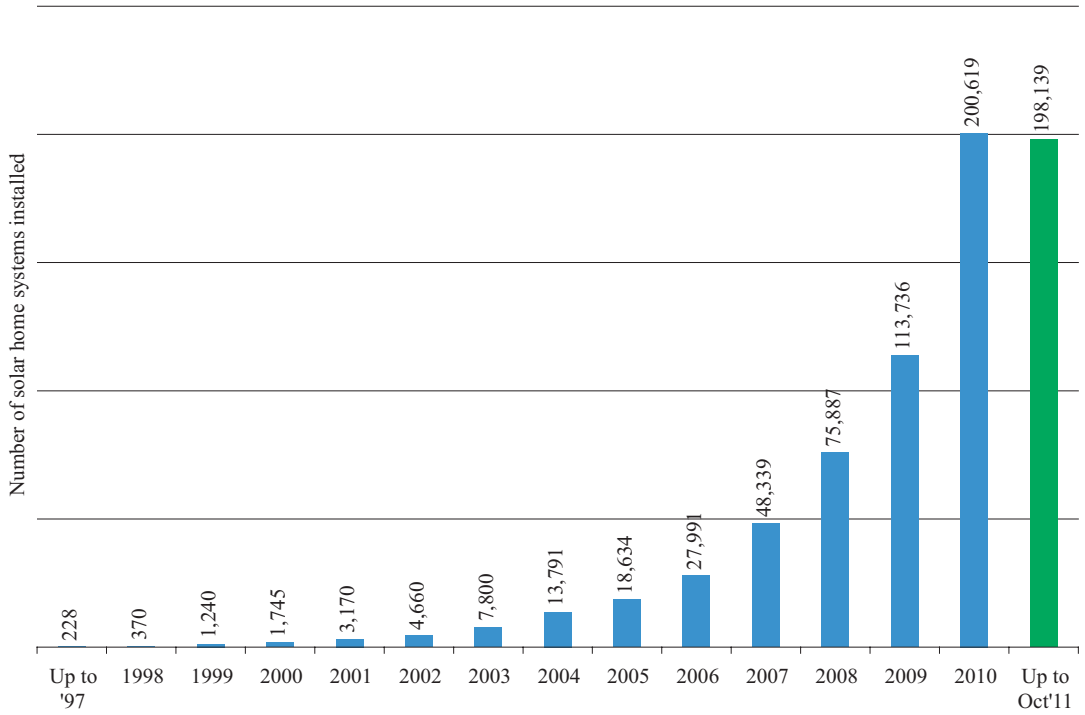

Figure 25.2 | Yearwise installation of solar home systems (SHS) in Bangladesh. Source: based on Grameen Shakti, 2011.

Project, funded by the World Bank and GEF and managed by the Infrastructure Development Company Limited (IDCOL), expected the installation of 50,000 systems by the end of 2007, but by then over 150,000 households had installed solar systems, and 7000 more were being added each month (REN21, 2008).

Three factors were important in the rapid diffusion of SHSs in Bangladesh. One was the availability of subsides from IDCOL to participating organizations that acted as distributors. This enabled these organizations to extend credit to buyers. The second was the creation in 1996 of Grameen Shakti, a not-for-profit company under the Grameen Bank that focused on bringing energy to rural areas. By 2007, it employed 1500 field staff, had trained 1000 engineers and 1000 local technicians, of which most were women, and had established a network of 390 village unit offices in Bangladesh's 64 districts. It was through these village unit offices that Grameen Shakti promoted SHSs. Soft credit through installments, which made SHSs affordable, community involvement in planning, which led to social acceptance, and effective after-sales service contributed to the rapid development of the SHS market in Bangladesh.[46] By the end of 2010, Grameen Shakti technicians had installed 518,220 Solar Home Systems and the number installed per year had risen dramatically as the capacities needed to put these systems into place developed (Grameen Shakti, 2011; see also Figure 25.2). The third factor was the role of Rahimafrooz Batteries Ltd., a local company that turned its experience in battery manufacture to the production of rechargeable batteries for PV systems. The company has since diversified into the design of charge controllers and fluorescent lamps for local manufacture. It has supplied 25,000 complete systems to distributors and provides training and technical support. In 2006, Rahimafrooz Batteries Ltd. was awarded an Ashden Award for sustainable energy (Ashden, 2006).

In addition to the "for-profit" sector, many foundations, NGOs, and social enterprises are now playing a role in developing local capacities for the diffusion of clean energy technologies, and in stimulating the development of supportive manufacturing and repair capabilities in developing countries. In Africa, for example, the African Rural Energy Enterprise Development (AREED) network,[47] funded by UNEP, GEF, and other donors, works through NGOs in Botswana, Zambia, Tanzania, Mali, Senegal, and Ghana (Agbemabiese, 2008) to simulate and support energy transitions in rural and urban areas by providing advisory services to small- and medium-sized enterprises (SMEs) and linking these to local sources of seed financing development of energy demand-side services (Brew-Hammond and Kemausuor, 2008).

46 Grameen Shakti was awarded the European Solar Award in 2003, the Ashden Award for Sustainable energy in 2006, and the Right Livelihood Award "for outstanding vision and work on behalf of our planet and its people" in 2007 (Right Livelihood Award, 2011).

47 The "REED" model has been implemented in Africa (AREED), Brazil (BREED) and China (CREED); see AREED, undated.

Box 25.5 | African Rural Energy Enterprise Development (AREED)

AREED's underlying philosophy and its innovative, networked approach makes it unique. Both of these characteristics encourage dialogue and the search for innovative solutions. AREED is, in its own words, based on the powerful idea that "impoverished people can transform their lives and break out of the vicious circle of poverty when they are empowered from the ground up" with proven, powerful, practical energy technologies. At the same time, collective experience from a variety of energy initiatives is driving renewed interest in alternative delivery models. This trend is manifested in the growing support for SMEs as versatile energy service providers capable of extending access to energy, while promoting poverty reduction and development through bioenergy systems such as the production and use of plant-based oils to power multifunctional platforms and village electrification schemes.

AREED also seeks to penetrate rural markets that would otherwise be unattractive to entities motivated solely by profit. Its focus is on "social enterprises" – defined as business organizations whose surpluses are reinvested in the business or in the community to achieve social objectives.

Source: AREED, undated.

In Senegal, AREED is working through Environment and Development Action in the Third World, an NGO, to develop a multifaceted market for solar energy technology that brings together local entrepreneurs, NGOs, government agencies, and financial service providers. With rising oil prices, the interest in solar energy has increased in Senegal, encouraged by government support for SMEs and solar technology. The agency for Rural Electrification through Local Initiatives "is responsible for the development of small energy business delivery through the use of solar technology" (Drame, 2008). Nonetheless, companies dealing in solar heaters went bankrupt (Drame, 2008). When the AREED program started, several of the bankrupt companies came together to form Africaine de Maintenance et d'Équipement (AME), a company that installs and maintains solar water heating systems. AME received a loan from AREED in 2001, which was repaid in full as the company's management capacity improved. A second loan went to Prosoleil, which manufactures solar water heating systems, and a third to Motagrisol, a producer of solar-powered milling machines (Drame, 2008). Working through the AREED network, a broader base for solar energy services is being built in Senegal.

25.5.3 Diffusion: "Scaling Up" and "Scaling Out" at the Project Level

Both the "scaling up" and "scaling out" of pilot projects are important in the diffusion of new energy technologies to users in rural, off-grid areas or to the urban poor. Scaling up involves moving from small-scale demonstration projects to larger, commercially viable enterprises that might benefit from economies of scale to reduce prices and thus increase sales. This process was discussed in Section 25.4.1 in connection with a series of European programs that demonstrated, tested, and are now moving towards the commercialization of electric and hydrogen fuel-cell buses. Scaling up can also be achieved through collaboration between research and users (see Sections 25.6 and 25.7).

Scaling out involves the diffusion of new technologies to new users. This section focuses on two energy technologies that are important in rural, off-grid areas and to the urban poor: multifunctional energy platforms (MFPs)[48] and improved cookstoves. The diffusion of these technologies to micro and small enterprises, households, and communities has proven challenging. The focus of this section is on how adaptive learning and the development of local capabilities for market-building can stimulate, support, and sustain a scaling out process.

25.5.3.1 The Multifunctional Platform

MFPs provide access to mechanical power for income generation in off-grid areas. UNDP's MFP Program was built on an earlier project by International Fund for Agricultural Development (IFAD) and UNIDO. Launched by UNDP in Mali in 1994,[49] it has since been extended to Burkina Faso, Ghana, Senegal,[50] and other West African countries with the financial assistance of a growing number of donors. Its 16-year history offers many insights into the challenges still facing the diffusion of new energy technologies in developing countries.

48 An MFP is a source of mechanical and electrical energy meant to reduce the need for repetitive manual labor, especially that of women in rural Africa. Typically, an MFP consists of a diesel engine (8–12 hp) mounted on a chassis that can power equipment such as grinding mills, de-huskers, de-hullers, oil press equipment, water pumps, and battery chargers.

49 The launch was followed by a preparatory phase and then the full pilot phase.

50 Due to conflicting figures and the absence of reference dates in a number of UNDP publications and other reports, only the first four West African countries in which the MFP program operated are discussed here, but this covers a 13-year period in the life of the program. In addition, recent independent initiatives to set up MFPs will also be mentioned.

One of the program's main objectives was the inclusion of village women in an income-generating activity. Women, through their village associations, would thus be the owners, managers and operators of the platforms and were trained in the necessary skills. They were also responsible for mobilizing a portion of the funds needed for the MFP's housing and tools. Although in some cases, men were employed to operate an MFP, it was not until the Ghana MFP project was launched in 2005 that ownership by individuals, both men and women, became a possibility. Another objective was sustainability, often the Achilles heel of such projects once donors are no longer involved, which was achieved by training and building up a network of mechanics and providing them with motorcycles so that they could repair the platforms whenever necessary.

MFP country projects proceeded in two phases. The project began in Mali with a three year pilot phase (1996–1999), during which 48 MFPs were installed.[51] This was followed by a first scaling out phase (2000–2004), at the end of which a total of 576 MFPs had been installed in Malian villages (UNDP, undated). The pace was somewhat slower in Burkina Faso, where 25 MFPs were installed during the pilot phase (2000–2003). A lack of consistent data makes it difficult to determine how many MFPs were installed in the national diffusion phase (2005–2009).[52] A recent UNDP press release, however, reported that MFPs have been installed in 441 localities in that country (UNDP, 2010). In Senegal, 44 MFPs were installed during the pilot phase (2002–2005) (UNDP, undated). The diffusion phase did not begin until two years later, with the support of the Bill and Melinda Gates Foundation and other funding sources. The additional funding also made possible the extension of the MFP programs in Mali and Burkina Faso. The Ghana MFP project began with a pilot phase (2005–2007), during which only 32 of the 40 platforms anticipated were actually installed because the budget "did not adequately capture potential issues of commodity inflation and change-orders" (Brew-Hammond and Crole-Rees, 2004; UNDP and UNOPS, 2008). This also slowed the start of the scaling out process, for which negotiations were only completed in 2009.

Unlike the emphasis on building local markets and the adaptive changes that were introduced during the pilot phase of the Solar Home Services project (Section 25.5.2), the design and implementation of the MFP project was marked by established routines and practices that slowed the diffusion process. The early MFP projects, for example, did not support the development of independent initiatives to establish MFPs. A duly registered women's association had to request a platform. Nonetheless, such initiatives began to emerge in Mali, where "19 platforms were installed without any subsidies from the project. In these cases, the villages directly contacted private artisans who had been trained by the project, and procured and installed the multifunctional platform on a commercial basis. These […] are not monitored by the project and no information has been gathered" (UNDP, 2004).

In contrast to the capacity development practices in the SHS cases, the MFP program also spent heavily on literacy training in addition to training in the management and operation of the MFPs.[53] This was costly but necessary in a program designed to enable rural women to assume ownership and management control of the MFP and to operate it. In its earlier phases, however, it might have contributed to a relatively narrow range of operations, such as milling and grinding, when a wider scope for income-generating activities through the operation of the platform – including sawing, welding, and water pumping – would have been possible but required a much higher financial outlay. This was noted in a review of the MFP project in Mali, which recommended measures such as increases in subsidies and help from other members of the community, such as men's associations (UNDP, 2004). The issue was raised again, however, in the Evaluation of the Ghana MFP pilot phase where the report recognized that "[t]here is a clear demand for other mechanized services at all MFPs visited during the evaluation […] More flexibility is needed here" (UNDP and UNOPS, 2008). Greater flexibility in adjusting to new interests, in accommodating the need for diversity in delivery models and in nurturing village-to-village learning and networking processes could have made a difference in the speed with which MFPs diffused.[54] This is particularly relevant where independent initiatives, such as the decision to replace imported diesel with jatropha oil,[55] have taken place with positive results in contexts as different as Maurolo, a small village in Mali, or Garalo, a much larger town in that country.[56]

Although the diffusion of multifunctional platforms has so far been slow, this is now changing. Feedback, flexibility, and adaptive learning are evident in the expansion of new services offered by MFPs in Mali, Burkina Faso, and Ghana, and the diversity of operational model approaches. In Ghana, of the 32 platforms installed, 11 are owned by individual women, 11 by groups and cooperatives (mostly women), nine by individual men, and one is run as a partnership (UNDP and UNOPS, 2008). Using MFPs as part of an expanding number of energy services such as water pumping and electricity provision is accelerating, and the capacities in engineering, finance, decision-making, and

51 The MFP program targeted villages with between 800 and 2000 people. This meant 2300 villages in Mali, 3200 villages in Burkina Faso, and 1400 villages in Senegal.

52 One UNDP source states that "[t]o-date 120 MFPs have been installed," but the document itself has no date (UNDP, undated).

53 A small number of men – five out of 30 trainees per literacy class and per MFP village – were also trained.

54 Deployment of energy platforms was based on a donor/government selection process and was not supportive of independent initiatives to redesign or install platforms. Recent research has shown that farmer-to-farmer learning processes can speed up the diffusion of new technologies in developing countries. They provide a tool for small-scale farmers that enables them to gain insight into their own performance in farm management, and to learn by comparing their performance with that of colleague farmers (Sinja et al., 2004; Taweekul et al., 2009).

55 Jatropha oil is a vegetable oil from the *Jatropha curcas* plant. When the plant's seeds are crushed, it produces a high-quality biodiesel.

56 Maurolo uses jatropha oil in its MFP; Garalo is using it for the generation of electricity (see Section 25.6.1; KITE, 2004).

monitoring are being developed. The diffusion process is also moving beyond the established MFP Programs in West Africa to East Africa, where discussions on the need for MFPs is underway in Tanzania (Caniels and Romijn, 2010) and two MFPs have been installed in Uganda (EPA, 2010a; 2010b). Changes are also taking place as the program opens to newcomer initiatives in the development of jatropha as a replacement for diesel by commercial enterprises such as Mali biocarbonate (Mali Biocarburant, 2010). Columbia University, working with Engineers without Boarders (USA), has developed and tested an engine modification kit and are working with a local NGO to test it further in Uganda (EPA, 2008).

25.5.3.2 Cookstoves

Improved cookstoves are another important addition to the portfolio of "new" energy technologies that serve multiple purposes (see also Chapters 4, 10, and 19). They can raise the level of energy efficiency and save on the amount and cost of wood and charcoal. Their design, production, repair, and use can also stimulate local learning and innovation and contribute to market creation and income-generating activities, as well as reduce damage to the environment and to the health of the women who are the primary users. The many possible benefits from this one "new" technology have made it the focus of donor attention for decades.

During the 1970s and early 1980s, international donor agencies introduced nearly 100 stove projects and programs. A review of these efforts by the Canadian International Development Research Centre (IDRC), however, showed that widespread diffusion was not taking place (Krugmann, 1988). The Energy Sector Management Assistance Program also reported on this in more detail in the mid-1990s, after which several World Bank projects were reoriented (Barnes et al., 1994). Nonetheless, this problem has persisted into the new millennium. Chapter 19 provides a table of 52 "improved" cookstoves that were developed from the mid-1980s to 2009 and distributed in Africa, Asia, and Latin America. Only three of these models – two in India and one in Africa – succeeded in achieving a distribution of over one million stoves. In the following section, we look briefly at some of the factors that contributed to the past failure and the emerging success of these models.

Two of the most important factors contributing to the failure of improved cookstove projects stem from the fact that they were designed in the North and transferred to the South. The former led to a choice of materials and associated production costs that tended to raise the price of stoves beyond local household income possibilities. It also led to inappropriate designs for users, mainly women, whose inputs were rarely sought. It also limited income-generating opportunities from the growth of local production and the development of skilled artisans for maintenance and repair.

Among the exceptions to this practice was the Kenyan jiko, a charcoal stove that was built and sold through conventional artisanal market channels. But even more important in understanding the speed and extent of the diffusion of jikos, in the absence of subsidies or special programs, were a number of design features that helped to build the market, provide opportunities for the development of local supply chains that supported the diffusion process, keep costs of the jiko low and prices within an affordable range for rural households. The stoves, for example, were made by local artisans and the insulation provided by ceramic liners was manufactured in local factories. When the liners wear out, artisans can either replace them or take the old jiko as part of the purchase price for a new one. The artisan then replaces the liner, refurbishes the stove, and resells it. Ceramic jikos are also much more energy efficient, and their cost varies with size and quality and can be bought for prices as low as US$2. According to a study by the German organization GTZ, between 1997 and 2001 about 1.6 million Kenyan ceramic jikos were sold, and "it became a model for a number of other stoves like the Lakech stove in Ethiopia" (Brew-Hammond et al., 2008).

Local design, manufacture, and repair were also important in the development and diffusion of improved mud chulhas with a chimney in India and a major factor in the reduction of smoke pollution in the homes of users. As many as 28 million improved chulhas, including replacement stoves, were sold from 1983–1998. While the chulhas have been praised for their positive impact on health, questions have been raised about their efficiency, particularly when the chimneys are replaced by the women themselves or by untrained artisans, with considerable loss in energy efficiency (Kishore and Ramana, 2002). Further research to upgrade the chulhas by lengthening the time between rebuilding mud walls and chimney and training programs for local artisans in repair and upgrading of the stoves would have improved their overall energy impact as well as contributing to local livelihoods.

More recently, the emergence of social entrepreneurship and microfinance in the Indian energy sector has led to the development of lower cost, more efficient stoves that emit little smoke and are able to reach the bottom-of-the-pyramid markets. These new start-ups, however, are struggling to fund additional research and larger-scale production that would help to reduce costs and prices (GVEP, 2009). They also face new competitors entering the market with "high-tech" wood and agricultural residue stoves designed in the North with the financial support of international foundations.

In the past few years, new stakeholders have become interested in stoves, including commercial European and US firms, with a view to capture carbon funds and reduce deforestation at the same time. Some completely different stove models ("second generation") were the result. These included scientifically designed models, such as those developed by Envirofit. These stoves look modern and guarantee good performance in terms of fuel efficiency and emissions. They are also not cheap and can be several times more expensive than traditional stoves. Contrary to traditionally improved stoves, second-generation stoves are

produced on a large scale in China[57] or in the industrialized world and imported into the developing countries. The role of traditional stove makers, as we shall see below, is minimal.

Envirofit, a nonprofit organization based in the United States, received donations and institutional support from the Shell Foundation that helped "to fund product development and early stage product commercialization" (Envirofit, 2010). The company was able to work closely with Colorado State University's Engines and Energy Conversion Laboratory to develop improved cookstoves based on new materials and processes for which patents are pending. Like the jiko, these cookstoves burn wood and residues, as opposed to new fuels such as liquid petroleum gas (LPG), but are more energy efficient than traditional stoves. Envirofit's business plan is based on high-volume, centralized manufacturing and global supply chain management that is expected to generate "strong margins" through their sales channels in developing countries (Envirofit, 2010). With a price tag of US$35, the diffusion of such stoves would require significant subsidies from international donors. In May 2008, Envirofit launched their cookstove business in India. Since then, the Shell Foundation "has helped them to develop market strategies which focus on rural villages across southwest India … One of the challenges was to make the stoves affordable to users" (Gomes, 2009).[58]

However, stoves from Envirofit are designed to use firewood and residues, and not charcoal, whereas the main urban market for cooking energy, particularly in Africa, is for charcoal. Charcoal is an efficient and convenient fuel for the end-user, but if production efficiencies are taken into account, it is no longer a very efficient fuel. Charcoal-using households use 30–100% more energy for cooking than firewood-using households, depending on the efficiencies of the stoves used (GTZ, 2010). Unless trees for charcoal making come from farmers' fields or plantations, deforestation may accelerate. Charcoal is a quickly growing commodity in urban areas, and it is also a lower cost cooking fuel than any of the modern alternatives such as kerosene, LPG, and electricity. Since towns are expanding rapidly across the developing world, its consumption is increasing rapidly. To meet broader development goals, strengthening capacities for the design and manufacture of improved cookstoves for charcoal and the development of the sustainable production of charcoal in developing countries could be of importance. E&CO, Inc. is doing just this.

A not-for-profit investment corporation founded in 1994, E&CO supports small and medium-sized enterprises involved in supplying clean energy technologies. It works closely with these local entrepreneurs and with local partners to support research, development, and production in developing countries. In collaboration with AREED, which provides key business support services as well as seed funding to local enterprises in the energy sector, E&CO provided a first loan of US$70,000 to Toyola Energy, a small start-up company making improved cookstoves in Ghana. Having trained in energy-efficient stove manufacturing under the Ghana household energy project in 2003, the proprietor, Suraj Wahab, was making a small number of charcoal stoves that "reduce the amount of charcoal needed for cooking by around 35% resulting in significant household savings" (EnergyAccess, 2010). By 2010, Toyola had produced and sold more than 50,000 stoves to households across Ghana and was the recipient of two further loans from E&CO, each in the amount of US$100,000.

This section took the discussion of informal institutions a step further in its identification of capacities needed for the development and diffusion of "new" renewable energy technologies such as wind, solar power, and woodfuels. These have an important role to play in meeting the energy needs, sustainable development goals, and economic and environmental objectives of communities in developed and developing countries. Critical factors in the success of such ventures are dialogue in the initial phases of project development and the inclusion of mechanisms for feedback and flexibility in project design. Dialogue between users and producers also contributes to the kind of signaling that creates awareness of opportunities for widening local markets and speeding up the process of technology diffusion.

For local entrepreneurs in developing countries to take advantage of these new flows of information, however, there will be a need to strengthen capacities for the local design, manufacture, repair, and distribution of new energy-related technologies, such as improved SHSs, cookstoves, and MFPs. As these cases have illustrated, however, the creation of new types of funding and the capacities to access these funds through stronger business support systems are also needed to make such potential benefits a reality.

25.6 Distributed Energy Systems and Development: A Multi-Goal Perspective

This section expands on the discussion above by looking at a variety of biofuels and the capacities and capacity development processes that could enable their local production and use in the generation of electricity and in building an evolving portfolio of clean energy technologies for the transport sector. It also explores the development of small and village-level hydro for on- and off-grid applications. Decentralized production of biofuels and distributed energy systems could contribute to the realization of development goals, while simultaneously moving towards an energy transition that includes smallholders and the poor.

25.6.1 Energy Access, Income Generation and Inclusion: Making Choices about Biofuels

Biofuels have had a checkered history. They are alternatively praised as a means to provide energy access, energy security, and reduced

57 Aprovecho Research Center, located in Cottage Grove, Oregon, is the designer and developer of improved "Rocket Cook Stoves," which it disseminates through its "not-just-for-profit entity" StoveTec, created in 2008. The stoves are mass produced in Shengzhou, China (ARC, 2011).

58 Richard Gomes is communications and business manager, Shell Foundation UK.

greenhouse gas emissions, and criticized as contributing to the destruction of tropical forests and competing with food crops for the use of agricultural land. As the world's population grows and climate change affects agricultural production, making choices about biofuels will require new skills, information, and capacities to analyze trade-offs and design, monitor, manage, and enforce policies that ensure sustainability (see Chapter 20).

By 2005, with oil prices again rising, interest worldwide has been attracted to liquid biofuels for the transport sector (see ESMAP, 2005b; 2010 for further information).[59] Although electric vehicles are also making a comeback in urban environments, levels of electricity output are insufficient to meet their widespread use in Europe in the near term[60] and are likely to be a niche or longer-term option, particularly in the developing world. Biofuels are also being developed for energy generation, thus creating new options for distributed energy in off-grid environments.[61] From an even broader, but longer-term development perspective, biofuels can open up opportunities in developing countries for what the OECD, in a recent study, has termed the "bioeconomy"[62] (OECD, 2009). Strengthening local research capacities, participating in collaborative research and development (R&D) efforts, and coordinating policies across government ministries are key elements in laying the foundation for the long-term development of the bioeconomy and the multiple options it will offer in the future (ESMAP, 2005a; OECD, 2009). In the past, this would have been dismissed as unrealistic, even as a long-term goal for developing countries. However, the recent development of biofuels from sugarcane, jatropha, and algae suggest that building a bioeconomy in the developing world is not an altogether unrealistic proposition, as the following examples illustrate. Evidence of the role that local R&D capacities can play in stimulating the growth of the bioeconomy in the developing world is already emerging.

In Brazil, for example, sugarcane-based ethanol was the first biofuel to be commercialized successfully in a developing country and perhaps in the world.[63] A long-term research effort that brought government, growers, and ethanol producers into the process was a major factor in bringing down prices and eliminating subsidies. It is important to emphasize here that land-use issues were not of major importance in Brazil, where sugar plantations were already in place and options for sugar exports were in decline.[64] The use of sugarcane as the feedstock for ethanol in Brazil has contributed to its overall positive climate benefit (UNEP, 2009). Most sugarcane plantations, however, were concentrated initially in the north-east and south-east regions of the country[65] and the need to transport ethanol around the country resulted in some negative effects on net CO_2 benefits. The plantation system, moreover, largely excluded smallholders from the biofuels sector.

In the development of biodiesel production the Brazilian government sought to include smallholders and the poor. A variety of inputs were identified for biodiesel and several of these are available in most regions of Brazil. They can be grown by smallholders and processed and distributed locally. Government policies have been put in place to encourage the purchase of feedstock for biodiesel from smallholders (Teixera et al., 2008). In keeping with earlier successful practices in the development of higher-yielding sugarcane varieties for ethanol production, the research that has made possible the development of crop varieties and production techniques for biodiesel was subsidized by the government and has been supported by both the public and private sectors.

Biodiesel from palm oil is an example of how this new approach is leading to a rethinking of the role that decentralization can play in strengthening smallholder production and in generating externalities. In the Amazon region of Brazil, oil palm trees are long-lived and abundant. Producing biodiesel from the palm oil of existing trees is an option with multiple benefits in areas where choices are few and the damage to forests is already great.[66] Palm oil biodiesel production would help resolve the problem of electrification in the Amazon region, which has the lowest electrification rate in the country (Coelho et al., 2005). Since 2002, the Brazilian Reference Center on Biomass (CENBIO), in collaboration with other research institutes, has been working to develop and test a rural electrification model for the Amazon based on the use of local palm oil (Coelho et al., 2003). This could result in "a quite significant improvement in [greenhouse gas] emissions compared to conventional

59 In 2010, the US Department of Energy awarded US$78 million to the National Alliance for Advanced Biofuels and Bioproducts and the National Advanced Biofuels Consortium.

60 See McKinsey and Company, 2010, a study prepared for 28 companies from the automobile, oil and gas, utilities, industrial gas, equipment car manufacturers, wind and electrolyser companies, one NGO and two government organizations. The report emphasizes the importance of developing a range of technologies that will ensure the long-term sustainability of mobility in Europe and in this connection, stresses the need to reassess the role of fuel-cell electric vehicles in the light of recent technological breakthroughs.

61 Taking advantage of their experience with flex-fuel engines in the transport sector, Brazil's Petrobras, in collaboration with General Electric, has upgraded an 87 MW power plant to operate using either natural gas or ethanol. General Electric was interested in this research project because in other countries it has some 770 turbines similar to those in the Brazilian plant that could be converted to run on ethanol. Both companies are members of the Model Fuels Consortium, whose goal is to accelerate adoptions of Green Fuels (GE, 2010; Petrobras, 2011).

62 The "bioeconomy" spans an array of sectors, including agriculture, health, environment, and industry.

63 For a case study of this process, see Chapter 24. Additional discussion is available in Chapter 11.

64 This resulted from a combination of the special trading arrangements concluded between the European Economic Community and its associated African, Caribbean, and Pacific states, and between the former Soviet Union and Cuba, and the production of sugar from beetroots in Europe and the development of corn syrup for use in prepared food and beverages in the United States.

65 Nowadays 80% of the alcohol production is from states in southeast (São Paulo, Parana, and Minas Gerais) and mideast states (Goias, Mato Grosso do Sul, Mato Grosso, and Tocantinhs). In Parana State sugarcane is produced by smallholders organized in cooperatives.

66 In a number of African countries, palm oil has also traditionally been used for lighting.

diesel. On the other hand, if areas that were not previously cultivated are converted to palm oil production, the net resulting balance can be dramatically negative" (UNEP, 2009).

On May 6, 2010, former President Lula da Silva announced the Program for Sustainable Production of Palm Oil on abandoned and degraded agricultural lands in the Amazon region. The program, designed to support poor farmers in the region, specifically prohibits the expansion of oil palm at the expense of native forests (Butler, 2010), although whether this can be enforced is debatable. Estimates of the production of biodiesel from harvesting palm nuts and processing the oil locally in the Amazon region put the cost of the biodiesel below that of the petroleum-based fuels currently transported to the region over land. In addition to this saving in fuel costs, the harvests and processing can provide local populations with income and potentially forestall further destruction of the rainforest to plant soybean destined for export as part of the animal feed chain.

Jatropha has been praised as a feedstock for biofuels because of its ability to grow on marginal land and in arid environments unsuitable for food crops. It is a particularly good substitute for petroleum-based diesel and kerosene, and can be used as a transport fuel or as a replacement for off-grid stationary power. Small-scale production of jatropha can also help to restore the productivity of degraded land (UNEP, 2009) and open new income-generating opportunities.

In Mali, for example, jatropha is now being grown on "marginal" and unused land to provide fuel for a local 300 kW power plant (UNEP, 2009; ACCESS SARL, 2010). In early 2007, rather than rely on imported diesel for a future off-grid generator, villagers from the commune of Garalo in Mali chose to plant jatropha.[67] Of the 440 hectares (ha) planted with jatropha, two ha were prepared as a nursery and 95% of the fields were planted by individual farmers,[68] of which 6% (25 ha) were for women (Burrel, 2008). The main purpose of the plant is to provide access to electricity for a range of energy services that include lighting, refrigeration, the use of welding equipment and agricultural processing machinery by businesses and workshops. It was also designed to reduce the cost of the village water pumping system by replacing the diesel genset then in use with electricity from the local mini-grid (Rijssenbeek and Togola, 2007).

Research and advisory services are playing an important role in the development of smallholder jatropha farms. In 2008, to assess the condition of the jatropha plants, a sample of 118 ha comprised of 100 fields in 21 of the villages, were surveyed by a local agronomist working with the International Crop Research Institute for the Semi-Arid Tropics. The capacity to form such linkages between farmers and research is critical for learning, problem solving, and the sustainability of projects that involve new technologies. Feedback from this survey, for example, has contributed to strengthening the positive outcomes of the project in two ways. First, the survey indicated that 71% of the farmers intercropped jatropha with food crops such as maize, sorghum, millet, peanut, sesame, and beans. These farmers had thus dealt with the assumed need to choose between food and fuel by developing a system that produced both. Second, the survey alerted farmers unfamiliar with jatropha cultivation to the need for wider spacing between plants if intercropping were to continue as the jatropha plants grew (Burrell, 2008).

In 2008, the power station in the Garalo township provided electricity to 230 clients, of which 198 are households, 19 are shops, restaurants, workshops, and mills, two are healthcare providers, seven are local government buildings, and four are places of worship.[69] This had increased to 251 consumers in 2010, according to ACCESS SARL, a Malian energy service provider that has been selected by the municipality to manage its power station and grid (ACCESS SARL, 2010). It is expected that the number of users will more than double over the next two or three years as the jatropha plants mature and the yields and incomes of smallholders increase. Local oil transformation is also contributing to income generation, economic growth, and poverty reduction in the broader community as access to and costs of energy services decline (Burrell, 2008).

Much of the success of this project can be attributed to strong community participation nurtured by a continuous dialogue and the availability of information and technical support from local agencies such as the Mali Folk Centre (Goertz, 2006; Burrell, 2008). This has led to considerable follow-up, experimentation, and local learning, for example, in shifting from the costly process of using plastic bags for seedlings in the nursery to the use of direct seeding in the fields. Improving methods of intercropping is another area that has benefited from local research and is serving to increase farmers' incomes.[70]

The problem with using jatropha oil for fuel arises when it is reconceptualized as an export commodity. Upscaling the smallholder model for the large-scale production of biodiesel fuel for the domestic market, and even more so for export, requires considerable rethinking.

First, the assumption that jatropha is a low-cost, low-input crop that grows virtually by itself is problematic in this new context. Recent research in India, for example, has shown that the price of jatropha oil depends upon increasing the yields, and that this in turn requires improved seeds that reach their potential when well watered and often when fertilized (Altenburg et al., 2008). The failure to reach anticipated yield levels has led to the abandonment of a number of joint ventures in India (Dogbevi, 2009a; 2009b).

67 The village worked closely with the Mali Folk Centre, a Malian NGO that is a member of the AREED network.

68 The remaining 5% were collective fields.

69 The data come from billing records. In addition to the clients, 45 public lights have been installed. Every client pays 500 CFA (approximately US$1) extra for these lights (Burrell, 2008).

70 Changes in billing practices are also under consideration to reduce the financial burden on customers.

Second, a larger volume of feedstock is needed. Regrouping land parcels into large-scale farms and increasing mechanization are new practices introduced as a means to increase yields. But these practices require substantial amounts of capital. They also lead to changes in the organizational model away from smallholder farming to cooperatives, in some cases, but more frequently into contract farming with multinational corporations as partners. These practices also result in the outright sale of land to local or foreign firms, resulting in the potential alienation of smallholder lands and requiring considerable attention to regulatory and other policies that currently do not exist.

Algae are yet another entrant into the biofuel chain that could contribute to clean energy technologies, the growth of the bioeconomy, and the broader process of sustainable development. In a popular (non-technical) classification for liquid fuels made from biomass, such fuels are discussed in terms of first, second, and third generations where the "different generations are distinguished primarily by the feedstocks from which they are derived and the extent to which they are (or are not) commercially developed" (Chapter 11). Algae are currently placed among third-generation biofuel fuels. However, "land use constraints, competition with food and demand for biomass with high caloric value have made marine based biomass an attractive alternative supply option over the past years […] Promising concepts for aquatic biomass include (1) land-based open ponds for microalgae, (2) horizontal lines between off shore infrastructure, e.g., wind farms for macroalgae (seaweed), and (3) vertical lines near shore in densely used areas and nutrient-rich areas for macroalgae" (Chapter 7). Marine algae use saline water, CO_2, and non-arable land. Located near point-sources of CO_2, such as factories and coal-fired power plants, hybrid production systems[71] open opportunities for clean-up,[72] while optimizing the system cost and contamination of production (Huntley and Redalje, 2006).

Algae technologies can also provide bio-based inputs or end products for a wide array of markets. Algae biomass, for example, can be converted to end applications such as biofuels and animal feed. Hydrotreated algal oil can be mixed in any ratio with conventional diesel or aviation fuel, and can then make use of the existing infrastructure. Of the algal biomass, approximately one-third can be converted into biofuels. Dried whole algae or the remaining dried defatted algal mass can be used as a source of high-quality protein in animal feed (Kiron et al., 2009) and in food products. Although the market for protein is likely to expand rapidly due to population growth, the supply of high-quality, algae-based protein may become greater than the growth in demand (Balagopal et al., 2010). A high supply could lower feed and food prices and change the structure of the animal feed and food industries.[73]

Microalgae are single-cell organisms that convert CO_2 and sunlight into biomass through photosynthesis. Compared with terrestrial alternatives, marine algae do this very efficiently. They have the potential to produce substantially more biomass per m^2 per day than conventional biofuel feedstocks, such as palm oil or rapeseed oil, but without the need for fresh water and minimizing the need for land, phosphates, and nitrates. Because the production of the end product can take place in a liquid medium, advanced industrial processing techniques are available that have the potential to reduce processing costs and allow scaling up to very large volumes.[74]

Production yields are directly dependent on the amount of light reaching the growing algae, so that the most efficient algae facilities will be located between latitudes 23.5°N and 23.5°S. Most development of know-how, however, is currently taking place in the infrastructure-rich United States. This opens opportunities to build capacities outside the US, particularly as the most effective, non-genetically engineered algae strains for any given commercial open pond facility are likely to be found locally. Expertise is rare anywhere at the moment, which necessitates global cooperation and the use of virtual teams that include researchers and other experts based in different locations. Developing countries could play an important role if domestic knowledge capabilities in these domains are strengthened. There are also interesting research, development, and testing opportunities in closed bio-reactor processes in developing countries, as current collaborative research between a German and a South African university illustrates.[75]

Solving the many engineering problems and market issues that new industries face requires bringing people together from different disciplines and different industries, as well as patience. This goes beyond earlier practices of consulting with researchers from different firms or industries. Instead, it opens a dialogue between disciplines that speak different languages, have different points of view, and may display different logic based on different value systems. As the discussion of open innovation systems in Section 25.7.1 shows, networks of this sort have already been put in place to speed up the process of problem solving

71 Hybrid systems combine (expensive) photo bioreactors with (contamination-prone) open ponds.

72 The closer, the more concentrated, and the purer the CO_2, the cheaper the cost of production will be.

73 An algal industry with a capacity of 450 kbd (1 kbd = 1000 barrels/day) of algal oil could supply up to 15% of the crude protein needed in the compound animal feed market by 2030, thus enriching crops such as protein-poor cassava for use as animal feed and reducing the damage to land and forests from soybean monocropping.

74 Biofuels must be both profitable and sustainable. Algae do not yet meet both criteria simultaneously. An important element of cost reduction is to maximize the biomass and/or algal oil produced per m^2 per day, which would minimize the physical footprint of a facility for a given plant capacity.

75 In 2009, Jacobs University (Germany) partnered with Nelson Mandela Metropolitan University (South Africa) to expand the testing of its photobioreactor, which currently uses marine microalgae to convert CO_2 from a coal-fired power plant, breweries, refineries, and cement factories in the Eastern Cape region into organic compounds through photosynthesis (Guetali SADC, 2009).

in a variety of new technologies. This form of cooperation should be stimulated and encouraged. Corporations that are the first to master this will be more successful in executing the associated complex integrated projects and create more value.

25.6.2 Small and Micro-Hydro: Bottom-up Solutions

Hydropower is the main source of renewably generated electricity in the world today and there is still considerable potential for exploitation, in particular in rural areas of developing countries (see Chapter 7, Section 7.6 and Chapter 11, Section 11.3). Many developing countries have tried to build small and micro hydro projects,[76] some for connection to grids and others for off-grid use. Where many projects failed is through a lack of local ownership: plants are designed and constructed by foreign firms with minimal input from local stakeholders. Once commissioned, plants are transferred to the local community, which then must assume operation and maintenance responsibilities as well as costs. This has had negative consequence for sustainability. We take a closer look at the experiences of China, Bhutan, and Rwanda here.

By the end of 2007, after 30 years of unremitting efforts, China had built more than 45,000 small hydropower (SHP) stations with a total installed capacity of about 50 gigawatts. Together, they generate 150 TWh/year and account for one-third of the total hydropower nationwide. By developing small hydropower, half of the territory of China, one-third of the counties, and over 300 million people had access to electricity in 2009 (REN21, 2009).

The large number of SHP plants in China is directly related to transmission system needs, government tax policies, and feed-in power rates. The Ministry of Water and Power also played an important role in this process by providing interest-free loans to China's rural utilities and technical assistance to ensure that locally developed plans conformed to national standards. Although large hydro plants can generate huge amounts of energy, the existing grid system prevented the efficient transmission of electricity to rural villages. By providing policy support and financial incentives, funding for renovating rural grids, especially through the Clean Development Mechanism (CDM) since 2004, and technical training, the state built pilot counties of primary rural electrification infrastructure and encouraged local governments and farmers to develop small hydropower to solve the problem of local access to electricity. This environment encouraged private companies to invest in the construction of small hydro plants, and up to 85% of the funding now comes from private sources (Zhao and Zhu, 2004). Zhejiang province is a case in point.

Severe power shortages in Zhejiang province necessitated reforms. Due to preferential government policies (a guaranteed power price, macro planning, and a standardized bidding process) and stable and high profits, the Zhejiang water resources industry has attracted the highest national amount of private investment in this sector. The national fund for grid construction was used to build the connecting infrastructure, while private funds were tapped to develop the small hydropower sources. Private investment covers 80% of installed small hydro capacity.

A wide range of investors have been involved in this process. Water resources enterprises, power corporations, individuals, overseas Chinese and shareholding corporations have cooperated in establishing corporations and limited companies. Shareholding SHP corporations, originally located in villages or counties, became provincial group corporations. This not only quickened the exploitation of hydropower resources, but also fostered water conservation, developed a wide range of local capabilities, and raised living standards.

Village-scale power, however, continues to be one of China's biggest challenges for isolated villages. Early project experience suggests that village power applications will require government assistance for some time due to economics, the challenges of management arrangements, and the need for local regulators and tariff frameworks. Most village-scale power systems managed by traditional utilities have not been successful in China. Other operating and management models are clearly needed. Even collecting tariffs high enough to cover operating and maintenance costs can be a challenge – about 1 RMB/kWh (or about US$0.10/kWh) seems to be about the maximum.

SHP development in China is decentralized and managed by local governments and people. The state encourages the development of local small hydro power resources – based on the principle of "self-construction, self-management, and self-consumption" and the policy of "those who invest should enjoy the revenue and ownership." The results have been impressive. The bottom-up development of village power schemes undertaken by local village organizations and business firms, seems to show a greater chance of success by coordinating mutual interests at the earliest stage of development, generating commitment through face-to-face communications with working people, and following a rigorous process for clarifying the interests, roles, and responsibilities of all parties.[77]

76 Definitions of small, micro-, and mini-hydropower vary across countries and can even include systems with a capacity of just a few megawatts. The United States India, and Brazil define microhydro as <100 kW and mini hydro as 100–1000 kW (Moreira and Poole, 1993). In China, small hydropower refers to plants with an installed capacity of up to 50 MW (Zhou et al., 2009). In Nepal, small, micro-, and mini-hydropower systems are defined respectively as plants with 1–15 MW (usually feeding into a grid), 100 kW-1 MW, sometimes stand-alone, but more often feeding into a grid. Micro installations with capacities of 5–100 kW usually provide power for a small community off-grid (AEPC and UNDP, 2009).

77 A bottom-up approach to rural electrification in Nepal also appears promising, although its lessons "are not being adopted and upscaled at a desired pace," despite the passage of a Local Self-Governance Act in 1999, and evidence that "local government bodies are dissatisfied with central agencies, which are perceived to be indifferent to local proposals including local program needs, objectives and modalities" (Nepal, 2007).

The Kingdom of Bhutan faced similar problems in its efforts to develop off-grid micro-hydro projects. Due to their lack of financial viability, the Bhutan Power Corporation has been reluctant to take over the management of the new micro-hydro plants (MHP) being built. When the Chendebji micro-hydro was commissioned in October 2005, an alternative model involving the community had to be developed. This community-based management model is being piloted in Chendebji and is expected to be refined and used for similar projects in the future. To ensure sustainability and diffusion of micro-hydropower in the rural areas, such projects should be coupled with the development of income-generating opportunities and a program of continuous training to maintain the skills of local plant operators (see Case Study 2, Section 25.11).

The situation in Rwanda differs from that in both Bhutan and China. A small, densely populated country, Rwanda had an available national electricity generation capacity of 71 MW in 2010 (Bensch et al., 2010). This provides access to about 10% of its 10 million people. Some 270 MHP sites have been identified, of which about 20 have been developed or are under development.[78] Grid expansion is rapid and sites that even five years ago were expected to remain more than 15 km from the national transmission grid are now close enough to be grid-connected. As a result, most MHP plants have a choice between connecting to the grid or not, based on a trade-off between incremental investments for transmission lines and incremental income from being able to sell 100% of the produced electricity.

Public funds were used to develop most of the MHP plants and operational responsibilities were, until recently, given to local communities. These were not able to manage the plants in a sustainable manner (GTZ, 2010). The national electricity company is not interested in managing these plants even when grid connected, as they are too small and associated management costs are too high compared to its larger plants. Over the past several years, a number of privately owned MHPs became operational and more are under construction. These are funded by a private sector participation program for the development of micro-hydro in Rwanda (Pigaht and van der Plas, 2009). Under this program, local entrepreneurs develop the plan for these plants jointly with beneficiary communities, secure commercial loans from local banks, and are financially supported by a government subsidy. Since plant owners have taken loans to finance part of the investment costs, they have every incentive to ensure that the plants continue to function properly. The government has now decided that management of all public MHP plants will be auctioned off to the private sector, and future MHP plants will only be established with contributions from the private sector. Although the cost of electricity from these plants is slightly higher than from 100% publicly financed plants to cover private financing costs, more funds are available for immediate development of village power systems. In addition, the sustainability of privately financed plants is likely to be higher, and plants are developed around locations with the highest interest among the local population (Pigaht and van der Plas, 2009).

Overall, there is great potential for the further development of hydropower, especially in rural areas of developing countries and with the participation of local communities and private sector players. But the successful development of this potential requires comprehensive government policies at the local, regional, and national levels. Such polices include financial support through taxes, feed-in tariffs, and soft loans; the creation of programs for technical assistance and capacity development in the design, maintenance, and management of small and micro-hydro; and changes in regulatory policies that make conditions more favorable for private sector investment in village-based micro-hydro projects. The success of targeted bottom-up approaches in China, Bhutan, Nepal and Rwanda illustrates the need for mutual interests to be accommodated through dialogues in which local government bodies are brought into the process early in the development of a project and a mechanism for continued dialogue over the life of the project is put in place.

This section has also illustrated that, in addition to enabling energy access, distributed energy systems based on biofuels could have an important role to play in the broader development process. The need to develop capacities for making choices about biofuels in technical, as well as economic and financial, terms, and in evaluating trade-offs is of critical importance in creating such benefits and ensuring their long-term sustainability. Greater attention, for example, should be paid to assessing whether, when, and how to scale up the production of biofuels in a given context. Strengthening the research and problem-solving capabilities of local universities and research institutes in agro-, bio-, and social sciences will be essential in supporting such policymaking processes. Developing these capabilities, however, can take many years at a time when decisions about energy transitions that involve biofuels require attention now. The next section explores the role that a variety of different forms of networking can play in contributing to the development of domestic capabilities for research, analysis, and innovation.

25.7 Strengthening and Sustaining Capacities for Networking and Innovation

In the last quarter of the 20th century, open and distributed innovation emerged as a response to new needs for knowledge sharing in the information technology and biopharmaceutical industries that were not being met by the existing patent system (Harhoff et al., 2007; Dechezlepretre et al., 2009). The networks and knowledge-sharing approaches that were developed helped to deal with the diversity of knowledge inputs that characterized these new technologies, enabled enterprises in developed countries to catch up with the technological frontier,[79] and contributed to more rapid problem solving that accelerated the diffusion of new technologies. Networks for knowledge sharing and collaborative research are now emerging in the field of new energy technologies.

78 This involves about 17 MW in plants with capacity of between 100 kW and 5 MW.

79 See the case studies of the international collaborative ventures of US firms in the telecommunications equipment industry, pharmaceuticals, biotechnology, aircraft, robotics, and automobiles (Mowery, 1988) and of European firms (Mytelka, 2001).

This section discusses the special features of open and distributed innovation approaches as they have emerged in the developed countries. It then focuses on the application of these approaches in developing countries, notably in the strengthening of university-industry linkages and in a variety of new knowledge networks that support research, analysis, and problem solving in new energy technologies, and thus speed their development and diffusion. From a multi-goal perspective, networks such as these are now also being designed to support broader development goals by reducing the brain drain from developing countries.

25.7.1 Networks for Open and Distributed Innovation

Open innovation explores the potential of an organization, i.e., a firm or university, in a networked environment (Chesbrough, 2006). A network culture provides an opportunity to connect more people, who embody a wider knowledge base, to an organization's mission.[80] The core insight of open innovation is the ability to use the world outside an institution to generate internally useful knowledge – and the core dependency of open innovation, in turn, is the need to make the flow of knowledge in and out of an institution a purposeful thing, not a random process.

A world of purposeful information flow is at odds with many of the business structures of the last 50 years, especially intellectual property rights. The idea of leveraging the sharing of knowledge as a key business strategy, rather than using intellectual property exclusively as a measure to prevent or exclude competition, is thus a novel one that has not yet resulted in the widespread adoption of models such as business-to-business networks or the collaborative research programs that are now common in the European Union.[81] There is, however, movement in this direction. The BIOS Project in Australia, for example, began with a single core patented technology for transferring genes in plants. It was developed specifically to avoid encumbrance from existing patents, so that users could develop plants without any fear of "reach through" claims affecting things that were as yet undiscovered. Now called the Initiative for Open Innovation, it offers a range of legal tools that allow the possibility for many classes of contracts other than patent licenses. These tools encourage new improvements to the underlying technology,[82] as well as improve the potential for profit-making into the covenant.

Other projects aim to go even further towards the creation of infrastructure for open innovation by specifically encouraging patent holders to make their patent portfolio available for licensing through public license offers that are open to everyone on reasonable terms, while retaining the defensive benefits of patents. This goal is based on the understanding that many patent holders have patented inventions that could have broad or new applications in areas that they did not anticipate, but they may not have a strategy to actively license them or offer them for such uses. By making public license offers on reasonable terms, patent holders can encourage others to seek out novel uses that could have important economic or environmental benefits (see Science Commons, 2011).

Capacity development in this area involves the creation and use of standard licenses for most uses of patents outside a company's core business space. It also creates open and widespread patent "landscapes" in key areas so that risks and opportunities are well understood and public-private partnerships to ensure that vendors are in place to provide services to entrepreneurs, large companies, and universities, each of which plays a key role in the innovation ecosystem under open innovation.

The second approach, generally called distributed innovation, is most closely associated with the open source software culture reflected in the development of Linux (Feller et al., 2005). Distributed innovation is less a modification of existing practices than a truly disruptive aspect of the network culture. In terms of innovation power, it consists of a collected set of individuals whose individual actions "snap together" into a coherent group through standard technical systems and digital networks. Distributed innovation has now spread from information and communications technologies to the biosciences, pharmaceuticals, environment, agriculture, and related energy technologies. Recent studies have provided evidence that this approach is able to speed problem solving in technologies that span multiple knowledge bases and have relevance to multiple disciplines involved in new energy technologies (Lakhani et al., 2007; Lakhani and Pannetta, 2007). InnoCentive, an online network that puts "seekers" in touch with "solvers" of technology and policy problems, for example, has begun to include energy-related problems on its list (see Case Study 3, Section 25.11).

A related development is the recent emergence of informal Internet discussion groups on subjects of importance to developing countries. Their purpose is to exchange information on a certain technology or process, use the collective experience of network members to solve problems posed by network participants and to advance knowledge and understanding of these technologies to a wider audience of commercial firms, researchers, government officials, and students. Among these, two well-known examples are the Stoves Discussion Group (Stoves, 2011) and the Microhydropower Discussion Group (microhydropower.net, 2011).

Scientific publications are also playing an important role in knowledge dissemination and network creation. The push to share knowledge has

80 For example, to contribute to internal projects from the outside, to take a project that fails to gather internal support forward using outside funding, to generate novel projects outside and "spin into" new internal projects.

81 These date back to the European Strategic Programme for Research and Development on Information Technologies (ESPRIT) in 1983. Funded in part by the European Union, each project must be cross-national and bring together at least one enterprise with other actors (universities, users) for collaborative research and technology development (RTD). Annual competitions are held to select projects for funding and all partners have full access to knowledge and technology developed within the project (Mytelka, 2001).

82 A plant created would be freely available, but if a licensee improved the gene transfer tool itself and patented the improvement, then the improvement would have to be made available back to all other licensees of the tool (IOI, 2011).

increased tremendously since the Internet became commonplace. "Open Source" publications[83] co-exist with for-fee publications, and numerous government organizations, donor organizations, UN Agencies, NGOs, and universities provide open access to reports and papers prepared by their staff or consultants.

25.7.2 University-Industry Linkages

Brazil has a long history of government support for domestic research, as the development of ethanol and biodiesel illustrates (see Section 25.6.1). The technology transfer offices in Brazilian universities and the development of collaborative relationships between universities/public research institutes and the enterprise sector trace their origins to the transition from a "top-down" system to one that operates at multiple levels – municipal, regional, national, and multinational. This transition allowed for the emergence of new initiatives by new actors, especially universities and industrial associations (Lahorgue et al., 2005). Technology parks, technology transfer offices (TTOs), science parks, and incubators have proliferated since the 1990s (Coutinho, 2001). But, despite these initiatives, Brazilian manufacturing firms have relatively low innovation capacity. Their spending on innovation is mainly related to the purchase of machinery and equipment and, to a lesser extent, on research and the development of new products and processes. In contrast with other countries, moreover, Brazilian companies do not receive significant public financing for these activities (BRASIL, 1996; 2004; 2007), and about 60% of R&D activities in Brazil are funded and carried out by the government (Cruz and Mello, 2006). But this includes major research institutes in state-controlled companies such as the Brazilian oil company, Petrobras, and the research and reference centers located in a number of Brazilian universities.

Petrobras was a pioneer in the creation of knowledge networks as a vehicle for the development of offshore oil technology at a time when low oil prices created a disincentive for major companies to invest in this technology. Between the late 1960s and the early 2000s, "Petrobras massively transformed its offshore technology networks […] from a passive learning network to an active learning network" and developed in-house research capabilities that later enabled them to engage in strategic networks that involved two-way flows of knowledge and collaborative research activities"[84] (Dantas and Bell, 2009). The reform of the power sector in the mid-1990s opened yet more opportunities for networking and collaborative research. From the start of the energy privatization process, and as a condition within the concession agreements, companies were obliged to invest 1% of annual net revenues in energy efficiency and R&D.[85] This was complemented in 2000 by the creation of "CT-Energy," a fund to support public interest research,[86] which specifically included energy R&D and energy efficiency among its "social benefit investments."

In 2002, the Brazilian government's White Book on Science, Technology and Innovation (see Portal do Ministério da Sciência e Technologia, 2002) focused on creating "an effective science, technology and innovation national system" in Brazil. This was followed by Brazil's current policy framework, the industrial, technological, and foreign trade policy, launched in 2003, the 2004 Innovation Law (10.973/2004), and the expansion of sectoral funds, including those earmarked for renewable energy technologies that encourage and financially support a broad range of energy-related networks.

Brazil currently has a substantial network of research groups, or reference centers. They serve as recognized regional or national centers of excellence in a specific domain and are also open information networks in the field of energy technology. Among the research groups and networked centers is the award-winning GreenSolar research group, whose multidisciplinary research on solar thermal energy technologies draws together university departments of civil and mechanical engineering, electronics, control and automation, architecture, computer science, and management.[87] GreenSolar also works closely with companies such as Electrobras and the main business association in this field, and ABRAVA, the Brazilian branch of the Global Solar Thermal Energy Council. Among the reference centers are CENBIO, which undertook the research on palm oil production in the Amazon (see Section 25.6.1),[88] and the Brazilian Reference Centre on Biofuels (CERBIO), which works in collaboration with the Paraná Technology Institute to undertake research, development, and innovation on biofuels. It also evaluates the technical feasibility and social and environmental impacts of these biofuels. CERBIO was chosen by the federal government to support the national biodiesel program, which brings together some 30 institutions including universities and enterprises. In this latter capacity, CERBIO is also part of the "Brazilian Service for Technical Answers," through which specialists address technical questions in various fields.

83 Such as www.ashden.com, www.scidev.net, and www.scirp.org/journal/lce.

84 The concept of two-way knowledge flows in collaborative research was developed and extensively applied to analyze strategic partnerships and networks in the European Union (Mytelka, 2001).

85 This measure was intended "to avoid the risk that the new companies, mostly owned by foreign investors, would transfer all their R&D efforts elsewhere, a trend already noted by […] Bourgeois and Jacquier-Roux, 2001" (Jannuzzi, 2005). See also www.annel.gov.br.

86 CT-Energy does not substitute for the obligation to invest, present in the concession contracts. The fund supports energy efficiency programs and initiatives that would not be considered by utilities or market agents, such as the development of energy efficiency standards, consumer training courses, promotion of events, scholarships or research grants directed to projects that will contribute to improvements in energy supply and use. The fund supports regional initiatives to develop local capacity and projects (Jannuzzi, 2005).

87 GreenSolar is based at the Pontificia Universidade Católica in Minas Gerais, Brazil.

88 Information on Brazilian zoning for sugarcane at both federal and state levels is presented in Chapter 20.

Like Brazil, South Africa issued a white paper on science and technology in 1996 outlining the concept of a national innovation system (DST, 1996). Three years later, it had become evident that, in the context of South Africa's complex socioeconomic challenges, more would need to be done to raise investment in science and technology. This led to the development of the South African research and development strategy, which provided funding for a range of technology missions that were central to innovation and to the promotion of economic and social development (Mehlomakulu, 2008). The strategy also recommended interventions to improve the efficiency and effectiveness of the national innovation system, including the establishment of a national agency to stimulate innovation and the introduction of legislation to encourage technology transfer from public research institutions to industry. After declining for much of the 1990s, gross expenditure on R&D has been rising steadily, approaching a level of 1% of GDP,[89] more than half of which is undertaken by industry and not government, as in Brazil.

In most of the "research-intensive" universities and science councils, TTOs were set up during the late 1990s and early 2000s at the initiative of the institutions themselves, who recognized the need for and were willing to devote some resources to this activity, as occurred in Brazil. Active government involvement in promoting technology transfer from public research organizations began shortly thereafter, leading to more TTOs.

While the newer TTOs are still in the process of institutionalizing the relevant policies, procedures, and practices, the more established TTOs have now accumulated some degree of experience and expertise. Patenting and licensing, nonetheless, remain low. Various factors have contributed to this (Wolson, 2008; Sibanda, 2009). The pipeline of invention disclosures is thin. Since the number of potential disclosures is related to institutional R&D expenditure (Heher, 2005), a smaller system is likely to yield fewer disclosures. Furthermore, researchers are often reluctant to make disclosures, whether due to a lack of interest or incentive or skepticism about the academic technology transfer endeavor. A relatively small pool of researchers with interest and experience in the technology transfer process also affects the quality of disclosures and, as a consequence, they are often not ideal subject matter for commercialization. The costs of patenting are high, and many institutions do not have adequate budgets to pursue international filings. Although the number of technology transfer practitioners is increasing, capacity remains limited, as do capacity-building opportunities. Finally, local licensing opportunities are scarce, with South African technology-led companies typically accessing their technology from abroad, in the belief that local institutions are, for the most part, not a valuable source of innovation, according to a 2005 Innovation Survey (DST, 2007) or are undertaking their own research. Both the South African Technology Innovation Agency and the new Intellectual Property Act provide for financial support and capacity-building activities, which are welcomed, and are expected to assist in overcoming some of the identified problems once they are up and running (see Case Study 4, Section 25.11).

There has also been some concern that South Africa is not capturing the benefits of its own R&D. However, while examples exist of technologies developed in South Africa that have been commercialized abroad, a recent study investigated some of these cases, but the data failed to identify any technologies that had been transferred overseas and successfully commercialized to the point that they were generating income to their current owners, without benefit to the original inventors (Pouris, 2008).

One example from the field of renewable energy clearly illustrates that commercialization outside the country is by no means synonymous with denying South Africa and South African inventors the optimal benefit of their innovations. The technology for cheap, thin-film, silicone-free photovoltaic cells was developed at the University of Johannesburg with support from the Innovation Fund, a government agency that promotes technological innovation. The university and the inventor set up a company in South Africa to commercialize the technology. The company's decision to license the technology to a German firm attracted strong criticism, on the basis that this was "unpatriotic" and with the implication that the technology was being "lost" to South Africa. But while the first plant was set up in Germany, plans are now afoot to build a South African manufacturing plant that will generate substantial investment and employment and essentially kick-start a new local industry. This is a collaboration between the German licensee and various local investors, including the company owned by the university and inventor. The local partners have also invested in the German firm, resulting in a cross-shareholding that has facilitated access to relevant expertise, know-how, suppliers, and finance that were not available within the country. Arguably, had efforts to set up a local plant been confined to South Africa, it would have taken far longer to build the necessary capacity and attract the funding required (Planting, 2006; Pouris, 2008; Reuters, 2009). While few would argue against licensing new technologies to new spin-out or start-up or existing domestic companies, this case shows that this is by no means the only way to capture value from a technology for the country.

25.7.3 Creating Knowledge Networks: South-South, North-South

Knowledge networks for joint research and problem solving, knowledge sharing, analysis, and long-term planning can contribute positively to the development and diffusion of new energy technologies in a number of ways. Such networks, for example, can potentially create confidence that attracts greater funding and might strengthen the sense of local ownership within the context of donor-supported projects. Participation in knowledge networks that strengthens local research capacities, moreover, can create incentives that reduce brain drain, thus contributing to

89 Gross expenditures on R&D rose from 0.6% of GDP in 1997 to 0.95% of GDP in 2006 (DST, 2006/2007).

the provision of context-specific inputs that are needed for policymaking, for problem solving, and for the design, development, and diffusion of new energy technologies. These benefits are, of course, potential. In this section, we explore some of the ways in which knowledge networks that provide such benefits have emerged and evolved. The focus is on developing and least developed countries where, until recently, such opportunities have been rare.

There is much concern in the developing world about the problem of brain drain. The challenges that this presents are exacerbated by the growing need for access to a continuous stream of knowledge and information in order to make choices about energy technologies and pathways towards energy transitions. Some efforts are being made through networks of centers of excellence, such as the Global Network on Energy for Sustainable Development (see GNESD, 2009), to provide inputs for policymaking in developing countries.

One of several partnerships in the field of energy that were launched at the World Summit on Sustainable Development (WSSD) in September 2002, Global Network on Energy for Sustainable Development (GNESD) became operational in 2004. GNESD received core funding from Germany and Denmark. It has also received initial support from France, Italy, the United Kingdom, the UN Foundation, UNDP, REEEP, and UNEP. It was originally composed of 21 public and private research centers and NGOs engaged in research, with a variety of different strengths in the energy area and situated in both developed and developing countries. However, over the years GNESD has evolved into a South-South knowledge network consisting of 10 centers of excellence. Current membership spans a number of subregions, focusing on policy-oriented research that addresses different aspects of energy access and Millennium Development Goals achievement. Some members have worked together before in other networks.[90] A number of the members are themselves networks; consequently, GNESD's reach is quite wide.

GNESD's work focuses on energy access, energy security, renewables and bioenergy for the poor – notably those in urban and peri-urban areas – and energy policy issues facing governments in the developing world. Within this framework, a steering committee, currently composed of representatives from eight member organizations in the developing world, three from OECD countries, and two from donor organizations, meet annually to decide on the network's thematic programs. The first of these focused on energy access issues. It reviewed existing energy policies in Africa, Asia, and Latin America to identify the effects of reforms that have been carried out in the past and to recommend policy measures that can increase the possibility of bringing energy to those currently without access. One of its outcomes was a publication on how to overcome barriers and unlock potentials in renewable energy technologies (GNESD, 2007) tailored to the needs of users, which was followed up by workshops in developing countries organized by member centers to disseminate their findings.[91] GNESD also undertakes research at the request of developing country governments. In 2010, the UN Secretary-General's Advisory Group on Energy and Climate Change recommended that "[e]xisting knowledge networks should be mobilized and new ones built […] to accelerate the transfer of best practices (with respect to modern energy system policies and regulations)," and specifically cited GNESD as "a good example of knowledge creation and sharing on energy policy analysis" (UN AGECC, 2010).

In the sciences, the challenges of the brain drain remain acute, and the benefits derived from earlier efforts to build North-South networks in the areas of health and biosciences have not relieved this. In July 2009, the Wellcome Trust[92] announced a grant of £30 million (US$47.9 million) over five years to support seven newly created research consortia based in Africa. The grant is renewable after an independent review. The approach is new in several ways. First, the objective is to strengthen research capacities in Africa itself. The seven consortia are thus based in Africa, each one headed by an African researcher, and their research will be conducted mainly in Africa. As Dr. Alex Ezeh, executive director at the African Population and Health Research Center in Kenya, who is leading the Consortium for Advanced Research Training in Africa, noted, "(n)otwithstanding the attention it has historically received, research capacity remains very weak in Africa. Existing research capacity-strengthening programs and collaborative partnerships in Africa are largely driven by Northern academic and research institutions" (Wellcome Trust, 2009). To this, Dr. Margaret Gyapong, director of the Dodowa Health Research Center of the Ghana Health Service and head of the new Research Institute for Infectious Diseases of Poverty, one of the seven consortia, added, "Africa is losing many of its best scientists to the brain drain, partly because of the absence of coordinated institutional strategies and national research environments […] poor integration of knowledge across disciplines, and a lack of consistent engagement with policymakers, users and community beneficiaries" (Looi, 2009). The seven consortia include 52 African institutions in 18 African countries, and have linkages to research centers in Australia, Denmark, Norway, Switzerland, the United Kingdom, and the United States. While it is still too early to evaluate its contribution to the development of research capacity in Africa; if successful, it might constitute a new approach to consortia development for energy transitions.

90 Interview with Daniel Bouille, Bariloche Foundation, Argentina, center representative.

91 Its second theme, renewable energy technologies, was launched in early 2005 and completed during 2006 and 2007. Two other themes were launched thereafter, one on urban and peri-urban access to energy, and the other on energy security. The former has already produced case studies of India, Senegal, Argentina, Thailand, and Kenya, and dissemination workshops have been held to discuss lessons from the needs assessment and the analysis for policies and programs for capacity building.

92 The Wellcome Trust is the United Kingdom's largest charity.

Box 25.6 | UNU Geothermal Training Programme

The United Nations University Geothermal Training Programme (UNU-GTP) is aimed at professionals employed by local organizations, public or private, in which geothermal work is already underway or starting up. Potential participants are nominated by their organizations and the selection process emphasizes direct insertion upon return (see UNU, 2011).

The GTP offers courses in nine fields related to geothermal technology and good environmental practice. The programs of individual participants are tailored to these fields so that, over time, teams are built up with the capacity to support local research, exploration, production energy, and environmental planning. This strengthens the "ownership" of geothermal resource planning in projects funded through development assistance and strengthens the set of capabilities needed for research, development, and planning in these countries.

The adoption of a regional approach in areas with large reserves of untapped geothermal potential has encouraged the development of knowledge networks that support local learning and have helped to attract investment in geothermal exploration and energy supply. The Rift Valley in East Africa illustrates this approach. It began with a gradual expansion in the number of participants from Rift Valley countries in the six-month training and research program. This was followed by the first "short course" in Africa, which brought together 33 participants from Kenya, Djibouti, Eritrea, Ethiopia, Tanzania, and Uganda, the six member countries of the African Rift Geothermal Energy Development Facility (ARGeo), a program supported by GEF, UNEP, and KfW, a German development bank (Hamlin, 2004). After successfully testing advanced seismic and drilling techniques in Kenya that will substantially reduce costs (UNEP, 2008), a five-year program of exploratory drilling in the ARGeo countries has been developed and funded (ARGeo, 2010).

A similar approach is being pursued in Central America (Fridleifsson, 2006).

In the field of new energy technologies, the role that training programs can play in supporting research, development, and diffusion of geothermal energy in developing countries has been already demonstrated by the United Nations University Geothermal Training Programme (UNU-GTP). Established in 1978 and located in Iceland, the program was designed to assist in establishing groups of specialists in selected organizations – research institutes, municipal energy utilities, and universities – in developing countries with significant geothermal potential. These groups, in turn, would create local capacity for the exploration, development, and use of geothermal energy in these countries (see UNU, 2010). Initially, the vehicle for capacity development was a six-month specialized training program that brought scientists and engineers from developing countries to Iceland. In 2005, this was complemented by "short courses" on thermal energy topics open to both specialists and decision makers from the public and private sectors. These workshops are held in the developing countries. Co-sponsored by local energy agencies, they include graduates of the UNU-GTP in their teaching staff (Georgsson, 2008).

In terms of standard assessments of project outputs and outcomes, the UNU-GTP has been very successful. Over the period 1979–2010, 452 scientists and engineers from 47 countries completed the program, including more than 75 from China, 53 from Kenya, 31 from the Philippines, 30 from El Salvador, and 27 from Ethiopia and Indonesia. Today, China is a world leader in the direct use of geothermal energy. Kenya, the Philippines, and El Salvador obtain 10–22% of their total electricity from geothermal energy, and Ethiopia has started its first geothermal power plant (see UNU, 2010).[93] What is unique about this program, however, is its many spillovers – some intended from the outset and others the product of iterative learning and adaptation processes.[94] These innovative practices have created incentives for trained personnel to return home and to stay in jobs for which they have been trained. This helps to meet the challenges of the brain drain, as well as contributing to the sustainability of geothermal research and local production once donor funding ends.

As the variety of new initiatives reviewed in this section illustrates, networking and open and distributed innovation can play an important role in providing the continuous flow of information, "research-based

93 Since its introduction in 2000, 25 have also graduated from the MSc program.

94 See Sections 25.3.1 and 25.3.2 for a discussion of these differences.

evidence," and analysis that governments need to make informed choices about energy technologies and pathways. However, as Simon Maxwell, director of the United Kingdom's Overseas Development Institute (ODI) points out, "engaging with policy requires more than just research skills" (Young, 2008). Researchers will need to work closely with policymakers throughout the research process, from identifying the problem to undertaking the research itself and drawing out the recommendations for policy and practice. These capabilities are not inherent in the research task, nor is collaboration of this sort the norm in policymaking practice. Working closely with researchers, bilateral and multilateral development organizations, and NGOs, ODI has developed an iterative approach to "engaging with policy" that draws on the concepts of complexity, on the tools of outcome mapping developed by the IDRC (see Section 25.3.1), and policy engagement tools developed by the ODI itself. The process of learning to work in partnership begins by mapping the political context around the policy issue, identifying the key participants and the desired changes in behavior. Developing an engagement strategy, analyzing internal capacities to effect change, and establishing the assessment tools and learning frameworks will then be needed to make alignment and learning in partnership happen (Young, 2008). As this list reveals, many new capacities, in the sense of habits, practices, norms, and values, will be developed in this process.

Participation in networks also strengthens the capacity of governments, local industry, research, and NGOs to innovate and speed up the processes of change. For this to benefit developing countries, however, a concerted effort must be made to strengthen local research capacity, foster a better understanding of open licensing practices in relation to intellectual property rights, and develop and implement policies that support networking and innovation. Innovation, as we have stressed from the outset, must be broadly conceptualized to include both the uptake of knowledge at the frontier and knowledge that is new to the user, community, or country, if not to the world. Problem-solving networks, especially in developing countries, are thus as important as those that lead to patented products and processes.

As the case studies in this section also illustrate, participation in networks and the capacities to innovate are not limited to South Africa and Brazil, but provide opportunities for a wide range of developing countries to move more rapidly towards an energy transition, as the example of geothermal energy showed.[95] A co-benefit of this process is that it can create the positive environment that encourages researchers to remain at home, thus reducing the brain drain.

95 Some of the smaller developing countries, of which Kenya (*jikos*, geothermal energy) and Cuba (modernization of thermoelectric plants, natural gas [Saenz, 2008]) are interesting examples, have forged ahead in specific energy-related areas, linking problem solving to the needs of local users.

25.8 Making and Managing Energy Transitions

This section focuses on the way capacities in the energy sector – notably skills, habits, practices, legal and other norms, and policies – have been built up. But, it also explores the extent to which they have been maintained over time, transferred to new applications, or progressively unlearned as they became less relevant in the course of an energy transition. We look at three very different cases from established oil and gas producers and exporters. In the first two, we focus on the build-up and erosion of R&D capabilities in Mexico's oil industry and its slow start in moving towards renewable energies and on the Abu Dhabi Economic Vision 2030, which is designed to turn the emirate into a knowledge-based leader in new and renewable energy technologies. The third case examines the approach to an energy transition process taken by the Netherlands.

25.8.1 From Oil to Clean Energy Systems: Policy Learning and Unlearning In Mexico

The discovery of giant oil deposits in Mexico during the late 1960s and early 1970s led to a production boom that turned Mexico into a major oil exporter. Over the next two decades, the Instituto Mexicano del Petróleo (IMP), the research arm of PEMEX, Mexico's National Petroleum Company, emerged as a major R&D center, with strong capabilities in exploration, development, and engineering projects, as well as flexible production planning. The IMP undertook basic and applied R&D, the training of researchers and personnel, and detailed engineering projects.[96] This would change as Mexico entered a period of economic instability.

With oil prices rising, interest rates at historically low levels, and import-substitution-led growth slowing down, the Mexican government yielded to the temptation to fuel economic growth by relying on oil revenues and external debt. This mode of development financing collapsed with the crisis of 1982. The "hands-off" model of economic liberalization that followed reoriented growth towards export-oriented industries, substantially reducing the share of oil revenues in total exports, but it did not bring about macroeconomic stability or sustained growth. The accumulation of reserves became negative in this period and after the Mexican financial crisis of 1995, a second surge in oil exports would again push annual production higher.

Since then, accelerated oil exploitation has been driven by a new investment model in which the burden of activity has been shifted to the private sector, leveraging these investments with internal debt. The adoption of these new financial schemes has had a strong negative impact on capacity building. During the crisis years, IMP's

96 "By the late 1970s, about 90% of the detail engineering of Pemex projects was developed in Mexico" (Guajardo, 2007).

capacities were not renewed, as PEMEX abandoned efforts to attract new investment and relied increasingly on technological outsourcing. The new investment model was based on build-operate-lease and build-operate-transfer operations carried out by foreign firms. In these turnkey projects, all R&D, licensing, design, engineering, and sometimes operation is undertaken by the contracting firms. The buyer acquires a ready-to-use plant (or the final product). By "buying" these capacities, this investment model eliminates the demand for local engineering and R&D skills, and therefore the learning space needed for local capacity building and the development of new enterprises and organizations. By the early 2000s, the output of Mexico's major oil fields, particularly the Cantarell field, had entered a period of decline, slightly ahead of other giant oil fields in the world (Höök et al., 2009). Nevertheless, production for export continued. Growing certainty about the nature and volume of deep-water reserves in the Gulf of Mexico convinced PEMEX officials that the company must rapidly engage in deep-water drilling and development in order to maintain the pace of extraction. This led to a relaxation of the legal constraints on subcontracting to private partners, on the grounds that PEMEX lacked technical and operational experience to exploit these offshore resources (see SENER, 2007).

Indeed, oil exploration, development, and production in deep waters require a different set of technologies and capacities. Drilling below 500 meters in the sea demands floating platforms, special drilling ships, and satellite guided systems, as well as robotized and other remote-controlled equipment and installations, all equipped to operate under extreme climatic and pressure conditions. Naturally, using these systems also requires specialized capabilities in project design and development that PEMEX clearly lacks. But this is what other firms at similar stages of technological development, such as Petrobras in Brazil, have done (Ballarin, 2002). Moreover, it is precisely what PEMEX did in the past.

The challenge goes beyond the difficulties of building efficient (and safe) deep-sea drilling platforms. Electricity generation in Mexico was opened to independent producers in 1993, and by 2008, the private share in generation had grown to 40%. The lack of incentives and a lowest-cost policy for new installed capacity meant that most capacity growth in combined-cycle gas turbines was also constructed via turnkey investment schemes. In addition to its negative impact on the development of local engineering and research capacities, this policy framework has blocked the adoption of renewable energy sources. A similar situation prevails in the development of wind energy (Borja et al., 2005), where turnkey investments are the rule. The Mexican government has since committed itself to exploiting existing, and developing new, renewable energy sources (SENER, 2006), and has recognized the role of technology R&D in this process (SENER, 2002). But in the absence of a coherent policy framework for capacity building beyond some support to basic research and market deregulation, there is little demand for detailed engineering, design, and R&D services from local institutes and firms. In the solar energy sector, for example, despite the accumulation of important capabilities in the Instituto de Investigaciones Eléctricas (IIE),[97] the lack of an industrial incentive framework has prevented spin-offs and transfers of knowledge and technology from the public to the private sector. Moreover, no local industry supplying photovoltaic components has developed. Movement towards an energy transition will thus require a rethinking of current practices and policies that shape incentives, innovation, and the diffusion of new energy technologies.

25.8.2 Abu Dhabi's Economic Vision for 2030

In contrast with Mexico, which "unlearned" earlier positive habits of capacity development, Abu Dhabi illustrates movement towards the learning of new habits and practices as it seeks to overcome its dependence on oil and gas, and to develop domestic capacities for an energy transition. Since the discovery of petroleum in 1958, Abu Dhabi's energy sector has been the primary driver of both economic development and environmental degradation. Industrial growth in the emirate, as in much of the Arab Gulf region, has involved the construction of thermal electric power plants, aluminum smelters, cement plants, oil refineries and platforms, and petrochemical and fertilizer plants. According to the World Resources Institute, the United Arab Emirates (UAE), of which Abu Dhabi is a member and the capital, is the world's second largest CO_2 emitter on a per capita basis (WRI, 2010).

In view of its small population, the transition to an oil and gas economy also brought with it a heavy reliance on foreign technology and on foreign labor and expertise to operate it. Efforts have been made to reduce the reliance on oil by diversifying into agriculture, manufacturing, tourism, and aviation; by re-exporting commerce; and by establishing free-zone facilities and telecommunications. And yet these have tended to exacerbate the problem. The region's member states face a growing challenge in maintaining the demographic balance between nationals and expatriates. In an interview in 2008, a human resource specialist from the Dubai Municipal Government reported that expatriates occupied 99% of jobs in the private sector and 91% in the public sector out of a total 3.1 million employees in the UAE: "Going by the trend, […] UAE nationals will account for less than four per cent" by 2020 (Ahmed, 2008).

Arab states have begun to implement a variety of schemes to encourage nationals into employment and to force private companies to hire more of them. So far, these efforts have been largely unsuccessful in reducing the reliance on expatriates and integrating nationals into the economy.

97 These include capabilities in resource assessment, project development, and plant and prototype design. IIE also defined the technical requirements for design and installation of PV systems with a nominal capacity of up to 30 kWp connected in parallel to the low-tension distribution network. Also, in collaboration with the Federal Electricity Commission and the Rural Development Program, the IIE provided engineering services that enabled the installation of over 40,000 solar panels (IIE, 2006).

The solution to this challenge lies primarily in the education system, which needs to prepare and equip students with not only the right skills and qualifications but also the work ethic to make them competitive in the job market. Education reforms and training initiatives are being put in place to address the skills gap and to ensure that the supply of suitably qualified employees meets the market's growing requirements, yet the outcomes of these efforts remain to be seen.

One encouraging development is the Abu Dhabi Economic Vision 2030,[98] launched in 2006, which identifies nine pillars that will form the architecture of the emirate's social, political, and economic future. These include the creation of a sustainable knowledge-based economy, for which the above education reforms and the Masdar initiative (see Case Study 5, Section 25.11) will be critical. Unlike Mexico, using the financial resources generated by the "energy-oil and gas" sector is a central element in the energy transition process envisaged in Abu Dhabi's vision of the future and its application in the Masdar initiative. To support the latter, the government has announced that renewable resources will meet 7% of the emirate's total power-generating capacity by 2020. It is estimated that this will create a market valued at US$ 6–8 billion, and will reduce CO_2 emissions by 2.4 million tonnes/year.[99]

Despite the progress made, the Masdar Initiative has not been without its problems. In October 2010, Abu Dhabi announced its intention to reduce the costs of the Masdar initiative by 15% and push the completion date from 2016 to between 2020 and 2025. As Sultan al Jaber, the chief executive of Masdar, emphasized, "The vision as a whole remains intact. No scale-back, no scale-down. There isn't a model or example anywhere around the world today that we can use. We have to come up with the answers ourselves" (*The National*, 2010). Partly in reaction to the impact of the financial crisis on property markets, this decision was also a response to lessons learned over the past several years in the design and construction of a carbon-neutral city. Concentrated solar power (CSP), which uses mirrors to reflect sunshine on to a central collection point, for example, is less effective in Abu Dhabi, where humidity and sand in the air can make the sun's rays less intense than anticipated. New approaches to CSP will have to be developed. The use of geothermal power in Abu Dhabi will also require new thinking, as the far deeper drilling required will be a more costly process than initially foreseen. These unexpected developments point to the need to make educational reform an integral part of any strategy to move from fossil-fuel-based economies to renewable energy systems and to the importance of systems thinking, interdisciplinary approaches and continuous feedback throughout a transition process.

98 The Abu Dhabi Economic Vision 2030 was designed based on the advice of development experts from Norway, Ireland, and New Zealand (Abu Dhabi, 2008).

99 As part of the Masdar initiative, Abu Dhabi has also created a US$50 million development fund that will be used to provide loans to support renewable energy projects in the developing world until 2016.

25.8.3 The Dutch Energy Transition Approach

An interesting attempt at working towards an energy transition to a low-carbon economy is the Dutch energy transition approach. It is significant because of its focus on transformative change, its reliance on bottom-up processes, and its enrolment of business and other non-state actors in the transformation process. It grew out of deliberations between innovation researchers and policymakers in 2000, in which policymakers came to accept that a traditional policy approach based on short-term goals formulated by various ministries (in an uncoordinated way) and cost-effectiveness will not work. They also recognized that fostering radical innovation requires a different approach, one that is more forward-looking, with attention to possibilities and barriers, drawing on ideas for innovative change among market actors and innovative thinkers, with policy aligned to identified transition paths. This new way of thinking has been described as follows:

> It is clear that working on fundamental changes to the energy system can only be successful if the government adjusts its policy instrumentarium accordingly. This means that the policy for research and development, the stimulation of demonstration projects, and the (large-scale) market introduction must be brought in line with the selected transition pathways. In addition, the suggestions for new policies put forward by the platforms must be taken seriously. At this point, the government faces a major challenge, because much of the current policy was formulated based on the classic way of thinking that is characterized by a top-down approach and dominated by short-term objectives, implemented by fragmented and individually-operating departments and ministries, on which market influences do not or hardly have any effect (Dietz et al., 2008).

At the heart of the energy transition project are the activities of seven "transition platforms": new gas, green resources, chain efficiency, sustainable electricity supply, sustainable mobility, built environment, and energy-producing greenhouses. These platforms bring together individuals from the private and the public sector, academia, and civil society to identify innovative system configurations in a particular field, to develop a common ambition for an area of energy use or energy conversion, to think up pathways and programs, and to suggest transition experiments. Through these platforms, 31 transition paths have been selected.

The portfolio of transition paths contains technological innovations at different stages of development. The choice is based on technologies in which there is expertise in the Netherlands and an interest from business actors to work on them.

Based on suggestions from the transition platforms, a transition action plan was formulated in 2006 with the following goals:

- reducing CO_2 emissions by 50% by 2050 in a growing economy;
- increasing the rate of energy saving from 1.2% to 1.5–2%/year;

Table 25.1 | The frontrunners' desk in the Netherlands.

Services for innovators	Services for policymakers
Obtain financial support from existing instruments	Make existing instruments more conducive for innovation
Contact relevant agencies and government staff	Improve policy coordination between and within ministries
Overcome legal problems and problems with permits	Encourage case-sensitive implementation of existing and new policy
Widen their network and strengthen the organizational set-up of the innovation trajectory	Encourage policy development in areas of the innovation chain that are not well covered
Provide business support and public relations help for successful market introduction	Be of service to businesses in a case-sensitive way

Source: Weterings, 2006.

- making the energy system progressively more sustainable; and
- creating new business.[100]

The platforms are intended to mobilize the interests of society and of business in innovative change and to promote learning and action. Issues of wider interest (or more strategic nature) are taken care of via a special council called the Regieorgaan Energietransitie Nederland.

The transition approach was consciously set up as a vehicle for coordinated socio-technical change and policy change. Through their involvement in the platforms, businesses are encouraged to work on and assist in the development of low-carbon innovations, including those that are not yet ready for the market. The platforms fulfill an intelligence function based on discussion, specially commissioned studies, and a coordinating function for emerging technology innovation systems.[101]

In addition to the transition platforms, an interesting policy innovation is the "front-runners' desk," created in 2004, which seeks to help innovative companies with problems they encounter, and to help policy to become more innovation friendly. Problems varied from difficulties with obtaining financial support (from government or the private sector), to problems with getting permits. Between January 2004 and March 2006, 69 companies approached the desk to discuss their problems. In 59% of cases, the problems were solved thanks to the intervention of the desk, in 12% of the cases the companies could not be helped, and in the remaining cases (29%), the desk was still dealing with the issue at the time of the evaluation (Weterings, 2006). Table 25.1 provides an overview of the functions of the front-runners' desk for innovators and policymakers.

The energy transition involves government agencies on different issues and at all levels. Some mechanism of cooperation is thus needed. Special arrangements have been set up for this task in the Netherlands, the most important of which is the Interdepartmental Project directorate Energy transition (IPE). The IPE plays an important role in "taking initiatives," "connecting and strengthening initiatives," "evaluate existing policy and to act upon the policy advice from the Regieorgaan and transition platforms," to "stimulate interdepartmental coordination" and to "make the overall transition approach more coherent" (Staatscourant, 2008). In drawing upon suggestions from the platforms, however, there is a danger of the transition process becoming a closed shop. Options outside the portfolio are at a disadvantage, but are not locked out. New initiatives may emerge outside the platforms through parliament or because certain powerful parties in society are able to secure policy support for it. This happened in the case of battery-powered electric vehicles, for which a coalition of NGOs, businesses (Essent, Better Place), finance (ING, Rabobank), and the Urgenda (a coalition for sustainability action) successfully lobbied ministers and parliament to provide special support to electric vehicles.

On the whole, policy coordination has improved in recent years. For example, battery-powered electric vehicles, hybrid electric vehicles and other low-emission vehicles are subject to special fiscal treatment. There is more cooperation between ministries and among government, business, research, and civil society. There is also more cooperation between previously separate national and regional initiatives.

Various kinds of capabilities are being created in a strategic way for technologies and policy through the Dutch transition approach. Areas for creating capabilities are being identified through the activities of the transition platforms, and they are supported by policy in a provisional manner. The government's ability to act to bring about systemic change has improved, and there is a commitment to transitional change that is absent in many countries. Indeed, the political discussion on low-carbon energy in many countries is narrowly focused on centralized choices of carbon capture and storage (CCS), and natural gas and nuclear power plants. These discussions are also taking place in the Netherlands, but more options can be explored through the energy transition approach.

100 The official goals in 2009 for 2020 were: 2% rate of energy saving a year, 20% share for renewable energy, and 30% reduction in CO_2 emissions.

101 As an illustration, in 2009, the platform for sustainable mobility will: (i) make recommendations for the fiscal treatment of clean vehicles; (ii) discuss the action plan on alternative mobility with leasing companies; (iii) examine how natural gas and green gas may pave the way for hydrogen; (iv) evaluate experiences with bus experiments funded in the first tender; (v) offer advice on how public transport concessions may be used for innovation; (vi) assist in the implementation of five pilots about smart grids and electric mobility; (vii) launch or stimulate pilots for sustainable biofuels (high blends and biogas) and hydrogen in five cities, in cooperation with Germany and the province of Flanders in Belgium (Kemp, 2010).

The Dutch approach is not without faults. The platforms are dominated by well-known energy companies (the insider-outsider problem). A second problem is that subsidies for energy investment are funded through general taxes, which makes those subsidies vulnerable to cuts. It is better to fund these through energy bills, as is the case in Germany, in order to create an element of continuity in energy transition policy. This takes on particular importance when governments change. Dutch clean energy policies have been characterized by major discontinuities that have hampered energy innovation (Verbong et al., 2008). Third, the liberalization agenda conflicted with the energy transition agenda. Its use in an add-on way contributed to policy incongruence (Kern and Howlett, 2009). This is not the fault of the energy transition approach, but the problem has not yet been resolved.

25.8.4 Moving Towards an Energy Transition

Oil- and gas-producing and exporting countries have faced considerable difficulty in overcoming the tendency to rely heavily on this one sector, to the detriment of greater economic diversity and flexibility. Significant new thinking and practices have emerged in these countries, although overcoming the challenges of path dependence, sunk costs, and established habits and practices to move towards an energy transition has been particularly difficult.

The broad set of initiatives discussed in this section provides pointers for working with and around habits, practices, and challenges in other environments. The Norwegian government, for example, created the Norwegian Petroleum Fund in 1990. All central government revenues from petroleum operations are deposited in this fund, all of which is invested abroad to provide a buffer between current petroleum revenues and the use of these revenues in the Norwegian economy. The government uses about 4% of its petroleum revenues annually (Norges Bank, 2004). The Norwegian energy innovation system also includes Enova SF, a public enterprise created in 2002 and owned by the Ministry of Petroleum and Energy. Enova SF advises the ministry on issues related to new renewable energies and energy efficiency, with the goal of reducing energy use. Its funding comes from a levy on the electricity distribution tariffs (Enova, undated; Borup et al., 2008). Brazil, already well along the pathway towards cleaner energy in the transport sector, is planning a development fund using oil revenues. Abu Dhabi's Masdar initiative has grown out of a similar process, and the Arab Gulf states are developing the education and research base needed for an energy transition that will involve more than simply importing technologies and expertise.

The policy dimension has also been important in moving towards energy transitions in these countries. Mexico, having moved away from a focus on building and sustaining capacity in the oil sector, is now on the brink of developing a cleaner energy strategy based on wind and solar power for which capacity development will be necessary. Some capacities have already developed within existing organizations, but policy coordination and new policy measures that provide the incentives and support the use of this new knowledge for innovation are lacking.

The Netherlands has adopted a particularly innovative approach to energy transition thinking and practice that provides pointers for others looking to work with and around existing habits and practices in their own environments. The approach is embodied in the role of energy platforms. These platforms bring together individuals from the private and public sectors, academia, and civil society to identify and make proposals to government about policies for different energy-related initiatives. They are not just "talk shops," but spaces for dialogue that inform the participants of their diverse interests, concerns, and goals. They mobilize and legitimize a process of change and the kinds of support measures that would be needed for movement along consensual pathways. Their proposals feed directly into the policy process.

25.9 Enhancing Capacity for Effective Participation at the International Level

A wide variety of new technology, energy, and environment issues are increasingly being dealt with at the international level and across many different venues. They include trade, intellectual property, and antidumping issues at the World Trade Organization (WTO); technology transfer and the future of a multilateral climate framework at meetings of the United Nations Framework Convention on Climate Change (UNFCCC); funding opportunities through the CDM under the Kyoto Protocol; the Global Environment Facility (GEF); and other funds managed by the World Bank. Enhancing the capacity for effective participation in international negotiations has thus become an arena within which substantive knowledge about the subject under negotiation will be needed, as well as the capacity to design projects for and secure access to the many funding sources now available for adaptation to climate change, and new energy technologies and their diffusion. This will require the strengthening of capacities for networking, learning, and innovation[102] along multiple dimensions.

Developing countries soon faced the rising transaction costs of settling antidumping complaints, which were first signaled in the controversies generated by the difficulties that developing countries encountered in accessing drugs to deal with HIV/Aids and the role of the Agreement on Trade-Related Aspects of Intellectual Property Rights. Like most developing countries, Brazil initially met this new international legal challenge by hiring foreign law firms. Subsequently, a few Brazilian law firms created departments specializing in WTO negotiations, and they signed agreements with government and major law schools in Brazil to create domestic expertise in international trade law. The presence of local lawyers on law school

102 For example, UNDP's "Capacity development for policy makers" project seeks to strengthen the national capacity of developing countries to develop policy options for addressing climate change, as inputs to the UNFCCC negotiations.

faculties helped to form expert groups that strengthened the capacity development process (Shaffer et al., 2008).

Further experiments in capacity development began when Brazil established an advanced WTO mission in Geneva and signed agreements with Brazilian schools of law and of international relations to create a training program in Geneva – the first of its kind in Brazil. This experiment played an important role in strengthening Brazil's capacity to participate in the more informal dispute settlement negotiations in Geneva, where many such disputes were actually resolved (Shaffer et al., 2008). The virtuous cycles of learning and practice further strengthened Brazil's network connections, with some surprisingly positive and unexpected benefits.[103]

25.9.1 Funding Energy Transitions: A Capacity Development Approach

The CDM, as a development financing mechanism, marks a new innovation in international environmental law and with it the need for a new set of capacities. The CDM is an emissions offset trading system that allows countries to meet their Kyoto targets by investing in emissions reduction projects in developing countries, where the marginal costs of GHG abatement are expected to be lower than in industrialized countries. It has the added purpose of helping to promote sustainable development and technology transfer to developing countries (Doranova, 2009).

After several years in operation, the results of the CDM are mixed. The mechanism has attracted considerable investment, with more than 4500 projects currently at some stage of development and approval (UNEP-Risø, 2011). But there are also a range of problems:

- there are concerns that many of these projects would have happened without the CDM (lack of additionality or environmental integrity);
- few projects promote sustainable development;
- projects are not distributed equally (especially in Africa);
- there are high administrative burdens and transaction costs; and
- there is unequal negotiating power among project participants (see van Asselt and Gupta, 2008).

The CDM has generally not spurred innovation and is not in and of itself poised to foster any type of energy transition in developing countries. There is also no firm evidence that the mechanism has encouraged participating companies in the North to move towards cleaner technology, rather than simply buying time. Many CDM projects are "end-of pipe" control technologies such as HFC-23 control projects,[104] which favor existing interests in pursuing the cheapest emissions reductions. Path dependence thus remains the driver, not change.

Multilateral climate negotiations are in a state of transition. This is not surprising, considering that they cover not only the respective emission cuts by different groups of countries, but also topics as wide as agriculture, deforestation, technology transfer, intellectual property rights, competitiveness, international transportation, and financial mechanisms to support climate change mitigation in developing countries. This requires a significant amount of capacity development with negotiators. The European Capacity Building Initiative (ECBI, 2011) is an initiative for sustained capacity building in support of international climate change negotiations. The ECBI promotes a more level playing field between government delegations during international climate change negotiations and aims to facilitate mutual understanding and trust, both between European and developing countries and among developing countries.

The most important topic for the foreseeable future in the climate change negotiations is financing and crediting. Moving forward approaches such as the Clean Development Fund, the existing Least Developed Country Fund, and the Special Climate Change Fund, requires specialized and substantive knowledge from all negotiators involved. Currently, most negotiators in the climate talks are career diplomats who lack sufficient knowledge of financial markets, technology development, and scientific fields relevant to climate change to lay the foundational framework for energy transitions. Negotiators too often do not have the capacity to develop a clear overview of the options on the negotiation table, let alone how they might reach strategic targets that are in the common interest.

The capacity to have a broad overview of the climate negotiations and to translate diplomatic decisions into action will be crucial in the next few years. This is especially the case now that the "collective commitment" that emerged in the Copenhagen Accord to provide "new and additional resources […] approaching US$30 billion to developing countries for adaptation, technology development and transfer and capacity building in the period 2010–12" (UNFCCC, 2009) has been confirmed at the UN Climate Change Conference in Cancún in December 2010. Developed countries also committed to a goal of jointly mobilizing US$100 billion a year by 2020, "in the context of meaningful mitigation actions and transparency on implementation" (UNFCCC, 2009). Such funds must focus on building capacity in developing countries.

103 An analysis of data on over 1300 antidumping investigations initiated by different countries against other WTO members showed that "those countries that are abundant in legal capacity are more likely to challenge AD duties brought against them and less likely to be targeted by AD duties in the first place. These results are especially striking in light of the fact that we control for these countries' market power, which make credible their threat to retaliate" (Busch et al., 2008).

104 The top-two renewable energy projects (after hydropower) are biomass (129) and wind (161) projects. Together, they generated 37,272,397,000 carbon credits (Certified Emission Reductions, or CERs), whereas the 18 HFC (fluoroform) projects in the CDM pipeline as of October 2009, generated 218,637,000 CERs. See UNEP-Risø, 2011.

Even if these funds were to be fully subscribed, there would still remain a vital need for capacity development to enable developing countries to participate effectively in international negotiations concerning the governance and use of these funds and to benefit from the various funding opportunities. There is also a need for the funding itself to support broader innovative capacity in low-carbon technologies in developing countries – not just a series of low-carbon hardware projects (e.g., Ockwell et al., 2009). Past practice has shown that funding mechanisms such as the CDM have had a limited impact on the development and diffusion of new energy technologies. Most developing countries do not have the capacity to design such projects or identify partners and work with them to do so. The CDM recognized this and began, rather late, to emphasize a needs assessment approach, but without the methodology and training that would make local choices possible. The CDM's own methodology, doing baseline studies and attempting to determine additionality, are meaningless in the context of least developed countries, where the capacity to undertake data collection and analysis and to evaluate choices is critical yet largely absent. Only in the past several years have UNEP and the GEF begun a series of workshops to fill the gap, as the case of Bahrain and the role of the Arabian Gulf University in that country illustrate (see Case Study 6, Section 25.11). Of particular interest is the way in which the use of local education and research institutes to train analysts in the developing world strengthens their capacity to support regional networks.

In conclusion, effective participation in the international system is critical for energy transitions. Although currently going through stages of learning, global regimes including the CDM have an important role to play in encouraging and supporting change. This cannot be done solely through financial flows. It must also provide legitimacy for citizen action. An equitable framework for legitimate engagement and negotiation in which stakeholders can participate at a substantive level is part of the global enabling environment that would ultimately enable the system to work for energy transitions.

25.10 Conclusions

Bringing cleaner, safe, and affordable energy and energy services to people, moving away from our current dependence on fossil fuels, and reducing the need for energy to the largest possible extent, are key energy challenges for society today in both developed and developing countries. Meeting these challenges will involve major changes in energy supply systems, energy-using technologies, and their associated practices. Improving trajectories based on fossil fuels and building supercritical coal-fired power plants will not enable us to meet these challenges – it will merely lead to problems in the future. Ultimately, we must shift to renewable and green energy sources, electric transport technologies, zero-energy buildings, and more efficient energy supply systems. The focus in this chapter, therefore, has not been on "policies for capacity development," in general, but on the challenges of energy transitions and the capacities and capacity development processes that are needed to overcome them.

As energy transitions will differ across countries, and perhaps even between regions within a country, these conclusions do not attempt to provide a definitive list of what should be done. But the experiences reviewed here do point to a number of principles that might usefully be applied when thinking about capacities and capacity development policies for sustainable energy transitions in a given environment. This takes us one step beyond the classic discussion about what needs to be done, and towards an exploration of ways in which such changes might be brought about in a variety of different contexts. It also opens opportunities for reflection on the multiple benefits that might be generated for livelihoods, learning, innovation, consensus building, and development, through the capacity development process.

25.10.1 Getting There from Here: First Principles

Energy transitions are long-term, socially embedded processes that involve changes in production and consumption patterns, knowledge, skills, formal and informal institutions, and the habits and practices of the actors involved. These characteristics have major consequences for the choice of an energy transition pathway today and the capacities that might be needed to move down that pathway successfully in the future. From this perspective, capacity development can no longer be seen as a simple aggregation of individual skills and competences or the introduction of a new "technology." In the course of an energy transition, moreover, capacities at the actor and systems levels, and the policies for capacity development themselves, will inevitably change. This will require feedback and the capacity for flexible adaptation over time. How might we deal with the uncertainties and complexities generated by such a process?

25.10.1.1 Principle 1: Understanding the Challenges

All change processes inevitably face challenges that emerge from established habits, practices, norms, and interests, or what we have called "informal institutions and path dependency." These can slow both the development and the diffusion of new energy technologies. In conjunction with the "lock-in" effects of earlier investment in physical plants, supplier linkages, infrastructure and skills, and efforts to move towards energy efficiency improvements are also slowed.

Understanding these informal institutions and learning to work with and around them in a given context are important first steps in an energy transition process. This principle was illustrated in a wide variety of cases that include efforts to improve energy end-use efficiency in transport (Section 25.4.1) and buildings (Section 25.4.3), the introduction of new energy technologies and their accompanying practices in the case of smart grids (Section 25.4.2) and wind turbines (Section

25.5.1), and the diffusion of solar home systems (Section 25.5.2) and cookstoves. What emerged from these studies is the need for dialogue (Section 25.5) of many sorts and at many levels in dealing with the challenges of energy transitions.

25.10.1.2 Principle 2: Dialogues Make a Difference

Dialogues may not "solve" these problems, but they do open channels for innovative ways to deal with them. Moreover, they open channels that traditional awareness-raising programs, based on public meetings, conferences, one-off consultations, and focus groups, cannot. For dialogues to work, confidence-building measures that recognize the legitimacy of local concerns, interests, and needs is a first step in gaining broad societal support for an energy transition. And this is the case whether it concerns renewable energies, lighting services, improved cookstoves, or personal mobility in the public transport system.

Dialogues must begin early in the process of conceptualization to be effective. This is when the identification of needs and problems and the range of options available and preferences for how to deal with them are first discussed. Dialogue should not be limited to the usual stakeholders, nor should solutions be reduced to a few predetermined options. An open mind should be kept vis-à-vis nonconventional solutions. This applies to both broad policy directives and the development of programs and projects at the local level. It is at this point in the process that a framework for domestic consensus building must be developed by involving the wider community in discussions about key issues and choices, as well as their consequences. One such approach consists of creating spaces for dialogue about transition pathways, processes, and policies that bring together members of the public and private sectors, academics, and civil society in what the Dutch have called transition platforms (Section 25.8.2).

Identifying relevant stakeholders and building the capacities needed to engage meaningfully in this new practice are essential in initiating and sustaining energy transition processes. Not all stakeholders will have the same view of a problem and possible solutions. In a dialogue, it is understood that the solution to barriers may not lie in support policies for the technology but in finding the appropriate technology configuration, which will require coalition building and stakeholder learning. This opens opportunities to reconsider the proposed solution, a process that may result in its rejection or major adaptation. "Not in my backyard" resistance may be turned into constructive dialogue focused on the question: if not this, then what else?

25.10.1.3 Principle 3: Dialogue Processes Have Wide Applicability in Energy Transitions

Dialogues will be needed throughout the lifetime of a program or project in an energy transition. To make dialogues meaningful, mechanisms for feedback and flexibility will have to be built into programs and projects – the former to legitimize the use of "negative" feedback as a positive incentive for change, and the latter to create space for adaptation to take place as energy transitions evolve.

Going beyond the project level, the emergence of decentralized and distributed processes, energy-related practices, and new technologies have raised the importance of local actors in decision-making processes. Examples include wind power in Germany, the Netherlands, and the United Kingdom, agriculture-based renewables in Brazil and Mali (Section 25.6.1) and micro hydro in China, Bhutan, Nepal, and Rwanda (Section 25.6.2). In this context, dialogue can become a useful bridging mechanism for consensus building across national and local levels.

Although the notion of dialogues has been in circulation for some time in the capacity development literature, the practice of designing projects through a dialogue has not been systematically applied (Section 25.3.1). Long-standing discussion on the need for developing country ownership of donor-funded projects can also benefit from this engagement in the dialogue process. The success of such an approach, however, depends critically on the extent to which those in partner countries have access to the knowledge and information they require to develop positions of their own. It also depends upon the extent to which experts from donor agencies have learned to engage in meaningful dialogue processes.

For least developed and many developing countries, the capacities to articulate their positions in international negotiations are also an issue. The experience of Brazil in international negotiations (Section 25.9) and the development of programs such as those at the Arabian Gulf University (Section 25.9 and Case Study 6, Section 25.11) suggest ways to meet this capacity development need. Indeed, UNDP, IDRC (Section 25.3.1) and ODI (Section 25.7.3), among others, have developed tools for this purpose.

25.10.2 Making Choices about Energy Transition Pathways

Access to knowledge and information – and the capacity to use such inputs – are critical in making choices about energy transitions, whether at the level of individual actors, communities, or national governments. Most developed and emerging economies have created national agencies for this purpose. These agencies monitor international developments and regularly undertake national surveys that provide comparative information for making choices among alternatives in both the short and the longer term. With access to a wide array of information on local and international conditions, and the capacity to use such data, these countries are developing methodologies that will enable them to move from static cost comparisons to analyses of factors that might affect longer-term costs and savings (Section 25.3.2). This longer-term perspective opens up opportunities for building flexibility into strategies for energy transitions and the necessary policies for capacity development.

Many developing countries, however, lack access to continuous flows of knowledge and information on new and improved energy technologies, the policies and practices of other governments, or enterprise strategies. But these countries' governments also face the challenge of collecting local and national data on the state of education, innovation, industry, energy use, and efficiency. Surveys and studies undertaken by UNESCO, UNIDO, and New Partnership for Africa's Development (NEPAD) attest to this.[105] Strengthening the capacities of governments, universities, NGOs, and other organizations in data collection and analysis can widen the range of choice of new energy technologies to meet local needs and expectations.

25.10.2.1 Principle 4: Accessing Knowledge and Information

Problem solving can be accelerated by developing channels for access to knowledge and information. These channels consequently encourage the more rapid diffusion of new energy technologies. The beneficiaries would be manifold, going beyond local governments, research bodies, and the banking and business sectors to include agricultural extension services, energy users, and intermediaries such as urban transport and utility companies, architects, and builders. National reference centers in Brazil (Section 25.7.2) and front-runner desks in the Netherlands (Section 25.8.2) are two examples of how this concept can be adapted to different contexts.

To encourage a more diversified set of criteria for rewards, such as research grants and promotions, policies will need to be put in place that stimulate and support linkages between research and users – whether in the business, health, government, NGO, or other sectors (Section 25.7.2). Research funding will also need to be made available for this purpose. This can take a number of forms. In Brazil, national reference centers are attached to universities and are supported by university research. Two quite different approaches linking R&D to its potential users are, first, CT-Energy, a fund created in Brazil to support "public interest research," including energy R&D and energy efficiency, and, second, the integrated approach to R&D, energy industries, and investment in the Masdar initiative (see Case Study 5, Section 25.11).

25.10.2.2 Principle 5: Create Opportunities for Interdisciplinarity and Systems Thinking

The higher education system is crucial for sustaining an energy transition, yet current practices will need to change if it is to play this role. The long-term and uncertain nature of energy transition processes requires flexibility that standard discipline-based educational and training programs do not often provide. This at least suggests there is more need for interdisciplinarity in graduate, postgraduate, continuing education, and training programs. In many countries, this will require policy changes at the national and university levels to create this flexibility now and thus strengthen the capacity for adaptive curricula changes as the relative importance of issues, technologies, and challenges change over time.

Interdisciplinarity impacts the speed with which new energy technologies are developed and diffused in disciplines where established practices mediate between the demand for and acceptance of these technologies. Examples include architecture, engineering, housing and construction, new materials, transport, urban planning (Section 25.4.3), and the biosciences (Section 25.6.1). Targeting these disciplines will enable university programs to offer a wider view of the issues and options that are currently available and to study and assess those that are on the horizon. For developing countries, interdisciplinarity could provide evidence-based research as an input into planning and policymaking processes across a wide spectrum of actors in civil society, the business sector, and government.

Managing energy transitions is another area in which universities could play an important role. They could create opportunities to update policymakers on the range of available options and strengthen the contribution of scientists and social scientists in decision-making processes. Both the rapid turnover in personnel at the middle and senior advisory and policy levels in developing countries, and the need for mobility to widen perspectives in the industrialized world, make continuous education for energy transitions imperative. Interdisciplinary masters-level programs designed to bring together scientists, and policymakers have a role to play here.

25.10.2.3 Principle 6: Use Knowledge Networks to Solve Problems during Energy Transitions

Open innovation practices and networking in industrialized countries are helping to speed up the pace of problem solving in a growing number of sectors. Users, especially companies, but also government agencies and community organizations, are becoming increasingly aware of its possibilities (see Case Study 3, Section 25.11). The core insight of this approach is the ability to use the world outside an organization to generate internally useful knowledge in a purposeful manner. This involves the development of networks and the capacities needed to use them.

Developing countries are moving in this direction now as well. In particular, they are strengthening their domestic research capacity (Section 25.7.3) and problem solving (Section 25.7.1), and they are facilitating adaptive changes in the course of energy transitions and supporting the process of making choices about energy pathways. It was a critical factor in boosting productivity and reducing costs in the development of ethanol from sugarcane in Brazil (Section 25.6.1). In Mali, with the

105 The lack of up-to-date statistical information in the surveys published by UN Agencies show how difficult it has been to collect comparable data at regular intervals from local ministries. The launch of innovation surveys by NEPAD has also faced a lack of trained personal and funding.

support of the local member of the AREED network, research has supported the growing of jatropha in a multi-cropping environment and the use of jatropha oil for power and electricity generation (Section 25.6.1). The UNEP-funded REED network, of which AREED is a member, has supported renewable energy enterprise development in Senegal (Section 25.5.2) and its GNESD network (Section 25.7.2). This network comprises centers of excellence in industrialized, emerging, and developing economies, undertakes joint energy policy-related research, and provides a space for knowledge sharing on the links between sustainable energy and other development and environmental priorities, as well as technology and policy options.

In the field of new energy technologies, United Nations University Geothermal Training Programme has designed its training program to deal with the problem of brain drain by strengthening capacities for local research, exploration, and the development and production of geothermal energy in East Africa. Participants in the six-month workshop in Iceland had jobs in this field in East Africa to which they would return. Bringing policymakers and practitioners from the region together in local workshops supported network building among these countries (Section 25.7.3).

25.10.3 Policies and Practices in Making and Sustaining Energy Transitions

The long-term, socially embedded nature of energy transition processes gives rise to various challenges. The choices made in selecting energy transition pathways are also inextricably linked to broader development issues and goals. These, too, must become visible as part of a dialogue process, and the tradeoffs must be made explicit. The case studies reviewed in this chapter make clear that in laying the foundation for an energy transition, it is necessary to work from a longer-term, systems perspective.

25.10.3.1 Principle 7: Energy Efficiency is a First Step towards an Energy Transition

Energy efficiency improvements can potentially bring about changes in existing habits and practices of energy use, but they do not in and of themselves constitute energy transitions. They are only one step on a path that might lead to a more transformative change. In designing energy efficiency programs, it is important to take a longer-term perspective that builds in a strategy for developing the steps to follow.

Urban public transportation provides a good example of how this might be done. Energy efficiency improvements in this sector are driven mainly by the need to reduce costs and increase fuel efficiency, especially where fuel is imported, and to address transport access issues. For instance, bus rapid transit (BRTs) systems – of which there are currently 47 around the world, including 16 in Latin America, several in Asia, and one in sub-Saharan Africa (Section 25.4.1) – provide relatively cheap and frequent bus services that widen access to employment opportunities. In some cases, they have also been designed to lure drivers away from their automobiles, thus reducing traffic congestion in urban areas, contributing to changes in current habits and practices, and reducing overall GHG emissions.

But there is a need to go beyond these objectives and develop a strategy that replaces fossil fuels with renewable energy. Examples of this can be found in programs such as the European Regions and Municipalities Partnership for Hydrogen and Fuel Cells, and in the creation of a private sector firm in Tanzania that produces biodiesel from used cooking oil, which it sells to the minibus (matatu) sector (Section 25.4.1).

25.10.3.2 Principle 8: Adopting a Multi-Goal Perspective in Energy Transition Strategies Can Generate Multiple Benefits

As the transport sector illustrates, an extensive array of multiple benefits can be envisaged as part of an energy transition process. Support for the development of biofuels in developing countries and their use in urban and rural areas is one way to create a continuous movement towards an energy transition over the long term. It also offers income-generating opportunities for rural smallholders who intercrop biofuel crops with food crops, as the examples of Garalo in Mali and the Brazilian Amazon region illustrate (Section 25.6.1). Adopting a multi-goal perspective starts with an analysis of local resource availability and the early identification of linkages and support structures that will be needed to build local markets for biofuels, and cleaner energy technologies such as cookstoves and multifunctional energy platforms. At the same time, such a perspective can help to identify alternatives to existing energy pathways. For this to take place, a multi-goal perspective must be consciously built into policies, programs, and financing mechanisms from the outset.

In both industrialized and developing countries, SMEs continue to be major drivers of innovation processes, as well as contributors to livelihoods and employment creation. Opening space and creating the support structures for the establishment of innovative SMEs in the provision of energy services has played a role in stimulating market growth and the diffusion of new energy technologies in such diverse areas as solar home systems, renewable energies, and off-grid energy access.

In creating small-scale energy solutions, knowledge of the local market is critical but needs to be complemented by networks and local organizations that help to strengthen business skills and the ability to adapt technologies to local needs, as the AREED examples show (Section 25.5). This requires users to have some domain knowledge

and technical skills, as well as the habits and practices that support learning and innovation. Financing for SMEs to develop such capabilities is scarce in developing countries. New international support programs that might strengthen capabilities to meet the challenges of development and climate change were envisaged in Copenhagen and in Cancun, at the 16th meeting of the Conference of the Parties, a decision was adopted to establish a Technology Mechanism comprised of a Technology Executive Committee and the Climate Technology Centre and Network (UNFCCC, 2011).

How these new organizations will operate still needs to be defined. Ensuring that developing countries have the capacities to participate meaningfully in future negotiations on programs and practices under the Technology Mechanism will be critical to their success and sustainability. As to funding, the European Parliament acknowledges that this will be a challenge but believes it to be feasible. Members of the European Parliament's "climate parliament" have formally proposed that at least 5% of the EU budget should be devoted to ensuring a rapid transition from fossil fuels to wind, solar, and other renewables in the European Union and a further one billion euro/year be used to support renewable energy in developing countries. Such funds could support local NGOs, domestic foundations, R&D, grant-making councils, and business support structures in developing countries, and take this process of building rural and peri-urban energy solutions into a broader program of market building and SME upgrading.

25.10.3.1 Principle 9: Consciously Pursue Market-Building Strategies as a Driver of Diffusion

The development of a conscious strategy of market building in energy-related projects and programs is also important in driving the widespread diffusion of new energy technologies in developing countries. The diffusion of solar home systems in Kenya, Sri Lanka, and Bangladesh (Section 25.5.2) and micro-hydro in China, Bhutan, and Nepal, illustrate some of the challenges and successes of bottom-up processes that take a market-building approach (Section 25.6.2 and Case Study 3, Section 25.11). The absence of such a strategy and its impact on diffusion is also clear, notably in the traditional approach to improved cookstoves. The latter relies on stoves designed abroad with expensive materials and that are imported, as opposed to stoves with longer local value chains, opportunities for local repair and manufacture, and thus with lower prices (Section 25.5.3). Similarly, the early experience in the diffusion of multifunctional energy platforms lacked a built-in feedback and adaptive learning strategy that limited market development and slowed the diffusion of these platforms (Section 25.5.3 and Case Study 2, Section 25.11). This is now changing, as the case of Garalo in Mali (Section 25.6.1) demonstrates. The provision of business services and coaching to start-ups and SMEs would stimulate the diffusion of clean and more efficient energy technologies at the same time as it opened opportunities for a wide range of benefits.

25.10.3.2 Principle 10: Governments are Critical Actors in Energy Transition Processes

As the above principles illustrate, a policy aimed at fostering energy transitions will need to involve a range of government bodies at various administrative levels in the analyzing of problems and the designing and implementing of policies. No government ministry can be expected to have all of the required instruments in its "arsenal." Adopting a systems approach and a multi-goal perspective will require dialogues across ministries and the creation of inter-ministerial teams for policy integration and coordination. Capacities for dialogue and policy coordination must therefore exist or be created.

Designing for flexibility over the course of an energy transition will require access to the knowledge needed to create a portfolio of options that allow for different development possibilities. The portfolio should build on existing capacities and the interests, concerns, and needs of local actors and national actors alike. Developing countries might begin this process by identifying those capacities that are needed across many renewable energy technologies and support universities in the development of interdisciplinary programs around each knowledge nexus. This would create the flexibility to move between different technologies as conditions change.

Another task for strategic decision makers is to develop the analytical capacity to create and manage a shifting portfolio of renewable options as technological frontiers are breached, costs decline, and needs change. This includes the ability to undertake comparative assessments of the impacts of different choices and combinations of choices, as well as how these change over time. These impacts could include energy efficiency, consumer habits and practices of energy use, GHGs and other emissions, job losses and gains, and inducements offered to move towards an energy transition. Linkages to local knowledge centers and participation in wider networks will be essential if governments are to play these roles.

Government, therefore, will be one of the key actors in the transition process at local, national, and international levels. Developing and keeping a focus on transformative change, however, cannot succeed in the absence of broad-based support, continuous dialogue, and a long-term, systems-based approach to change.

25.11 Case Studies

25.11.1 Case Study 1: Path Dependence and Lock-in: Decentralized Energy in the United Kingdom

Efforts to increase the contribution from decentralized energy in the United Kingdom have been underway for over 10 years,[106] driven mainly

106 These efforts date back to the report of the government-industry Embedded Generation Working Group, *Report into Network Access Issues: A Consultation Document* (DTI, 2001).

by government targets to expand the use of renewable energy (including small-scale installations) – but also by a desire to explore more fully the scope for district heating, smart distribution grids, and more active participation by individuals and communities in the United Kingdom's low carbon transition (HM Government, 2009). Progress with many forms of decentralized energy has been slow. One of the reasons for this is that the existing system is highly centralized, and the United Kingdom has no recent tradition of decentralized electricity production (Foresight, 2008). This means that local institutions that understand local needs, such as local authorities, play a relatively minor role in decisions on energy investments and strategies. Another barrier is local opposition, particularly to proposals for wind farms from which many communities feel they have little to gain (Toke et al., 2008). In addition, there are economic and financial barriers. Small-scale renewable and low-carbon energy technologies tend to have high capital costs, and can in some cases face additional economic barriers such as the costs of connections to the grid.

The regulation of the electricity system provides a good illustration of the barriers to decentralization – and also how recent reforms are attempting to tackle them. Technical challenges arise because significant increases in decentralized electricity generation will have a particularly strong impact on the existing electricity grid, which was not designed for that purpose. Furthermore, decentralized generation is not just about connecting new plants to the system, but also about innovation and transformation of the system. Decentralization is part of a more general move to a more complex electricity system in the United Kingdom, which includes smart meters in homes, more sophisticated supply-demand balancing facilitated by smart grids, and the possible diffusion of plug-in electric vehicles (DECC, 2009).

Associated regulatory challenges arise because a more decentralized electricity system requires distribution network operators to play a more active role in managing their networks – and therefore need the appropriate skills and incentives to do so. The technical and regulatory impacts of decentralized generation will vary according to whether the approach taken is a piecemeal connection or a transformation of the system (Sauter and Bauknecht, 2009). In the former case, each generator is appraised with reference to the current system and is connected as a "one off." In the latter case, innovative solutions are needed for the development of generation and network infrastructure, and must work in conjunction with demand-side measures. The United Kingdom's price-based approach to regulation, for example, allows network companies to increase their charges by the retail price index minus an efficiency factor – a formula known as RPI-X. While it has been argued that this should act as a driver of innovation, it only does so if the aim of the innovation is to increase the efficiency of current network operations. As a result, innovations that would facilitate significant changes to the architecture and operation of networks have not been encouraged.

Some tentative moves to encourage innovation were introduced in 2005, but the impacts were limited (Woodman, 2006), largely because the innovative capacity within network companies started from a very low base, and the incentives were too weak and limited. It is only recently (in April 2010) that the regulator, the Office of Gas and Electricity Markets (Ofgem) has introduced significant new incentives for innovation in the form of a Low Carbon Networks Fund (Ofgem, 2010). This is designed to provide a much stronger rationale for distribution companies to move in the direction of smarter grids that could not only include decentralized generators, but also encompass the early rollout of electric vehicles and integrate the demand side through smart meters – something that the government supports (e.g., DECC, 2009). However, it remains to be seen what impact the new Ofgem fund will have, and whether it will be enough to overcome historical barriers to decentralized energy systems.

25.11.2 Case Study 2: A Bottom-up Approach for Micro-Hydro in Bhutan

The development of a hydropower industry is recognized as the primary driving force for economic development in the Kingdom of Bhutan. The Power System Master Plan (PSMP, 2004) identified technically and economically feasible and potential hydropower sites that could provide a total of 23,760 MW of electricity. The current installed generating capacity is 1505 MW.[107]

Bhutan's rural electrification efforts are guided by "Bhutan 2020," a policy document that set a target of providing electricity to 50% of the rural population by 2012, and to all households by 2020. The policy also seeks to transform the role of the state from that of a "provider" to an "enabler." Bhutan's clear policy directives and its Electricity Act 2001, which provided for free licenses up to 500 kW, are helping to stimulate development of micro-hydropower.

The high cost of extending the grid, however, has made it difficult to connect a large percentage of the rural population to the national power grid. Based on past rural electrification projects, it is estimated that electrifying one rural household costs about US$1800. This needs to be financed by the government, and on-grid rural consumers receive substantial operational subsidies.[108]

In the past, the Bhutan Power Corporation owned, managed, operated, and maintained the country's micro-hydropower plants. However, due to the corporation's lack of financial viability, it has been reluctant to take over the management of the new micro-hydros being built. Thus, when the Chendebji micro-hydro plant was commissioned in October 2005, an alternative model involving the community had to be developed. The community-based management model now being piloted in

107 This includes the recently commissioned Tala hydropower project.

108 The average rural consumer utilizes less than 50 kWh/month and falls in the lowest tariff category of US$0.013/kWh. The estimated cost of supplying electricity to rural households is about US$0.10/kWh.

Chendebji is expected to be refined and the lessons learned applied in future projects.

In particular, the development of micro-hydropower should be coupled with the creation of income-generating opportunities that will enhance the economic self-reliance of rural communities. Further, by integrating micro-hydropower with the grid at higher feed-in tariffs, the sale of surplus power could improve load management and displace the need for government subsidies. Finally, training programs are needed to maintain the skills of local plant operators, and education campaigns are necessary to raise consumers' awareness of the need for energy conservation.

25.11.3 Case Study 3: How Open Innovation Systems Speed Problem Solving: InnoCentive

Most of the work on distributed innovation systems has focused on software development. In a recent study, a team of researchers looked at the value of openness in scientific problem solving in the life sciences (Lakhani et al., 2007). The study considered a diversity of disciplines, several of which are relevant in the development of biofuels and other renewable energy sources.

Unlike the open source software approach, the InnoCentive network was not a spontaneous development but an offshoot of a multinational pharmaceutical firm, Eli Lilly. Its creation recognized both the explosion of knowledge and the combinatorial nature of knowledge bases in the technologies that emerged in the last quarter of the 20th century.

InnoCentive describes itself as an "open innovation community of smart, creative people, who provide solutions to tough problems" (InnoCentive, 2011). Membership of InnoCentive is open to anyone who is attracted both by the challenge of solving problems and by the financial rewards that are attached. The notion that this is a community along the lines of the open source software community is misleading, however. InnoCentive's problem solvers rarely interact among themselves or with the seekers. Another difference lies in the "openness" of the knowledge produced by solvers, who must sign an agreement upon joining InnoCentive under which all rights to the knowledge they generate belong to the seeker.

Despite the absence of a free flow of knowledge and open access to and use of the knowledge generated by solvers – both of which are arguably among the factors that enable open innovation systems to speed the pace of innovation and diffusion – InnoCentive has served to accelerate problem solving for seekers who are willing to share some information with solvers. One study, for example, illustrates the efficacy of this approach in the case of "166 discrete scientific problems from the research laboratories of 26 firms from 10 different countries between June 2001 and January 2005" (Lakhani et al., 2007). Firms came from a variety of industries, including agrochemicals, biotechnology, chemicals, and pharmaceuticals, and most had attempted to solve the problem within their own laboratories. Out of 166 problems, 49 (29.5%) were solved using this approach (Lakhani et al., 2007).

The outreach that such an approach permits is interesting for problem solving. "On average, 240 (sd: 195, range: 19–1058) individuals examined each detailed problem statement and 10 (sd: 14, range: 0–103) individuals submitted solutions for evaluation" (Lakhani et al., 2007). More recent data provide a higher rate of problems solved. Of the "(a) round 900 challenges that have been posted so far by 150 firms […] (m)ore than 400 have been solved" (*The Economist*, 2009). The range of seekers and problems has already extended to the renewable energy sector (Bent, 2009).

25.11.4 Case Study 4: Creating a Policy Framework for Innovation and Technology Transfer in South Africa

The South African white paper on science and technology (DST, 1996) created a National System of Innovation based framework, for key enabling policies and strategies that would inform the strategic development of science and technology in post-apartheid South Africa. In 2002, the national R&D strategy, implemented by the Department of Science and Technology, aimed to improve the impact of the white paper by identifying interventions needed to address systemic weaknesses. One of these involved improving the protection and management of intellectual property from publicly financed research as a way to "bridge the innovation chasm."

New legislation aiming to address this issue has recently been passed. It prescribes in some detail the policies, processes, and structures that recipients of public R&D funding will have to institute in managing their intellectual property and provides for the establishment of a National Intellectual Property Management Office and Intellectual Property Fund to assist in financing the costs of obtaining intellectual property protection. The question of whether the legislation has struck the right balance between creating an enabling environment and regulating relevant activities continues to generate debate. This is of particular importance in the South African context, where more than half of R&D expenditure comes from industry. The focus of the legislation on publicly funded research could therefore potentially limit the overall impact of these interventions.

With regard to local university-industry linkages, for example, until now, the ownership of intellectual property arising out of collaborative research or industry-sponsored research at universities has been a matter of negotiation. Under the new legislation, the circumstances under which a company may own intellectual property have been significantly reduced. There is concern that this might act as a deterrent to companies sponsoring research at, or collaborating with, universities (Wolson, 2007).

The R&D strategy also recommended that a core agency be set up to stimulate technological innovation by aligning, coordinating, and providing a single point of strategic direction for a range of existing and anticipated innovation support instruments. In the first instance, this will involve consolidating several existing agencies and institutions, mainly from within the Department of Science and Technology, under the umbrella of the new Technology Innovation Agency. The new policy instruments aimed at promoting innovation and the transfer and commercialization of technology bode well for a supportive environment. It is hoped that they are implemented in a flexible, enabling, and responsive manner so as to successfully cultivate the anticipated improvements in the systems.

25.1.1 Case Study 5: The Masdar Initiative

Abu Dhabi has taken a bold step towards creating a knowledge-based economy. The Masdar initiative, driven by the Abu Dhabi Future Energy Company, is designed to be a global cooperative platform for engagement in the search for solutions to pressing issues such as energy security, climate change, and the development of human expertise in sustainability. If successful, it will also serve to position Abu Dhabi as a world-class R&D hub for new energy technologies and drive the commercialization and adoption of these and other technologies in sustainable energy, carbon management, and water conservation. In parallel with "Vision 2030," Masdar will also assist economic diversification and the development of a knowledge-based economy, while enhancing Abu Dhabi's record of environmental stewardship (see Masdar, 2011).

Masdar has five business units. Its Carbon Management Unit is developing greenhouse gas emission reduction projects, creating value by trading carbon Certified Emission Reduction certificates under the CDM of the Kyoto Protocol. The unit also develops sustainable technologies, including large-scale projects that generate sizable carbon emission reductions, focusing on CCS. This unit presumes the sustainability of the CDM and the global carbon market beyond 2012. Among its projects are a partnership with Bahrain's National Oil and Gas Authority to reduce carbon emissions derived from energy efficiency projects in the Bahraini oil industry and the development of a national carbon capture network to reduce Abu Dhabi's carbon footprint. The first phase of the network will capture around 6.5 million tonnes of CO_2 from power plants and industrial facilities for injection into oil reservoirs for enhanced oil recovery. Natural gas will be processed to hydrogen and CO_2, with the former being used for power generation and the latter re-injected into oil fields.

The Industries Unit invests globally and locally to establish a portfolio of production assets to provide Masdar access to technology and markets for the renewable energy value chain. The unit's current flagship investment is Masdar PV, which was created in April 2008 with the goal of becoming a top-three global thin-film PV manufacturer. A US$600 million phase-one investment will fund the construction of plants in Germany and Abu Dhabi with a combined annual output of 210 MW.

The Masdar Institute of Science and Technology, developed in cooperation with the Massachusetts Institute of Technology, offers masters- and doctoral-level degree programs focused on the science and engineering of advanced energy and sustainable technologies. The aim is to develop a pool of highly skilled scientists, engineers, managers, and technicians capable of accelerating the development of technology in the region and globally. The first class of 92 students, of which 13% are UAE nationals,[109] started in September 2009. A faculty of 20 academics from 11 countries, eight of whom are from Arab origins, has been recruited from internationally renowned universities.

Masdar's property development unit is currently constructing the carbon-neutral Masdar City I, soon to become home to 40,000 residents as well as research centers and companies with expertise in clean technology. The International Renewable Energy Agency is also located here, though it is uncertain whether much research will actually be conducted at its headquarters.

The utility assets and management unit aims to secure for Masdar a leading position in future energy markets by building a renewable energy portfolio through investments in companies with promising technology. The unit is positioned as a renewable energy power project developer, in bridging the gap between equipment manufacturers that lack project development capital and local utilities that lack the renewable energy economics, knowledge, and know-how. The current focus is on CSP, PV, wind, and waste-to-energy systems.

Within this framework, Masdar recently connected a 10 MW PV plant to the electricity grid, which will reduce Abu Dhabi's carbon footprint by 15,000 tonnes/year and will supply all the energy needs of the Masdar Institute of Science Technology. The plant, consisting of 87,777 panels (50% thin film and 50% crystalline silicon) is projected to generate 17,500 MWh of clean energy each year. A thin-film plant was expected to begin production in late 2010. Other new projects include the construction and operation of a 500 MW hydrogen-fired power plant[110] and a 100 MW CSP plant that will use parabolic trough technology. This is planned to be the first of many CSP plants in Abu Dhabi that will feed green power into the grid.

25.1.1 Case Study 6: Strengthening Effective Participation at the International Level: The Arabian Gulf University

The Arabian Gulf University (AGU) was established in Bahrain in 1979 and as a regional university was the first of its kind. With the founding of the Gulf Cooperation Council (GCC) in 1981, AGU became a regional

109 The remaining students came from 22 countries, including Algeria, Egypt, Eritrea, Germany, the Netherlands, Iceland, India, Mexico, Morocco, Nigeria, Pakistan, Palestine, Taiwan, Turkey, the United States, and the United Kingdom.

110 The project is a joint venture between BP, Rio Tinto, and Hydrogen Energy, a UK-based company that produces low-carbon hydrogen for electricity generation.

institution of the GCC with the objective of contributing to regional integration and development in the region and strengthening regional efforts in human resources development. It has since become a center for building research and training capacities on energy and the environment in the GCC countries and strengthening their participation on such issues at the international level.

AGU's unique teaching program is based on a multidisciplinary, integrated studies approach that emphasizes problem-based learning through case studies. To ensure flexibility in responding to the emerging development needs of the region, the AGU has adopted a flexible structure based on programs rather than rigid departments, focusing on technology and the environment. The latter was further strengthened by the creation of the Sheikh Zayed Al Nahyan Academic Chair of Environmental Sciences in 1998, which aims to enhance research and capacities in resource management and environmental issues. Two major milestones have been the launch of the environmental management program at AGU in 2004 and the creation of the Zayed seminar series. The seminars are particularly important as a networking mechanism across the region which, IPCC models predict, will become considerably hotter and drier over the century. Gelil (2010) observes, "If the Arab countries have failed, for decades, to join hands on most fronts, the climate change problem might be a 'golden opportunity' to start."

Five seminars have now been held. The first laid the basis for the Environmental Management Program at AGU. The others examined the potential of alternative energy in the GCC, sustainable cities, and the issues of climate change, energy, water, and food security in the Arab region. The seminars were attended by 400 participants from the GCC, of whom 57% were from the academic community, 23% from government agencies, 15% from the private sector, and the remaining 5% from NGOs, the media, etc. Although the seminars could play an important role in knowledge production and sharing, the low level of participation by governments and policymakers from the region thus far limits opportunities for joint problem solving and policy coordination.

The AGU has begun to gain credibility and name recognition that is enabling it to help strengthen the capacity of Bahrain and other Arab Gulf countries to participate in international energy negotiations, and to benefit from financial and technical assistance programs provided by GEF and other agencies. The AGU has assisted the government of Bahrain to develop its initial national communication to the UNFCCC in 2005. It subsequently was invited to lead two of the research teams that prepared the Kingdom of Bahrain's second national communication. The studies provided assessments of the vulnerability of biodiversity and natural ecosystems to climate change and of mitigation measures. In addition, the project was designed to strengthen Bahrain's human, institutional, scientific, technical, and informational capacities. Moreover, it was designed to enhance its ability to respond to the challenges of climate change and meet its obligations, as a Non-Annex I Party, towards UNFCCC, and therefore each proposed activity of the project included an element of capacity development. Staff from Bahrain's Environmental Agency participated in the research projects, managed the process, and participated in training throughout the project. At the end of the project, the staff of the agency will establish a unit to address all issues related to climate change.

The AGU is also working as a collaborating center of UNEP in the preparation of the Global Environment Outlook (GEO). AGU faculty members have contributed to the West Asia chapter in the series of GEO reports, the latest of which was GEO-4, published in 2007 (UNEP, 2007). The holder of the Zayed Academic Chair has also been a member of the team of international experts led by the International Institute for Sustainable Development, which developed the GEO Integrated Environmental Assessment training manual used by UNEP to build national and regional capacity to undertake these assessments and prepare GEO national reports. The manual has been used in training activities in a number of Arab countries, including Egypt, Jordan, Yemen, and Qatar (UNEP and IISD, 2008).

IV Annexes I to IV

ANNEX I

Acronyms, Abbreviations and Chemical Symbols

Acronyms, Abbreviations and Chemical Symbols

1P	proven reserves
2P	proved plus probable reserves
3P	proved plus probable plus possible reserves
ABC	atmospheric brown cloud
ABNT	Associação Brasileira de Normas Técnicas (Brazilian National Standards Organization)
ABS	advanced biomass stoves
AC	alternating current
ACCESS	Australian Community Climate and Earth-System Simulator
ACEEE	American Council for an Energy-Efficient Economy
ACP	African, Caribbean, and Pacific states
ADB	Asian Development Bank
AEFP	America's Energy Future Panel
AER	all electric range
AEU	annual energy use
AfDB	African Development Bank
AFR	Sub-Saharan Africa region
AGC-21	Advanced Gas Conversion for the 21st Century
AGECC	United Nations Secretary-General's Advisory Group on Energy and Climate Change
AGR	advanced gas reactor
AGU	Arabian Gulf University (Bahrain)
AIA	American Institute of Architects
AIRE	Atlantic Interoperability Initiative to Reduce Emissions
Al_2O_3	alumina
ALRI	acute lower respiratory infection
AME	Africaine de Maintenance et d'Équipement (solar water heating equipment and maintenance company based in Dakar)
AMI	advanced metering infrastructure
AMM	automatic meter management
AMR	automated meter reading
ANL	Argonne National Laboratory (United States)
ANME	National Agency for Energy Management (Tunisia)
ANSI	American National Standards Institute
AOT40	accumulated O_3 exposure over a threshold of 40 parts per billion
API	American Petroleum Institute
APINA	Air Pollution Information Network for Africa
APS	(IEA World Energy Outlook) Alternative Policy Scenario
AQG	air quality guidelines
AREED	African Rural Energy Enterprise Development
ARGeo	African Rift Geothermal Energy Development Facility
ARI	acute respiratory infections
ARMZ	Atomredmetzoloto JSC (Russia)
ASHRAE	American Society of Heating, Refrigeration and Air Conditioning Engineers
ASME	American Society of Mechanical Engineers
ASN	Nuclear Safety Authority (France)
ASP	average selling price
ASPIRE	Asia and Pacific Initiative to Reduce Emissions
ASU	acid separation unit
ATR	autothermal reformer/reforming
AVR	Arbeitsgemeinschaft Versuchsreaktor (a prototype pebble bed reactor in West Germany)
BAPS	(IEA) Beyond Alternative Policy Scenario
BAT	best available technology
BAU	business-as-usual
BC	black carbon
BCIRA	British Cast Iron Research Association
BCL	brown coal liquefaction
BDCPM	brushless direct-current permanent magnet motors
BEDP	Bagasse Energy Development Programme (Mauritius)
BEE	Bureau of Energy Efficiency (India)
BEFS	Bioenergy and Food Security
BEOP	breakeven oil price
BEV	battery-powered electric vehicle
BGR	Bundesanstalt für Geowissenschaften und Rohstoffe (Federal Institute for Geosciences and Natural Resources – Germany)
BIGCC	biomass integrated gasification combined cycle
BII	biomass input index
BioCCS	bioenergy carbon capture and storage
BiPV	building-integrated photovoltaic
BMTC	Bangalore Metropolitan Transport Corporation
BOS	balance-of-systems
BP	British Petroleum
BPL	below-the-poverty line
BRIC	Brazil, Russia, India, and China
BRICS	Brazil, Russia, India, China, and South Africa
BRIMCS	Brazil, Russia, India, Mexico, China, and South Africa
BRT	bus(-based) rapid transit (system)
BTG	biomass to gasoline via methanol intermediate
BTG-RC-CCS	BTG plant with recycle synthesis design and CO_2 capture and storage

BTG-RC-V	BTG plant with recycle synthesis design and CO_2 venting
BTL	Biomass-to-Liquids, where liquids refers to Fischer-Tropsch fuels
BTL-RC-CCS	BTL plant with recycle synthesis design and CO_2 capture and storage
BTL-RC-V	BTL plant with recycle synthesis design and CO_2 venting
BUENAS	Bottom-up Energy Analysis System
BWR	boiling water reactor
C	carbon
C_2F_6	Hexafluoroethane – CFC-116
CAEP	Committee on Aviation Environmental Protection
CAES	compressed-air energy system
CAFE	corporate average fuel economy
CAGR	compound annual growth rate
CANDU	Canada Deuterium Uranium reactor
CAP	climate-active pollutant
CARNFCHT	Committee on Assessment of Resource Needs for Fuel Cell and Hydrogen Technologies (United States)
CARTA	Consortium for Advanced Research Training in Africa
CASBEE	Comprehensive Assessment System for Built Environment Efficiency
CBIGCC-CCS	coal/biomass integrated gasification combined cycle with CO_2 capture and storage
CBIGCC-V	coal/biomass integrated gasification combined cycle with CO_2 venting
CBM	coal-bed methane
CBTG	coal + biomass to gasoline
CBTG1	coal + biomass to gasoline, with reduced biomass/coal input ratio (relative to CBTG)
CBTG1-PB-CCS	CBTG1 plant with partial bypass of syngas and with CO_2 capture and storage
CBTG-PB-CCS	CBTG plant with partial bypass of syngas and with CO_2 capture and storage
CBTG-RC-CCS	CBTG plant with recycle synthesis design and with CO_2 capture and storage
CBTL	coal + biomass to liquids, where liquids refers to Fischer-Tropsch fuels
CBTL1	coal + biomass to FTL, with reduced biomass/coal input ratio (relative to CBTL)
CBTL1-OTA-CCS	CBTL1 plant with OT synthesis design and with aggressive CO_2 capture and storage
CBTL1-OT-CCS	CBTL1 plant with OT synthesis design and with CO_2 capture and storage
CBTL2	coal + biomass to FTL, with reduced biomass/coal input ratio (relative to CBTL1)
CBTL2-OTA-CCS	CBTL plant with OT synthesis design and with aggressive CO_2 capture and storage
CBTL2-OT-CCS	CBTL1 plant with OT synthesis design and with CO_2 capture and storage
CBTL-OT-CCS	CBTL plant with once-through synthesis design and with CO_2 capture and storage
CBTL-OT-V	CBTL plant with once-through synthesis design and with CO_2 venting
CBTL-RC-CCS	CBTL plant with RC synthesis design and with CO_2 capture and storage
CBWP	community-based woodfuel
CC	chilled ceiling
CCGT	combined cycle gas turbine
CCLP	Chevron coal liquefaction
CCP	CO_2 capture project
CCS	carbon (dioxide) capture and storage
CDM	clean development mechanism
CEMAC	Communauté Economique et Monétaire de l'Afrique Centrale (Economic and Monetary Community of Central Africa)
CEN	European Committee for Standardization
CENBIO	Centre Brasileiro de Referência em Biomass (Brazilian Reference Center on Biomass)
CENELEC	The European Committee for Electrotechnical Standardization
CEPCI	Chemical Engineering Plant Cost Index
CER	certified emissions reduction (in the CDM)
CERBIO	Centro Brasileiro de Referência em Biocombustíveis (Brazilian Reference Center on Biofuels)
CERM	coordinated emergency response mechanism
CERN	European Organization for Nuclear Research
CERTS	Consortium for Electricity Reliability Solutions
CF	capacity factor
CF_4	Tetrafluoromethane – CFC-14
CFB	circulating fluidized bed
CFC	Chlorofluorocarbon
CFC-14	Tetrafluoromethane – CF_4
CFC-116	Hexafluoroethylene – C_2F_6
CFL	compact fluorescent lamps/light bulbs
CGNPC	China Guangdong Nuclear Power Holding Company
$(CH_2)_4(COOH)_2$	adipic acid
CH_3OH	methanol
CH_4	methane
CHP	combined heat and power
CIGCC	coal integrated gasification combined cycle
CIGCC-CCS	coal integrated gasification combined cycle with CO_2 capture and storage
CIGCC-V	coal integrated gasification combined cycle with CO_2 venting
CIGI	Centre for International Governance Innovation
CLE	current and planned legislation

CLEEN	Consortium for Continuous Low Energy, Emissions, and Noise (United States)
ClO_2	Chlorine dioxide
CMH	ceramic and metal halide
CNG	compressed natural gas
CNNC	China National Nuclear Corporation
CO	carbon monoxide
CO_2	carbon dioxide
CO_2-eq	carbon dioxide equivalent
CO_2CRC	Cooperative Research Centre for Greenhouse Gas Technologies
CODP	crude oil derived products
COGEN	cogeneration
Combi-Plant	Combined Power Plant (for renewable energy)
COP	coefficient of performance
COPD	chronic obstructive pulmonary disease
COPD	crude oil products displaced
COS	carbonyl sulfide
CPA	Centrally Planned Asia and China region
CPRs	common pool resources
CPWD	Central Public Works Department (India)
CRA	Comparative Risk Assessment
CREED	China Rural Energy Enterprise Development
CSE	coast of saved energy
CSF	consol synthetic fuel
CSI	Cement Sustainability Initiative
CSIR	Council for Scientific and Industrial Research (South Africa)
CSLF	Carbon Sequestration Leadership Forum
CSM	Centre de Stockage de la Manche (a radioactive waste depository in France)
CSP	concentrating/ed solar power
CSS	cyclic steam stimulation
CTF	Clean Technology Fund
CTG	coal-to-gasoline via methanol intermediate
CTG-PB-CCS	coal-to-gasoline with partial bypass of syngas past methanol synthesis and with CO_2 capture and storage
CTG-PB-V	coal-to-gasoline with partial bypass of syngas past methanol synthesis and with CO_2 venting
CTG-RC-CCS	coal-to-gasoline plant with recycle design for methanol synthesis and with CO_2 capture and storage
CTL	coal-to-liquids, where liquids refers to Fischer-Tropsch fuels
CTL-OT-CCS	CTL plant with OT synthesis island design and with CO_2 capture and storage
CTL-OT-V	CTL plant with OT synthesis island design and with CO_2 venting
CTL-RC-CCS	CTL plant with OT synthesis island design and with CO_2 capture and storage
CTL-RC-V	CTL plant with RC synthesis island design and with CO_2 venting
CTSL	catalytic two-stage liquefaction
DAC	Development Assistance Committee (OECD)
DAE	Department of Atomic Energy (India)
DALY	disability-adjusted life year
DBC	divided blast cupola
DC	direct current
DCAP	downstream plus upstream CO_2 capture
DCAP-1	downstream plus upstream CO_2 capture (with reference to DME production from coal)
DCAP-2	more aggressive downstream plus upstream CO_2 capture (with DME production from coal)
DCAP-3	most aggressive downstream plus upstream CO_2 capture (with DME production from coal)
DCC	development cost charge
DCV	demand-controlled ventilation
DECC	Department of Energy and Climate Change (United Kingdom)
DER	distributed energy resources
DFID	Department for International Development (United Kingdom)
DG	distributed generation
DLR	Deutsches Zentrum für Luft- und Raumfahrt (German Aerospace Center)
DME	Department of Minerals and Energy
DME	dimethyl ether
DNI	direct normal irradiation
DOAS	dedicated outdoor air supply
DRI	direct reduced iron
DSM	demand-side management
DV	displacement ventilation
E & P	exploration and production
EAF	electric arc furnace
EBRD	European Bank for Reconstruction and Development
EC	European Commission
ECBI	European Capacity Building Initiative
ECBM	enhanced coal bed methane
ECOWAS	Economic Community of West African States
ÉDF	Électricité de France
EDGAR	Emissions Database for Global Atmospheric Research
EDI	Energy Development Index
EEA	European Environment Agency
EEB	energy efficiency in buildings
EEDSM	Energy Efficiency and Demand-Side Management
EES	electric energy storage
EESL	Energy Efficiency Services Limited
EEU	Central and Eastern Europe region
EGS	enhanced geothermal systems
EI	energy intensity

EIB	European Investment Bank
EIFS	External Insulation and Finishing System
EITI	Extractive Industries Transparency Initiative
EMBRAPA	Empresa Brasileira de Pesquisa Agropecuária
EMF	Energy Modeling Forum
ENDA-TM	Environment and Development Action in the Third World (Senegal)
EOR	enhanced oil recovery
EPA	Environment Protection Agency
EPBD	Energy Performance of Buildings Directive (European Union)
EPC	energy performance contracting
EPFL	École Polytechnique Fédérale de Lausanne (Swiss Federal Institute of Technology in Lausanne)
EPI	Energy Performance Indicator
EPR	European Pressurized Reactor
EPRI	Electric Power Research Institute
ESAP	Energy Sector Assistance Programme
ESCO	energy service company
ESDP	Energy Service Delivery Project
ESP	electrostatic precipitator
ESPRIT	European Strategic Programme for Research and Development on Information Technologies
ETC	Enrichment Technology Company
ETI	energy technology innovation
ETIS	Energy Technology Innovation System
EtOH	ethanol
ETS	emission trading scheme
EU	European Union
EUR	estimated ultimate recoverable oil
EURODIF	European Gaseous Diffusion Uranium Enrichment Consortium
EV	electric vehicle
EWEA	European Wind Energy Association
EWG	Energy Watch Group
EWM	excess winter mortality
FAO	Food and Agriculture Organization (of the United Nations)
FBE	Free Basic Electricity (South Africa)
FC	fuel cell
FCC	fluid catalytic cracker
FCV	fuel cell vehicles
FDI	foreign direct investment
FE	fuel efficiency
FEED	Front End Engineering Design
FERC	Federal Energy Regulatory Commission
FGD	flue gas desulphurization
FIREX	fast ignition experiment (Japan)
FIT	feed-in tariffs
FLE	frozen legislation
FQD	Fuel Quality Directive
FSR	fast-spectrum reactor
FSU	Former Soviet Union region
F-T	Fischer-Tropsch
FTL	Fischer-Tropsch Liquids
G20	Group of Twenty (international group of finance ministers and central bank governors from 20 major economies)
G7	Group of Seven (international finance group consisting of the finance ministers from seven industrialized nations)
G8	Group of Eight (forum for the governments of eight of the world's largest economies)
GAEZ	Global Agro-Ecological Zoning
GAINS	Greenhouse Gas and Air Pollution Interactions and Synergies
GBTL	natural gas + biomass-to-liquids, where liquids refers to Fischer-Tropsch fuels
GBTL-OT-CCS	GBTL plant with once-through synthesis design and with CO_2 capture and storage
GBTL-OT-V	GBTL plant with once-through synthesis design and with CO_2 venting
GCC	Gulf Cooperation Council
GCCSI	Global Carbon Capture and Storage Institute
GCV	gross calorific value
GDF	Gaz de France
GDP	Gross Domestic Product
GEA	Global Energy Assessment
GECF	Gas Exporting Countries Forum
GEE	global exposure equivalent
GEF	Global Environment Facility
genset	engine-generator
GEO	Global Environment Outlook
GFAAF	Global Framework for Aviation Alternative Fuels
GHG	greenhouse gas
GHGI	greenhouse gas emission index
GIS	geographic information system
GLASOD	Global Assessment of Human-induced Soil Degradation
GM	General Motors
GMT	global mean surface temperature
GNEP	Global Nuclear Energy Partnership
GNESD	Global Network on Energy for Sustainable Development
GPT	general purpose technologies
GPU	ground power unit
GRP	gross regional product
GTAP	Global Trade Analysis Project
GTI	Gas Technology Institute
gTKP	Global Transport Knowledge Partnership
GTL	(natural) gas-to-liquids, where liquids refers to Fischer-Tropsch fuels
GWEC	Global Wind Energy Council

GWP	global warming potential
H	atomic hydrogen
H_2	molecular hydrogen
H_2O	water
H_2S	hydrogen sulfide
ha	hectare
HCFC	hydrochlorofluorocarbons (hydrogenated fluorocarbons)
HCO_3-	bicarbonate ion
HDD	heating degree day
HDI	Human Development Index
HDR	Human Development Report (UNDP)
HEU	highly (energy) enriched uranium (containing 20% or more 235U)
HEV	hybrid electric vehicle
HFC	hydrogen fuel cell
HFC-134a	CH_2FCF_3
HFCV	hydrogen fuel cell vehicles
HFO	heavy fuel oil
HG	mercury
hh	household
HHSFU	household solid fuel use
HHV	higher heating value
HIR	halogen infrared-reflecting
HIV/AIDS	Human Immunodeficiency Virus /Acquired Immune Deficiency Syndrome
HLW	high-level waste
HNO_3	nitric acid
HRJ	hydro-treated renewable jet
HRSG	heat recovery steam generator
HV	hybrid vehicles
HVAC	heating, ventilation, and air conditioning
HVDC	high voltage direct current
HWR	heavy-water reactor
HyRaMP	European Regions and Municipalities Partnership for Hydrogen and Fuel Cells
IAASTD	International Assessment of Agricultural Knowledge, Science and Technology for Development
IAEA	International Atomic Energy Agency
IAI	International Aluminium Institute
IARC	International Agency for Research on Cancer
IC	internal combustion
ICAO	International Civil Aviation Organization
ICE	internal combustion engine
ICEF	India-Canada Environment Facility
ICRISAT	International Crop Research Institute for the Semi-Arid Tropics
ICS	improved cook stove
ICT	information and communication technology
IDCOL	Infrastructure Development Company Limited
IDP	integrated design process
IDRC	International Development Research Centre (Canada)
IEA	International Energy Agency
IEA-OES-IA	IEA Ocean Energy Systems Implementing Agreement
IEA-PVPS	International Energy Agency-Photovoltaic Power Systems Programme
IEEE	Institute of Electrical and Electronics Engineers
IEF	International Energy Forum
IEP	International Energy Program
IFA	International Fertilizer Industry Association
IFES	Integrated food energy systems
IFPRI	International Food Policy Research Institute
IGCC	integrated (coal) gasification combined cycle
IHD	ischemic heart disease
IIASA	International Institute for Applied Systems Analysis
IIDP	Institute for Infectious Diseases of Poverty (Ghana)
IIE	Instituto de Investigaciones Eléctricas (Electric Research Institute – Mexico)
IISD	International Institute for Sustainable Development
ILO	International Labour Organization
ILUC	indirect land-use charge
IMAGE	Integrated Model to Assess the Global Environment
IMO	International Maritime Organization
IMP	Instituto Mexicano del Petróleo (Mexican Institute of Petroleum)
INMM	Institute for Nuclear Materials Management
INPO	Institute of Nuclear Power Operations (United States)
INPRO	International Project on Innovative Nuclear Reactors and Fuel Cycles (IAEA)
INSAG	International Nuclear Safety Advisory Group (IAEA)
I-O	input-output
IOC	international oil company
IOI	Initiative for Open Innovation
IP	intellectual property
IPAM	Instituto de Pesquisa Ambiental da Amazônia (Amazon Environmental Research Institute)
IPCC	Intergovernmental Panel on Climate Change
IPE	Interdepartmental Project directorate Energy transition
IPFM	International Panel on Fissile Materials
IPR	intellectual property right
IRENA	International Renewable Energy Agency
IRRE	internal rate of return on equity

IRSN	Institut de Radioprotection et de Sûreté Nucléaire (Institute of Radioprotection and Nuclear Safety – France)
ISEW	Index of Sustainable Economic Welfare
ISG	integrated starter/generator
ISL	in situ leaching
ISO	Independent System Operators
ISO	International Organization for Standardization
ISP	Integrated service provider
ITER	international thermonuclear experimental reactor
IUEC	International Uranium Enrichment Center
IWMI	International Water Management Institute
JI	Joint Implementation
JNFL	Japan Nuclear Fuel Limited
JODI	Joined Oil Data Initiative
KAERI	Korea Atomic Energy Research Institute
KBS	Kenya Bureau of Standards
KCJ	Kenya Ceramic Jiko
KiKK	Kinderkrebs in der Umgebung von Kernkraftwerken (Childhood Cancer in the Vicinity of Nuclear Power Plants – Germany)
LAC	Latin America and the Caribbean region
LbD	learning by doing
LBNL	Lawrence Berkeley National Laboratory
LbU	learning by using
LCA	life cycle assessment
LCIA	life-cycle impact assessment
LCFS	low-carbon fuel standard
LCOE	levelized cost of electricity/energy
LCOF	levelized cost of fuel
LCOH	levelized cost of heat
LDC	least-developed country
LDCF	Least Developed Country Fund (UNFCCC/GEF)
LDV	light-duty vehicle
LED	light-emitting diode
LEED	Leadership in Energy and Environmental Design
LEU	low-enriched uranium (containing less than 20% 235U)
LHV	lower heating value
LIC	low-income country
LNG	liquefied natural gas
LPG	liquefied petroleum gas (propane/butane mixture)
LRT	light rapid transit
LRTAP	long range transboundary air pollution
LSE	liquid solvent extraction
LUI	land-use intensity
LVPCC	Latrobe Valley Post Combustion Capture Project
LWR	light-water reactor
LZC	low- and zero-carbon technologies
MAGICC	Model for the Assessment of Greenhouse-gas Induced Climate Change
MALT	mise à la terre
MDC	minimum dispatch cost
MDG	Millennium Development Goal
MDO	marine diesel oil
MEA	Middle East and North Africa region
MEA	Millennium Ecosystem Assessment
MEA	monoethanolamine
MEE	Middle East
MEM	Microgrid energy management
MEPS	minimum efficiency performance standards
MEPS	minimal energy performance standards
MER	market exchange rates
MESSAGE	Model for Energy Supply Strategy Alternatives and their General Environmental Impact
MeOH	methanol
MFP	multifunctional energy platform
MFR	maximum feasible reduction
MH	microhydropower
MHD	magnetohydrodynamics
MHP	micro-hydro plants
MIC	middle-income country
MNRE	Ministry of New and Renewable Energy
MOE	Ministry of the Environment
MOX	mixed oxide
MPI	multidimensional poverty index
MS	modal shift
MSA	methane sulfonic acid
MSW	municipal solid waste
MTBE	methyl tert-butyl ether
MTG	methanol to gasoline
MURE	Mesures d'Utilisation Rationelle de l'Énergie (Rational Use of Energy Measures)
MVA	manufacturing value added
MVA	monitoring, verification, and accounting
MVR	mechanical vapor recompression
N	atomic nitrogen
N_2	molecular nitrogen
N_2O	nitrous oxide
NAAQOs	National Ambient Air Quality Objectives
NAAQS	National Ambient Air Quality Standards
NAM	North America region
NATCARB	National Carbon Explorer
NDRC	National Development and Reform Commission
NEA	Nuclear Energy Agency (OECD)
NEDO	New Energy and Industrial Technology Development Organization
NEF	new energy finance
NELFA	Natural Energy Laboratory of Hawaii Authority
NEPAD	New Partnership for Africa's Development
NER	net energy ratio
NES	National Electrification Scheme

NESRP	Northern Electrification and System Reinforcement Project
NETL	National Energy Technology Laboratory (United States)
NFCRs	naturally fractured carbonate reservoirs
NFPA	National Fire Protection Association
NG	natural gas
NGCC	natural gas combined cycle
NGCC-CCS	natural gas combined cycle with CO_2 capture and storage
NGCC-V	natural gas combined cycle with CO_2 vented
NGL	natural gas liquids
NGO	non-governmental organization
NH_3	ammonia
NIF	National Ignition Facility
NiMH	nickel-metal hydride (batteries)
NMEEE	National Mission on Enhanced Energy Efficiency
NMT	non-motorized transport/transportation
NMV	non-motorized vehicles
NMVOC	non-methane volatile organic carbon
NO	nitric oxide
NO_x	nitrogen oxides (the sum of NO and NO_2) atomic oxygen
NOC	national oil company
NPC	National Petroleum Council
NPP	net primary production
NPP	nuclear power plant
NPT	Treaty on the Non-Proliferation of Nuclear Weapons (Non-Proliferation Treaty)
Nr	reactive nitrogen
NPV	net present value
NRC	National Research Council
NRES	new renewable energy sources
NS	new stock
NSG	Nuclear Suppliers Group
O_2	molecular oxygen
O_3	ozone
O&M	operating and maintenance
OC	organic carbon
ODA	official development assistance
ODS	ozone-depleting substances
ODI	Overseas Development Institute
OECD	Organisation for Economic Co-operation and Development
Ofgem	Office of Gas and Electricity Markets
OLADE	Organizacion Latinoamericana de Energia (Latin America Energy Organization)
OLED	organic light-emitting diode
OPEC	Organization of the Petroleum Exporting Countries
OSA	Other South Asia region
OSART	Operation Safety Review Team (IAEA)
-OT-	once-through (referring to design of synthesis island)
-OTA-	once-through (referring to design of synthesis island) with aggressive CO_2 capture design
OTEC	ocean thermal energy conversion
PACE	property-assessed clean energy
PAF	population attributable fraction
PAH	polycyclic aromatic hydrocarbon
PAO	Pacific OECD region
PAS	Other Pacific Asia region
-PB-	partial bypass (referring to design of methanol synthesis island)
PBS	Palli Biddut Samities (rural electricity cooperatives in Bangladesh)
PC	personal computer
PC	pulverized coal
PCBs	polychlorinated biphenyls
PC-CCS	pulverized coal plant with CO_2 capture and storage
PCM	phase change material
PC-V	pulverized coal plant with CO_2 venting
PDF	probability density functions
PDVSA	Petróleos de Venezuela Sociedad Anonima (Oils of Venezuela, the Venezuelan state-owned petroleum company)
PE	private equity
PEA	Provincial Electricity Authority
PEI	Princeton Environmental Institute

ZEFI	zero-emission fuels index

ANNEX II

Technical Guidelines: Common terms, definitions and units used in GEA

Technical Guidelines: Common terms, definitions and units used in GEA

This document provides technical guidelines for common terms, definitions, and units used in various chapters of the Global Energy Assessment (GEA). Additionally, it covers the proposed spatial resolution (definition of regional aggregates), base year values, units and definition of energy, and sectorial definitions.

Definition and aggregation of GEA Regions

Three different levels of regional aggregations are used in GEA, each of which serves for different purposes and levels of analysis.

1. ***5 regions***: This aggregation is the common, consistent denominator across the different models proposed to be used in GEA. Thus, it represents the minimum level of spatial disaggregation for all analytical input/output data within GEA that involved modeling work. For instance, data for the GEA pathways are available systematically for the 5 GEA regions only. This is the highest (i.e., minimum) level of spatial disaggregation across all GEA chapters.

2. ***11 Regions:*** This is the spatial resolution available for all IIASA models used in GEA, which provided the backbone especially for the GEA scenario work for developing the pathways. Input data used in GEA modeling work (e.g., resource potentials, present energy use patterns, technology characteristics that are regionally different, etc.) have been provided at least at the level of these 11 world regions. The 11 regional aggregations represent just an approximate denominator across all models used within GEA. Data for 11 regions are available for specific scenarios and for a limited set of models only. The results of the GEA pathways are documented in detail at the interactive web-based GEA scenario database hosted by IIASA: www.iiasa.ac.at/web-apps/ene/geadb.

Table 1 | 5 Regions.

Regional acronyms	Regional definition
OECD90	UNFCCC Annex I countries
REF	Eastern Europe and Former Soviet Union
ASIA	Asia excl. OECD90 countries
MAF	Middle East and Africa
LAC	Latin America and the Caribbean

OECD90 = Includes the OECD90 countries, therefore encompassing the countries included below (11 region) in the regions WEU, NAM and PAO.

REF = Countries undergoing economic reform, i.e. countries listed under the regions EEU and FSU below (11 regions).

ASIA = The countries included in the regions SAS, PAS and CPA are aggregated into this region.

MAF = This region includes the Middle East and African countries that make up the regions AFR and MEA above.

LAC = This region includes the Latin American countries that make up the LAC region above.

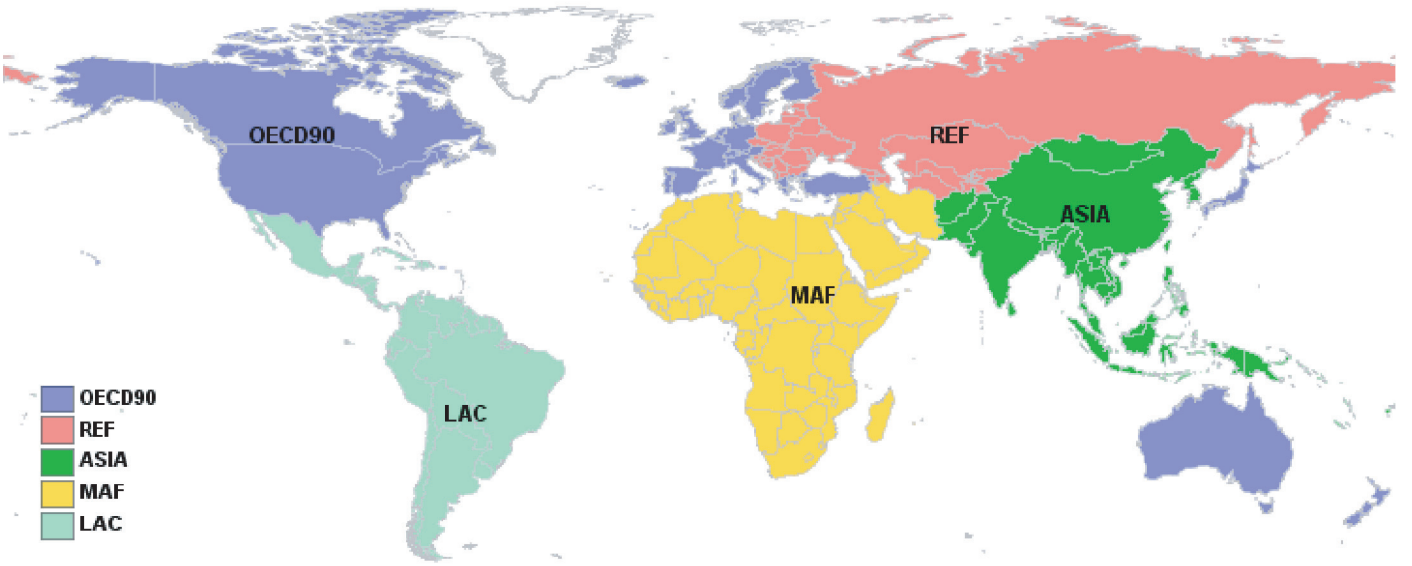

Figure 1 | Minimum GEA regional detail (5 regions).

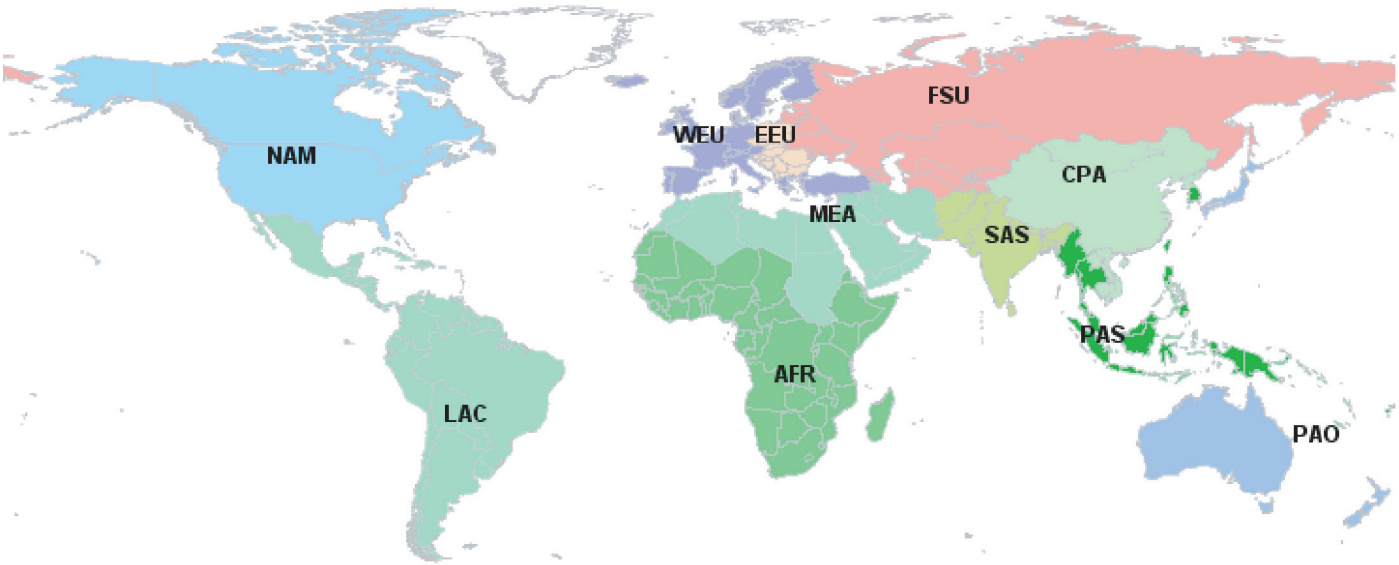

Figure 2 | GEA Scenario Model Regions (11 regions).

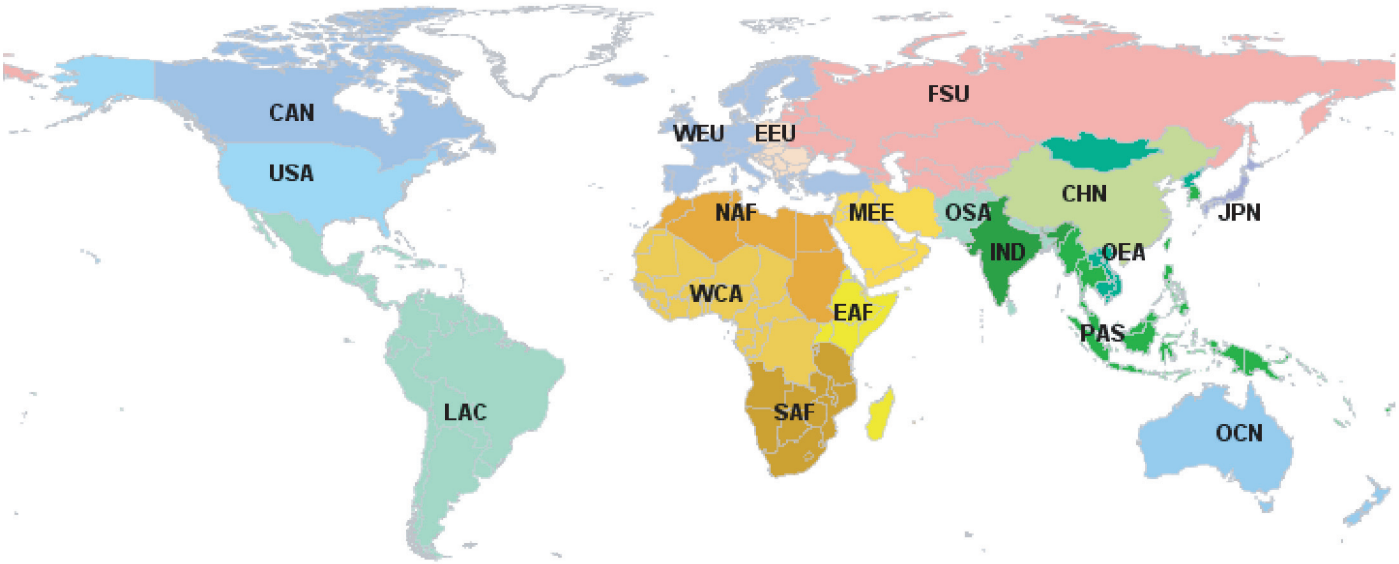

Figure 3 | Detailed GEA Regions (18 regions).

3. ***18 regions***: This is the minimum spatial disaggregation needed to reconcile the regional definition differences across models used within GEA (e.g., including IMAGE models). This regional definition was used for all salient analytical work within GEA, e.g., for describing base year patterns of energy end-use and supply, energy access, resource potentials (fossil and renewable), technology deployment, policy implementation, etc. When available data did not permit the representation of all 18 regions, the 11 regions defined above was used, or alternatively at least the 5 GEA Regions. Base year (2005) proportional scaling techniques are suggested in cases where only 5-regional input data are available but finer regional detail is required.

Base Year: 2005

A common GEA base year is 2005. This is the year for which most critical energy statistics were available in time for GEA's analytical work. More recent data where provided wherever available.

Table 2 | 11 Regions.

Regional acronyms	Regional definition
NAM	North America
WEU	Western Europe
PAO	Pacific OECD
EEU	Central and Eastern Europe
FSU	Former Soviet Union
CPA	Centrally Planned Asia and China
SAS	South Asia
PAS	Other Pacific Asia
MEA	Middle East and North Africa
LAC	Latin America and the Caribbean
AFR	Sub-Saharan Africa

NAM = North America (Canada, Guam, Puerto Rico, United States of America, British Virgin Islands)

WEU = Western Europe (Andorra, Austria, Belgium, Cyprus, Denmark, Finland, France, Germany, Greece, Greenland, Holy See, Iceland, Ireland, Italy, Liechtenstein, Luxembourg, Malta, Monaco, Netherlands, Norway, Portugal, San Marino, Spain, Sweden, Switzerland, Turkey, United Kingdom)

PAO = Pacific OECD (Australia, Japan, New Zealand)

EEU = Central and Eastern Europe (Albania, Bosnia and Herzegovina, Bulgaria, Croatia, Czech Republic, Estonia, The former Yugoslav Rep. of Macedonia, Hungary, Latvia, Lithuania, Montenegro, Poland, Romania, Serbia, Slovak Republic, Slovenia)

FSU = Newly independent states of the former Soviet Union (Armenia, Azerbaijan, Belarus, Georgia, Kazakhstan, Kyrgyzstan, Republic of Moldova, Russian Federation, Tajikistan, Turkmenistan, Ukraine, Uzbekistan)

CPA = Centrally planned Asia and China (Cambodia, China (incl. Hong Kong and Macao), Korea (DPR), Laos (PDR), Mongolia, Viet Nam)

SAS = South Asia (Afghanistan, Bangladesh, Bhutan, India, Maldives, Nepal, Pakistan, Sri Lanka)

PAS = Other Pacific Asia (American Samoa, Brunei Darussalam, Fiji, French Polynesia, Kiribati, Indonesia, Malaysia, Marshall Islands, Micronesia, Myanmar, Nauru, New Caledonia, Palau, Papua, New Guinea, Philippines, Republic of Korea, Samoa, Singapore, Solomon Islands, Taiwan (China), Thailand, Timor-Leste, Tonga, Tuvalu, Vanuatu)

MEA = Middle East and North Africa (Algeria, Bahrain, Egypt (Arab Republic), Iraq, Iran (Islamic Republic), Israel, Jordan, Kuwait, Lebanon, Libya/SPLAJ, Morocco, Occupied Palestine Territory, Oman, Qatar, Saudi Arabia, South Sudan, Syria (Arab Republic), Tunisia, United Arab Emirates, Western Sahara, Yemen)

LAC = Latin America and the Caribbean (Antigua and Barbuda, Argentina, Bahamas, Barbados, Belize, Bermuda, Bolivia, Brazil, Chile, Colombia, Costa Rica, Cuba, Dominica, Dominican Republic, Ecuador, El Salvador, French Guiana, Grenada, Guadeloupe, Guatemala, Guyana, Haiti, Honduras, Jamaica, Miartinique, Mexico, Netherlands Antilles, Nicaragua, Panama, Paraguay, Peru, Saint Kitts and Nevis, Santa Lucia, Saint Vincent and the Grenadines, Suriname, Trinidad and Tobago, Uruguay, Venezuela)

AFR = Sub-Saharan Africa (Angola, Benin, Botswana, Burkina Faso, Burundi, Cameroon, Cape Verde, Central African Republic, Chad, Comoros, Cote d'Ivoire, Congo (DR), Djibouti, Equatorial Guinea, Eritrea, Ethiopia, Gabon, Gambia, Ghana, Guinea, Guinea-Bissau, Kenya, Lesotho, Liberia, Madagascar, Malawi, Mali, Mauritania, Mauritius, Mozambique, Namibia, Niger, Nigeria, Reunion, Rwanda, Sao Tome and Principe, Senegal, Seychelles, Sierra Leone, Somalia, South Africa, Saint Helena, Swaziland, Tanzania, Togo, Uganda, Zambia, Zimbabwe)

Table 3 | 18 Regions.

Regional acronyms	Regional definition
USA	United States of America
CAN	Canada
WEU	Western Europe, incl. Turkey
EEU	Central and Eastern Europe
FSU	Former Soviet Union
NAF	Northern Africa
EAF	Eastern Africa
WCA	Western and Central Africa
SAF	Southern Africa
MEE	Middle East
CHN	China
OEA	Other East Asia
IND	India
OSA	Other South Asia
JPN	Japan
PAS	Other Pacific Asia
OCN	Australia, New Zealand, and other Oceania
LAC	Latin America and the Caribbean

USA = Unites States (Guam, Puerto Rico, United States of America, British Virgin Islands)

CAN = Canada

WEU = Western Europe (Andorra, Austria, Belgium, Cyprus, Denmark, Finland, France, Germany, Greece, Greenland, Holy See, Iceland, Ireland, Italy, Liechtenstein, Luxembourg, Malta, Monaco, Netherlands, Norway, Portugal, San Marino, Spain, Sweden, Switzerland, Turkey, United Kingdom)

EEU = Central and Eastern Europe (Albania, Bosnia and Herzegovina, Bulgaria, Croatia, Czech Republic, Estonia, The former Yugoslav Rep. of Macedonia, Hungary, Latvia, Lithuania, Montenegro, Poland, Romania, Serbia, Slovak Republic, Slovenia)

FSU = Newly independent states of the former Soviet Union (Armenia, Azerbaijan, Belarus, Georgia, Kazakhstan, Kyrgyzstan, Republic of Moldova, Russian Federation, Tajikistan, Turkmenistan, Ukraine, Uzbekistan)

NAF = North Africa (Algeria, Egypt (Arab Republic), Libya/SPLAJ, Morocco, Sudan, Tunisia)

EAF = Eastern Africa (Burundi, Eritrea, Ethiopia, Kenya, Madagascar, Mauritius, Seychelles, Somalia, Uganda)

WCA = Western and Central Africa (Benin, Burkina Faso, Cameroon, Cape Verde, Central African Republic, Chad, Comoros, Cote d'Ivoire, Congo (DR), Djibouti, Equatorial Guinea, Gabon, Gambia, Ghana, Guinea, Guinea-Bissau, Liberia, Mali, Mauritania, Niger, Nigeria, Sao Tome and Principe, Senegal, Sierra Leone, Togo)

SAF = Southern Africa (Angola, Botswana, Burundi, Malawi, Mozambique, Namibia, Reunion, Rwanda, Saint Helena, South Africa, Swaziland, Tanzania, Zambia, Zimbabwe)

MEE = Middle East (Bahrain, Iraq, Iran (Islamic Republic), Israel, Jordan, Kuwait, Lebanon, Occupied Palastine Territory, Oman, Qatar, Saudi Arabia, Syria (Arab Republic), United Arab Emirates, Western Sahara, Yemen)

CHN = China (incl. Hong Kong and Macao)

OEA = Other East Asia (Cambodia, Korea (DPR), Laos (PDR), Mongolia, Viet Nam)

Economic data are expressed in 2005 US$. GDP at constant (2005) prices in US$ was calculated using the following equations:

$$\text{GDP at constant (2005) price in national currency}_i(t) = \frac{\text{GDP at current price}_i(t)}{\frac{\text{GDP deflator}_i(t)}{\text{GDP deflator}_i(2005)}}$$

$$\text{GDP at constant (2005) price in US\$}_i(t) = \frac{\text{GDP in constant (2005) price in national currency}_i(t)}{\text{XRATE}_i(2005)}$$

Where, i = country indicator, t = year indicator, $\text{XRATE}_i(2005)$ = annual average market exchange rate in 2005 [Local currency / US$].

For example, 272 [billion 2007 Euro] GDP in Austria can be converted in 326 [billion 2005 US$] as follows:

$$262\ [2005\ \text{Euro}] = \frac{272\ [2007\ \text{Euro}]}{\left(\frac{112.93\ [\text{GDP deflator (2007)}]}{108.51\ [\text{GDP deflator (2005)}]}\right)}$$

$$326\ [2005\ \text{US\$}] = \frac{262\ [2005\ \text{Euro}]}{(0.803\ [\text{XRATE (2005)}])}$$

All relevant data series for each country is from the World Economic Outlook (WEO) database by IMF at: www.imf.org/external/data.htm.

Depending on the specific context, economic indicators were presented in purchasing power parity (PPP) or market exchange rates (MER). In either case, the choice of PPP or MER should be clearly stated in the text and figures. The equations above are given for market exchange rates (XRATE). For using PPPs, above XRATE needs to be replaced by the following term:

Table 3 | ***(cont.)***

IND = India

OSA = Other South Asia (Afghanistan, Bangladesh, Bhutan, Maldives, Nepal, Pakistan, Sri Lanka)

JPN = Japan

OCN = Oceania (Australia, New Zealand)

PAS = Other Pacific Asia (American Samoa, Brunei Darussalam, Fiji, French Polynesia, Gilbert-Kiribati, Indonesia, Malaysia, Marshall Islands, Micronesia, Myanmar, Nauru, New Caledonia, Palau, Papua, New Guinea, Philippines, Republic of Korea, Singapore, Solomon Islands, Taiwan (China), Thailand, Timor-Leste, Tonga, Tuvalu, Vanuatu, Samoa)

LAC = Latin America and the Caribbean (Antigua and Barbuda, Argentina, Bahamas, Barbados, Belize, Bermuda, Bolivia, Brazil, Chile, Colombia, Costa Rica, Cuba, Dominica, Dominican Republic, Ecuador, El Salvador, French Guiana, Grenada, Guadeloupe, Guatemala, Guyana, Haiti, Honduras, Jamaica, Martinique, Mexico, Netherlands Antilles, Nicaragua, Panama, Paraguay, Peru, Saint Kitts and Nevis, Santa Lucia, Saint Vincent and the Grenadines, Suriname, Trinidad and Tobago, Uruguay, Venezuela)

Table 4 | Sample XRATE for major currencies.

Local Currency	XRATE [Local Currency / US$] in 2005
Euro	0.803
British Pound	0.549
Japanese Yen	108.9
Chinese Yuan	8.195
Canadian Dollar	1.211
Australian Dollar	1.309

$$\frac{\text{GDP at local currency } (t = 2005)}{\text{GDP-PPP in nternation \$ } (t = 2005)}$$

The relevant statistics are available from the World Development Indicators (World Bank, 2007).

Discount Rate

The discount rate represents the annual rate at which the effects of future events are reduced so as to be comparable to the effect of present events. Assumptions in regard to the discount rate adopted have important implications when considering medium- to long-term scenarios. However, there is no rate universally accepted since it is laden with value judgment. For practical reasons, GEA adopted a uniform rate of 5% throughout. Other rates are used in specific cases (e.g. from the literature) whenever possible with a clear reference to the rate used is made in such instances.

Energy Flows (Joules)

Both *final* and *primary energy* use levels are reported systematically in GEA using SI units (i.e., Joules or multiples thereof, and to allow for additional units, e.g., kWh if so desired, but always keeping the Joules common denominator). Often alternative units from original sources in the literature are shown in addition to the SI units. For the sectorial end-use chapters, only final energy is reported to avoid the risk of double counting.

Table 5 | Units based on SI.

Physical quantity	Unit	Symbol
Length	meter	m
Mass	kilogram	kg
Time	second	s
Thermodynamic temperature	Kelvin	K
Energy	Joule	J
Power	Watt	W
Temperature	Degree Celsius	°C

Table 6 | Selected SI prefix.

Prefix	Symbol	10^n
exa-	E	10^{18}
peta	P	10^{15}
tera	T	10^{12}
giga	G	10^{9}
mega	M	10^{6}
kilo	k	10^{3}
hector	h	10^{2}
deca	da	10
-	-	10^{0}
deci	d	10^{-1}
centi	c	10^{-2}
milli	m	10^{-3}
micro	μ	10^{-6}
nano	n	10^{-9}
pico	p	10^{-12}
femto	f	10^{-15}

Accounting of Primary Energy

A consistent methodology was used for converting non-combustible and non-fossil energy (e.g., renewable and nuclear energy for electricity generation) to primary energy equivalent across the assessment. A widely accepted method for the accounting of primary energy from these sources does not exist. Studies in the past have either used the substitution equivalent method, assuming specific efficiencies for renewable sources, or they have applied the direct equivalent method, which accounts the energy output (e.g., electricity) of above energy sources as their primary energy. The SRES (IPCC, 2000) have used the direct equivalent method, while e.g., Nakicenovic et al. (1998) and the IPCC (2007) have applied uniform conversion efficiencies across different sources (38.6% and 33%, respectively). Other assessments, such as the World Energy Assessment (UNDP, 2004) or the World Energy Outlook (IEA, 2007a), combine both methods, and assume different conversion factors for different conversion technologies (in the WEA, for instance, nuclear: 3, hydro, wind and solar: 1, geothermal: 10).

It was decided to keep the accounting methodology transparent and as simple as possible in GEA given that a widely accepted and consistent method across different studies does not exist. As a guide for the selection of the conversion efficiency, a global average efficiency of electricity and heat generation for the year 2005 was used. This corresponds to an average efficiency of 35% for electricity generation, and 85% for heat generation (IEA, 2007b). For example, 1[EJ] of electricity generated by wind or nuclear at the secondary energy level is accounted as 2.86 [EJ] (i.e., 1/0.35) at the primary energy level. Likewise, 1[EJ] of heat generated (and used as heat) by solar or geothermal is accounted as 1.17 [EJ] at the primary energy level (i.e., 1/0.85). See Chapter 1 for further discussion of primary energy accounting methods.

Accounting of Heating Values

To maintain clarity and consistency throughout the report, the heating value of a substance, i.e., the amount of heat released during combustion of a specified amount, is expressed in J/kg.

Heating values are clearly defined in the text as either HHV (Higher Heating Value) or LHV (Lower Heating Value). It is assumed that heating values are given as LHV unless explicitly noted in the text as HHV. The difference is that HHV includes the energy of condensation of the water vapor contained in the combustion products.

Sectorial Definitions

The reporting and analysis within GEA's sectorial chapters adheres strictly to the principle of *mutual exclusiveness.*

Therefore, efficiency improvement (or carbon reduction) potentials for end-use sectors (e.g., industry) are always strictly separated from corresponding "upstream" energy systems/sectors (e.g., electricity generation). For example, emissions reductions (e.g., from the electricity generation sector) at the supply side need to be discussed/accounted in the "upstream" GEA chapter, while the end-use demand chapters should report emission/energy reduction potentials due to fuel substitution and energy conservation in that end-use sector only. Thus, sectorial assessments were not "inflated" by accounting for (often unrelated) "upstream" energy systems changes that should be reported separately. The GEA energy modeling framework enabled a rigorous and consistent accounting across sectors and the impacts of policy measures at the sector level.

Asmerom Gilau
Triple "E" Systems Inc., USA

Stephen Gitonga
United Nations Development Programme

Robert Goldston
Princeton Plasma Physics Laboratory, USA

Andreas Goldthau
Central European University, Hungary

Luis Gomez-Echeverri
International Institute for Applied Systems Analysis, Austria

Peter Graham
University of New South Wales, Australia

Arnulf Grubler
International Institute for Applied Systems Analysis, Austria and Yale University, USA

Helmut Haberl
Klagenfurt University, Austria

Richard Haeuber
United States Environmental Protection Agency

Keisuke Hanaki
University of Tokyo, Japan

Maureen Hand
National Renewable Energy Laboratory, USA

Danny Harvey
University of Toronto, Canada

Marianne Haug
University of Hohenheim, Germany

Kebin He
Tsinghua University, China

Marko Hekkert
Utrecht University, the Netherlands

Fancisco Hernandez
Lund University, Sweden

Sergio Tirado Herrero
Central European University, Hungary

Edgar Hertwich
Norwegian University of Science and Technology

Conrado Heruela
United Nations Environment Programme

Kevin Hicks
Stockholm Environment Institute, University of York, UK

Monique Hoogwijk
Ecofys, the Netherlands

Richard Hosier
World Bank, USA

Alison Hughes
University of Cape Town, South Africa

Larry Hughes
Dalhousie University, Canada

Jane Hupe
International Civil Aviation Organization, Canada

Toshiaki Ichinose
National Institute for Environmental Studies, Japan

Morna Isaac
PBL Netherlands Environmental Assessment Agency, the Netherlands

Mark Jaccard
Simon Fraser University, Canada

Staffan Jacobsson
Chalmers University of Technology, Sweden

Jill Jäger
Sustainable Europe Research Institute, Austria

Martin Jakob
Swiss Federal Institute of Technology Zurich

Kathryn Janda
Oxford University, UK

Gilberto Jannuzzi
University of Campinas, Brazil

Jaap Jansen
Energy Research Centre of the Netherlands

Jessica Jewell
Central European University, Hungary

Kejun Jiang
Energy Research Institute, China

Yi Jiang
Tsinghua University, China

Eberhard Jochem
Fraunhofer Institute for Systems and Innovation Research, Germany

Thomas B. Johansson
Lund University, Sweden

Francis X. Johnson
Stockholm Environment Institute, Stockholm University, Sweden

Arthur Johnson
Hydrate Energy International, USA

Ian Johnson
Club of Rome, Switzerland

Suzana Kahn Ribeiro
Federal University of Rio de Janeiro, Brazil

Mikiko Kainuma
National Institute for Environmental Studies, Japan

Daniel Kammen
University of California, Berkeley, USA

Shinji Kaneko
Hiroshima University, Japan

Stephen Karekezi
AFREPREN/FWD, Kenya

Anders Karlqvist
Swedish Polar Research Secretariat

Tadahiro Katsuta
Meiji University, Japan

James E. Keirstead
Imperial College London, UK

Francis Kemausuor
Kwame Nkrumah University of Science and Technology, Ghana

René Kemp
United Nations University-MERIT, the Netherlands

Ruud Kempener
Harvard University, USA

John Kimani
AFREPREN/FWD, Kenya

Osamu Kimura
Central Research Institute of Electric Power Industry, Japan

Patrick Kinney
Columbia University, USA

Bernadette Kiss
Lund University, Sweden

Tord Kjellstrom
Umea University, Sweden

Zbigniew Klimont
International Institute for Applied Systems Analysis, Austria

Shigeki Kobayashi
Toyota Central R&D Laboratories, Japan

Peter Kolp
International Institute for Applied Systems Analysis, Austria

Christian Kornevall
World Business Council for Sustainable Development, Switzerland

Reza Kowsari
University of British Columbia, Canada

Diana Kraft
REN21, France

Fridolin Krausmann
Klagenfurt University, Austria

Wolfram Krewitt†
German Air and Space Agency

Volker Krey
International Institute for Applied Systems Analysis, Austria

Sivanappan Kumar
Asian Institute of Technology, Thailand

Rattan Lal
The Ohio State University, USA

Eric D. Larson
Princeton University and Climate Central, USA

Hans Larsen
Technical University of Denmark

Rik Leemans
Wageningen University, the Netherlands

Sylvie Lemmet
United Nations Environment Programme

Philippe Lempp
German Development Ministry, Germany

Manfred Lenzen
University of Sydney, Australia

Zheng Li
Tsinghua University, China

Vladimir Likhachev
Russian Academy of Sciences

Guangjian Liu
North China Electric Power University

Jeff Logan
National Renewable Energy Laboratory, USA

Oswaldo Lucon
São Paulo State Environment Agency, Brazil

John Lund
Geo-Heat Center, Oregon Institute of Technology, USA

Nora Lustig
Tulane University, USA

Jordan Macknick
National Renewable Energy Laboratory, USA

Mili Majumdar
The Energy and Resources Institute, India

François Maréchal
Swiss Federal Institute of Technology Lausanne, Switzerland

Omar Masera
National Autonomous University of Mexico

Denise L. Mauzerall
Princeton University, USA

Peter McCabe
Commonwealth Scientific and Industrial Research Organisation, Australia

David McCollum
University of California, Davis, USA

Charles McCombie
Independent Consultant

Susan McDade
United Nations Development Programme

Aimee T. McKane
Lawrence Berkeley National Laboratory, USA

Thomas McKone
Lawrence Berkeley National Laboratory, USA

James E. McMahon
Lawrence Berkeley National Laboratory, USA

Anthony McMichael
Australian National University

Michael McNeil
Lawrence Berkeley National Laboratory, USA

Mark Mehos
National Renewable Energy Laboratory, USA

Tim Merrigan
National Renewable Energy Laboratory, USA

Jacqui Meyers
Commonwealth Scientific and Industrial Research Organisation, Australia

Alan Miller
International Finance Corporation, USA

Sevastianos Mirasgedis
National Observatory of Athens, Greece

Catherine Mitchell
University of Exeter, UK

Vijay Modi
Columbia University, USA

Joachim Monkelbaan
International Centre for Trade and Sustainable Development, Switzerland

José Roberto Moreira
Biomass Users Network, Brazil

Granger Morgan
Carnegie Mellon University, USA

Siwa Msangi
International Food Policy Research Institute, USA

Adrian Muller
University of Zurich, Switzerland and Swiss Federal Institute of Technology Zurich

Mohan Munasinghe
Munasinghe Institute for Development, Sri Lanka and University of Manchester, UK

Luis Mundaca
Lund University, Sweden

Shuzo Murakami
Keio University, Japan

Iyngararasan Mylvakanam
United Nations Environment Programme

Lynn K. Mytelka
United Nations University-MERIT, the Netherlands

Yu Nagai
Vienna University of Technology, Austria

Koji Nagano
Central Research Institute of Electric Power Industry, Japan

Hitomi Nakanishi
University of Canberra, Australia

Nebojsa Nakicenovic
International Institute for Applied Systems Analysis and Vienna University of Technology, Austria

Lena Neij
Lund University, Sweden

Gregory Nemet
University of Wisconsin, USA

George L. Nicolaides
Wildcat Venture Management, USA

Hans Nilsson
FourFact, Sweden

Aleksandra Novikova
Climate Policy Initiative, German Institute for Economic Research

Victoria Novikova
Oxford University, UK

Virginia Sonntag O'Brien
REN21, France

Anastasia O'Rourke
BigRoom Inc., Canada

Peter Odell
Erasmus University Rotterdam, the Netherlands.

Michael Ohadi
Universitys of Maryland, USA

Marina Olshanskaya
United Nations Development Programme

Shonali Pachauri
International Institute for Applied Systems Analysis, Austria

Saptarshi Pal
Central European University, Hungary

Shamik Pal
Institute of Engineering and Management, India

Debajit Palit
The Energy and Resources Institute, India

Riddhi Panse
Indian Institute of Technology-Bombay

Mahesh Patankar
Independent Energy Sector Consultant

Anand Patwardhan
Indian Institute of Technology-Bombay

Ksenia Petrichenko
Central European University, Hungary

Hector Pistonesi
Bariloche Foundation, Argentina

Christoph Plutzar
Klagenfurt University, Austria

Gisela Prasad
University of Cape Town, South Africa

Ndola Prata
University of California, Berkeley, USA
