Executive Summary

Analysis in Chapter 12 shows that a radical transformation of the fossil energy landscape is feasible for simultaneously meeting the multiple sustainability goals of wider access to modern energy carriers, reduced air pollution health risks, enhanced energy security, and major greenhouse gas (GHG) emissions reductions.

Fossil fuels will dominate energy use for decades to come. Two findings apply to developing and industrialized countries alike. First, fossil fuels must be used judiciously – by designing energy systems for which the quality of energy *supply* is well matched to the quality of energy *service* required, and by exploiting other opportunities for realizing high efficiencies. Second, continued use of coal and other fossil fuels in a carbon-constrained world requires that carbon capture and storage (CCS) becomes a major carbon mitigation activity.

Since developing and industrialized countries have different energy priorities, strategies for fossil energy development will be different between these regions in the short term, but must converge in the long term. The focus in developing countries should be on increasing access to modern and clean energy carriers, building new manufacturing and energy infrastructures that anticipate the evolution to low carbon energy systems, and exploiting the rapid growth in these infrastructures to facilitate introduction of the advanced energy technologies needed to meet sustainability goals. Rapidly growing economies are good theaters for innovation. In industrialized countries, where energy infrastructures are largely already in place, a high priority should be overhauling existing coal power plant sites to add additional capabilities (such as coproduction of power and fuels) and CCS. (Simply switching from coal to natural gas power generation without CCS will not achieve the ultimately needed deep carbon emission reductions.)

Analysis in Chapter 12 highlights the essential technology-related requirements for a radical transformation of the fossil energy landscape: (i) continued enhancement of unit energy conversion efficiencies, (ii) successful commercial deployment of carbon capture and storage, (iii) co-utilization of fossil and renewable energy in the same facilities, and (iv) efficient coproduction of multiple energy carriers at the same facilities.

Among the fossil fuel-using technologies described in this chapter, only coproduction strategies using some biomass with the fossil fuel and with CCS have characteristics such that they can simultaneously address all four of the major energy-related societal challenges identified by GEA, as shown in Figure 12.1. It is plausible that these technologies could begin to be deployed in the relatively near term (2015–2020) because nearly all of the technology components of such systems are already in commercial use. Hydrogen made from fossil fuels with CCS is an energy option in the long term, but infrastructure challenges associated with hydrogen distribution and end use (especially for mobile applications) amplify the magnitude of the fossil energy challenge and are likely to limit hydrogen as an option in the near term. Other energy options may emerge in the post-2050 timeframe, and some ideas are touched upon briefly in this chapter.

The energy performance, cost, and GHG emissions of many of the power generation and coproduction technologies described in this chapter are summarized in Table 12.1 and Table 12.2. (Similar metrics for hydrogen production from fossil fuels and for smaller scale coproduction systems that coprocess biomass and coal or biomass and natural gas can be found in the main body of this chapter.)

Table 12.2 includes coal-biomass coprocessing systems with CCS that provide liquid fuels and electricity via coproduction. These technologies are attractive both as repowering and repurposing options for existing coal power plant sites and for greenfield projects. The economics of such systems depends on the greenhouse gas emissions price and the oil price, as discussed quantitatively in this chapter.

Clear benefits of this coproduction approach include:

- greatly reduced carbon emissions for electricity and transportation fuels;
- enhanced energy supply security;

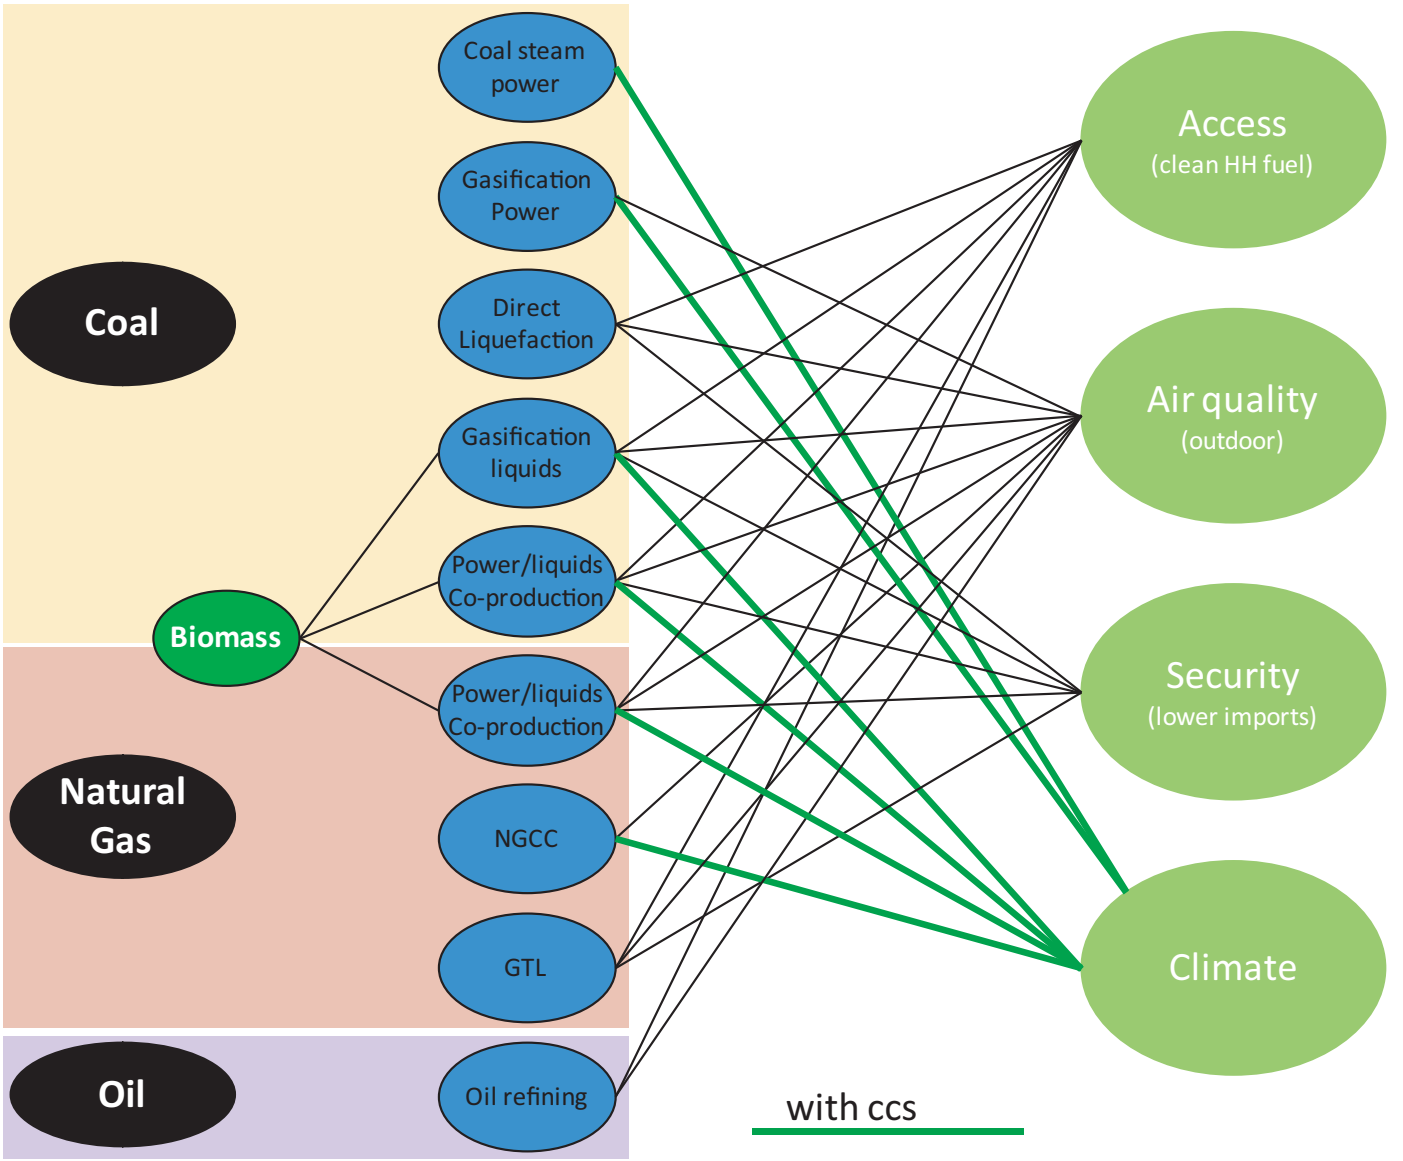

Figure 12.1 | Commercial or near-commercial fossil energy technologies discussed in this chapter and their suitability for addressing four major energy-related challenges. Among the listed technology options, only coproduction systems (that include coprocessing of some biomass) are capable of addressing all major challenges.

- provision of transportation fuels that are less polluting in terms of conventional air pollutants than petroleum-derived fuels;
- provision of super-clean synthetic cooking fuels such as liquefied petroleum gas (LPG) and dimethyl ether (DME) as alternatives to cooking with biomass and coal, which is critically important for developing countries; and
- greatly reduced severe health damage costs due to particulate matter ($PM_{2.5}$) air pollution from conventional coal power plants.

Coprocessing biomass with coal in these systems requires half or less biomass to provide low-carbon transport fuels as required for advanced fuels made only from biomass, such as cellulosic ethanol.

Table 12.1 | Performance and cost estimates in US_{2007} from this chapter for power generating technologies under US conditions. (To express costs in other-year US$, use the Chemical Engineering Plant Cost Index as shown in Figure 12.4 and discussed in text accompanying it.)

	Installed cost (US/kW_e)	Capacity (MW_e)	Levelized electricity cost[a] (US$/MWh)	Plant inputs (MW HHV)			Life cycle GHG[c] $kgCO_2$-eq per MWh

a Assuming capacity factor of 0.85. Prices assumed (US/GJ_{HHV}) for coal, biomass, and natural gas are US$2.04, US$5, and US$5.11, respectively.
b As-received biomass moisture content is 15% by weight.
c Includes GHG emissions associated with feedstock production and delivery to the power plant.

Coproduction also represents a promising approach for gaining early market experience with CCS, because CO_2 capture is easier in coproduction than for stand-alone power plants. In the near term, coproduction could serve as a bridge to enabling CCS as a routine activity for biomass energy, with corresponding negative greenhouse gas emissions, in the post-2030 era. Analysis in this chapter shows that this could plausibly become a major industrial activity under a carbon mitigation policy for economically poor but biomass-rich regions, where it could make clean cooking fuels widely available and affordable in the regions while making major contributions to decarbonization of the transport sector worldwide.

No technological breakthroughs are needed to get started with coproduction strategies, but there are formidable institutional hurdles created by the need to manage two disparate feedstocks (coal and biomass) and provide

Table 12.2 | Summary of performance and cost estimates in US_{2007} from this chapter for alternative coproduction systems. Electricity is coproduced (to greater or lesser degree) with liquid fuels in all of these systems. FTL refers to Fischer-Tropsch liquids. MTG stands for methanol-to-gasoline. (To express costs in other-year US$, use the Chemical Engineering Plant Cost Index as shown in Figure 12.4 and discussed in text accompanying it.)

a bbl_{eq}/d is energy-equivalent barrels (LHV basis) per day of petroleum-derived fuels that could be replaced by the synthetic liquids.
b LHV is lower heating value and HHV is higher heating value.
c As-received biomass moisture content is 15% by weight.
d GHGI = system wide life cycle GHG emissions for production and consumption of the energy products divided by emissions from a reference system producing the same amount of liquid fuels and electricity. Here the reference system consists of equivalent crude oil-derived liquid fuels plus electricity from a stand-alone new supercritical pulverized coal power plant venting CO_2. See Table 12.15, note (c) for additional details.

simultaneously three products (liquid fuels, electricity, and CO_2) serving three different commodity markets. Creative public policies can help overcome these and other hurdles. Most importantly:

- Policy is urgently needed that sets a price on greenhouse gas emissions high enough to motivate CCS as a commercial activity.
- Stricter limits on air pollution are needed, especially from existing coal power plants and from indoor direct combustion sources. For the latter, policies should be designed to induce a shift, especially among the poor, from cooking by direct combustion of biomass or coal to using clean fluid fuels. Added costs that would result from

stricter air pollution limits can be justified on the basis of the large reductions in public health damage costs that would follow.

- Incentives are urgently needed that specifically target integrated CCS demonstration projects at megascale. To minimize spending on such incentives, governments should aim to pursue projects from which maximum learning is derived per dollar spent. This would include multilateral financial support for these demonstrations, since all countries needing CCS technologies will benefit from these early projects if the learning is well documented and shared.

- Policies are needed that support early deployment of promising new technologies and systems at commercial scale, such as coproduction with CCS. Without incentives for first-of-a-kind projects that offer major public benefits, promising new technologies will enter the market slowly or not at all. Incentives should include ones that encourage new inter-industry partnerships where needed. It is desirable that policy instruments specify performance goals rather than specific technologies, and maximize use of market forces in meeting the goals.

- CO_2 storage prospects are not well known in many countries where sorely-needed clean liquid cooking fuels could be produced from coal or biomass while storing byproduct CO_2 underground. This is especially true for many biomass-rich but coal-poor countries. Detailed assessments of CO_2 storage prospects are needed on a reservoir-by-reservoir basis in these countries. Financial support for these assessments from the international community would be appropriate.

- International collaboration is needed to speed up the needed global energy transformation, including assistance from industrialized to developing countries for technological and institutional capacity development.

- New public policies are needed to facilitate industrial collaborations between companies producing transportation fuels, electricity, and clean cooking fuels and to encourage coprocessing of coal and biomass in regions having significant supplies of both (e.g., United States and China). It is desirable that policy instruments specify performance rather than technology and maximize use of market forces in meeting performance goals.

12.1 Introduction

In 2009, the world used 11,164 million tonnes of oil equivalent (Mtoe) or 469 exajoules (EJ) of commercial energy in total, nearly 90% of which was from fossil sources (BP, 2010). Due to advantages in cost, technological maturity and established industry and infrastructure, fossil energies are very likely to remain as a major component of world energy supply for several decades (especially coal-based power generation and liquid hydrocarbon fuels for transport), even as the world increasingly transitions to renewable energy technologies. At the same time, as discussed in earlier chapters, the world today faces four major challenges stemming from fossil energy use: a widespread lack of access to affordable modern energy carriers (Chapter 2), climate change (Chapter 3), air pollution (Chapter 4), and energy insecurity (Chapter 5). Given that continued use of fossil fuels is likely for at least the next several decades, how can they be used to address effectively these four challenges? This question frames the content of this chapter. Figure 12.2 shows the broad filtering criteria applied to focus the discussion in this chapter.

A technology "missing" from Figure 12.2 is combined heat and power (CHP). Large energy and environmental benefits can be achieved by replacing separate stand-alone power and heat production systems with CHP. Carbon emission reductions can be especially significant when stand-alone coal-fired systems are replaced with natural gas fired CHP systems (Krause et al., 1994). We do not discuss CHP in this chapter in large part because the analysis presented on this topic in the World Energy Assessment (Williams, 2000) is still relevant today.

Hydrogen as a vehicle fuel is also not analyzed in this chapter. Technologies for fossil fuel conversion to hydrogen are described, but because hydrogen distribution and end-use infrastructural challenges associated with using it in vehicles likely would require at least several decades to overcome, the emphasis on transportation fuels in this chapter is on liquid fuels that can be made from hydrocarbon (fossil or biomass) resources.

In Chapter 12, power generation technologies are discussed in Section 12.2 with an emphasis on their ability to reduce carbon emissions. Section 12.3 discusses the possibilities for carbon mitigation in conventional petroleum refineries. Section 12.4 discusses alternative transportation fuel technologies that can ease energy security tension and also help reduce carbon emissions from transportation. Section 12.5 discusses roles of non-petroleum feedstocks for production of clean household fuels that can help to address the problem of the widespread lack of access to modern energy carriers. In Section 12.6, strategies for coproduction of electricity and fuels are discussed. These offer the prospects for comprehensive solutions to using fossil fuels efficiently, economically, and with low environmental impacts, both in retrofitting

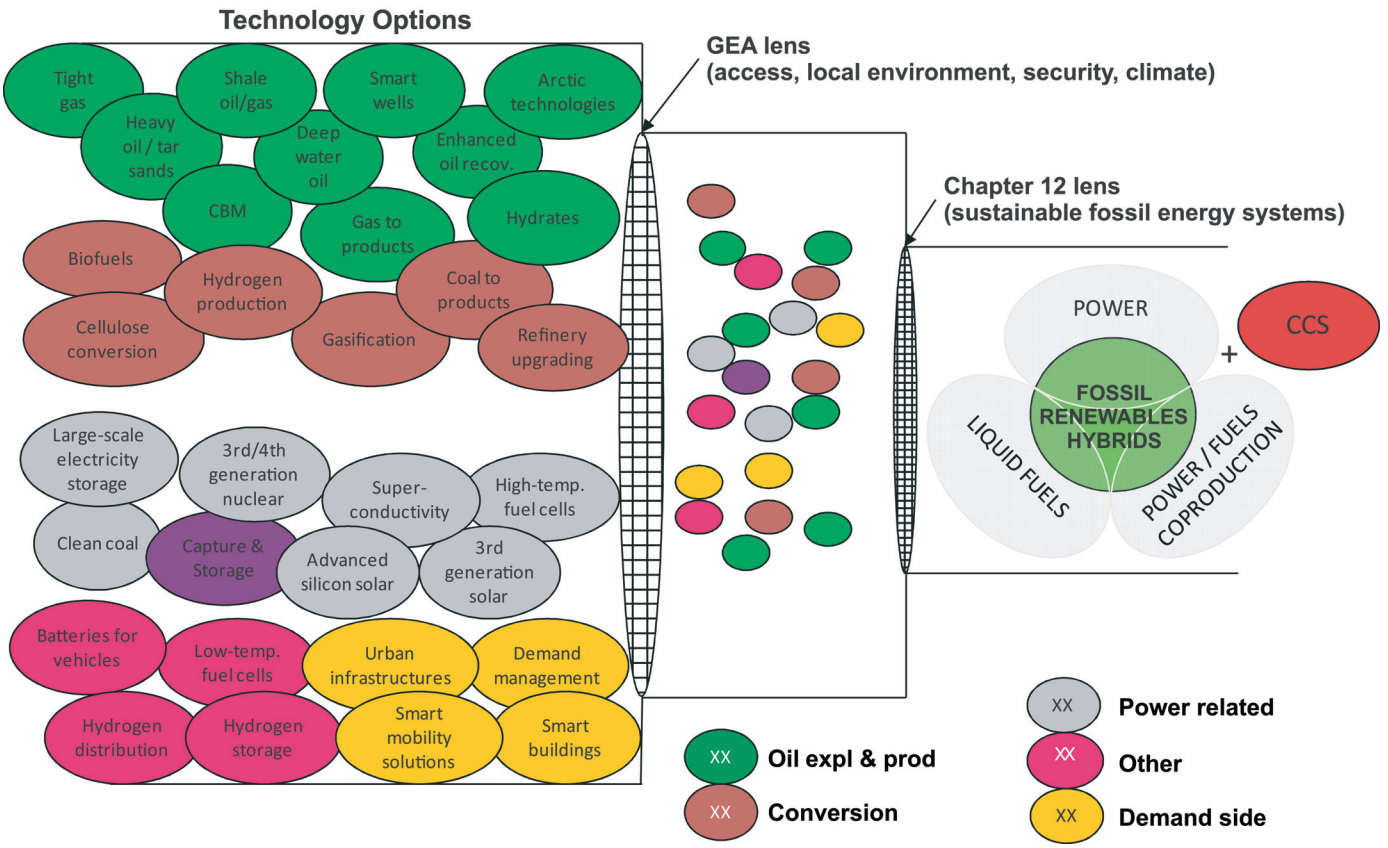

Figure 12.2 | Technology filters for this chapter.

existing energy facilities and in new installations needed to meet growing energy demands. Section 12.7 touches briefly on long-term technology options. Section 12.8 steps back from technology to consider strategic and policy issues.

12.2 Fossil Energy Technologies for Power Generation

For the foreseeable future, electricity will be one of the major energy carriers used by society. The problem lies in the large amount of fossil energy (and emissions) associated with electricity generation today to meet global demands.

Fossil fuels are the predominant primary energy at present in the world, accounting for nearly 90% of commercial energy use (BP, 2010). They are also the dominant fuel for power generation: producing about two thirds of our electricity today and projected to provide a similar fraction in 2035 (IEA, 2010). Today, fossil fuels are the most mature and economic source for power generation. However, they also account for most local conventional pollution and global carbon dioxide emissions. The future of fossil energy power generation in a carbon-constrained world depends on a compromise between growth in electricity demand and reduction in carbon dioxide emissions.

This section focuses on comparing the energy, environmental, and economic performance of fossil energy power generation technologies including coal-steam power, integrated coal gasification combined cycle (IGCC) and natural gas combined cycle (NGCC) with and without carbon capture and storage (CCS). The section also touches on other issues related to sustainable development, including water usage, health damage from environmental pollution, and co-utilization of coal with biomass, reflecting the intention of this section to explore alternatives for using fossil energy wisely and with lower carbon emissions.

12.2.1 Overview of Global Electricity Demand and Supply

The International Energy Agency (IEA) describes current and projected future electricity demand and supply (IEA, 2010). Here we cite relevant numbers from the IEA to give a general overview of fossil energy power generation.

12.2.1.1 Current Electricity Demand and Supply

Electricity is the "blood" of modern society that supports human prosperity. Electricity demand has invariably increased along with economic growth. In 2008, world end-use energy utilization was 8423 Mtoe (354 EJ) (IEA, 2010), including coal, oil, natural gas, electricity, heat, biomass, and waste. Oil usage ranked first with a fraction of 42%. Electricity was second, at 17%. This indicates the importance of electricity in modern society.

In 2008, 16,814 terawatt hours (TWh) of electricity was consumed in end uses globally but with a regional imbalance. Member countries of the Organisation for Economic Co-operation and Development (OECD), with 18% of world population,[1] consumed 9244 TWh (55% of the total). Non-OECD countries, with 82% of world population, consumed 7570 TWh (45%). Per capita electricity demand in non-OECD countries was about 1300 kilowatt hours (kWh) per person, or only one sixth of that in OECD countries. Today, some 1.4 billion people still have no electricity supply, some 85% of them in rural areas (IEA, 2010). No access to electricity means not only energy deprivation, but also a lower capacity for economic growth, which has deep and long-term impacts.

The largest electricity consumption, 3814 TWh (23% of the world total) among OECD countries is by the United States. Among developing countries, China has the largest electricity consumption, 2884 TWh (15% of world total). Since China has about 20% of the world's population, per capita electricity consumption there is still lower than the world average.

The two countries also lead in power production. In 2008, the total electricity generation globally was 20,183 TWh, of which 53% was in OECD countries. The United States and China were the largest power-generating countries in OECD and in the developing world, respectively, accounting for 22% and 17% of global power production. Power generation in Africa was only 621 TWh, or 3% of the global total.

Total global power generating capacity was 4719 gigawatts (GW) in 2008. The primary energy sources used for power generation by percentage were coal (41%), oil (5%), natural gas (21%), nuclear (14%), hydro (16%), and other renewable energy (3%). The share of fossil energy power capacity (coal, oil, and gas) is 67%.

The primary energy used for power generation differs by geographical region, depending on resource endowments as well as the state of economic and technological development. In general, the share of nuclear power is much higher in OECD countries (26% in 2008) than in non-OECD countries (5% in 2008). This may be due to the advantage of OECD countries in mastering nuclear technology as well as their economic power. Hydropower depends on resource availability. The share of hydropower is 40% in Latin America, for example. In countries with abundant coal, coal-steam power is the low-cost choice. In China, India and the United States, respectively, coal power accounts for about 79%, 69%, and 49% of power generation. Natural gas is the best feedstock among fossil fuels for power generation in the sense of energy efficiency and environmental pollution. However, its application depends either on resources or on economic power. This resource is available in Russia, for example, with 48% of its power from natural gas, and in the Middle East, with 58%. The impact of economic power is evident in the use of natural gas by OECD countries, with 22% of their power from natural gas, in contrast to non-OECD Asia, with 10%.

1 The total population of OECD countries was 1.18 billion in 2007. The total population in the world was 6.6 billion.

In China, because natural gas is rare and valuable, only 1% of power generation is from natural gas.

Globally, power generation is one of the major sources of CO_2 emissions, accounting for 11.9 gigatonne (Gt) in 2008, or 41% of the world's total fossil fuel CO_2 emissions. In many developing countries, however, conventional environmental pollution is considered a more urgent issue than CO_2 emissions because of the damage to the environment and human health it is causing today. China's emissions of sulfur oxides and nitrogen oxides (SO_x and NO_x) and dust were 25.9 million tonnes (Mt), 15.2 Mt, and 10.9 Mt in 2006. Contributions from power generation were 45%, 41%, and 29%, respectively (State Environmental Protection Administration of China, 2007). India's emissions of sulfur dioxide (SO_2), NO_x, and particulate matter less than 2.5 micrometers in diameter ($PM_{2.5}$) were 6.7 Mt, 4.1 Mt, and 4.7 Mt in 2005. The reduction of conventional pollutants is imperative and urgent for both countries.

Public health costs of air pollution (especially SO_x, NO_x, and PM) from fossil fuel power generation are discussed later in this section. A large amount of new power generation infrastructure is being established daily in developing countries, especially in countries such as China and India that are undergoing rapid industrialization and urbanization. It is of great importance for the sustainable development of societies like China's and India's to find ways to simultaneously address conventional pollutant emissions and carbon emissions.

12.2.1.2 Future Electricity Demand and Supply Expansion

In the "current policies" scenario of the World Energy Outlook 2010 (IEA, 2010), world electricity demand is projected to increase 95% from 2008 to 2035, reaching 32,919 TWh. Every region of the world is projected to increase, though at different rates. The increase in non-OECD consumption accounts for 82% of the total projected global increase. Even in this case, annual per capita electricity consumption in non-OECD countries only reaches 4600 kWh, about half the average for OECD countries (9200 kWh). In Africa, annual per capita electricity consumption is projected to increase only modestly, to 700 kWh per person.

In this scenario, which assumes a future world with essentially no price on carbon emissions, China is projected to have the largest increase in both total electricity consumption and annual per capita consumption among developing countries. China's electricity consumption is projected to be 9420 TWh in 2035, surpassing the United States as the world's largest consumer. The large projected increase in annual per capita consumption in China brings it to 6400 kWh, a level slightly under 70% of the OECD average.

In the current policies scenario, world power production is projected to increase by 90% from 2008 to 2035, reaching 38,423 TWh. Likewise, total installed power generation capacity is projected to be 8875 GW, representing an 88% increase compared to 2008. The share of electricity by source is projected to change only modestly from 2008 to 2035: coal from 41% to 43%, oil from 5% to 2%, natural gas from 22% to 21%, nuclear from 14% to 11%, hydropower from 16% to 13%, and renewable energy (other than hydro) from 3% to 10%.

Correspondingly, global CO_2 emissions from fossil fuels are projected to increase by 46%, going from 29,260 Mt in 2008 to 42,589 Mt in 2035. CO_2 emissions from power generation are projected to increase by 59% to 18,931 Mt. Together, China and India account for 75% of the total projected global increase in power sector CO_2 emissions from 2008 to 2035. Power sector emissions in 2035 are projected to be 7130 Mt in China and 2068 Mt in India. Overall, emissions from coal power top the global list. Emissions from coal power are projected to be 14,403 Mt, accounting for 76% of all power generation emissions and one third of total global fossil fuel emissions.

12.2.2 Steam Electric Power Generation Using Pulverized Coal

12.2.2.1 Process description

At present, coal-steam power based on the Rankine cycle is the most commonly applied power generation technology worldwide. Utility coal boilers are generally divided into pulverized coal (PC) and circulating fluidized bed (CFB) units, which describes the method of combustion in the furnace. Since it is the predominant form of coal-steam power generation, PC combustion is the main focus of the discussion here. Some basic information about CFB is provided in Box 12.1, including coal-biomass cofiring, an option that is attracting increased attention with the drive toward greater use of renewable energy.

Figure 12.3 shows the process of a typical pulverized coal combustion power plant. Major equipment includes the boiler, steam turbine, and electric generator. The system can be simply described by following the fluid loops inside the process.

- Water and steam loop: This is the working fluid in the power plant. Cold water from the condenser is boiled and converted into superheated steam and sent to the steam turbine where it expands to generate mechanical rotating power. This mechanical power drives an electric generator to generate electricity, which is then transformed into high voltage and sent into the electricity grid. The steam exhausted from the turbine is cooled in the condenser and then sent back to the boiler to repeat the cycle.

- Air-flue gas loop: Air from the atmosphere is pumped into the boiler furnace to provide combustion air to burn the coal, the hot combustion products from which heat the water-steam loop. After releasing heat, the flue gas first goes through a selective catalytic reduction unit to get rid of NO_x, then to an electrostatic precipitator to reduce

Box 12.1 | Other Combustion Options

Circulating fluidized bed (CFB) combustion power generation technology was originally developed as a low-cost approach to sulfur control and to facilitate the use of low-quality coals. Currently, the main objective is to facilitate the use of low-quality coals.

In fluidized bed coal combustion, coal is crushed into pieces smaller than 10 mm and mixed with a large amount of fluidized bed material to burn inside the furnace. The typical bed temperature is 850°C, an appropriate level to minimize formation of thermal NO_x. Limestone is fed into the furnace along with coal in order to absorb sulfur dioxide formed during combustion. Up to 90% or more of the sulfur can be removed by simply adding limestone. This makes CFB a favorite lower-cost clean coal technology in developing countries. In China, for example, more than 2000 CFB boilers are in operation and the largest unit capacity is 300 MW. Units up to 600 MW (supercritical CFB boilers) are under development.

The energy efficiency of CFB units in general scores moderately lower than their PC counterparts for the same steam parameters due to slightly higher parasitic power consumption. With regard to carbon emissions, CFB units are somewhat less competitive because limestone used for in-situ desulphurization emits CO_2. Capital costs are slightly higher than for PC plants because of the requirements for more auxiliary facilities and anti-erosion refractory.

Cofiring coal and biomass provides a flexible method for using biomass, the supply of which may fluctuate seasonally. Cofiring coal and biomass reduces net carbon emissions compared to pure coal burning. Cofiring can also increase the efficiency of biomass use compared to a small scale power plant fired purely by biomass. Cofiring with coal is an efficient and effective way to use biomass and also to offset carbon emissions from coal power generation, at least until large-scale biomass use for fuel production becomes a reality. As for capital cost, there is one plant in China that has retrofitted an existing 140 MW PC boiler to utilize up to 20% (heat) biomass. The results also would be indicative for a CFB boiler. The incremental cost corresponding to 20% biomass power is much lower than the specific initial capital investment of a new biomass-fired power plant – and its efficiency is much higher.

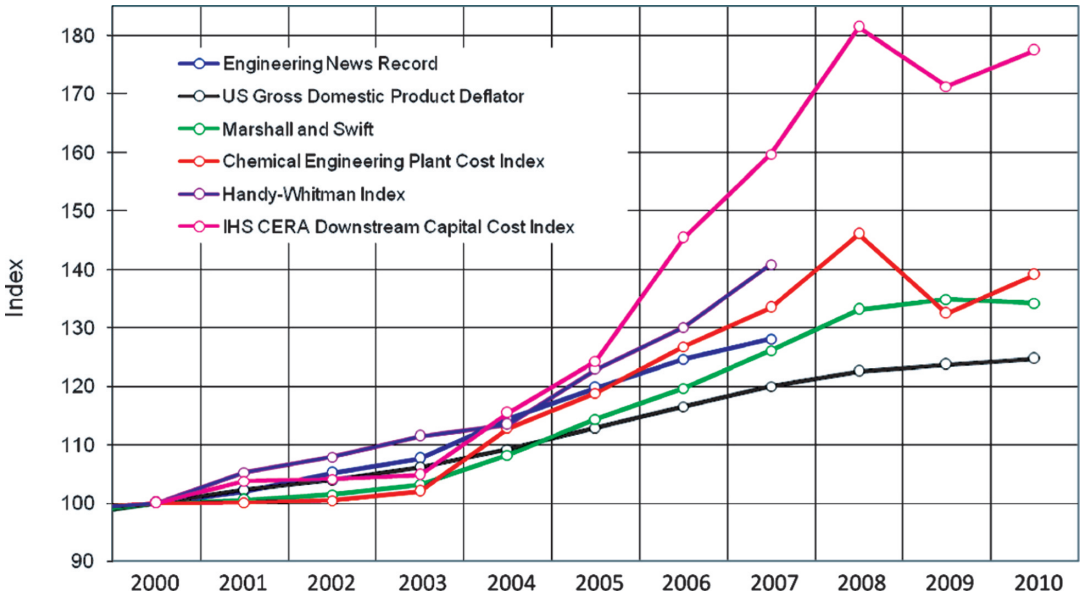

Figure 12.4 | Alternative cost indices, each normalized to 100 in year 2000. The Chemical Engineering Plant Cost Index is the most appropriate one to use for many of the energy supply systems discussed in this chapter. Source: updated from Kreutz et al., 2008.

dust, and then through flue gas desulphurization to get rid of SO_x. The cleaned flue gas returns to the atmosphere via the stack.

- Cooling water loop: Low temperature cooling water is sent to the condenser to condense the exhausted steam at the outlet of the steam turbine. Normally, the lower the temperature of the cooling water, the higher the efficiency of the power plant. Cooling water is supplied either from a water pond within the power plant or from the river or sea. In the first case, water is recycled and a cooling tower is required (as shown in Figure 12.3). Evaporation in the cooling tower causes a transfer of cooling water to the atmosphere, comprising the major water use for a power plant.

12.2.2.2 Efficiency and Steam Conditions

The net efficiency of a power plant is defined as the amount of electric power sent to the grid divided by the total energy input as coal. The efficiency depends mainly on the temperature and pressure of the steam as it enters the steam turbine. Coal-steam power plants can be classified as subcritical, supercritical, and ultra-supercritical, depending on the conditions of the steam entering the turbine. Steam parameters and typical corresponding efficiency levels are shown in Table 12.3.

To further improve the efficiency of pulverized coal power plants, development efforts are ongoing on advanced supercritical pulverized coal designs, with steam operating temperatures of 700°C. The main hurdles are related to development of high-temperature materials. The efficiency target for such plants is as high as 50% (Quinkertz, 2010). Gains in efficiency translate to reduced CO_2 emission/MWh. It is conceivable that this technology may become available before carbon capture and storage can be widely applied, because it represents an incremental improvement on a technology with which there is already considerable commercial experience. Thus, this technology may serve to help reduce carbon emissions from coal-fired power generation in the near term.

12.2.2.3 Construction Costs

There were sharp increases in construction costs for new power plants in the middle part of the past decade, particularly in OECD countries. The increases have been especially marked in the United States as evidenced by the much higher rate of increase than GDP of various cost indices relevant to the energy and power sectors (Figure 12.4). Table 12.4 provides a view from one power plant equipment manufacturer of the factors influencing cost trends. The main factors contributing to the increasing

Table 12.3 | Classification of coal-steam power plants according to steam conditions.

Classification of power plant	Temperature (C)	Pressure (MPa)	Efficiency (%)	Typical unit capacity (MW)
Subcritical	~540	16.7	38	300–600
Supercritical	~560	~25	40–42	600
Ultra-supercritical	>560	>25	42–45	600–1000

Table 12.4 | One power plant vendor's view of factors influencing power plant pricing.

-transformers	(+60%–90%)
Engineering and plant start up	↗
Additional factors	
Transportation and logistic costs	↗
Power plant demand	↗
Cost of capital and inflation	→

Note: Vertical arrow (↑) = large increase; slanted arrow (↗) = moderate increase; horizontal arrow (→) =no increase

Source: IEA, 2008a.

costs in OECD countries were (i) substantial increases in raw materials costs, e.g., a quadrupling in the cost of iron ore and a doubling in the price of steel between 2003 and 2008 (IEA, 2008a), (ii) higher demand for materials generally, (iii) higher crude oil prices, (iv) increases in labor costs due to shortages of engineering, construction, and procurement personnel, and (v) a weakening US dollar during the decade.

Cost escalations for other parts of the world may be different. As an example, Table 12.5 summarizes the actual capital investment for coal and natural gas power in China. The investment levels were quite stable during 2004–2007. The main reason for this is that the major component technologies are manufactured locally.

In this chapter, unless otherwise indicated, we have expressed costs in US_{2007}. We have used the Chemical Engineering Plant Cost Index (CEPCI) to adjust costs from other year values. As Figure 12.4 shows, using the CEPCI and 2007 as the reference year captures most of the escalation observed in the decade: the index for 2007 is approximately the same as for 2009 (i.e., no relative price increases) and only modestly lower than the preliminary value reported for 2010.[2]

12.2.2.4 Carbon Capture from Coal Steam Power Plant

Two approaches can be considered for capture of CO_2 from a steam electric plant. One way is to capture CO_2 from the flue gases of a conventional plant (referred to as post-combustion capture). A second alternative is to use oxygen rather than air for the combustion ("oxyfuel" combustion). The advantage of the latter over post-combustion is the greater ease of CO_2 separation from the flue gases, which is accomplished by condensing out water from the combustion product mix of mainly CO_2 and water vapor. Offsetting this advantage are the significant added costs for an air separation plant and the fundamental power plant redesign required. (See Chapter 13 for additional discussion of this technology.)

Representative mass and energy balances of subcritical and supercritical coal power plants with and without post-combustion carbon capture are shown in Figures 12.5 and 12.6. Their energy, economic and environmental performances are shown in Table 12.6.[3, 4] The important messages revealed by comparing power plants without and with CCS are:

- The energy efficiency of both subcritical and supercritical power plants decrease by ~12 percentage points with the addition of carbon capture and storage. This is mainly due to steam consumption for regeneration of the solvent used to capture the CO_2 and mechanical power consumption for CO_2 compression.
- Water consumption more than doubles in both cases due to the large amount of heat required for regenerating the solvent used to capture the CO_2.
- The cost of electricity will nearly double (Table 12.6).

12.2.3 Gasification-based Power Generation

12.2.3.1 Technology

The first demonstration of gasification-based power generation at a significant scale dates to the early 1970s in Europe (163 MW plant in Lünen, Germany (Morehead and Hannemann, 2005)) and the mid-1980s in the United States (100 MWe Cool Water project (Alpert et al., 1987)). Since this time there has been considerable development of the technology, several commercial demonstration projects, and a few fully-commercial implementations in applications with low-cost waste feedstocks such

2 The GEA technical guidelines provide methodological assistance for readers who want to convert these numbers to alternative year prices, e.g. the 2005 numbers used in most other chapters.

3 In this table, and as much as possible elsewhere in this chapter, we show both lower heating value (LHV) and higher heating value (HHV) for fuels. We have chosen not to use only LHV (the convention in much of Europe) for several reasons: (*i*) LHV can be an ambiguous value in the case of biomass (and we include some analysis of biomass/coal systems in this chapter); (*ii*) the US convention for energy prices is HHV; (*iii*) using LHV implies that the latent heat of condensation from combustion of a fuel is not recoverable. In fact, it can, and is, recovered in some circumstances; and (*iv*) use of HHV in this chapter motivates a search for opportunities to capture this latent heat in other applications – and is thus a good index for a carbon-constrained world.

4 These performance and cost estimates (and some subsequent estimates in this chapter) are based on the work of Woods et al. (2007). At approximately the time the writing of this chapter was completed, an updating of the work of Woods et al. was published (Haslbeck et al., 2010). A comparison of estimates in the original study and the revised study reveals only modest differences in plant efficiencies and installed capital costs. For example, total installed plant costs ($/kW) in the revised study (in US_{2007}) are lower by 1.5–5% for pulverized-coal plants and for natural gas combined cycle plants. Unit costs are 9–16% lower for coal integrated gasification combined cycle (CIGCC) plants.

Table 12.5 | Capital costs (nominal RMB/kW)[a] for thermal power plants in China.

Type / capacity	2004	2005	2006	2007
	Cost (2004 RMB/kW)	Cost (2005 RMB/kW)	Cost (2006 RMB/kW)	Cost (2007 RMB/kW)
Subcritical PC / 2x300 MW	4853	4596	4292	4401
Supercritical PC / 2x600 MW	4074	3919	3608	3643
Ultra supercritical PC / 2x1000 MW	4128	3924	3604	3724
NGCC / 2x300 MW, GE, 9F	3106	3060	3039	3155
NGCC / 2x180 MW, GE, 9E	3137	2946	2912	2998

a For reference, the exchange rate in mid-2008 was US$1 = RMB6.9.

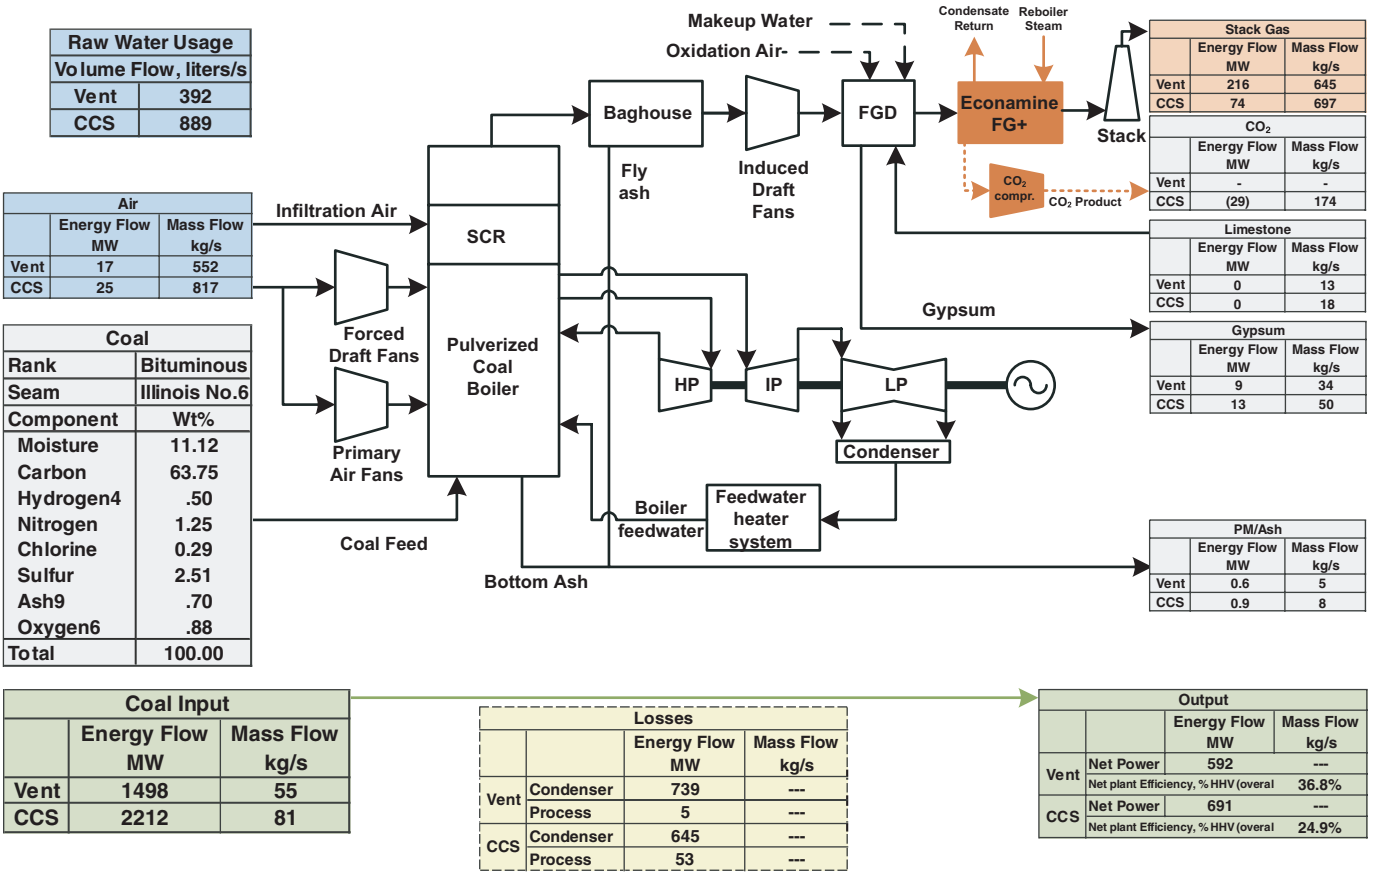

Figure 12.5 | Mass and energy balance of a typical subcritical power plant without and with carbon capture ('Vent' and 'CCS,' respectively). In the case with CCS, the net power output accounts for CO_2 compression to 153 bar, which is assumed to be sufficient to transport and inject the CO_2 into an underground storage reservoir. Source: based on Woods et al., 2007.

as petroleum residuals. Gasification-based power generation with fossil fuels, including coal and petroleum residuals, is thus commercial technology, but without widespread operating experience. A distinguishing feature of integrated gasification combined cycle (IGCC) technology is the very low emissions of conventional pollutants that can be achieved, especially SO_2 and particulates. Interest in IGCC has grown recently in part because of the prospectively lower cost of producing low-carbon electricity from coal compared to the cost with pulverized coal (PC) combustion technologies with post-combustion CO_2 capture.

Figure 12.7 is a simplified representation of a coal-IGCC system (CIGCC). Coal, water (or steam), and pure oxygen[5] are fed to a

5 The oxygen for gasification is produced in a dedicated air separation unit (ASU), with some or all of the air feed to the ASU coming from the compressor of the gas turbine. When 100% of the air used in the ASU originates from the gas turbine, the plant is regarded as fully integrated (and the name integrated gasification combined cycle derives from this feature) and has the highest efficiency in theory. In practice, however, full integration has proved operationally difficult. Most IGCC facilities today consider a maximum of 50% of the ASU air requirement being provided by the gas turbine.

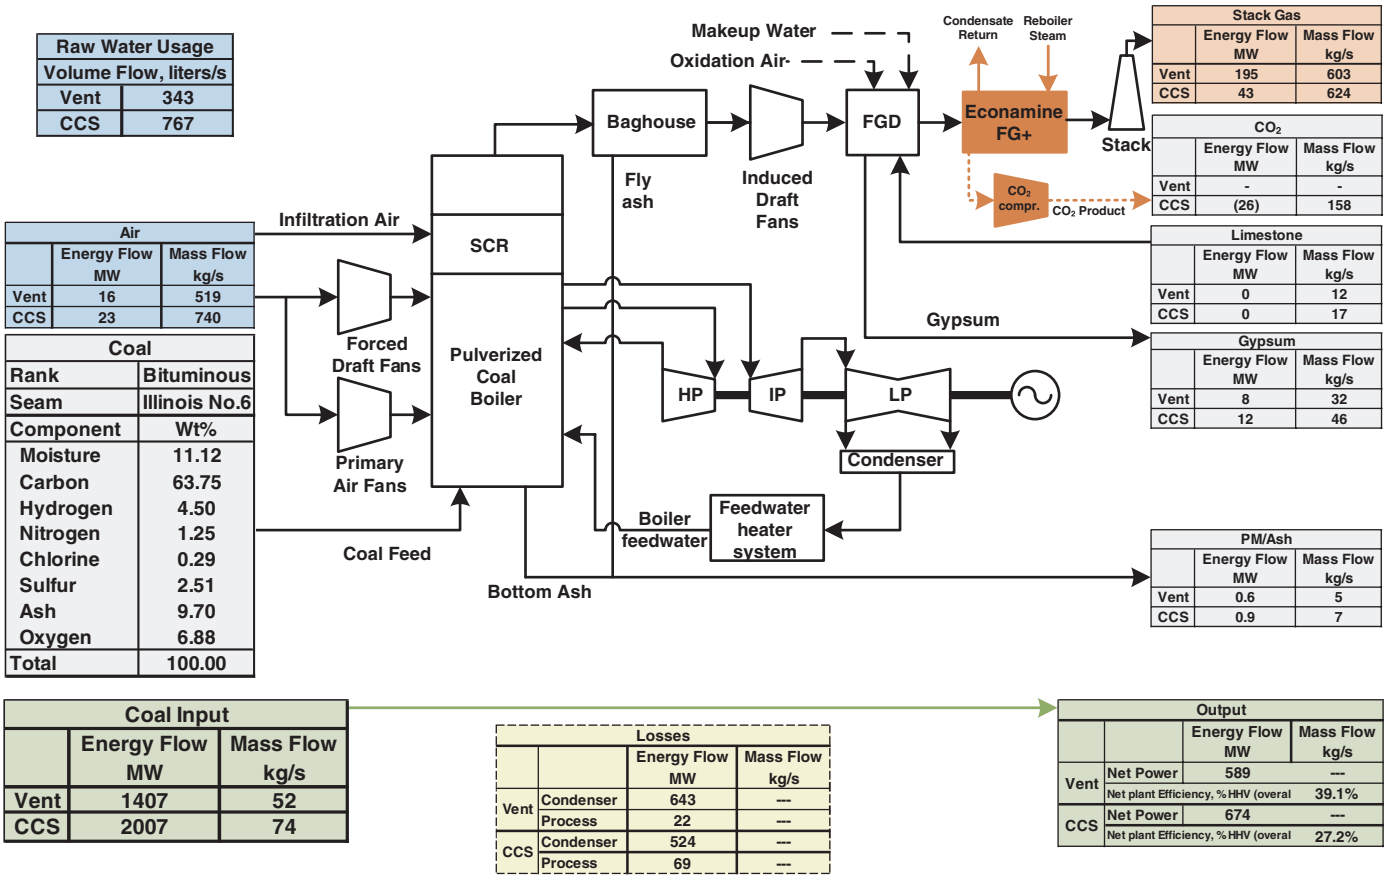

Figure 12.6 | Mass and energy balance of a typical supercritical power plant without and with carbon capture ('Vent' and 'CCS,' respectively). In the case with CCS, the net power output accounts for CO_2 compression to 153 bar, which is assumed to be sufficient to transport and inject the CO_2 into an underground storage reservoir. Source: based on Woods et al., 2007.

pressurized gasifier in which partial oxidation reactions occur, along with some water gas shift reaction. The resultant syngas, composed mainly of CO and H_2, is cooled and cleaned, including removal of essentially all particulate matter, which might otherwise create operating difficulties in downstream processes. Sulfur compounds in the syngas (primarily H_2S, with some COS (carbonyl sulfide)) are then removed, e.g., using the Selexol® physical absorption process, to ensure that air emissions limits are met. The syngas is then fed to a gas turbine designed to operate on a CO and H_2 mixture. The turbine generates power, and its high temperature exhaust passes to a heat recovery steam generator (HRSG) to generate superheated steam. The steam drives a steam turbine bottoming cycle to generate additional power.

If CO_2 is to be captured for storage, three additional steps are required (orange shading in Figure 12.7). First, the composition of the cleaned syngas is adjusted following gasification via the water gas shift reaction to primarily H_2 and CO_2. This is followed by capture of both H_2S and CO_2 in the acid gas removal step, and then by compression of the captured CO_2 to an elevated pressure for pipeline transport to a storage site for underground injection. Typically, CO_2 that would otherwise have been emitted to the atmosphere can be reduced by 90% using these additional steps.

Several different coal gasifier designs are offered by vendors. Two key features that differentiate designs are the type of feeding system (dry coal feed or coal-water slurry feed) and the syngas cooling strategy (radiant cooling or quench cooling). Dry-feed gasifiers are able to utilize a range of coal types, including lower-rank coals (lignite, sub-bituminous). Slurry-feed gasifiers cannot utilize lower-rank coals because the oxygen requirements for reaching the high temperature needed for effective gasification become prohibitive. Dry-feed gasifiers have higher efficiencies than slurry-feed gasifiers when both are operating on bituminous coal. On the other hand, slurry-feed gasifiers can operate at considerably higher pressures than dry-feed gasifiers, which can be advantageous in some circumstances. The use of radiant syngas cooling generally provides for higher overall plant efficiency than quench cooling, but also requires greater capital investment. For IGCC-CCS systems, the efficiency advantage with radiant cooling is offset to a significant degree by the added benefit with quench cooling of saturating the syngas with moisture, which avoids the need to raise steam for injection to the water gas shift (WGS) reactor.

Table 12.6 | Performance and cost estimates for PC power plants burning bituminous coal.

	Subcritical steam cycle		Supercritical steam cycle	
CO_2 vented or captured/stored →	Vent	CCS	Vent	CCS

Hg emissions, gHg/MWh_{net}	0.005	0.007	0.005	0.007
Installed capital cost (US siting, $US_{2007}$$)				
Total plant cost (TPC), million $US_{2007}$$	880	1,642	894	1,617
Specific TCP, $US_{2007}$$/kWnet	1,598	2,987	1,625	2,961
Levelized generating cost, $US_{2007}$$/MWh[b]				
Capital (at 14.38% capital charge rate)	33.1	61.8	33.6	61.3
O&M (at 4% of TPC per yr)	8.6	16.0	8.7	15.9
Coal (at 2.04 US$/GJ, HHV)	19.9	29.5	18.7	26.9
CO_2 transportation and storage	0	7.0	0	6.4
Levelized cost of electricity, $US_{2007}$$/MWh	61.6	114.4	61.1	110.5

a Life cycle GHG emissions include CO_2 emissions at the plant plus emissions (expressed as CO_2-eq) that occur during coal mining and transportation.

b The following assumptions, representing US financial conditions, are adopted for all levelized cost calculations: coal price (US$/$GJ_{HHV}$) is 2.04; annual operating and maintenance (O&M) costs are 4% of total plant cost; the annual capital charge rate on TPI is 14.38%; TPI is total plant investment (TPC plus interest during construction); the capacity factor for power-only plants is 85%; the capacity factor for plants (described later) that produce liquid fuels or hydrogen (with or without coproduct electricity) is 90%. Also, costs for pipeline transportation and underground injection of compressed (150 bar) CO_2 are estimated based on work by Ogden, 2003; Ogden, 2004, as discussed in Liu et al., 2011a.

12.2.3.2 IGCC Energy and Environmental Performance

Figure 12.8 illustrates the rising trend in plant efficiencies for IGCC systems since the first plant was installed in the early 1970s. The figure also illustrates the generally higher efficiencies achievable using dry-feed gasifiers. There is a future potential for raising IGCC efficiencies through various technological means, e.g., by adapting the latest generation of gas turbines to operate on syngas, by adopting more efficient air separation technologies that are under development today, and others.

A detailed material and energy balance developed by engineers at the US National Energy Technology Laboratory (Woods et al., 2007) is shown in Figure 12.9 for a coal-IGCC system using a slurry-feed gasifier and venting CO_2 to the atmosphere. Figure 12.9 also shows a balance for a similar IGCC design, but with CO_2 capture and compression. Table 12.7 summarizes the performance of these two designs and shows estimates also from Woods et al. (2007) for two alternative IGCC designs using different gasifier technologies. With venting of CO_2, the electricity generating efficiencies for these three designs range from 38–41% (HHV basis). Capturing 90% of the generated CO_2 and compressing it for storage incurs a six to nine percentage point efficiency penalty depending on the design (or a 16–22% reduction in electricity output per unit of coal input). Emissions of conventional pollutants are low, especially SO_2 and PM, regardless of whether CO_2 is vented or captured.

Gasification-based power generation can also be utilized with biomass feedstocks. The right two columns in Table 12.7 show performance estimates for biomass-IGCC (BIGCC) systems made for this chapter by a team at the Princeton Environmental Institute (PEI) at Princeton University. For consistency of comparisons, PEI estimates for two CIGCC systems are also shown.[6] Feedstock collection and delivery logistics for biomass use will generally limit BIGCC plant sizes. The BIGCC systems shown in Table 12.7 are designed for a biomass input capacity of about 3000 t/day dry biomass fed to a pressurized oxygen-blown fluidized-bed gasifier (such as the one originally developed at the Gas Technology Institute (GTI) in the 1980s, the license for which is now owned by Carbona).

With venting of CO_2, the BIGCC system efficiency exceeds that of a CIGCC system by several percentage points due primarily to three factors: reduced onsite electricity use for supplying oxygen (since biomass itself contains some oxygen and the gasification temperature with biomass is much lower than with coal), no requirement for sulfur removal (since most biomass has negligibly low sulfur content), and less nitrogen injection in the gas turbine for NO_x control due to the higher methane content of biomass-derived syngas (which yields lower combustion flame temperatures compared with coal-derived syngas).

A key benefit of utilizing biomass is the negative greenhouse gas emissions that can be achieved. Even with CCS, a CIGCC will still release some CO_2 to the atmosphere. When biomass is used, the CO_2 that is stored underground originated in the atmosphere, so net life cycle GHG emissions (including emissions associated with growing the biomass) are negative (Table 12.7).

6 The Princeton CIGCC estimates, which are based on designs with slurry-feed gasification and syngas quench cooling (rather than radiant cooling), are consistent with the estimates of the National Energy Technology Laboratory, US Department of Energy.

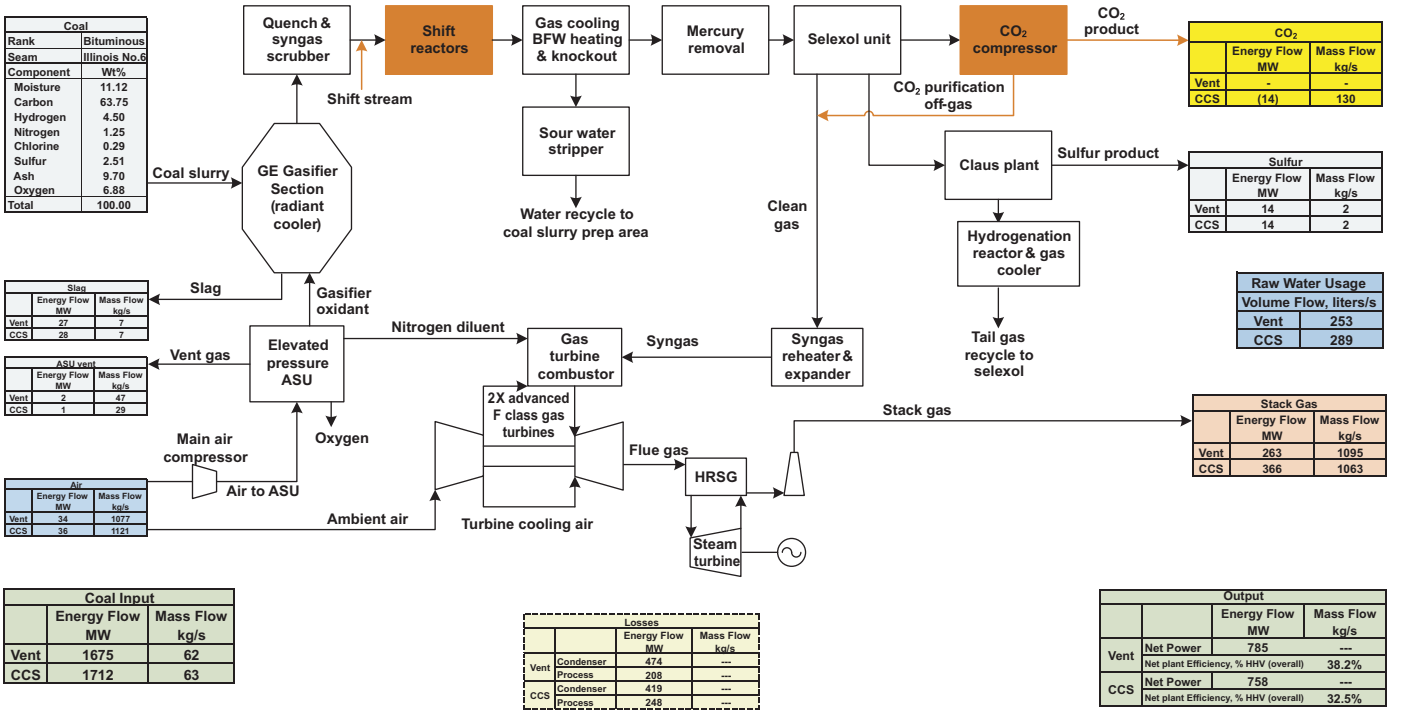

Figure 12.9 | Mass/energy balance for a coal-IGCC plant using slurry-feed gasifier, radiant syngas cooling without and with CO_2 capture ('Vent' and 'CCS,' respectively). In the CCS case, the net power output accounts for CO_2 compression to 153 bar, which is assumed to be sufficient to transport and inject the CO_2 into an underground storage reservoir. Source: based on Woods et al., 2007.

12.2.3.3 IGCC Economic Performance

The lack of a clear cost advantage for IGCC technology is an important reason that the technology has not yet seen widespread commercial deployment, despite having been first demonstrated commercially in the 1970s. While IGCC systems have clear environmental benefits over combustion systems for coal power generation, the least costly IGCC electricity (under US conditions, Table 12.7) is not less costly than electricity from a new supercritical-steam pulverized coal (PC) plant when CO_2 capture/storage is not considered (Table 12.6).

For CIGCC systems with CCS, specific capital costs (US$/kW) increase by 30–40% compared with IGCCs that vent CO_2 (Table 12.7), with correspondingly higher levelized costs of electricity generation. But the levelized cost of electricity (LCOE) generation for a CIGCC-CCS system is considerably lower than for a PC-CCS system, because supercritical pulverized coal plants require even higher incremental capital investment for CCS and sacrifice more efficiency points in the process. As shown in Figure 12.10, the LCOE for CIGCC-CCS reaches the LCOE for a pulverized coal plant with CO_2 venting (PC-V plant) at a much lower GHG emission price (US$55/t$CO_2$-eq) compared to that for the PC-CCS plant (US$75/t$CO_2$-eq). In the BIGCC-CCS case, although the LCOE at US$0/t$CO_2$-eq is much greater than for all the other options shown, its LCOE reaches that for a PC-V plant at a still lower GHG emission price (US$42/t$CO_2$-eq) because of the strong downward slope of the LCOE curve that arises from the negative GHG emissions for this option.

12.2.4 Natural Gas Combined Cycle Technology

Natural gas-fired combined cycles are among the cleanest and most efficient fossil fuel based power generating technologies. A natural gas combined cycle (NGCC) consists of a Brayton (gas turbine) cycle, the exhaust heat from which passes through a heat recovery steam generator to raise steam for a Rankine (steam turbine) bottoming cycle. The mass and energy balance shown in Figure 12.11 is for a NGCC with an overall efficiency of 50.8% on a HHV basis. With state of the art gas turbine technologies, NGCCs can reach efficiencies up to about 55% (HHV basis).

Since the hydrogen/carbon ratio of methane is relatively high, the volumetric CO_2 concentration in the flue gas of a NGCC is low, typically about 5%. The low partial pressure of CO_2 in flue gases requires use of an amine solvent for post-combustion CO_2 capture (Figure 12.11). (See also Chapter 13.) Regenerating the solvent requires considerable energy, leading to high efficiency penalties for NGCC systems with CCS. In the example case shown in Figure 12.11, the efficiency penalty is about seven percentage points. More detailed comparison data are shown in Table 12.8.

To reduce the energy penalty for CO_2 capture, some companies are developing CO_2 recycling processes that re-circulate part of the exhaust gas back to the inlet of the gas turbine compressor, resulting in a higher CO_2 concentration in the flue gases.

a Performance and capital costs from Woods et al., 2007. Capital costs escalated to January-mid US_{2007} costs using the ratio of the 2007 average chemical engineering plant cost index to the January 2007 value (1.03). Levelized electricity costs calculated assuming financing parameters described in note (c) below.

b These are previously unpublished estimates that have been made for this chapter using the methodology and assumptions consistent with the work of Liu et al., 2011a. For cases utilizing biomass, the moisture content of the delivered biomass is 15%. No separate biomass drying step is included.

c See note (b) of Table 12.6 for financial parameter assumptions.

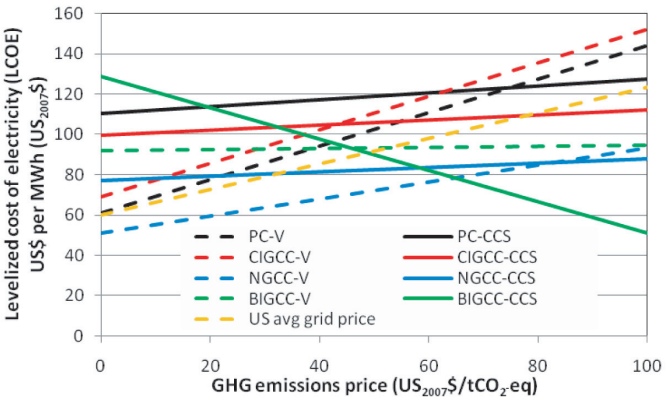

Figure 12.10 | Estimated levelized cost of electricity generation (LCOE) for alternative technologies as a function of GHG emissions price. (See Table 12.6, Table 12.7, and Table 12.8 for detailed cost assumptions.) The CIGCC and BIGCC systems shown here correspond to the PEI performance and cost estimates shown in Table 12.7.) Also shown is the 2007 average price paid to electricity generators in the United States (at zero GHG price) and how this price would change with GHG emissions price if the emissions are assumed to be the US grid-average for 2007 (636 $kgCO_2$-eq/MWh).

The minimum GHG emissions price needed to motivate adding CCS to a NGCC plant (US$83/$tCO_2$-eq) is even higher than for a PC plant, as a result of the much lower concentration of CO_2 in the flue gas and the smaller amount of CO_2 emitted per kWh of electricity. However, for the assumed fuel prices in Figure 12.10, the LCOE for NGCC-CCS at this GHG emissions price is lower than for any of the coal options considered.

12.2.5 Health Damage Costs of Power Plants

Air pollution (especially SO_x, NO_x, and particulate matter) from fossil fuel power generation imposes public health costs that are not reflected in power generating costs discussed to this point in this chapter. The health damage costs vary with the power generating fuel and technology, as well as with income level and demographics of the exposed populations (NRC, 2010). There are inherent and large uncertainties in estimating health damage costs, but a preponderance of published studies suggests that costs are significant in many cases, especially with coal-fired power generation

located near population centers. We discuss here estimates of costs of damages due to air pollution in the United States, China, and Europe.

The environmental and cost impacts of air-pollution control strategies are explicitly considered in the future-pathways analysis presented in Chapter 17. Details of the pollutant emissions projections are discussed in Section 17.5.2, and Section 17.7 concludes that stringent policies for climate mitigation to decarbonize the energy system may bring the co-benefit of reducing air pollution control costs by up to 75% globally, with attendant reductions in health impacts and related damage costs of the type we discuss here. Also Chapter 4 addresses the interaction of energy and health in detail.

12.2.5.1 United States

Since publication of the pioneering Harvard School of Public Health study (Pope III et al., 1995), it has been known that the most significant health hazards from air pollution are associated with small "$PM_{2.5}$" particles (particulate matter with particle diameters less than 2.5 microns). Inhaled, these small particles become lodged in and build up in the alveoli of the lungs and give rise to significant life-shortening. $PM_{2.5}$ particles are emitted directly by power plants and other combustion systems and also formed in the atmosphere from gaseous primary emissions of SO_2 and NO_x.

One study (Abt Associates Inc., 2000) estimated that over 30,000 premature deaths each year were attributable to fine particle pollution from power plants near the turn of the century in the United States. An analysis by the United States Environmental Protection Agency (US EPA, 1997) estimated an average life-shortening of 14 years for a person dying prematurely as a result of exposure to fine particle air pollution in the United States.

A recent Harvard School of Public Health study (Levy et al., 2009) has systematically assessed the public health damage costs for air pollution from 407 coal power plants in the United States that account for over 90% of US power plant SO_2 and direct $PM_{2.5}$ emissions and over 80% of NO_x emissions. The most significant health damages are the result of premature deaths arising from $PM_{2.5}$ air pollution. The authors of this report estimated median costs of emissions (US$/tonne) based on estimated dollar values of the health damages, as well as values at the 5th and 95th percentiles for uncertainty. In the left-most column in Table 12.9, the median estimates of health damages (US$/tonne) from this study[7] are applied to average emission rates for US existing coal power plants in 2007. This table shows that SO_2 emissions account for over 70% of the total health damage costs.

At the median level of health damage cost estimates, the specific cost of health damages (US$87/MWh) is 2.5 times the direct cost of electricity from a fully-depreciated coal plant (US$35/MWh).[8] At the 5th and 95th percentiles of uncertainty (see Table 12.9, note d) the public health damage costs would amount to 1.3 times and 4.5 times the private cost of generation for written-off plants.

Coal power plant owners would like to keep old written-off units running as long as possible because they are so profitable – the average US selling price for electricity is about twice the generation cost for a written-off plant. However, these plants are profitable only in terms of private costs – not total societal costs. Taking into account

7 Another major study for the United States (NRC, 2010) that used a similar methodology as Levy et al. (2009) found considerably lower damage costs, highlighting the inherent uncertainties involved in externality costing. Nevertheless, the two studies can be reconciled largely by the fact that the National Research Council study uses a concentration-response function for premature mortality based on Pope et al. (2002), rather than on the more recent work by Schwartz et al. (2008).

8 This is based on average conditions for US coal power plants in 2009: HHV efficiency of 32.6% and an average coal price for power generators of $2.08/GJ (EIA, 2010b) and an operation and maintenance cost of $11.93/MWh for existing coal power plants as estimated in Simbeck and Roekpooritat (2009).

a In 2009 total emissions of SO_2 and NO_x from coal power plants in the US power sector were 5.19 and 1.81 Mt, respectively (US EIA, 2010a) when generation from coal in the power sector totaled 1749 million MWh. For $PM_{2.5}$ it is assumed that in 2009 the $PM_{2.5}$ emission rate is based on the median 1999 estimate of 0.0413 lb per million BTU (17.8 gm/GJ) of coal input for the 407 coal plants investigated in Levy et al. (2009).

b Emission rates for SO_2, NO_x, and PM from these new plants are from Woods et al. (2007). For PC plants the emission rates are based on BACT (best available control technologies), exceeding NPPS (new source performance standards) requirements. For CIGCC plants, the emission rates are based on the Electric Power Research Institute's Coal Fleet User Design Basis Specification. $PM_{2.5}$ emissions are assumed to be 0.62 x PM emissions, following Dockery and Pope (1994).

c For XTL-OT-CCS plants emission rates for NO_x and $PM_{2.5}$ are assumed to be the same per MWh of gross gas turbine output as for CIGCC-CCS plants, but the SO_2 emission rate is assumed to be zero because protecting synthesis catalysts requires reducing the sulfurous compounds in syngas essentially to zero.

d For 407 US coal power plants (which accounted in 1999 for over 90% of US power plant emissions of SO_2 and $PM_{2.5}$ and over 80% of US power plant emissions of NO_x) median estimates of health damage costs were found to be US$20.9, US$5.3, and US$79.3 per kg for SO_2, NO_x, and $PM_{2.5}$, respectively, in 1999 (Levy et al., 2009). These valuations were assumed for all the alternative power plants in this table. At the 5th and 95th percentiles for uncertainty, the damage costs (in US_{2007}) were estimated to be, respectively, US$11.0 and US$35.3 per kg for SO_2, US$2.0 and US$9.4 per kg for NO_x, and US$45.2 and US$198.4/kg for $PM_{2.5}$. At the 5th and 95th percentiles for uncertainty, total health damage costs for US coal-fired power plants are US$45.0/MWh and US$159.5/MWh, respectively.

health damages from air pollution and considering the low estimate of health damage costs presented in Table 12.9 (5th percentile of uncertainty (see Table 12.9, note d)) the total cost of generation (private cost for a written-off plant + air pollution damage cost) would be 37% higher than the US average electricity generation price in 2009 (US$58/MWh). This is the case without any cost assigned to greenhouse gas emissions.

Estimates of health damage costs from air pollution are also indicated for alternative new power plants in Table 12.9, based on emission rate estimates from Tables 12.7 and 12.8. This table shows that damage costs are extremely low for NGCC plants, still significant for new subcritical or supercritical PC-V plants, but quite low for all the plants with CCS. The XTL-CCS plants in the table refer to plants that co-produce electricity and Fischer-Tropsch Liquids (FTL) transportation fuels from X, where X is coal, biomass, or coal+biomass (as will be described in detail in later sections of this chapter). The XTL-CCS plants are characterized by damage costs that are half or less than the damage costs for all the coal stand-alone power plants with CCS. The emission for the PC-CCS plants are low because the SO_2 level in the flue gas has to be reduced to extremely low levels upstream of the amine scrubber to prevent amine solvent degradation. Similarly, in the XTL-CCS case, protecting downstream process catalysts requires removal of sulfur.

12.2.5.2 China

Studies of health damage costs due to air pollution are more limited for China, and studies specific to pollution from electric power generation are even scarcer. Studies that have estimated public health costs of air pollution in China include those published by the World Bank (World Bank, 1997; World Bank and SEPA, 2007) and jointly by Harvard and Tsinghua Universities (Ho and Nielsen, 2007; Ho and Jorgenson, 2008).

The Harvard/Tsinghua study (Ho and Jorgenson, 2008) is the only one that has attempted to estimate health damage costs due to power generation in China. It estimated total air pollution damage costs (from all activities) in China using a willingness-to-pay approach (Hammitt and Zhou, 2006). The estimated total cost of premature deaths, chronic bronchitis, and asthma attacks was RMB_{2002}213 billion, or about

Table 12.10 | Estimated health damage costs in billion RMB_{2003} (billion US$)[a] due to urban outdoor air pollution in China in 2003 (WB and SEPA, 2007).

	Excess deaths	Chronic bronchitis	Direct hospital costs	Indirect hospital costs	Total	% GDP
Adjusted human capital approach						
95th percentile	178.7 (25.5)	47.7 (6.8)	4.82 (0.69)	0.670 (0.096)	231.8 (33.1)	1.8
Average	110.9 (15.8)	42.5 (6.1)	3.41 (0.49)	0.470 (0.067)	157.3 (22.5)	1.2
5th percentile	35.8 (5.1)	36.9 (5.3)	1.88 (0.27)	0.264 (0.038)	74.9 (10.7)	0.57
Willingness-to-pay approach						
95th percentile	641.1 (91.6)	136.7 (19.5)	4.82 (0.69)	0.670 (0.096)	783.3 (111.9)	4.9
Average	394.0 (56.3)	122.1 (17.4	3.41 (0.49)	0.470 (0.067)	519.9 (74.3)	3.3
5th percentile	135.6 (19.4)	106.2 (15.2)	1.88 (0.27)	0.264 (0.038)	243.9 (34.8)	1.6

a Estimated costs in 2003 Yuan RMB have been converted to US$ using a nominal exchange rate of 7 RMB/US$.

US$30 billion at a nominal exchange rate of 7 RMB/US$. The study also estimated that 28% of the total damage cost, or about RMB60 billion (US$8.6 billion), was attributable to electric power generation. Assuming that most of the health damage was due to coal-fired generation, which accounted for about 81% of power generated in 2002 (1338 TWh) (National Bureau of Statistics China, 2007), the estimated health damage cost was about RMB0.044/kWh (US$0.006/kWh) of coal fired generation.

The Harvard/Tsinghua estimate of total health damage cost due to air pollution is on the low end of costs estimated in the joint study by the World Bank and China State Environmental Protection Administration. That study found the average health damage costs in 2003 to be equivalent to 1.2–3.3% of GDP (RMB157–520 billion, or US$23–76 billion, assuming 7 RMB/US$). The low estimate was based on a human-capital estimation approach and the high figure was based on a willingness-to-pay approach. Uncertainty ranges in the damage costs were also estimated (Table 12.10). If 28% of total damage costs are attributed to electric power generation (as indicated by the Harvard/Tsinghua study), and coal power generation is assumed to contribute most of these damages, then the range of damage costs per kWh of coal-fired power (1580 TWh in 2003) based on Table 12.10 is RMB0.047–0.14 / kWh (US$0.007–0.02/kWh).[9]

Taken together, the World Bank/SEPA and the Harvard/Tsinghua studies suggest that health damage costs from electric power generation in the middle of this decade were equivalent to between 10–40% of the cost of new coal power generation in China today. This is far lower than damage costs estimated for the United States, and is explained in part by the large difference in per capita income between the two countries, which reduces individuals' willingness to pay to avoid health damages, as well as lower medical costs in China and fewer health impacts being included in the damage estimates for China as compared to the US estimates (US-China Joint Economic Research Group, 2007).

As per capita incomes rise in China, the willingness to pay to avoid health damages will rise proportionately; China's GDP is expected to more than quadruple between 2005 and 2030 (IEA, 2007). At the same time coal power generation is expected to increase substantially, and pollution controls are expected to tighten significantly in this period. Also, the geographical distribution of population in relation to power plants may be significantly different in 2030 from that at present. Studies taking into account trends for these several factors are needed to understand better prospective health damage costs per MWh of coal power generation in the 2030 time frame.

12.2.5.3 Europe

The ExternE Study in Europe was carried out over a period of more than 15 years beginning in the early 1990s. It involved a comprehensive and detailed assessment of air pollution and global warming damage costs from the lifecycle of energy use in Europe, estimated on the basis of the principle of willingness to pay to avoid damages (Rabl and Spadaro, 2000; Friedrich, 2005). Estimates were published in the late 1990s for 14 countries (CIEMAT, 1999) and additional estimates were published in 2004 for three countries in Eastern Europe (Melichar et al., 2004a). The estimates correspond to the technologies and demographics in these countries in the mid-to-late 1990s. A reassessment of damage costs today would yield different results, but it is difficult to guess whether damage costs would be lower, due to improved pollution controls, or higher, due to higher population densities and higher per capita incomes. (The latter translates into higher levels of willingness to pay to avoid damages.)

The original ExternE estimates indicate that health damage costs from conventional power generation in Europe are not inconsequential. Table 12.11

9 Another study, involving some of the same authors as the Harvard/Tsinghua study, estimated health damage costs from SO_2 emissions in the power sector to be RMB6555/t (US-China Joint Economic Research Group, 2007). The average SO_2 emissions rate from coal-fired power plants in China in 2005 was 5.4 g/kWh (based on total SO_2 emission from power sector of 11.12 million tonnes (Gao et al., 2009) and 2,047 TWh of thermal power generation (National Bureau of Statistics China, 2007). This gives a much higher damage cost estimate of RMB0.36/kWh (US$0.051/kWh using a nominal exchange rate of 7 RMB/US$).

Table 12.11 | Estimated health damage costs of power generation in 17 European countries, as of mid/late 1990s.

Country[a]	Health damage costs (US_{2007} per MWh)							
	COAL				NATURAL GAS			
	Power Plant Emissions		Other fuel cycle	Total	Power Plant Emissions		Other fuel cycle	Total
	Mortality	Morbidity			Mortality	Morbidity		
Austria					2	1	0	**3**
Belgium	25	4	0	**29**				
Czech Rep.[b]	9	4	5	**17**				
Finland	3	1	1	**5**				
France	65	13	0	**79**	15	3	0	**18**
Germany	17	2	2	**21**	4	1	2	**7**
Greece					3	1	0	**4**
Holland	11	2	0	**13**	3	1	0	**4**
Hungary[b]	76	37	1	**114**	6	3	0	**9**
Ireland	47	9	0	**57**				
Italy					9	2	0	**11**
Norway					0	0	0	**0**
Poland[b]	30	19	6	**56**				
Portugal	26	5	11	**42**	0	0	0	**1**
Spain	35	6	1	**42**	5	1	0	**6**
Sweden	1	0	2	**3**				
UK	32	6	0	**38**	4	1	0	**5**

a Except for Czech Republic, Hungary, and Poland, original estimates given by CIEMAT, 1999 in 1995 ECU/MWh have been converted to US_{2007}/MWh by assuming 1.25 US$/ECU and using the ratio of 2007:1995 US GDP deflators (1.3).

b Original estimates given by Melichar et al., 2004b in 2002 Euro/MWh have been converted to US_{2007}/MWh by assuming 1.25 US$/Euro and using the ratio of 2007:2002 US GDP deflators (1.15).

shows these estimates by country for coal and for natural gas-fired power generation. Damages with coal are considerably higher than with natural gas. Also, there is a wide range in estimates for coal-fired generation damages from one country to another. Costs in Finland and Sweden are under US$5/MWh, most likely reflecting the low density of populated areas, the high level of pollution control technologies, and the modest amount of coal-fired power generation in these countries. The majority of countries in Western Europe have damage costs in the range of US$40–80/MWh – comparable to the cost of electricity production for a new coal-fired power plant. At the extreme high end is Hungary at US$114/MWh.

12.3 Technological Changes at Refineries and Opportunities for CCS

12.3.1 Context

12.3.1.1 Demand for Liquid Fuels

Liquid fuels are the world's single largest source of energy and are expected by many to remain so for decades to come. The United States Energy Information Administration (US EIA) (2010b) forecasts an increase in world liquid fuel consumption from 86 million bbl/day in 2007 (192 EJ/yr) to 111 million bbl/day in 2035 (248 EJ/yr) (Figure 12.12). The US EIA projects this increase to occur primarily in non-OECD Asia (a 93% increase for that region), followed by Central and South America, and the Middle East. Liquid fuel share of world energy use drops from 35% in 2007 to 30% in 2035, still remaining the single largest global source of energy. The vast majority of these liquids (96% in 2007 and 80–91% projected for 2035) are from conventional petroleum, with the rest coming from unconventional sources, including heavy oil and tar-sand bitumen (processed in refineries and tar sand upgraders), biofuels, coal-to-liquids and gas-to-liquids plants (Figure 12.13). Biofuels, such as renewable diesel, may be coprocessed in oil refineries but are unlikely to amount to more than 1% of total refinery throughput by 2035. Transportation accounted for nearly half of all liquid consumption in 2007, with industry accounting for about a third. The transportation fraction is projected to reach 60% by 2035, with industry falling to 29% (Figure 12.14).

These projections are consistent with trends over the past decade. From 1998 to 2008, petroleum consumption grew by 15%, with Central and

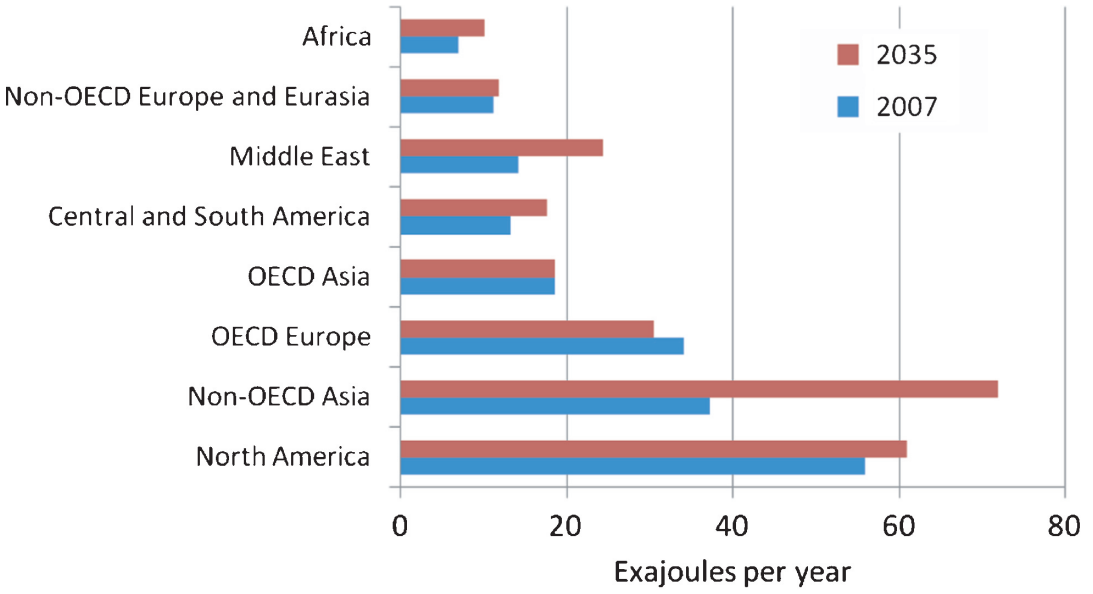

Figure 12.12 | World liquids consumption by region. Source: based on US EIA, 2010a.

South America, China, India, and the Middle East accounting for 72% of the increase (BP, 2009). The US EIA projection is also largely consistent with projections in *The Outlook for Energy: A View to 2030* (ExxonMobil, 2009). ExxonMobil has forecast world liquid fuel demand of 108 million bbl/day by 2030 (241 EJ/yr), with transportation fuel demand of 62 million bbl/day (138 EJ/yr). They expect 94% of the latter demand to be met from oil, 5% from biofuels, and 1% from natural gas. In this *Outlook*, US demand for transportation fuels peaks around 2015 and declines by 10% to 13 million bbl/day by 2030 (29 EJ/yr), the European Union demand stays flat at about 9 million bbl/day (20 EJ/yr), and China's demand triples to 8 million bbl/day (18 EJ/yr).

The IEA (2009a) forecasts global oil demand of 105 million bbl/day in 2030 (234 EJ/yr) with 97% of the increase from transportation fuels and all growth in the non-OECD countries. Their 450 Scenario (an aggressive timetable of actions to limit atmospheric greenhouse gas concentration to 450 ppm CO_2-eq) projects oil demand lower by 12 million bbl/day (27 EJ/yr), but still higher than current demand.

Forecasts of biofuel use are in the range of 3–6 million bbl/day by 2030 (6.7–13 EJ/yr). ExxonMobil expects about 3 million bbl/day (6.7 EJ/yr) with 30% from US corn ethanol, 30% from Brazil sugar cane and the remaining from biodiesel worldwide. The US EIA (2009b) forecasts 5.9 million bbl/day (13 EJ/yr), assuming that cellulosic technology will be significant from 2012.

12.3.1.2 Crude Oil Supply

World oil reserves have increased steadily over the past several decades, despite periodic predictions to the contrary. They have increased from 998 billion barrels (bbl) in 1988 (6088 EJ) to 1069 billion bbl in 1998 (6521 EJ) to 1258 billion bbl (7674 EJ) at the end of 2008 (BP, 2009). Current proven reserves are sufficient for the next 40 years and it is widely assumed that additional reserves are yet to be discovered. (See Chapter 7 for additional discussion of oil reserves.) There is a significant mismatch, however, between the location of reserves and the centers of demand for liquid fuels. This mismatch is likely to become more pronounced. For example, regions where 75% of fuel demand is located hold only 9.5% of the current reserves (Table 12.12). The extensive need to import crude oil that major fuel consuming countries face will continue, with its concomitant supply security concerns. It should be noted, however, that, since the first short oil embargo and the Iranian revolution in the mid- and late seventies, and despite several wars and conflicts in oil-producing regions, there has been no world supply disruption that would justify uneconomic or environmentally unsound measures and investment for the sake of "security." Indeed, the world's fastest-growing oil importer, China, has successfully embarked on a course of securing supplies all over the world through alliances and outright acquisition of reserves.

Crude oil is primarily categorized and priced by its gravity and sulfur content with heavier, more sour crudes being the cheapest and most difficult to process into usable, lighter fuels. About 20% of world reserves are classified as "sweet," i.e., light, low sulfur crudes, 65% are "light or medium sour," and 15% "heavy sour." This mix will change slowly over the next couple of decades, probably with more sour and heavy sour crudes in production. Any new refining capacity being built now will readily accommodate anticipated crude mix changes.

Estimates for reserves of heavy and extra heavy oil, bitumen from oil sands, and shale oil vary depending on technology and economic

feasibility assumptions but are generally considered to be approximately 3735 EJ and resources in place to be approximately 56,000 EJ (Table 7.8), with only a minor fraction produced to date.

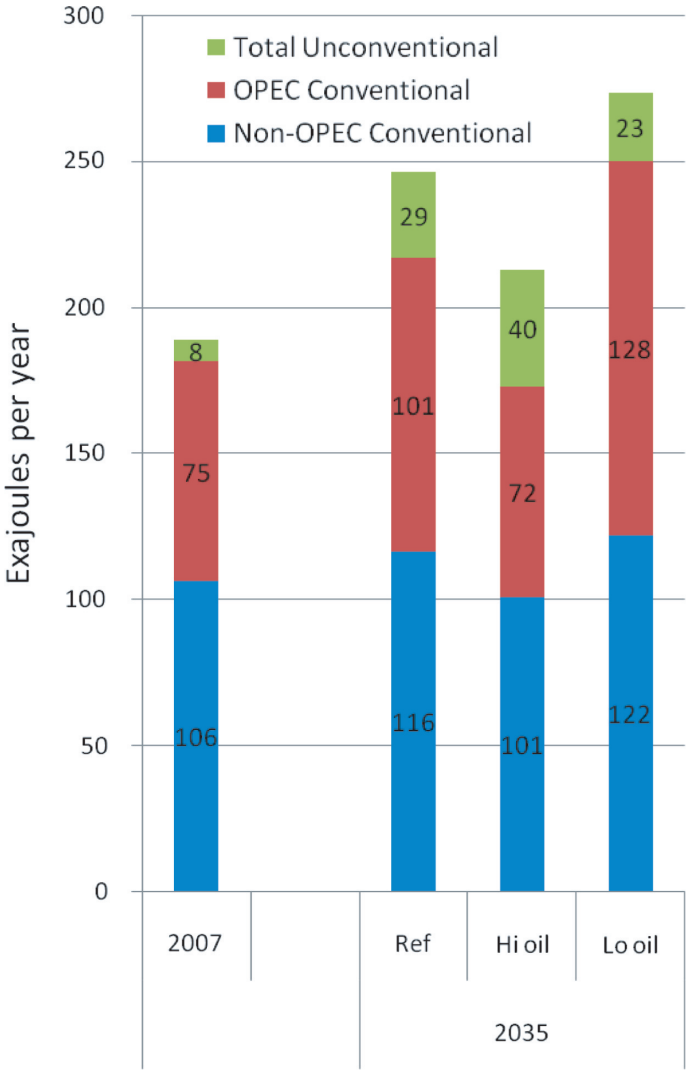

Figure 12.13 | Projections of world liquids supply in 2035 for three alternative oil price projections. Source: based on US EIA, 2010a.

12.3.1.3 Oil Refining Capacity

Global refining capacity (Table 12.13) increased by 11% in the last decade with 69% of the increase occurring in China, India and the Middle East and 15% in the United States. These numbers do not include the new 580,000 BD refinery added to the Reliance complex at Jamnagar (India) that started up in 2009 and makes Jamnagar one of the largest and most modern refinery sites in the world. Nor do the numbers include the 240,000 BD Fujian refinery expansion that also started in 2009 in China. Future capacity additions will generally follow the liquid

fuels demand with most new capacity expected in non-OECD Asia. In the United States and the European Union, some capacity will be shut down for economic reasons (e.g., in 2010 Valero announced the permanent shutdown of its Delaware refinery, or 7% of its capacity, and BP announced plans to sell its Texas City, Texas, and Carson, California, refineries) while some revamps and expansions will occur in the United States for processing heavy Canadian crude. China is expected to add around 3 million bbl/day of capacity by 2015 while shutting some of the smaller, less efficient refineries that have a combined capacity of between 1 million bbl/day and 1.5 million bbl/day.

12.3.2 Refining Technology and Economics

Refineries are complex processing plants that can generally handle a wide range of crude oil feedstocks and produce hundreds of products of varying specifications. No two refineries are alike. Each one has been designed for a particular market and presumed crude slate and then modified over time as product specifications, environmental regulations, and crude supply economics evolve. The complexity of a particular refinery results from the trade-off between the costs of investment and operating vs the capability to process heavier, less expensive crudes and produce lighter, higher-value transportation fuels or petrochemicals.

The major conversion processes in refining have not changed fundamentally for about six decades, though there have been steady, significant improvements and occasional breakthroughs in product yields, product quality, energy efficiency, and environmental performance. A brief description of refining technology as well as a detailed analysis of life cycle GHG emissions of petroleum-based fuels has been given by the National Energy Technology Laboratory, US Department of Energy (NETL, 2008).

Briefly, crude oil is heated in fired furnaces and separated into different boiling point fractions in atmospheric and vacuum distillation columns. The simplest refining configuration today is a hydroskimming/topping refinery processing a light sweet crude. It includes only a reformer and a distillate hydrotreater in addition to distillation. The reformer increases the octane of gasoline-range boiling material (naphtha) by dehydrogenating naphthenes into aromatics, isomerizing linear paraffins into branched ones, and converting paraffins into aromatics over a fixed-bed catalyst at moderate pressure. Hydrogen is produced as a by-product. The hydrotreater removes sulfur in a high pressure hydrogen atmosphere by converting it to hydrogen sulfide, also over a fixed bed catalyst. Such a refinery would produce LPG, gasoline, kerosene/jet fuel, diesel/heating oil, and a large amount (30–35%) of low-value heavy fuels.

The next step would be to add a fluid catalytic cracker (FCC) to convert some of these heavy fuels, products from the vacuum distillation column, into diesel, gasoline and lighter gases. The FCC is a complex, atmospheric pressure process where oil vapor is contacted with a fluidized circulating catalyst. Coke is deposited and then burned off continuously from the catalyst in a regeneration step. The FCC is a major source of refinery carbon dioxide and other emissions. In modern refineries, a great deal of equipment is required to reduce sulfur/nitrogen oxides and catalyst particulate emissions from FCC units. An FCC feed hydrotreater, operating at higher pressure than the distillate hydrotreater, would desulfurize the FCC feed and improve the FCC light product yields by saturating aromatic rings. Such a medium conversion refinery would process higher-sulfur crudes and create higher value products than the hydroskimming refinery.

The next step would be to add a coker, a thermal cracking process that can handle the heaviest residue from vacuum distillation and convert it to diesel, gasoline, lighter gases and solid petroleum coke. Such a high conversion refinery could handle the heaviest crudes in its feed and create the maximum value-added between feed and products. In the early 1980s some complex catalytic units were built to hydrotreat heavy residues but the simpler coking process has been the economic choice worldwide since then.

Another major conversion process is hydrocracking, which handles feed similar to the FCC but cracks it in a very high pressure hydrogen atmosphere over a fixed catalyst bed. A refinery can have either of the two catalytic cracking processes or both. Hydrocracking capacity worldwide is about one third that of FCC. Hydrocracking is preferable when a

higher diesel/gasoline ratio is needed and is particularly suited for making very-low-sulfur products. Other refinery processes include (i) naphtha hydrotreating, necessary to treat the reformer feed or for gasoline fractions to meet current low-sulfur specifications, (ii) alkylation that converts FCC gases into high-octane gasoline material, (iii) isomerization, a reforming process that increases the octane of light naphtha, (iv) visbreaking, another thermal process for heavy residues, and (v) a multitude of treating processes to remove impurities and contaminants from various intermediate and product streams.

As refinery complexity and feedstock flexibility increases, more severe hydrotreating for distillates and FCC feed may require more hydrogen than is produced by the reformer; a hydrocracker will definitely require another source of hydrogen. A refinery then needs a hydrogen plant or needs to import hydrogen from an external facility. Most refineries use natural gas and refinery off-gas to produce hydrogen through steam reforming. There are several options and technological opportunities in this area. In 1999, BOC Gases (now a part of The Linde Group) and BP Amoco developed a partial oxidation scheme using the Texaco gasification process to supply hydrogen to a new refinery hydrocracker in Bulwer Island, Australia, and to recover pure carbon dioxide (Ramprasad et al., 1999). Depending on the investment cost and the availability or cost of natural gas, refineries can also use gasification of residues or even of petroleum coke. The Shell Group's Pernis refinery in the Netherlands, one of its largest facilities at 400,000 bbl/day, chose a 1650 t/day heavy residue gasification route to produce hydrogen for a new hydrocracker (Shell, 2009).

12.3.2.1 Heavy Oils Technology

The production of heavy oils and bitumen from tar sands generally requires use of steam in one of several techniques, e.g. cyclic steam stimulation, steam assisted gravity drainage, horizontal cyclic steam, or some combination of these (Anonymous, 2008). If heavy oil is to be transported to a distant refining center, lighter oil must be used as diluent to allow flow in a pipeline. Alternatively, such oil can be partially processed where it is produced and a "syncrude" product then shipped to conventional refineries. The processing of very heavy oil or tar sands occurs through application of essentially conventional refining technology. Coking is the major conversion process, followed by severe hydrotreating of the ensuing products before further processing. As crude oil prices rose in the 2004–2007 period, a great deal of investment was initiated to upgrade Canadian tar sands and to process Canadian heavy oil in northern US refineries.

12.3.2.2 Refining Economics

Refining is a capital-intensive and competitive industry that has not been particularly profitable in the long term, except for short periods and in specific "niche" markets. The most recent example is the "Golden Age" of refining in the United States, lasting less than four years, which was caused by a steep global demand increase and unexpected shutdown of refining capacity. Refining margins are determined by market forces and are affected primarily by factors such as the balance between product demand and available refinery capacity, the differential price between heavy and light crudes, and the global balance of fuel oil. (High differentials and low fuel oil prices tend to cause refineries with simpler "topping" configurations to cut production as their variable margins reach break-even and to favor refineries with cracking capacity that can convert the heavier oils.)

As with other commodities, periodic overbuilding of capacity has caused margins to be cyclical and weather or operational variations in available capacity have caused volatility. New capacity costs have historically been around US$10,000/bbl/day of capacity but have risen to US$20,000–30,000 in recent years. Generally, margins have not justified new capacity construction in OECD countries. Government policies or incentives, niche supply or market conditions, or particular synergies with other petrochemical or power projects have supported new capacity additions, primarily in Asia. With the Golden Age in the past, nonmandatory investments in refining will be difficult to justify in OECD countries in the future.

12.3.3 Greenhouse Gas Emissions

12.3.3.1 Extent of Refinery Emissions in the Life Cycle of Petroleum-based Fuels

Emissions of carbon dioxide from stationary fossil fuel sources account for 60% of total global fossil fuel emissions. Of the major stationary sources, refineries account for 6%, cement manufacture for 7%, and power generation for 78% (CO_2 Capture Project, 2009). A detailed analysis of life cycle GHG emissions of petroleum-based fuels has been conducted by NETL (2008; 2009). The scope of this work is extensive and includes analysis of the impact of different crude sources on the GHG emissions of transportation fuels sold in the United States. A summary of some of their results is given in Figure 12.15. Not surprisingly, a key conclusion is that the extent of GHG emissions that is attributed to refinery processing itself is small (6–10%), compared to the ultimate use of the fuels (80–83%). NETL (2008) conclude that the best way to reduce transportation life cycle GHG emissions is by lower overall use of fuels through more efficient modes of transportation and vehicle efficiency. They estimate, as an example, that seven miles per gallon improvement in light vehicle efficiency would be equivalent to eliminating all oil production, transportation, and processing "well-to-tank" emissions. They consider refineries already efficient and cite ongoing continuous improvement programs in the US industry. Although their study is centered on US transportation fuels, this conclusion is quite general. New capacity in Asia is being built to very high standards of efficiency and environmental performance and, as smaller, less efficient refineries are phased out for economic as well as environmental reasons, global refinery emissions will decrease on a continuing basis.

	GHG emissions ($kgCO_2$-eq/GJ LHV)	Conventional Gasoline	Conventional Diesel	Kerosene-Type Jet Fuel
Well-to-Tank	Crude Oil Extraction	6.9	6.3	6.4
Well-to-Tank	Crude Oil Transport	1.3	1.2	1.2
Well-to-Tank	Refinery Operations	9.3	9.0	5.7
Well-to-Tank	Finished Fuels Transport	1.0	0.9	0.9
Well-to-Wheels/Wake	Combustion of Fuel	72.6	72.7	73.6
	Totals	**91.1**	**90.1**	**87.8**

Figure 12.15 | Baseline life cycle emissions of CO_2-eq for fuels derived from petroleum and sold or distributed in the United States in 2005. Source: based on NETL, 2009.

Emissions from the production and transportation of heavy oils are higher by 9.5–14 $kgCO_2/GJ_{LHV}$ diesel (NETL, 2009), than those from more conventional crudes, which vary by comparable amounts from each other. An analysis of the GHG emissions associated with the production and transportation of different crudes and heavy oils must be conducted in terms of global impact. There is little overall benefit, for example, if the use of particular crude or heavy oil is limited in the United States through a carbon tax or other regulatory measures only to route this crude to an alternative refining center elsewhere in the world. Opportunities for reducing flaring during production, which are higher for some crudes, no doubt will be pursued. The upgrading of heavy oil lends itself to carbon capture and sequestration. Refineries constantly optimize their crude mix on a global basis based on the demand of their market, their configuration, and the cost of crudes relative to their value for a specific refinery. If a globally consistent and well-designed cap-and-trade system emerges, the cost associated with specific feedstocks, including conventional crudes, heavy crudes, or tar sands, should lead to the optimal use of all global resources.

12.3.3.2 Opportunities for Carbon Capture from Refinery Emissions

Carbon dioxide capture at a refinery has been studied by the CO_2 Capture Project, a partnership of seven major energy companies working closely with government organizations, academic bodies, and global research institutes (CO_2 Capture Project, 2009). The major sources of emissions considered are boilers and fired heaters, fluid catalytic cracker units, and hydrogen production operations. The FCC unit has its own intrinsic combustion emissions due to coke burning during catalyst regeneration. Emissions from other major processes, such as crude distillation, hydrotreating, and hydrocracking, are generated by fired heaters used in the process. Fired heaters can be treated as a group and are amenable to common analysis, optimization, consolidation, and carbon capture approaches. Three CO_2 capture approaches are being considered:

- post-combustion: absorption of flue gas CO_2 from major sources into MEA (monoethanolamine) solution;
- oxy-firing: use of oxygen instead of air in combustion to produce a high concentration of CO_2 in the flue gases thus facilitating capture; and
- pre-combustion: gasification to produce a hydrogen-rich fuel and separate CO_2 prior to combustion.

Two recent studies associated with CO_2 Capture Project have considered opportunities for carbon capture in refineries. Shell (van Straelen et al., 2009) has evaluated the feasibility of post-combustion capture at a world-scale refinery. They identified scale (1–2 $MtCO_2/yr$) and CO_2 concentration (above about 8%) to be major factors in the cost-effectiveness

of refinery carbon capture. They concluded that the best opportunities lie in capturing the emissions from hydrogen production (5–20% of refinery emissions) and large flue gas stacks (another 30% of emissions), finding smaller sources unlikely to be practical. They estimated that such carbon capture would be economical at carbon trading "3–4 times higher than the current." Shell is also studying opportunities for oxy-firing burners and operating the FCC regeneration on oxygen, so as to facilitate CO_2 capture from flue gases. Petrobras and Lummus (de Mello et al., 2009) have studied post-combustion and oxy-firing the FCC and concluded that oxy-firing is feasible and more cost-effective although it would entail higher investment. They did not show absolute cost estimates for using such technology.

The FCC is a major source of refinery emissions. This process has been dominant globally and especially in China for a number of reasons. It was the choice of Reliance for the new refinery in Jamnagar, Gujarat, India. For new capacity, understanding the impact of high carbon costs on the choice of catalytic cracking technology would be worthwhile, especially if demand for diesel continues to increase, as it has in Europe over the last decade.

12.3.4 Conclusions

Current refining technology is likely to continue as the major source of liquid fuels for the next few decades. The global refining industry will grow with some capacity shifting from the OECD, especially the United States, to non-OECD Asian countries, primarily China. Significant technological or regulatory breakthroughs would be needed to change this course, given the scale, technological maturity, and economic fundamentals of this industry. Nevertheless, material opportunities for continuous improvement to decrease refinery GHG emissions and for carbon capture exist and should be developed further.

12.4 Transportation Fuels from Non-petroleum Feedstocks

Fossil fuels other than petroleum can be converted to transportation fuels. Technologies are available and commercially operated today for converting natural gas, coal, or biomass into liquids that closely resemble diesel and gasoline derived from crude oil. These processes involve converting the gas, coal, or biomass first into a synthesis gas (primarily CO and H_2) that is then reacted over specialized catalysts to form liquid hydrocarbons. The most widely used synthesis process for making transportation fuels today is Fischer-Tropsch (F-T) synthesis. The crude Fischer-Tropsch liquid product (FTL) can be refined into middle distillate fuels (65–85% of the final liquid volume produced), naphtha or gasoline (15–25% of the final product), and heavy waxes or lubricating oils (0–30% of the final product) (Fleisch et al., 2002). Oxygenated fuels, such as methanol, higher alcohols (C3 to C8, propanol to octanol), or dimethyl ether (DME), can also be produced from synthesis gas using different catalysts, and methanol can be further processed catalytically into synthetic gasoline and synthetic liquefied petroleum gas (LPG). There are other technologies, not yet commercialized, that pursue conversion through other intermediates than synthesis gas such as acetylene (Biello, 2009) or methanesulfonic acid (MSA) (Richards, 2005). Technology is also available for direct liquefaction of coal to produce a mix of products, including synthetic gasoline, diesel, LPG, and jet fuel, as well as a variety of chemicals.

12.4.1 Gas to Liquids

It is estimated that nearly 40% (or 71 trillion cubic meters) of the world's current natural gas reserves are "remote" or "stranded," defined as too far from the market place for economic delivery via pipelines. Natural gas resources in Australia, Trinidad and Tobago, and Qatar are good examples. In these instances, gas monetization is sought via liquefying the gas for shipping. The siting of facilities to re-gasify liquefied natural gas is now very challenging in many countries so, increasingly, gas monetization is being pursued via conversion to liquid fuels and chemicals. The high oil prices of recent years are providing a significant impetus for these so-called gas-to-liquids (GTL) efforts. Another driver for the advancement of GTL is the reduction or elimination of the flaring of associated gas. Rather than flaring gas associated with crude oil production, it could be converted via GTL technology into a synthetic crude oil and blended with the produced crude oil for shipping to refineries. The estimated 425 million cubic meters of gas flared daily if converted via GTL technology could produce some 1.5 million bbl/day (3.3 EJ/yr) of additional liquid hydrocarbon products.

Billions of dollars have been invested in GTL technology development over the last several decades by major oil companies and several technology companies. The investment has been primarily in technology for Fischer-Tropsch conversion. (The term GTL in popular usage usually refers to Fischer-Tropsch systems.) A lower level of investment has gone into technologies for producing other liquids, including methanol, higher alcohols, DME, and synthetic gasoline (via methanol). At current rates of commercial deployment, GTL systems could be displacing as much as 1 million bbl/day (2.2 EJ/yr) of petroleum-derived transportation fuels by 2020.

12.4.1.1 Fischer-Tropsch Technology

Transportation fuels are produced by Fischer-Tropsch processing, with chemical feedstocks as byproducts. F-T systems consist of three major integrated sub-systems: (i) syngas production, (ii) syngas conversion to a syncrude, and (iii) syncrude upgrading to finished products.

First, syngas (consisting predominantly of CO and H_2) is produced from methane (CH_4) by reforming using one of a variety of proven technologies. For smaller plants, steam methane reforming (SMR) is the technology of choice where natural gas is reacted with steam at

high temperatures and pressures in an externally-heated multi-tubular reactor over a nickel-based catalyst. At plant sizes over about 10,000 bbl/day, autothermal reforming (ATR) or partial oxidation reforming (POX) have become the norm. (The larger size justifies the costs of a dedicated onsite air separation unit for oxygen production.) In these systems, part of the natural gas is combusted with oxygen and the hot combustion products (CO_2 and H_2O) react with additional natural gas over a nickel-based catalyst to form syngas. Most of the heat requirements of the endothermic reforming reaction are met by the heat from the combustion process.

Following reforming, syngas is converted over a catalyst into predominantly long chain paraffinic hydrocarbons with water as a side product. The reaction is quite exothermic and great care must be taken to remove the heat from the reaction vessels. Cobalt-based catalysts have become the norm because of their much higher activity and selectivity for producing the desired paraffins compared with traditional iron-based catalysts. The former are optimized to produce a heavy wax intermediate and reduce the formation of lighter material (C1 to C5). The CO_2 yield from the F-T reactor is less than 1%. The wax is hydrotreated with additional hydrogen in the "upgrading" section to make primarily diesel and naphtha as well as other high value materials such as lube oils, jet fuel, and detergents. The iron-based catalysts produce a broader product portfolio including branched hydrocarbons (gasoline), olefins, and oxygenates along with the paraffins. They still find applications in coal-to-liquids because of the water gas shift activity of these catalysts, which produces additional hydrogen from CO through reaction with water. Coal-to-liquids are discussed further in Section 12.6.

Upgrading of F-T syncrude to finished products, the third and final step in a GTL system, is a well-proven conventional refining step. Paraffinic hydrocarbon chains are hydrocracked into shorter chains, predominantly in the diesel range (C_8 to C_{13} hydrocarbons). A small desirable degree of isomerisation can be achieved to provide proper diesel blending properties.

The basic catalytic reaction for syngas conversion was discovered in the 1920s by Franz Fischer and Hans Tropsch, two German scientists. It was sparingly used after its discovery, but there has been a resurgence of interest over the last 30 years supported by billions of dollars of research and development investments. A number of technologies that use proprietary catalysts have been developed by Sasol, Shell, ExxonMobil and other companies:

- Sasol, a South African company, has almost 50 years of experience with F-T technology, mostly in connection with coal conversion. Current production at their Sasolburg and Secunda facilities in South Africa is about 135,000 bbl/day (from coal). Cumulative production of F-T fuels using Sasol technology exceeds one billion barrels. The Sasol process has undergone significant advancements over the years from the original fixed bed technology (Arge process) to a circulating bed process (Advanced Synthol Process). The Petroleum Oil and Gas Corporation of South Africa (PetroSA), the state-owned GTL producer, started up its Mossgas plant in 1993 based on Sasol technology and now produces 22,500 bbl/day of finished products. The latest Sasol technology development is its Slurry Phase process. The process was commercialized in the Oryx GTL facility in Ras Laffan, Qatar, in 2006, which produces about 34,000 bbl/day and cost nearly US$1 billion to build. The process involves bubbling hot syngas through a slurry consisting of catalyst particles suspended in liquid hydrocarbon products. The capacity of a single Sasol slurry reactor is 17,500 bbl/day. In partnership with Chevron and the Nigerian National Petroleum Corporation, Sasol is providing technology, engineering services and engineering support for the construction of a carbon-copy of the Oryx facility on a site adjacent to the Escravos River in Nigeria. The Escravos GTL plant will convert about 8.5 million cubic meters per day of currently-flared gas into 22,300 bbl/day of diesel, 10,800 bbl/day of naphtha and 1000 bbl/day of LPG. The project was hit by global construction cost escalations starting in 2007 and may end up costing more than five times the same-sized Oryx plant, some US$5.9 billion.
- Shell is the other leader in commercial gas-to-liquids experience as a result of its GTL plant in Bintulu, Malaysia (the Shell Middle Distillate Synthesis plant). The Shell technology is a tubular fixed bed reactor containing a proprietary cobalt-based catalyst. The Bintulu plant was designed to convert 2.8 million m^3/day of gas into 12,500 bbl/day of GTL products. It started operation in May 1993. In 1997, an explosion in the air separation unit damaged the plant. The plant was rebuilt and production restarted in mid-2000 and has been operating since that time at full capacity. The Bintulu plant was the inspiration for Shell's Pearl gas-to-liquids project in Ras Laffan, Qatar. Pearl is designed to produce 140,000 bbl/day in four trains of 35,000 bbl/day each. The trains are planned to come online between 2011 and 2014. The overall project cost announced in 2001 of US$5 billion has ballooned to allegedly US$20 billion (nominal estimate, circa 2008), mainly due to escalating construction costs. However, the oil price has risen fourfold as well, making all products more valuable and compensating for the higher capital costs.
- ExxonMobil's Advanced Gas Conversion for the 21st Century (AGC-21) is a Fischer-Tropsch hydrocarbon synthesis process that converts syngas to heavy hydrocarbons over a cobalt-based catalyst suspended in a slurry. The AGC-21 hydrocarbon synthesis technology is protected by about 1200 patents and has not yet been operated commercially. In the last decade, ExxonMobil explored several commercialization options. It advanced a 160,000 bbl/day project in Qatar, but abandoned the project (and perhaps the technology) in 2006.
- BP has been involved with GTL technology since the 1980s. It operated a GTL test facility in Nikiski, Alaska, from 2002–2009 and continues to pursue commercial applications. The test facility converted about three million cubic feet of natural gas into an estimated 300 barrels of synthetic crude a day. The BP technology uses a cobalt-based catalyst in a tubular fixed bed reactor. BP is licensing the technology and is pursuing projects around the globe.

- Conoco was an aggressive player in GTL starting in 1998, pursuing a catalytic partial oxidation process for syngas production and a slurry phase reactor with cobalt-based catalyst for F-T conversion. A 400 bbl/day pilot plant in Ponca City, Oklahoma, was approved in 2001, and a large commercial project in Qatar was being pursued. However, the technology was abandoned shortly after Conoco merged with Phillips in 2002.

- Rentech is focused on the development of an iron-based catalyst in a slurry-phase process to be able to utilize syngas derived from not only natural gas but also solid or liquid hydrocarbon feedstocks. The Rentech F-T process was verified in a 235 bbl/day facility in Pueblo, Colorado, in 1993. Rentech is licensing their technology and pursing numerous projects with different feedstocks.

- Syntroleum's GTL process has been under development since the 1980s. It involves the use of a cobalt-based catalyst in a slurry to convert syngas produced from a proprietary air-fed autothermal reformer. A 70 bbl/day demonstration facility was successfully operated, but no commercial project has advanced.

- World GTL in partnership with Petrotrin, the Petroleum Company of Trinidad and Tobago, is building a small GTL plant using a refurbished and re-engineered methanol plant. They have developed their own cobalt based, multi-tubular F-T technology. There have been significant cost overruns and the project went into receivership in 2010. Nevertheless, the 2,250 bbl/day plant is expected to come on line in 2012, and World GTL is targeting small gas fields and associated gas with its low-cost modular technology.

- There are a number of related advanced technology developments underway. Petrobras is piloting a micro-reactor based GTL system developed by Velocys and CompactGTL (CompactGTL, 2010). Microreactors are low-cost modular systems where the reactions and the heat exchange are conducted in small channels of about 1mm diameter. These systems have a much smaller footprint than conventional systems and could be deployed on platforms or floating vessels to convert off-shore associated gas. Another major development underway for more than 15 years is the use of ionic membranes to separate oxygen from air and to react the oxygen with natural gas to syngas. A smaller footprint and cost reduction of 25% or more over conventional reformers have been touted by the lead developer, Air Products (Air Products, 2008).

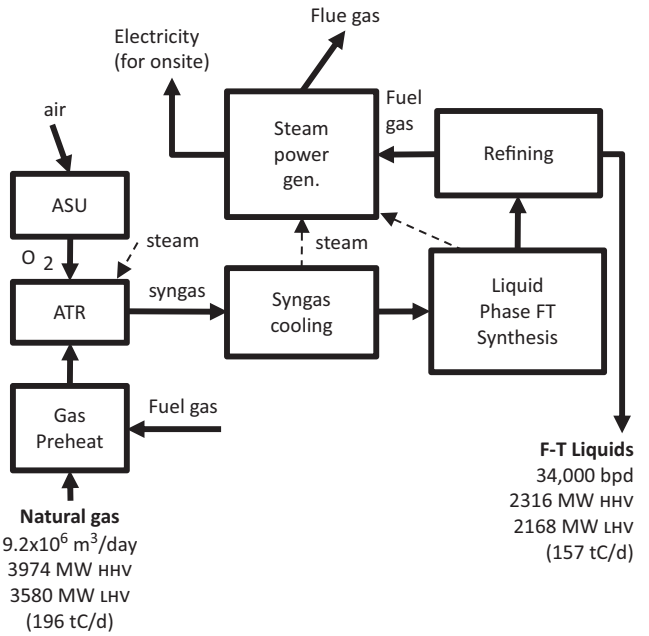

Figure 12.16 | Overall energy and carbon balance for a modern two-train GTL facility. Source: based on Simbeck and Wilhelm, 2007.

Energy and Environmental Performance of F-T Systems

The energy efficiency of a large modern commercial GTL plant today (see Figure 12.16) is about 60–65% on a LHV basis (53–58% HHV basis). Its carbon efficiency (fraction of carbon input as natural gas that appears in the liquid products) will reach 75–80%. For comparison, the methanol process is more efficient than GTL with today's advanced technologies already having energy and carbon efficiencies of about 70% and 85%, respectively.

Two processes basically determine the overall efficiency of a GTL plant: (1) the inherent water production in the conversion of methane to higher hydrocarbons (typically one barrel of water will be produced for every barrel of hydrocarbon liquid) and (2) process fuel losses, which refers to the combustion of some of the feed methane (or fuel gas derived therefrom) to provide the heat needed for reforming. From a theoretical perspective, the overall methane-to-liquids reaction can be represented as:

$$(12+x)CH_4+(5.5+2x)O_2 \Rightarrow C_{12}H_{26}+(11+2x)H_2O+x(CO_2) \qquad (1)$$

The maximum efficiency will be for the case where x is zero (no net CO_2 produced). This theoretical maximum is 78% (LHV). The remaining 22% of the input energy went into making water. At this maximum thermal efficiency, the methane carbon conversion into liquid products would be 100%. For a carbon efficiency of 75% (approximately the level with current technology), x is about three. Technology advances are projected to raise energy and carbon efficiencies to as high as 73% and 90%, respectively, within the next decade (Fleisch et al., 2003). This would make the carbon efficiency of the GTL process comparable to that of petroleum refining.

For a large, modern GTL facility that vents CO_2, the life cycle GHG emissions associated with the F-T liquid products amounts to some 101 $kgCO_2$-eq/GJ_{LHV} (where GJ stands for gigajoule) or about 10% above GHG emissions associated with an equivalent amount of crude-oil

derived products.[10, 11] The prospects for reducing these emissions are limited, since only a relatively small amount of CO_2 is available for capture. If available CO_2 were to be captured at a GTL facility today, life cycle GHG emissions would be about 10% below emissions from an equivalent amount of crude-oil derived products. The expectation is that further advances in GTL technology will reduce the amount of CO_2 available for capture, which makes this figure a lower bound on potential GHG emissions of GTL fuels.

Prospective F-T Economics

The gap is widening between the value of natural gas and that of liquid transportation fuels such as diesel and gasoline, influenced by oil prices consistently above US$60/bbl and increasing bullishness regarding future natural gas supplies (see Section 12.7.2.2). In the largest market, the United States, gasoline and diesel sold for two to four times Henry Hub natural gas prices on an energy equivalent basis in recent times (Henry Hub is the pricing point for natural gas futures contracts traded on the New York Mercantile Exchange). During most of the 1980s and 1990s, gas hovered around US$2/GJ while diesel and gasoline averaged US$4–6/GJ. More recently, the gap has widened because of plentiful gas supplies and the capping of gas prices by coal in the competition for power generation. In 2009, we have seen gas prices below US$3/GJ while low sulphur diesel was at US$14/GJ and above. These are strong economic drivers for GTL especially with commercially proven technologies. It can be shown that at oil prices of US$60/bbl, a delivered gas price of about US$8/GJ is needed to achieve a similar net present value for GTL and LNG (liquefied natural gas) projects. At higher oil prices and/or lower gas prices, GTL is economically advantaged over LNG while at lower oil prices and/or higher gas prices LNG is the economic choice.

The economics for an integrated upstream gas field and GTL plant will typically be more attractive than those for a stand-alone GTL plant. Shell's 140,000 bbl/day Pearl project is an example of an integrated project. It includes gas production platforms, gas processing plants and the GTL facilities. The economic returns from the condensates and LPG in the natural gas are high, putting less demand on the return from the GTL project.

Capital costs of GTL Fischer-Tropsch projects dropped from about US_{2005}80,000 per bbl/day (US_{1991}60,000) of installed capacity in 1991 for Mossgas to just below US_{2005}29,000 per bbl/day (US_{2006}30,000) installed capacity for Oryx in 2006. These costs made GTL economic with oil at US$20/bbl. Capital costs have more than doubled in the last four years, however, due to sky rocketing oil prices and the corresponding increases in project costs in the oil and gas industry. Many GTL projects have been delayed for a "cooling down" period. However, the first train of the Shell Pearl project started up in mid-2011, to be followed by the other three trains through 2014. This project may prove the techno-economic attractiveness of large scale GTL once and for all and set the stage for widespread global applications with ongoing improvements. Meanwhile, research and development is continuing and will also contribute to reducing capital costs as it has in the past.

Thus, GTL has the potential to become a prominent part of the international energy business. Continued high oil prices and the widening gap between gas prices and oil prices will favor GTL projects. Most importantly, the concerns of technology risks will wane with commercial plants operating safely and reliably around the world. The problem of technology access will disappear: an increasing number of licensing opportunities and patents are expiring.

12.4.1.2 Methanol to Gasoline

Production of methanol from natural gas is a well-established technology (Cheng and Kung, 1994; Olah et al., 2009). Methanol consumption globally exceeds 40 Mt/yr primarily in chemical processing. Use of methanol as a vehicle fuel attracts considerable interest in some provinces of China today (Dolan, 2008), as it did in the 1970s and 1980s in the United States, where interest has since faded largely as a result of health and environmental concerns from the use of methanol-derived MTBE (methyl tert-butyl ether) as an additive to gasoline. There is renewed interest in higher alcohols for both gasoline and diesel blending (IGP, 2010). These alcohols overcome some disadvantages of methanol and ethanol and have been shown to increase engine efficiencies and lower tailpipe emissions (Yacoub et al., 1997). Furthermore, there is now growing interest in China, the United States and elsewhere in the production of synthetic gasoline from synthesis gas via a methanol intermediate. This so-called methanol-to-gasoline process is the subject of this section.

The first step is methanol production by reforming of natural gas into synthesis gas (CO and H_2), which is then converted over a catalyst to methanol. The two most common reforming technologies, SMR and ATR, have been described in Section 12.4.1.1. A syngas H_2/CO ratio of about two leaving the reformer will optimize methanol synthesis yields, but reforming typically yields a syngas with H_2/CO higher than two. One option for reducing the H_2/CO ratio is to feed recycled CO_2 to the reformer. Katofsky (Katofsky, 1993) showed that this has the benefit of increasing methanol yield and overall process efficiency by several percentage points.

Two companies currently offer technology for synthesis of gasoline from methanol. A key distinction between the technologies is that the technology offered by Haldor Topsoe utilizes an initial single-step conversion of syngas into DME/methanol, followed by conversion to gasoline

10 This estimate includes 9.10 $kgCO_2$-eq/GJ_{LHV} associated with extraction, preprocessing, and transportation of the feedstock natural gas (based on the GREET model (Argonne National Laboratory, 2008)).

11 If natural gas that would otherwise have been flared (a relatively small potential resource for GTL) were the feedstock, then the net life cycle GHG emissions associated with these GTL fuels would be considerably less than for equivalent petroleum-derived fuels, since the GTL fuels would be displacing the petroleum-derived fuels (FWI, 2004) while eliminating the emissions from the flared gas.

in a separate reactor (Nielsen, 2009). The ExxonMobil process involves methanol production from syngas followed by partial conversion of methanol to DME in a separate reactor, followed by conversion of the DME/methanol mixture into gasoline in a third reactor (Tabak et al., 2009). In either case, most of the DME/methanol mixture that flows to the gasoline synthesis reactor is converted in a single pass over the catalyst. Some propane/butane (LPG) and a small amount of methane are coproducts.

Because the H/C ratio of methane is higher than that of the final gasoline product, no significant CO_2 by-product stream is available for capture and storage, giving natural gas-to-MTG systems a carbon footprint not substantially different from petroleum-derived gasoline.

12.4.2 Direct Coal Liquefaction

Direct coal liquefaction refers to a process in which pulverized coal reacts with a hydrogen-donor solvent over a catalyst, causing hydrocracking of the coal into liquids. Direct liquefaction is distinct from indirect liquefaction. As discussed in Section 12.4.3, indirect liquefaction utilizes coal gasification followed by a separate catalytic step to convert the gasified product into liquid fuels. (Fischer-Tropsch fuels are perhaps the best known of the different fuels that can be produced via indirect liquefaction.)

Direct coal liquefaction will produce not only gasoline, diesel, LPG, and jet fuel, but also a variety of chemicals such as benzene, toluene, xylene, and other raw olefins to further produce ethylene and propylene. The reaction can be summarized as follows:

$$nC + (n+1)H_2 \rightarrow C_nH_{2n+2} \quad (2)$$

The first generation of direct coal liquefaction technology was developed during World War II. Germany was the first country to realize the industrialization of direct coal liquefaction. Twelve direct coal liquefaction plants were built and the total capacity exceeded 4 Mt/yr. However, the first generation technology was limited by its harsh reaction condition (Pressure: around 70 MPa) and costly catalysts. After World War II, all the plants were shut down due to technical defects and economic disadvantage driven by the development of cheap oil. The 1970s oil crisis brought attention back to direct coal liquefaction. Many countries developed a wide range of modern coal liquefaction technologies (Pressure: 10~30 MPa and less expensive catalysts): American H-Coal and Hydrocarbon Technology, Inc. (HTI), the German Integrated Gross Oil Refining (IGOR) technology, the Japanese NEDOL technology, and others. These technologies completed 350~600 t/day pilot tests but did not achieve large scale industrialization. Table 12.14 lists known technologies developed to at least the 50 t/day coal input scale. The main differences between these processes lie in catalysts, reactors, hydrogen donor solvents, and system design.

Table 12.14 | World testing of coal liquefaction technologies.

Single stage processes	Two stage processes
• Kohleoel (Ruhrkohle, Germany) • NEDOL (NEDO, Japan) • H-Coal (HRI, USA) • Exxon Donor Solvent (EDS) (Exxon, USA) • SRC-I and II (Gulf Oil, USA) • Imhausen high-pressure (Germany) • Conoco zinc chloride (Conoco, USA)	• Catalytic Two-Stage Liquefaction (CTSL) (USDOE and HRI, now HTI, USA) • Liquid Solvent Extraction (LSE) (British Coal Corp., UK) • Brown Coal Liquefaction (BCL) (NEDO, Japan) • Consol Synthetic Fuel (CSF) (Consolidation Coal Co, USA) • Lummus ITSL (Lummus Crest, USA) • Chevron Coal Liquefaction (CCLP) (Chevron, USA) • Kerr-McGee ITSL (Kerr-McGee, USA) • Mitsubishi Solvolysis (Mitsubishi Heavy Industries, Japan) • Pyrosol (Saarbergwerke, Germany) • Amoco CC-TSL (Amoco, USA) • Supercritical Gas Extraction (SGE) (British Coal Corp., UK)

Source: DTI, 1999.

The most active country today in direct liquefaction is China, which became a net oil importing country in 1993. Since then, the fraction of oil imported has been increasing, and it reached about 50% by the end of 2008. Concern about energy security gives impetus for making oil from coal in China. Direct coal liquefaction became a major candidate because it is believed to be more energy efficient and less water consuming than many alternatives.

In 2001, China's Shenhua Group, the largest coal company in the world, started development of a demonstration project to produce one Mt/yr of liquids from coal by direct liquefaction. In early 2009, the facility conducted the first test run which lasted about 300 hours and then shut down as planned. This project is ongoing and is expected to provide improved understanding about potential energy and economic performances of this technology (see Box 12.2).

12.4.2.1 Process Description

Direct coal liquefaction includes a catalytic liquefaction step in the presence of hydrogen followed by solid-liquid separation and upgrading. Pulverized coal is blended with a solvent and the catalyst, together making a coal slurry. In the liquefaction unit, weak-bond breaking is achieved, leading to free radical hydrogenation. Then, the inorganic minerals and un-reacted coal are removed by a series of solid-liquid separation processes such as vacuum distillation, filtration, extraction, and sedimentation. Finally, a catalytic hydrogenation process is required to increase the hydrogen-to-carbon ratio in the liquid product and remove impure elements.

Generally speaking, apart from anthracite, all other types of coal can be liquefied to some extent. In rough terms, the difficulty of liquefaction increases with the age of the coal: peat < young lignite < lignite < high-volatile bituminous coal < low-volatile bituminous coal. In addition, excessive ash content also has a negative impact on coal liquefaction.

Box 12.2 | Shenhua Direct Coal Liquefaction Demonstration Project

China's Shenhua Group's direct coal liquefaction demonstration project in Ordos, Inner Mongolia Autonomous Region, China, is designed to produce 1 Mt/yr of oil. The Chinese government approved the project in 2001, construction started in August 2004, and the first testing run succeeded in early 2009.

Shenhua developed its own synthetic catalyst to lower costs. Hydrogen donor solvent cycle is used to mitigate the slurry properties. A slurry bed compulsory intra-circulation reactor is used to improve the capacity of reaction. A mix of advanced and mature unit technologies reduces project risks.

The process flow of Shenhua direct coal liquefaction project is shown in Figure 12.17. At present, 1.08 Mt of liquefied oil can be produced with the input of 4.10 Mt of coal, of which 1.32 Mt is used for hydrogen production and 0.53 Mt for industrial boiler firing. Of the liquefied oil, 70% is diesel and 20% is naphtha. The naphtha products, with a high content of aromatics, are very good reforming materials. The water consumption in this project is about 7 to 8 tonnes of water per tonne of product.

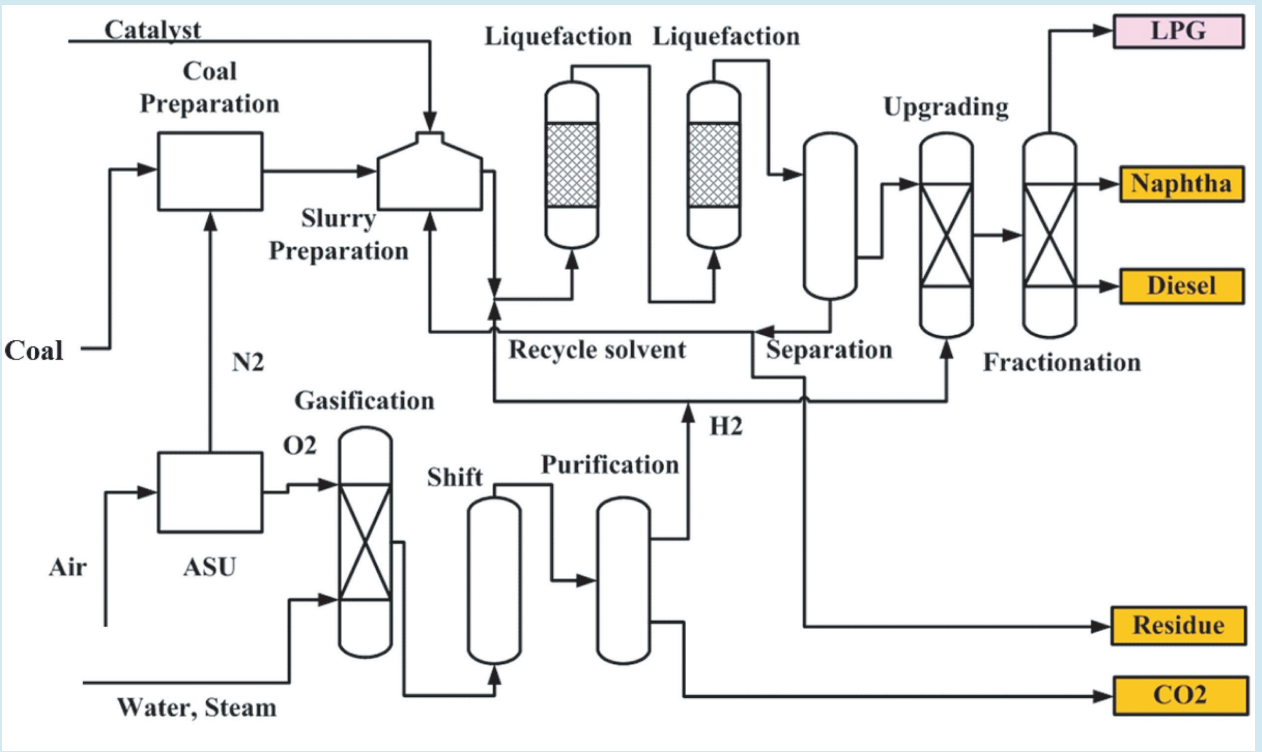

Figure 12.17 | Shenhua direct coal liquefaction demonstration project process flow.

The liquefied oil from direct coal liquefaction, including naphtha, diesel, and liquefied heavy oil, retains some characteristics of raw coal, such as a high content of aromatic hydrocarbons and hetero-atoms (e.g., Oxygen, Nitrogen). A process of hydrogenation is carried out to upgrade the quality of the liquefied oil, which causes the refining costs to be much higher than for conventional petroleum refining.

12.4.2.2 Resource Consumption and Economic Performance

Compared with indirect coal liquefaction and other coal conversion technologies, the efficiency of direct coal liquefaction is higher, up to 60%. Shenhua estimates that the coal consumption of a direct coal liquefaction project is about 0.061 tonne of coal equivalent (tce) per

GJ of liquid product, compared with 0.075 tce/GJ for indirect coal liquefaction.

Water consumption is always a big concern for coal conversion. Compared to other conversion technologies, direct coal liquefaction appears to be relatively lower in specific water consumption at about 8 t water per metric tonne of product (t/t), compared with about 11–12 t/t for indirect coal liquefaction. Water is mainly consumed in the gasification unit for providing hydrogen for hydrocracking and the hydrogenation upgrading processes.

The investment of a direct coal liquefaction plant is still uncertain. The first-of-a-kind plant may cost US$100,000 to US$150,000 per bbl/day output capacity. This number can be decreased with further technology development and improvements in engineering.

12.4.2.3 Carbon Dioxide Emissions

In a coal liquefaction plant producing one Mt/yr of liquids, the carbon dioxide emissions will amount to more than 3.6 Mt/yr, excluding emissions from combustion of the liquid products. The plant CO_2 emissions are predominantly (about 80% of emissions) from the hydrogen production unit. The CO_2 leaves this unit in high concentration (87–99%), which can facilitate low-cost capture of CO_2 for underground storage. (Other CO_2-containing emission streams, e.g., flue gas from the flare system, have relatively low concentrations of CO_2, making capture for storage more difficult.) About one-third of carbon input as coal is available for capture as a relatively pure stream from the H_2 production plant. In this respect, direct coal liquefaction has some similarity to gasification-based coal-to-fuels and coal-to-chemicals processes, since a pure stream of CO_2 is available (just as there is in gasification-based processes). For additional discussion of direct versus indirect liquefaction, see Williams and Larson (2003) and Lepinski et al. (2009).

12.4.3 Gasification-based Liquid Fuels from Coal (and/or Biomass)

There is growing interest in making synthetic fuels from coal – known as coal-to-liquid (CTL) fuels – in light of coal's relatively low prices and the abundance of coal in China, the United States, and other countries that are not politically volatile. Much of this attention has been focused on so-called indirect liquefaction to produce Fischer-Tropsch liquids (Bechtel Corporation et al., 2003; van Bibber et al., 2007; Bartis et al., 2008; AEFP, 2009). Synthetic gasoline (made via a methanol intermediate, see Section 12.4.1.2) is also beginning to attract interest (AEFP, 2009).

Coal can do much to improve energy security if it is used to make liquid fuels. Moreover, these synfuels would be cleaner than the crude oil products they would displace (having essentially zero sulfur and other contaminants and low aromatics content). Also, if produced using modern entrained flow gasifiers, the air pollutant emissions from the production facility would be extremely low. When synthetic fuels are made from coal without capture and storage of by-product CO_2, however, net fuel-cycle GHG emissions are about double those from petroleum fuels they would displace (AEFP, 2009). And even with carbon capture and storage (CCS), the net GHG emission rate would be only about the same as the crude oil products displaced.

One approach to reducing GHG emissions below petroleum-fuel levels is to exploit negative GHG emissions opportunities to offset the emissions. One important opportunity is synthetic fuels production from biomass with CCS (Larson et al., 2006). An intrinsic feature of synthetic fuels production from coal or biomass is the production of a by-product stream of pure CO_2, accounting for about one half of the carbon in the feedstock. If this CO_2 can be captured and stored via CCS while producing synthetic fuels from sustainably grown biomass, the biofuels produced would be characterized by strong negative GHG emissions, because of the geological storage of photosynthetic CO_2. However, sustainably-recovered biomass is expensive, and the size of the biomass-to-liquid (BTL) facilities will be limited by the quantities of biomass that can be gathered in a single location – which implies high specific capital costs for BTL.

The shortcomings of the BTL with CCS option could be overcome to an extent by coprocessing biomass with coal in the same facility. The economies of scale inherent in coal conversion could thereby be exploited and the average feedstock cost would be lower than for a pure BTL plant. And if CCS were carried out at the facility, the negative CO_2 emissions associated with the biomass could offset the unavoidable positive emissions with coal (Figure 12.18), leading to liquid fuels with low, zero, or negative fuel-cycle emissions depending on the relative amounts of coal and biomass input (AEFP, 2009; Larson et al., 2010; Liu et al., 2011a). Interest in the CBTL-CCS concept is growing in the United States (Tarka et al., 2009).

The equipment for gasification-based production of liquid fuels from coal and biomass are commercial or nearly-commercial in all cases. Coal gasifiers are commercially available and deployable today, with more than 420 gasifiers already in commercial use in some 140 facilities worldwide (AEFP, 2009). The technology for cogasifying biomass and coal is close to being ready for commercial deployment; the commercial Buggenum IGCC facility in the Netherlands has been cogasifying coal and some biomass in a coal gasifier since 2006 (van Haperen and de Kler, 2007). Stand-alone biomass gasification technology is an estimated five to eight years from being ready for commercial-scale deployment (AEFP, 2009). Technologies for converting syngas into Fischer-Tropsch diesel and gasoline are in commercial use today. Those for making synthetic gasoline via methanol can be considered commercially deployable (AEFP, 2009), with technology offered by vendors such as Haldor-Topsoe (Nielsen, 2009) and ExxonMobil (Tabak et al., 2009), and projects in development (Doyle, 2008; ExxonMobil, 2009). See Section 12.4.1.2.

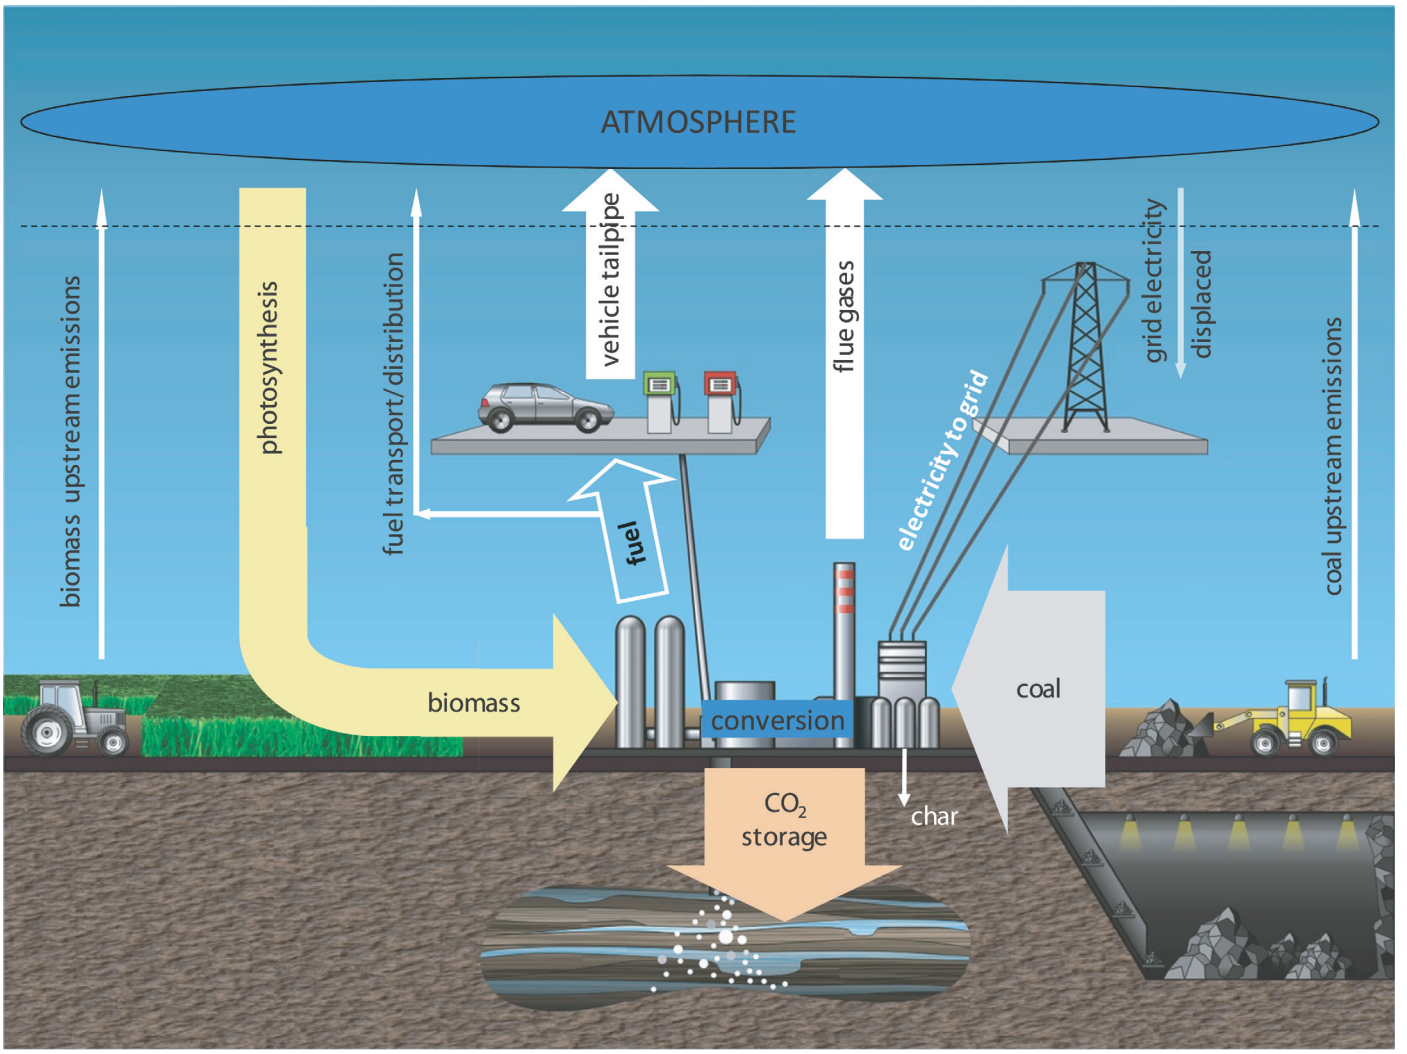

Figure 12.18 | Carbon flows for conversion of coal and biomass to liquid fuels and electricity. When biomass is approximately 30% of the feedstock input (on a higher heating value basis), the net fuel cycle GHG emissions associated with the produced liquid fuels and electricity would be less than 10% of the emissions for the displaced fossil fuels. Source: Larson et al., 2010.

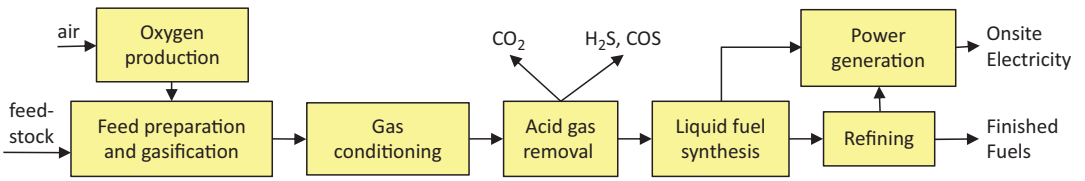

Figure 12.19 | Production of liquid fuels from coal and/or biomass feedstocks.

12.4.3.1 Process Descriptions

Figure 12.19 illustrates generically gasification-based production of liquid fuels from coal or biomass. The feedstock is gasified in oxygen and steam, with subsequent gas conditioning that includes cleaning of the raw synthesis gas (syngas) and in some cases adjusting the composition of the syngas using a water gas shift reaction to achieve the requisite H_2:CO ratio for downstream catalyst-assisted synthesis into liquids. Prior to synthesis, CO_2 and sulfur compounds are removed in the acid gas removal step to increase the effectiveness and reduce the required size of downstream equipment, as well as avoid sulfur poisoning of catalysts. The CO_2 may be vented (-V) or captured and stored underground (-CCS). The liquid fuel synthesis island is designed with recycle (RC) of unconverted syngas to maximize liquids production. A purge stream from the recycle loop, together with light gases generated in the refining area, provide fuel for power generation, which primarily goes to meet onsite needs. (Alternatively, as discussed in Section 12.6, if none – or only some – of the unconverted syngas is recycled, the

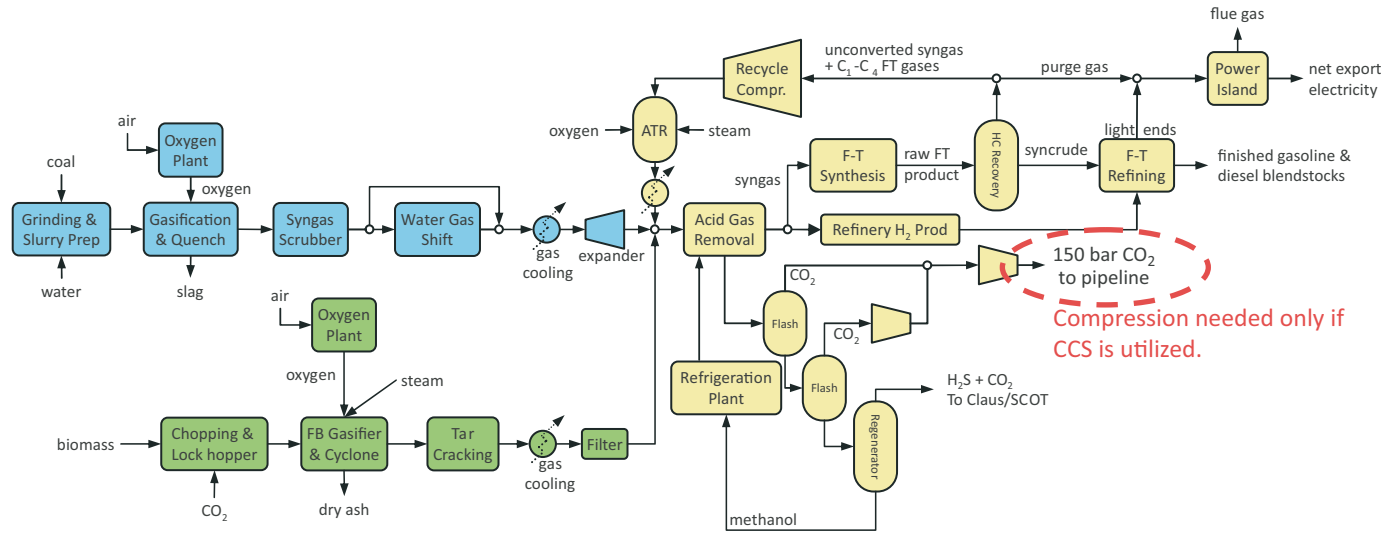

Figure 12.20 | Alternative process configurations for maximizing production of FTL from coal (CTL-RC-CCS, blue-shaded components) or from biomass (BTL-RC-CCS, green-shaded components) with capture and storage of carbon. Yellow-shaded components are common to both CTL and BTL systems.

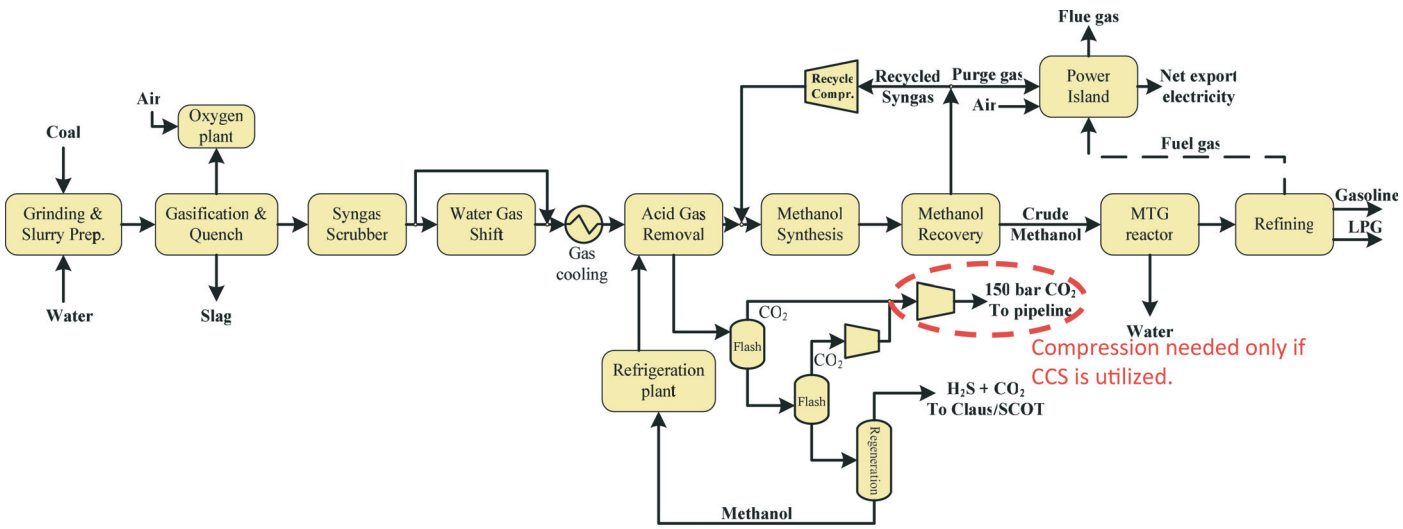

Figure 12.21 | Plant configurations for maximizing gasoline output with only coal as input feedstock.

unconverted syngas can be used to increase electricity generation and provide an exportable electricity co-product.)

More detailed process depictions of coal conversion into F-T fuels are shown in Figure 12.20 (blue and yellow shading). Figure 12.21 shows coal conversion to synthetic gasoline. In these particular plant designs, a slurry of bituminous coal and water is fed into a pressurized gasifier along with oxygen from a dedicated onsite cryogenic air separation unit. The syngas leaving the gasifier is wet-scrubbed before some of it enters a water gas shift reactor. The fraction of the syngas sent to the WGS reactor is adjusted to ensure an appropriate H_2:CO ratio for the later synthesis reactor. Following the WGS reactor, the syngas is cooled in preparation for acid gas removal and, in the case of F-T production, expanded to near the pressure required for later synthesis. CO_2 and H_2S are then removed by the acid gas removal system. Several acid gas removal technologies are commercially available (see Chapter 13). A physical absorption process using chilled methanol (e.g., Rectisol®) is indicated in Figures 12.20 and 12.21. The captured H_2S is processed via a Claus/SCOT system into elemental sulfur. The captured CO_2 can be either vented to the atmosphere or compressed to a supercritical state for pipeline delivery and underground injection for storage. Following acid gas removal, the syngas is delivered to the synthesis reactor.

In the case of F-T synthesis (Figure 12.20) most of the syngas passes to the synthesis reactor, where it reacts over a catalyst to produce a mixture of olefinic and paraffinic hydrocarbons. When an iron-based synthesis catalyst is used, the syngas H_2:CO ratio entering the reactor

is about one, and the raw liquid product is a mix of hydrocarbons with a wide range of carbon numbers. With a cobalt-based catalyst, the ratio is about two, and the liquid product is largely heavy hydrocarbons (waxes). After synthesis, unconverted syngas and light gases generated during synthesis are recycled back to the synthesis reactor to increase F-T liquids production. (In some situations, separation for sale of the light components that constitute LPG may be economic.) The recycled gases undergo ATR to convert light hydrocarbons, resulting in a stream returning to the synthesis reactor that consists primarily of CO, H_2, and CO_2. A small portion of the recycle gases are drawn off as a purge stream to avoid the buildup of inert gases in the recycle loop. The purge gases are mixed with light hydrocarbons produced in the F-T refining area, and the mixture of gases is burned in the boiler of a steam turbine power system. Electricity production is primarily to meet onsite needs.

The final step in FTL production is refining of the raw liquid product (mostly a crude diesel and naphtha). Hydrogen addition is typically required in this step. In the design shown in Figure 12.20, some syngas is diverted upstream of synthesis for use in producing the requisite hydrogen. A minimum refining step is required to stabilize the liquid products if they are to be shipped to a conventional refinery for further refining. This minimum step includes hydrogenation of the naphtha and diesel range hydrocarbons and hydrocracking of the heavier hydrocarbons (waxes). Alternatively, further refining to finished diesel and gasoline blendstocks can be done onsite. Reforming of the naphtha fraction is required in this case to produce an acceptable gasoline blendstock (Liu et al., 2011a; Guo et al., 2011). The naphtha could be sold instead as a chemical feedstock, thereby avoiding added cost and energy expenditures for catalytic reforming, but chemical markets for naphtha are relatively small (compared to gasoline markets), so this would be a limited option if FTL production were to become widespread.

In the particular process shown in Figure 12.21 for making synthetic gasoline via methanol (MTG) from syngas, the first step following acid gas removal is methanol synthesis, for which the requisite syngas H_2:CO ratio is about two and optimal pressure is 50–100 bar (considerably higher than for F-T synthesis). Most of the unconverted syngas is recycled to increase methanol production, with a small purge stream extracted to avoid building up inert gases. (No reformer is required in the recycle loop as in the FTL design, since there is no significant hydrocarbon content in this stream.) The crude liquid methanol is vaporized and sent to a DME reactor, where it is catalytically converted to an equilibrium mixture of methanol, dimethyl ether and water. The mixture flows to the MTG reactor, where most of the gas is converted in a single pass over a catalyst into gasoline-range hydrocarbons. Some propane/butane (LPG) and a small amount of methane are coproducts. The liquid products are sent for fractionation and finishing (primarily durene treatment), resulting in finished gasoline and LPG products. The purge gas from the methanol synthesis area and light gases evolved in the MTG area fuel the power island, where a steam cycle generates all the electricity needed to run the facility plus a modest amount of export electricity.

Process designs for making FTL or MTG from biomass feedstocks would be similar to those described above for coal conversion. Figure 12.20 shows a configuration for FTL from biomass (BTL) (green plus yellow shading). There are important differences from the coal design (also shown in Figure 12.20): (i) a pressurized fluidized-bed gasifier, which avoids the energy-intensive grinding of biomass that is required with an entrained flow gasifier and enables ash to be removed as a dry material that might be returned to the field for its inorganic nutrient content; (ii) a tar cracking step following gasification to convert into light gases the heavy hydrocarbons that form at typical biomass gasification temperatures (which are lower than coal gasification temperatures) and that would otherwise condense and cause operating difficulties downstream; (iii) reforming of the recycle stream in the MTG design due in part to the higher methane production from biomass gasification compared to coal gasification.

As noted earlier, shortcomings of the BTL option include high feedstock costs and steep scale economies for the plant capital cost. These challenges can be mitigated by coprocessing some biomass with coal (CBTL) (Blades et al., 2008; Tarka et al., 2009; Liu et al., 2011a). Figure 12.20 (all colors of shading) shows a detailed design for a coal/biomass coprocessing system to make FTL fuels (CBTL) utilizing separate coal and biomass gasifiers. With different downstream processing steps, synthetic gasoline could similarly be produced from coal and biomass (CBTG).

12.4.3.2 Performance Estimates

Results from a set of detailed and self-consistent designs and performance simulations of coal and/or biomass conversion to FTL and MTG transportation fuels are presented in Table 12.15. (Illinois #6 bituminous is the coal type, and switchgrass is the biomass type.) The simulations utilize design assumptions for each unit operation (gasification, water gas shift, acid gas removal, FTL synthesis, MTG synthesis, etc.) that are consistent with performance that has been demonstrated in existing commercial applications for all except biomass gasification/tar cracking. For the latter, design assumptions are based on pilot-plant performance. The greenhouse gas emissions estimates include net life cycle emissions for synfuel production and consumption, including emissions associated with activities upstream of the conversion plant, such as coal mining and biomass growing, harvesting, and transportation, as well as emissions downstream of the plant, including transport of the liquid products to refueling stations and combustion of the fuels in vehicles. The process of making synthetic gasoline has some efficiency benefit. For systems using only coal as feedstock and producing liquid fuels at a rate of 50,000 petroleum-fuel-equivalent barrels per day of liquids, Table 12.15 indicates that when making synthetic gasoline (MTG) more of the input coal is converted to liquid fuel (and less to electricity) than for the FTL designs considered here. The result is an overall efficiency advantage of about 5 percentage points for MTG due to the intrinsically higher thermodynamic efficiency of converting syngas to liquids compared to converting it to electricity. There is only

b If all emissions are charged to gasoline and/or diesel fuels.

c GHGI, the greenhouse gas emissions index, is the system wide life cycle GHG emissions for production and consumption of the energy products relative to emissions from a reference system producing the same amount of liquid fuels and electricity. For FTL systems, the reference liquid fuels are a mix of gasoline and diesel from crude oil for which the average GHG emission rate is 91.6 $kgCO_2$-eq/GJ_{LHV}. For MTG systems the reference liquid fuels are gasoline and LPG having life cycle GHG emission rates of 91.3 $kgCO_2$-eq/GJ_{LHV} and 86.0 $kgCO_2$-eq/GJ_{LHV}, respectively. In all cases the reference system electricity is assumed to be from a new supercritical pulverized coal power plant for which the average GHG emissions rate is 830.5 $kgCO_2$-eq/MWh_e.

Source: Liu et al., 2011a; Liu et al., forthcoming.

about 1.5 percentage points penalty in efficiency (with either MTG or FTL) when CCS is added. The penalty is primarily due to the added electricity needed onsite to compress the captured CO_2 for transport and injection underground.

For systems described in Table 12.15 that use biomass it is assumed that the total biomass input is 1 Mt/yr (dry basis), a practical limit on the biomass delivery rate. For pure biomass systems (see Figure 12.20), this implies a liquid fuel production capacity of 4500–4600 bbl/day. The

overall efficiency for the biomass FTL design is modestly higher than that for the coal-FTL plant. For the MTG plant, however, the efficiency is lower than for the coal-only design due to the syngas compression required in the biomass design to raise the pressure of the syngas to that needed for methanol synthesis. (The gasification pressure is higher for coal than for biomass, so no syngas compressor is required in the coal-to-gasoline designs.) The need for reforming in the recycle loop also contributes to the reduced efficiency for biomass conversion to MTG relative to coal.

The carbon mitigation performance of alternative options is indicated by a greenhouse gas emissions index (GHGI), the system wide life cycle GHG emissions relative to emissions from a reference system producing the same amount of fuels and electricity. It is assumed that the reference system consists of equivalent crude oil-derived liquid fuels and electricity from a new stand-alone supercritical pulverized coal power plant venting CO_2. The GHGI for each option is listed at the bottom of Table 12.15 and summarized in Figure 12.22. For coal conversion to FTL or MTG without capture of CO_2, GHGI is 1.7 to 1.8 and GHGI is 0.9 to 1.0 with CCS. For biomass conversion, fuel cycle GHG emissions are < 0.07 when CO_2 is vented and strongly negative when CO_2 is captured and stored. For the designs coprocessing coal and biomass (see Figure 12.20), a mix (about 55% coal and 45% biomass, HHV basis) is chosen so that GHGI < 0.1. This GHGI constraint and the assumption of a biomass processing rate of 1 Mt/yr dry biomass imply that the liquid fuel production capacity is about 10,000 bbl/day in the CBTL and CBTG designs.

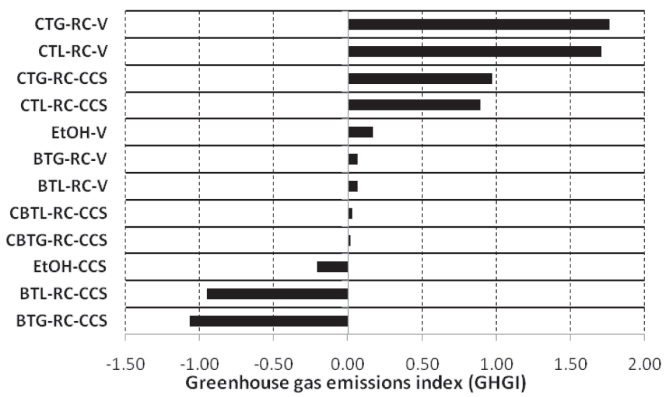

Figure 12.22 | Values of GHGI for the synthetic fuel options described in Table 12.15, along with the GHGI for future cellulosic-biomass ethanol technologies. See Table 12.15, note (c) for definition of GHGI. For details on the cellulosic ethanol options see Box 12.3 and Liu et al., 2011a.

Biomass is a relatively scarce resource and the only carbon-bearing renewable energy source. Thus, the effectiveness of its use is an important consideration. Figure 12.23 shows one measure of effectiveness: liters of low/zero-GHG gasoline-equivalent FTL or MTG fuel produced per dry tonne of biomass consumed. Shown for comparison is an estimate for future cellulosic ethanol (EtOH) made (without and with CCS) from switchgrass biomass via enzymatic hydrolysis. Not surprisingly, with the FTL and MTG systems that coprocess coal and biomass, the total liquid fuel produced per unit of biomass input is high (because of the coal coprocessing). In the case of pure biomass FTL and MTG and EtOH systems with CCS, it is assumed that the negative GHG emissions provide "room in the atmosphere" for using some conventional crude oil-derived fuels while maintaining overall zero net GHG emissions. The total low-C liquid fuel yields for the cellulosic ethanol production options would be comparable to the biomass-only FTL and MTG systems that vent CO_2 but less than half the yields of low carbon fuels realized for all FTL and MTG systems with CCS.

12.4.3.3 Cost Estimates

For each of the plant designs described in Table 12.15, cost estimates are given in Table 12.16. Costs are reported here in US_{2007} as discussed in Section 12.2.2.3.

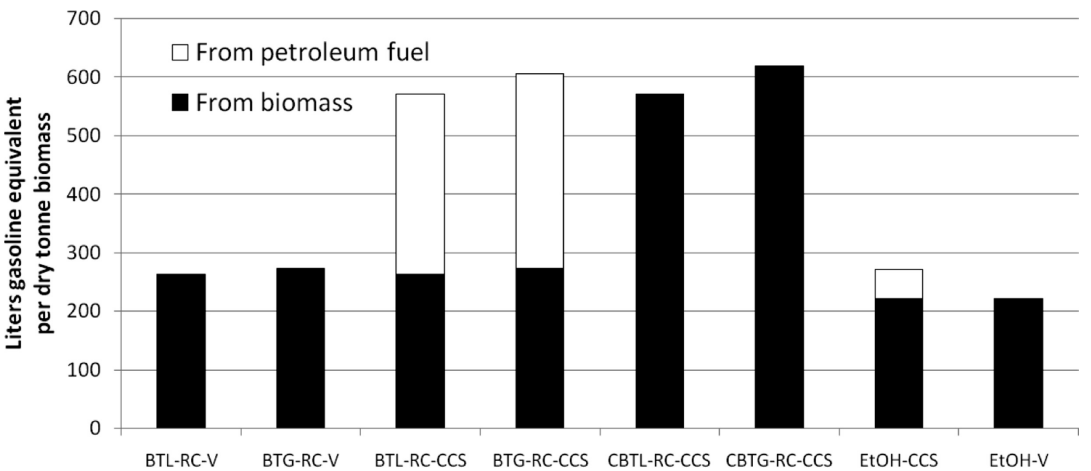

Figure 12.23 | Yields of low/zero net GHG emitting liquid fuels from biomass, liters of gasoline equivalent per dry tonne. For the biomass-only designs that incorporate CCS (BTL-RC-CCS, BTG-RC-CCS, and EtOH-CCS), life cycle GHG emissions are negative, leaving "room in the atmosphere" for some crude oil-derived fuel that can be used while keeping zero net GHG emissions for the biomass + crude oil-derived liquid fuels. Based on Liu et al., 2011a. See also Box 12.3 for a discussion of the cellulosic ethanol options.

a See note (b) of Table 12.6 for financial parameter assumptions.

b The breakeven oil price (BEOP) is calculated assuming the LPG co-product is sold for its wholesale price assuming the crude oil price is US$100/bbl. The wholesale price of LPG is determined as a function of crude oil price from a regression correlation of wholesale propane prices and refiner crude oil acquisition costs in the United States (propane (US$/bbl) = 0.7212 * Crude acquisition cost (US$/bbl) + 5.2468). See Kreutz et al., 2008 for additional discussion of the BEOP calculation.

Source: Liu et al., 2011a; Liu et al., forthcoming.

Specific capital costs for coal conversion without CCS range from US$81,000 per bbl/day to US$98,000 per bbl/day. Adding CCS involves a relatively small cost increment, since the primary additional cost is equipment for CO_2 compression. Specific costs for biomass conversion are considerably higher due largely to the much smaller scale of the conversion facility. Systems coprocessing coal and biomass are larger in scale than biomass-only systems, but smaller than the coal-only systems, which largely accounts for the intermediate level of specific capital costs.

Table 12.16 also shows both the levelized cost of fuel (LCOF) production and the crude oil price at which the FTL and MTG fuels would compete with petroleum-derived fuels when the price of GHG emissions is zero. For the coal-only plants, capital charges are the most significant production cost component, while for biomass-only facilities capital and feedstock are of comparable importance. For systems that vent CO_2 the breakeven oil price (BEOP) is in the range US$48–61/bbl for coal plants and US$126–133/bbl for biomass plants. For systems with CCS the BEOP is in the range

US$53–67/bbl for coal plants, US$137–145/bbl for biomass plants, and US$96–111/bbl for plants that coprocess coal and biomass.

As shown in Figure 12.24, when non-zero GHG emissions prices are considered, the relative economics of alternative process designs can be considerably different from those in Table 12.16. At GHG emission prices above a modest US$10–20/t$CO_2$-eq the –CCS variant of each option realizes a lower BEOP than the –V variant because the cost of CO_2 capture is low as a result of the production of a by-product stream of pure CO_2 as an intrinsic part of the design of gasification-based liquid fuels production. At GHG emission prices above US$65–75/t$CO_2$-eq the biomass –CCS option realizes a lower BEOP than the corresponding coal –CCS option (with more than 10 times the output capacity), as a result of the strong negative GHG emission rates for the biomass with –CCS options.

12.4.4 Hydrogen from Non-petroleum Feedstocks for Transportation

Hydrogen production from fossil fuels, the subject of this section, is well-established commercially in petroleum refining, ammonia production, and other industries where hydrogen is needed as a chemical feedstock.

H_2 produced electrolytically from non-carbon energy sources (wind, solar) is more costly than projected costs of making H_2 with ultra-low GHG emissions from coal or natural gas with CCS (Williams, 2002). The higher cost is largely because electricity purchases account for the largest share of total H_2 production costs with electrolysis. Wind and solar electricity are still more expensive than fossil fuel electricity today, despite reductions in costs for wind or solar electricity and escalations in costs for construction of fossil energy conversion facilities. A key point is that electrolytic H_2 could plausibly be competitive as a transportation fuel (via use in fuel cell vehicles) only if offpeak/low-cost electricity (regardless of source) is used to make H_2. But only a tiny fraction of transportation fuel demand (which globally is 1.6 times electricity generation) could be satisfied with H_2 from offpeak electricity (a small fraction of total electricity).

Hydrogen is not used as a transportation fuel today, but its attractions in this application include the potential for low emissions of local pollutants and of greenhouse gases, as well as the energy security benefits arising from being able to shift transportation from oil dependence. Such attractions have made research on distribution and end-use systems for H_2 as a transportation fuel the focus of important government research and development programs in the United States, China, and elsewhere beginning in the 1990s. However, these R&D efforts have brought recognition that there are still major challenges to be overcome in H_2 delivery infrastructure and end use before it can become a real option for the transportation sector (CASFHPU, 2004; Agnolucci, 2007; CARNFCHT, 2008). Here we limit our discussion to a review of technologies for hydrogen production.

Globally, natural gas is the most commonly used feedstock for hydrogen production (Consonni and Vigano, 2005; Rostrup-Nielsen, 2005), but hydrogen can also be made from coal (Chiesa et al., 2005; Kreutz et al., 2005), as is the predominant commercial practice in China. Hydrogen can also be produced from biomass in systems closely resembling those for coal conversion (Hamelinck and Faaij, 2002; Lau et al., 2002).

Figure 12.25 shows a simplified block flow diagram for hydrogen production from coal. Gasification technologies for production of CO and H_2-rich synthesis gas from coal and biomass have been discussed in Section

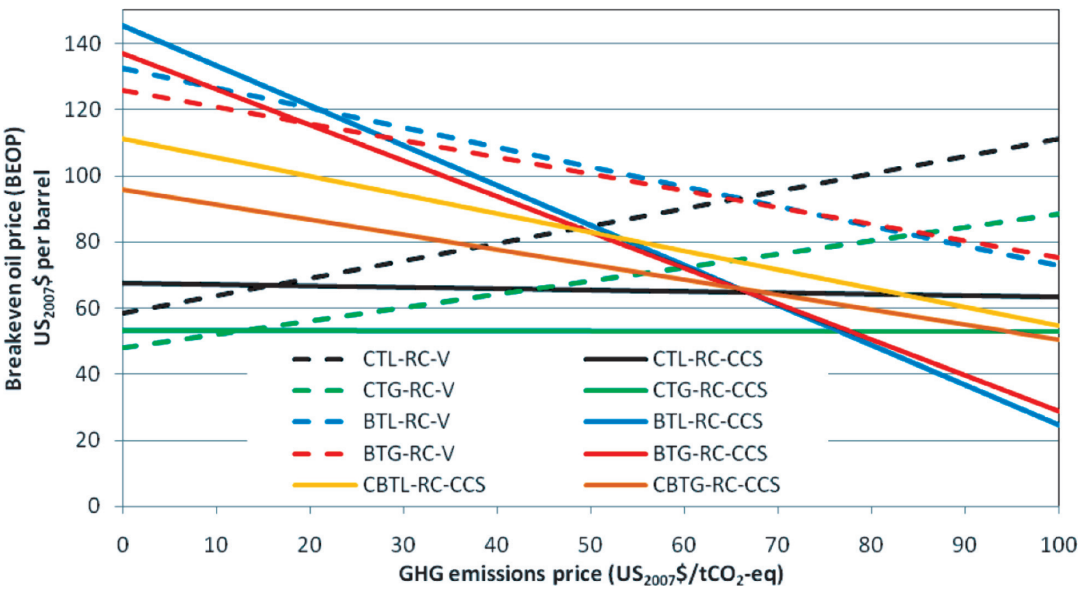

Figure 12.24 | Breakeven oil prices (US_{2007}) as a function of GHG emission price for coal, biomass, and coal/biomass conversion to FTL or MTG. (See Table 12.6, note (b) for financial parameter assumptions. Also, electricity sales are assumed at the US average grid price plotted in Figure 12.10.)

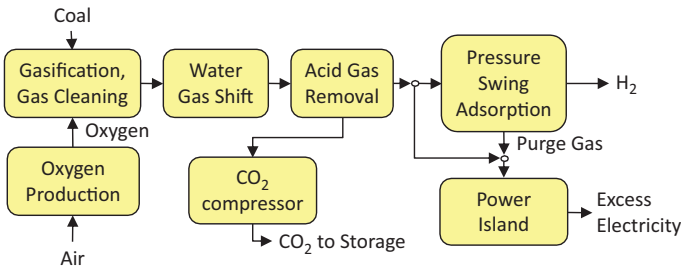

Figure 12.25 | Simplified process diagram for H_2 production from coal with CO_2 capture.

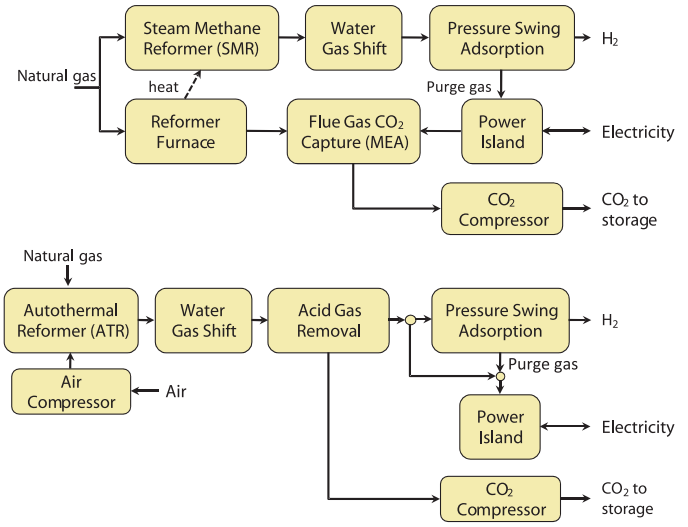

Figure 12.26 | Simplified process diagrams for H_2 production from natural gas via steam-methane reforming (top) or via autothermal reforming (bottom). When CO_2 is captured for storage (as shown), import of electricity may be required to meet on-site needs. Without CO_2 capture, there can be net electricity exports to the grid from the facility.

12.4.3.1. Gasification is followed by a water gas shift, after which sulfur species are removed to prevent poisoning of downstream catalysts. This presents a natural point for also removing CO_2 with little added capital cost. Acid gas removal using a physical solvent (e.g., methanol, as in the Rectisol process) would typically be used because of the elevated pressure of the gas mixture containing the acid gases. The captured sulfur is recovered from the solvent and converted, for sale or disposal, to elemental sulfur using the Claus/SCOT process. The captured CO_2 can be compressed for pipeline transport to an underground storage site. Following acid gas removal, the remaining hydrogen-rich stream is concentrated using pressure swing adsorption (PSA) technology to purity as high as 99.999%. Purge gases from the PSA, supplemented as needed by some syngas bypassing the PSA, are burned in the power island to provide the electricity needs of the plant and additional exportable power.

For hydrogen production from natural gas (Figure 12.26), syngas can be produced using any of several different reforming technologies (Rostrup-Nielsen and Rostrup-Nielsen, 2002). The two most common, SMR and ATR, have been discussed in Section 12.4.1.1. With natural gas conversion based on SMR (Figure 12.26, top), sulfur removal is not needed following the water gas shift, since any sulfur present in the methane input to the plant has been removed prior to the SMR to avoid poisoning the SMR catalyst. If CO_2 is to be captured for storage, this would most effectively be accomplished using an acid gas removal system on the flue gases from the power island and the reformer furnace. This design enables maximum CO_2 capture, because all flue gases are collected before CO_2 removal. However, the low-pressure of the CO_2 in the flue gases requires using a chemical solvent (such as MEA) to effectively capture the CO_2. The work to subsequently compress the captured CO_2 for pipeline transport will be higher than in the systems producing hydrogen using ATR, for which the CO_2 is available at a higher starting pressure. For a system using ATR (Figure 12.26, bottom), capture of CO_2 would take place after the water gas shift using a physical solvent, such as Rectisol.

Table 12.17 summarizes comparative mass and energy balance simulation results developed for this chapter for hydrogen production. It is based on detailed system designs represented in simplified form in Figures 12.25 and 12.26. For designs that capture CO_2, the overall energy efficiency of coproducing hydrogen and electricity is 67% with coal and 74% with natural gas. The efficiency penalty for systems that capture CO_2 compared with systems that vent the CO_2 is largest for the natural gas case using SMR (Figure 12.26, upper). This is due to the substantial heat required to liberate the dissolved CO_2 from the solvent used to capture it. The heat is provided as steam extracted from the power island, which reduces the on-site power generation significantly. Natural gas conversion using the ATR also requires some net import of electricity due to the substantial power requirements for air separation and CO_2 compression.

Capital and operating cost estimates for the systems described in Table 12.17 are provided in Table 12.18 using the same framework and component capital cost database as for systems described in Sections 12.4.3 and 12.6. Hydrogen production costs using natural gas, despite the considerably lower capital cost intensity compared with coal designs, are nevertheless higher than for coal due to the much higher assumed feedstock prices. Production costs with natural gas are also higher in the CCS cases due to the need to purchase electricity to operate the facility rather than selling excess electricity to the grid.

The final row of Table 12.18 shows the avoided cost of CO_2 emissions when CCS is considered. The avoided cost for coal is modest (US$11/$tCO_2$-eq) because capturing the CO_2 at these plants involves only adding a CO_2 compressor. The situation is similar for the natural gas system using ATR, but the avoided CO_2 cost is higher than for a coal-CCS design of comparable scale because the added cost includes that for acid-gas capture in addition to a CO_2 compressor. (The cost for acid gas removal is modest because only half as much CO_2 must be captured as in the coal case due to the lower carbon intensity of natural gas.) In the SMR design for natural gas, costs for the added equipment to capture dilute CO_2 from flue gases and compress it are charged against the CO_2, leading to relatively higher avoided costs.

b Results based on performance simulations of Zhang, 2005.
c GHGI, the greenhouse gas emissions index, is the system wide life cycle GHG emissions for production of H_2 and electricity relative to emissions from a reference system producing the same amount of H_2 and electricity. The reference system consists of large-scale centralized H_2 production by steam reforming of natural gas, with lifecycle emissions of 9.22 $kgCO_2$-eq/kgH_2 (NRC, 2004), plus electricity from a supercritical pulverized coal power plant with GHG emissions rate of 830.5 $kgCO_2$-eq/MWhe.
d In the GHGI calculation, net electricity consumed in these process designs is charged 830.5 $kgCO_2$-eq/MWhe. All other designs in this table have net exports of electricity.

Cost of avoided CO_2, US_{2007}/tCO_2ed	–	11	–	47	–	17

a Component costs are based on Liu et al., 2011a, except for: SMR (Simbeck, 2004); ATR (Simbeck and Wilhelm, 2007); MEA system (Kreutz et al., 2005; Woods et al., 2007).

b In the case of N.gas SMR with CCS, only the WGS cost is included in this line since acid gas removal is done via MEA (separate cost line) and no sulfur treatment via Claus/SCOT is needed.

c See note (b) of Table 12.6 for financial parameter assumptions.

d Levelized H_2 production cost for system with CCS minus that for system without CCS, divided by the difference in system-wide life cycle emissions of CO_2-eq/GJ_{LHV} of H_2 (given in Table 12.17).

Figure 12.27 plots hydrogen production costs as a function of the price of greenhouse gas emissions. Coal provides the least costly low-GHG hydrogen (US$10–12/$GJ_{LHV}$) in the system with CCS for a GHG emission price above US$10/$tCO_2$-eq.

An important final comparison is between the costs of hydrogen production with CCS and those for low-GHG liquid fuels. For GHG emission prices from US$0–100/$tCO_2$-eq, the lowest production costs for low-GHG liquid fuels are with systems that coproduce liquids and power (see Section 12.6). Liquid fuel costs from such systems are $US15–17/$GJ_{LHV}$ depending on the GHG emissions price (see Figure 12.36). This is higher than the US$10–12/$GJ_{LHV}$ estimated for hydrogen (Figure 12.27). But use of hydrogen for transportation will require new delivery and refueling infrastructures, as well as new vehicle technologies, unlike for petroleum-like liquid fuels.

Cost estimates in the literature for new infrastructure in the United States delivering H_2 from centralized production facilities to vehicle fuel tanks are much higher than for new infrastructure for liquid fuels. Published hydrogen infrastructure cost estimates include $US_{2007}$$14–16/GJ_{LHV} (Ogden et al., 2004), $US_{2007}$$9–20/GJ_{LHV} (Mintz et al., 2002), and $US_{2007}$$44/GJ_{LHV} (Simbeck, 2003). Compared to these costs, the new-infrastructure costs for delivery of liquid fuels, particularly petroleum-like fuels, would be small. Moreover, in the industrialized countries, the investment in a full liquid fuel infrastructure has already been made. Thus, when production and delivery infrastructure costs are considered together, delivered hydrogen costs would be significantly higher than delivered costs for liquid fuels.

Beyond questions around fuel delivery infrastructure, it remains uncertain when the cost of hydrogen fuel cell vehicles, which have been the focus of considerable development efforts over the past two decades, can be reduced to competitive levels. One study (IEA, 2009a) estimates that in the near term the GHG emissions price needed to induce by market forces a shift to hybrid fuel cell vehicles is more than US$1000/$tCO_2$-eq when the crude oil price is US$60/bbl and almost US$800/t with US$120/bbl of crude oil. The major technical challenges for fuel cell vehicles are difficulties of onboard H_2 storage due to its low volumetric energy density and high projected costs for fuel cell engines (in part due to platinum requirements). These challenges may not be insurmountable, but overcoming them will require time and sustained large government investments in R&D (CARNFCHT, 2008).[12] Thus, it is likely to be many decades before H_2 fuel cell vehicles will be in a position to make significant contributions toward reducing GHG emissions.

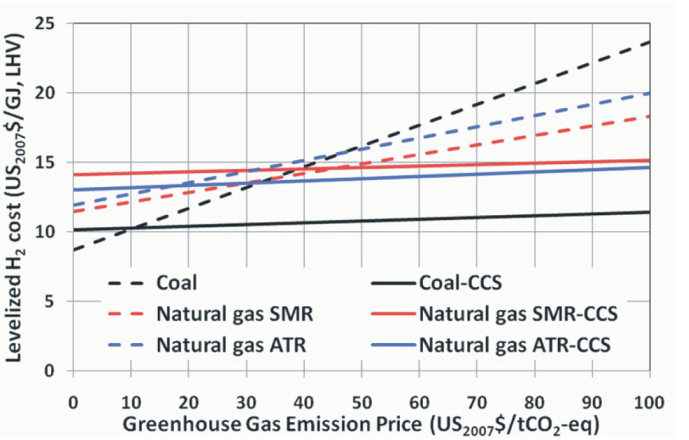

Figure 12.27 | Levelized hydrogen production costs as a function of GHG emissions price. (See Table 12.6, note (b) for financial parameter assumptions. Also, electricity sales are assumed at the US average grid price plotted in Figure 12.10.) Source: based on Simbeck, 2004; Simbeck and Wilhelm, 2007; Liu et al., 2011a.

12.5 Clean Household Fuels Derived from Non-petroleum Feedstocks

Studies have shown that human welfare, as measured by the Human Development Index (HDI), increases with diminishing returns as the level of modern energy services provided increases (WEA, 2004). The HDI increase is especially large for provision of the first increments of modern energy carriers to satisfy basic needs such as cooking and heating, for which demand is very inelastic (cooking and boiling water are essential for survival). There is wide recognition of the importance of the role that electricity plays in economic development and the fact that more than a billion people do not have access even to the minimal amounts of electricity required to satisfy basic needs. Similarly, it is recognized that there are nearly three billion people who cook their food today using traditional open fires inside their homes, suffering considerable health damages in the process (see Hutton et al., 2006 and Chapters 4, 17, and 19).

Fluid hydrocarbon fuels offer a much cleaner means of providing cooking services than solid fuels (Smith, 2002). Moreover, fluid fuels enable much higher efficiency (Dutt and Ravindranath, 1993) and controllability than cooking with solid fuels.[13] Historical real data confirm the gains from efficiency and controllability (Figure 12.28). Such gains along with consideration that a shift to cooking with clean fuels leads to demands on a global basis that are relatively small compared to energy demands for other purposes, means that a relatively small amount of fluid fuel would be sufficient to replace all current solid fuel used for cooking.

12 Waning enthusiasm for addressing these challenges was evident in the Obama Administration's proposed 2010 Department of Energy (DOE) budget, which included a cut in the federal hydrogen fuel cell research and deployment budget by more than two thirds, eliminating funds for the H_2 fuel cell vehicle program and market transformation programs.

13 Consider LPG stoves. Not only are they much more energy-efficient than biomass stoves, but also an LPG stove can be instantly turned on and off with the demand for cooking services, whereas a biomass stove must be started up long before cooking begins and continue burning long after cooking stops. Of course, the continued burning of biomass after a meal is cooked in the evening may often be for lighting. This implies that, if LPG is to be substituted for biomass for cooking, this cooking fuel switch should often be accompanied by the introduction of alternative means for lighting.

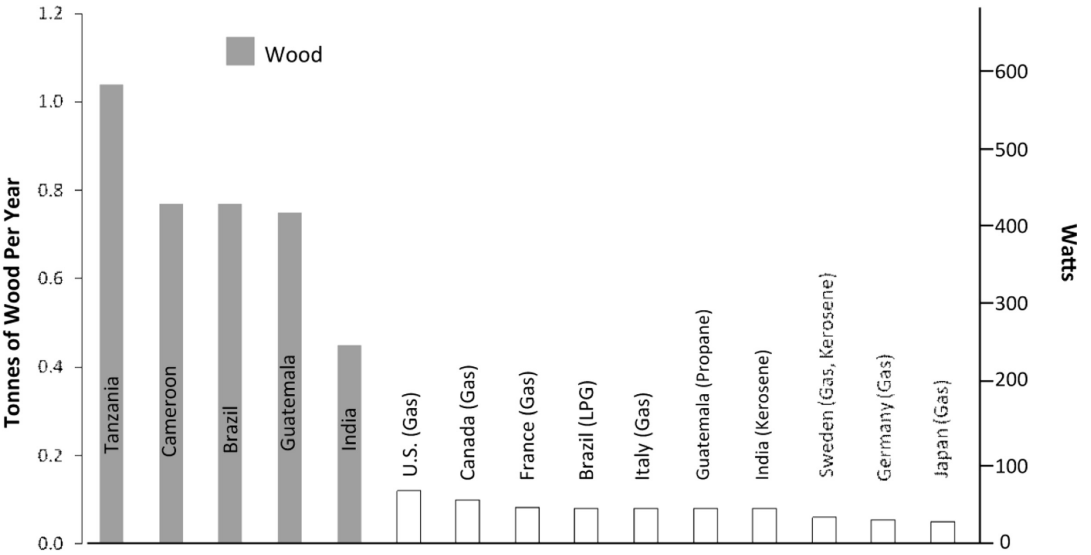

Figure 12.28 | Per capita energy use rate for cooking in the early 1980s. For both wood stoves and stoves burning high-quality energy carriers, the per capita energy use rate is in Watts; for wood fuel, the rate is also in t/yr of dry wood. (Assuming 1 tonne = 18 GJ, 1 t/yr = 570 Watts). Source: Goldemberg et al., 1985.

For perspective, suppose that all three billion people currently using solid fuels for cooking were instead to use liquefied petroleum gas (LPG) at an estimated average needed rate of 25 kg/capita/yr (36 W/capita).[14] The total annual requirement would be 3.4 EJ/yr, or 1.3% of current total global oil and gas consumption.

A shift from solid to fluid fuels for cooking would yield substantial public benefits in terms of improved public health and time saved not spent collecting solid fuels, which would make time available to pursue educational and other opportunities (see Chapter 4). Another benefit would be reduced deforestation, to the extent that some biomass collected for cooking is removed unsustainably from forests.

Such considerations have led to proposals for concerted global efforts to replace solid cooking fuels with clean fluid fuels worldwide (Goldemberg et al., 2004; IEA, 2006; WHO, 2006; GACS, 2011).

Concerns about rising costs of and overdependence on petroleum imports have created interest in alternatives to petroleum-derived fluid cooking fuels such as kerosene and LPG. This section discusses production systems for expanding clean fluid cooking fuel supplies. It considers the use of synthetic fluid fuels (synthetic LPG and DME) derived via gasification of coal and/or biomass, without and with carbon capture and storage. Coal and biomass are the most widely available feedstocks in regions where solid fuels are now used for cooking. DME as a cooking fuel could also be made from natural gas (Naqvi, 2002). The growing optimism that shale gas might prove to be widely available (see Section 12.7.2.2) suggests also giving close attention to DME derived from natural gas for cooking, though this topic is not covered here.

12.5.1 Dimethyl Ether from Coal

Dimethyl ether is a colorless gas at ambient temperature and pressure, with a slight ethereal odor. It requires mild pressurization, similar to that required for LPG, to be stored as a liquid. It burns with a clean blue flame over a wide range of air/fuel ratios. It can be used as a diesel engine fuel (Semelsberger et al., 2006) or blended with LPG for use as a household or commercial sector fuel. In the latter application, the focus of the discussion here, the DME can be blended up to about 25% by volume without the need to change end-use combustion equipment. Table 12.19 compares some physical properties of DME with those of the two main constituents of LPG.

Until recently, DME was used primarily as an aerosol propellant in hair sprays and other personal care products and was produced globally at a rate of about 150,000 t/yr (Naqvi, 2002).This production level has increased dramatically in the past few years, with the added DME being used primarily as an LPG supplement for household use. The increase has been most substantial in China, where an estimated total DME production capacity of nearly 14 Mt/yr from coal have recently commenced production or construction, and a comparable amount of additional capacity is at various planning, feasibility, or engineering stages (Zheng et al., 2010).

Production of DME from synthesis gas is similar in many respects to synthesis of methanol, a well-established commercial process. In fact, a key step in the synthesis process is catalytic synthesis of methanol, followed

14 In a spreadsheet accompanying the World Health Organization paper (Hutton et al., 2006) that was made available to the authors, estimates were developed by this WHO group of the LPG that would be required to replace direct use of biomass for cooking in regions throughout the world. Worldwide the average per capita amount of LPG needed annually was estimated to be 24.6 kg, but this rate varies from an average of 14.3 kg for Africa, to 25.6 kg for the region including India, to 29.3 kg for the region including China, to 47.0 kg for the region including Brazil.

Table 12.19 | Physical properties of DME, propane, and butane.

	DME	Propane	Butane
Boiling point (°C)	–24.9	–42.1	–0.5
Vapor pressure ant 20°C (bar)	5.1	8.4	2.1
Liquid density at 20°C (kg/m³)	668	501	610
Lower heating value (MJ/kg)	28.4	46.4	45.7
Auto-ignition temperature at 1 atm pressure (°C)	235 – 350	470	365

Source: Larson and Yang, 2004.

by dehydration of methanol to form DME: $2CH_3OH \leftrightarrow CH_3OCH_3 + H_2O$. Methanol can be synthesized at one plant location and transported to another location where dehydration can be done. This is how most DME has historically been produced. Alternatively, methanol and dehydration plants can be integrated at a single facility. Moreover, technology is now available for a single-step synthesis of DME from syngas: some methanol synthesis catalyst and some dehydration catalyst are used together in the same reactor so that methanol is dehydrated as it forms. The single-step synthesis chemistry can be represented as follows: $3CO + 3H_2 \leftrightarrow CH_3OCH_3 + CO_2$. This approach gives rise to higher yields than the traditional two-step process and so is likely to be the technology of choice in the future.

Figure 12.29 illustrates one possible process arrangement for converting coal to DME. Coal is gasified in oxygen to produce a raw syngas that is cooled and cleaned before having its H_2:CO ratio adjusted in a water-gas-shift reactor (using a sulfur-tolerant catalyst) to an optimum value for subsequent catalytic synthesis of DME. The synthesis step can use a recycle of unconverted gas to increase DME production or a single-pass of the gas through the synthesis reactor ("once-through" design). The unconverted gas can be burned in a gas turbine/steam turbine combined cycle to generate coproduct electricity. Removal of CO_2 is an essential part of the DME production process, since excess CO_2 reduces the efficiency of the downstream synthesis step and would also necessitate larger downstream equipment. The captured CO_2 can be released to the atmosphere or compressed for pipeline transport and underground storage.

Celik et al. (2004), building on work by Larson and Ren (2003), present detailed process designs and production costs for large-scale single-step "once-through" DME synthesis systems starting with coal as the feedstock. Designs with and without CCS were analyzed (Table 12.20). For the design labeled "UCAP" (shorthand for "upstream CO_2 capture"), CO_2 for storage is captured upstream of the DME synthesis area (as depicted in Figure 12.29). Only about 30% of the carbon in the coal feedstock is captured in this case. Nearly 70% of the carbon is released to the atmosphere as flue gas from the power island and when the product DME is burned. For the systems labeled DCAP (shorthand for "downstream plus upstream CO_2 capture"), additional CO_2 is removed by subjecting the unconverted syngas after synthesis to varying levels

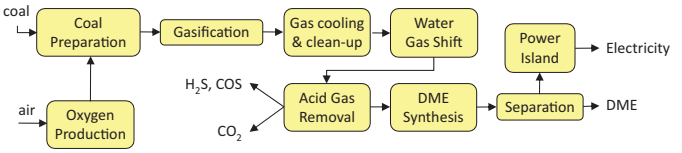

Figure 12.29 | Process steps for DME production from coal.

of water gas shift before the power island. In the case with the highest amount of CO_2 capture (DCAP-3), nearly 80% of the carbon in the coal is captured.

The GHGI, defined in Table 12.20 note (b), without CCS is 1.3. The UCAP design reduces this to 0.94. With more aggressive CCS (DCAP designs), greenhouse gas emissions can be reduced to less than 50% of the reference system emissions. The cost of avoided CO_2 emissions relative to the VENT design are modest for the UCAP case (last row, Table 12.20), since the cost of capture is an intrinsic part of the DME production process regardless of whether CO_2 storage is contemplated. Costs of avoided CO_2 emission are higher for the DCAP designs because the cost for the additional CO_2 capture equipment is fully charged to CO_2 capture.

The added capture equipment also leads to higher DME production costs. For US conditions, with the financial assumptions noted in Table 12.20 (note d), the VENT design produces DME at an estimated cost of US$423/tLPG-eq, corresponding to a breakeven crude oil price (BEOP) of about US$40/bbl. The BEOP is only slightly higher for the UCAP case, but significantly higher for the DCAP cases, reaching US$81/bbl for the DCAP-3 design. Larson and Yang (2004) estimate that costs of DME production in China today might be 15% lower than these estimates for US conditions.

12.5.2 Synthetic LPG from Coal and/or Biomass

Clean cooking fuels can also be produced from coal and/or biomass via the F-T or methanol-to-gasoline processes described in Section 12.4.3. The designs discussed there are for production of synthetic transportation fuels as the primary products, but significant quantities of C3 and C4 hydrocarbons are produced as intermediate or final products. In either system, these lighter hydrocarbons can be separated from the heavier transportation fuel products for sale as synthetic LPG.

For the design of the F-T systems described earlier, it was assumed that the light hydrocarbon fraction was consumed internally as a component of the fuel gas for the power island. Alternatively, the lighter fraction could have been separated as an additional coproduct. The raw synthesis product can contain as much as 20% by weight of C3 and C4 compounds that constitute synthetic LPG.

Table 12.20 | Performance and cost (US_{2007}) estimates for DME production from coal with different levels of CCS. "UCAP" refers to designs with CO_2 removal upstream of DME synthesis (as in Figure 12.29). "DCAP" refers to designs that additionally capture some CO_2 downstream of synthesis. Three alternative downstream capture designs are considered. See Celik et al. (2004) for details.

a Including emissions associated with coal mining and delivery (1.024 kgC-eq/$GJ_{COAL,LHV}$), emissions at the conversion plant, and emissions from combustion of the DME.

b GHGI, the greenhouse gas emissions index, is the system wide life cycle GHG emissions for production of DME and electricity relative to emissions from a reference system. The reference system consists of LPG from conventional sources, with estimated lifecycle emissions 86 $kgCO_2$/GJ_{LHV}, plus electricity from a supercritical pulverized coal power plant with GHG emissions rate of 830.5 $kgCO_2$-eq/MWhe.

c Converted from US_{2003} in Celik et al. (2004) to US_{2007} using the Chemical Engineering Plant Cost Index.

d Assuming 7% interest during construction, 15% per year capital charge, 80% capacity factor, annual O&M cost of 4% of overnight capital cost, coal cost of US$2.04/GJ, electricity revenue of US$60/MWh (the 2007 US average generator sale price), and CO_2 transport and storage cost of US$15/$tCO_2$, and zero GHG emissions price.

e A linear regression of monthly wholesale propane price and refiner acquisition cost for crude oil in the United States for the period October 1990 to March 2009 US EIA, 2009b gives the following correlation: Propane price (US$/gallon) = 0.0168 * (US$/bbl_{oil}) + 0.133 [R^2 = 0.92]. Assuming the propane density given in Table 12.19, the breakeven oil price in US$/bbl is (US$/$t_{propane}$ – 70.13) / 8.87. We assume this correlation holds equally for LPG.

f This is the difference in US$/$GJ_{LHV}$ levelized cost of DME production with CO_2 capture and the VENT design divided by the difference in system-wide life cycle emissions of CO_2-eq/GJ_{LHV} of DME.

Table 12.21 | Key features of alternative process designs for producing synthetic gasoline and LPG from coal and/or biomass.

Process description[a]	Output capacities		LPG output (10^6 kg/y)	TPC (millionUS_{2007})	Biomass fraction (HHV)	Biomass input (10^6 dt/y)	CO_2 storage rate (10^6 t/y)	CCS primary energy penalty (%)	GHGI[b]
	Gasoline (bbl/day)	Electricity (MW_e)							
CTG-PB-V	32,579	959	125	4,110	0	0	0	–	1.37
CTG-PB-CCS	32,579	760	125	4,310	0	0	10.2	9.8	0.56
CBTG1-PB-CCS	32,579	782	123	4,526	0.1	0.99	10.3	9.5	0.40
CBTG-PB-CCS	11,582	292	42.2	2,086	0.29	1.0	3.7	8.9	0.098
BTG-RC-V	2,315	16.0	8.72	475	1.0	0.5	0	–	0.066
BTG-RC-CCS	2,315	10.2	8.72	482	1.0	0.5	0.513	5.7	– 1.07

a CTG = coal to gasoline+LPG; CBTG = coal+biomass to gasoline+LPG; CBTG1 = coal+biomass to gasoline+LPG with reduced biomass fraction; BTG = biomass to gasoline+LPG; PB = partial bypass of syngas around synthesis island for use in power island; RC = recycle of unconverted syngas to maximize liquids production; V = venting of CO_2; CCS = carbon capture and storage.

b GHGI, the greenhouse gas emissions index, is the system wide life cycle GHG emissions for production and consumption of the energy products relative to emissions from a reference system producing the same amount of liquid fuels and electricity. The reference system consists of electricity from a stand-alone new supercritical pulverized coal power plant venting CO_2 plus equivalent crude oil-derived liquid fuels. For details, see Table 12.15, note (c).

For the MTG systems described in Section 12.4.3, a synthetic LPG coproduct is produced, equivalent to about 10% of the synthetic gasoline output (LHV energy basis, see Table 12.15). Systems such as this one might contribute to addressing the challenge of providing universal access to clean cooking fuels, as discussed in the next section.

12.5.3 Co-providing synthetic cooking and transport fuels in the context of a carbon mitigation policy

Increasing conventional LPG use to meet the basic cooking fuel needs of those currently cooking with solid fuels would make a relatively small total energy impact and GHG emission impact. As such, one might argue that meeting the critical energy needs of the energy poor should not be constrained by a requirement that access to energy be provided in a manner consistent with simultaneously mitigating the climate change impacts of the cooking fuel consumed.

In some cases, however, a strong carbon mitigation policy may actually improve the prospects for providing clean energy to satisfy basic cooking needs. This judgment is illustrated here by considering the technology (Table 12.21) and economics (Figure 12.30) of six MTG process designs. Figure 12.30 shows that for five of these systems the economics improve with GHG price. These five systems (four of which involve CCS[15] and four of which involve biomass) all offer substantial reductions in GHG emission rates relative to the crude oil derived products (CODP) and PC-V coal electricity displaced (see final column in Table 12.21). The two pure biomass designs in this table have been discussed in Section 12.4.3. The other four designs, which involve the generation of electricity as a major co-product, are described in Section 12.6.

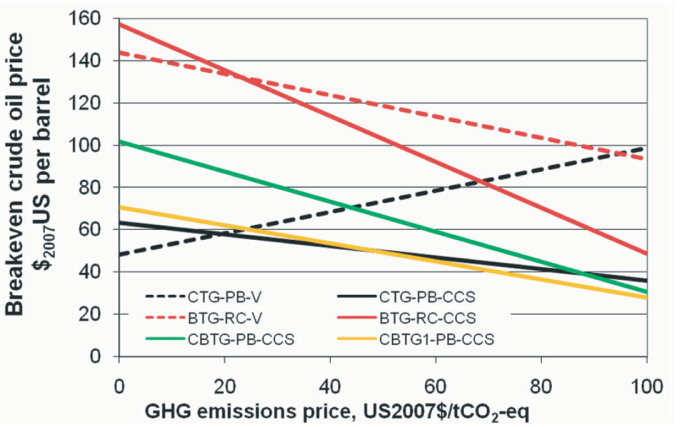

Figure 12.30 | Breakeven crude oil price (BEOP) as a function of the GHG emissions price for the MTG options described in Table 12.21. (See Table 12.6, note (b) and Table 12.16, note (b) for financial parameter and other assumptions. Electricity sales are assumed at the US average grid price plotted in Figure 12.10.)

Key observations can be made about the relative economics of the six MTG options:

- CTG-PB-CCS is a coal-only option offering a 44% reduction in system-wide GHG emissions relative to the CODP and PC-V electricity displaced. It offers less costly gasoline than the GHG-emissions-intensive CTG-PB-V for GHG emissions prices greater than US$20/$tCO_2$-eq.
- CTG-PB-CCS and CBTG1-PB-CCS (an option with biomass accounting for 10% of input energy offering a 60% reduction in system-wide

15 For all CCS options it is assumed that the captured CO_2 is compressed to 150 bar, transported 100 km, and stored 2 km underground in a deep saline formation via wells for which the maximum injectivity is 2500 tonnes per well per day.

GHG emissions) are both competitive as gasoline providers when crude oil is US$70/bbl at zero GHG emissions price.

- CBTG1-PB-CCS offers less costly gasoline than both CTG-PB-V and CTG-PB-CCS for GHG emissions prices greater than US$50/$tCO_2$-eq.
- CBTG-PB-CCS is an option with biomass accounting for 30% of input energy offering a 90% reduction in system-wide GHG emissions. It could provide gasoline at the least cost of all the options shown at GHG emissions prices greater than about US$100/$tCO_2$-eq.
- BTG-RC-CCS is an option for which biomass accounts for 100% of input energy offering strongly negative GHG emissions. It could provide less costly gasoline than gasoline derived from US$90/bbl of crude oil at GHG emissions prices greater than US$62/$tCO_2$-eq.
- BTG-RC-V can provide less costly gasoline than gasoline derived from US$90/bbl of crude oil at GHG emissions prices greater than US$106/$tCO_2$-eq.
- BTG-RC-CCS can provide less costly gasoline than BTG-RC-V at GHG emissions prices greater than US$23/$tCO_2$-eq.[16]

Analysis in the *World Energy Outlook* 2009 (IEA, 2009b) is helpful in understanding the relative competiveness of alternative technologies in Table 12.21 in a world with high oil prices and policies that constrain GHG emissions. The *Outlook* considers the current situation regarding carbon trading and analyzes prices for crude oil and for GHG emissions for a world on a path toward ultimate stabilization of GHG concentrations in the atmosphere at 450 ppmv. The IEA estimates for its 450 ppmv stabilization scenario that: (i) the world oil price would be stable during 2020–2030 at US$90/bbl (considerably lower than the oil price in this period for the IEA Reference Scenario), (ii) if there were separate emissions trading regimes for OECD+ countries and for other major economies (China, Russia, Brazil, South Africa, Middle East), the GHG emissions price would rise from US$50/t to US$110/t in OECD+ countries between 2020–2030 and would reach US$65/t in other major economies by 2030; and (iii) if there were a single global carbon market for emissions trading, the global GHG emissions price would be US$70/t by 2030.

Thus under such carbon policy constraints, well before 2030, the processes of CTG-PB-CCS and CBTG1-PB-CCS would become cost competitive in both OECD+ and Other Major Economies. Also, CBTG-PB-CCS technologies would be cost-competitive in the post-2030 time frame in OECD+ countries. Early experience, prior to 2030, with widespread deployment of CTG-PB-CCS and CBTG1-PB-CCS technologies in coal-rich regions such as the United States and China would establish in the market all the technological components needed for subsequent deployment of CBTG-PB-CCS in coal-rich regions and BTG-RC-CCS in coal-poor but biomass-rich regions. The economic prospects for BTG-RC-V are not auspicious, although the BTG-RC-CCS option is prospectively economically viable in coal-poor but biomass-rich regions in the period after 2030 where there is adequate CO_2 storage capacity and emissions trading opportunities. For example, when the crude oil price is US$90/bbl, when coal coprocessing is not a realistic option, and the emissions trading price is US$70/t the BTG-RC-CCS option would be highly competitive.

12.5.3.1 Two Thought Experiments

Two thought experiments are presented here, one for China (a coal-rich region) and one for Africa (a biomass-rich but coal-poor region). In this experiment, both regions are under a carbon policy constraint. The discussion focuses on the strategic linkages between providing fuels/electricity for transportation on the one hand, versus providing LPG to satisfy basic human needs for cooking on the other hand.

China

Why China? China is a good candidate for early deployment of CTG-PB-CCS and CBTG1-PB-CCS technologies to make simultaneously liquid fuels for transportation and LPG for cooking. There are many reasons:

- China is a coal-rich country, accounting for more than 70% of coal use by developing countries in 2007 (IEA, 2009b).
- China has a strong coal gasification-based chemical process industry (making gasoline is very much like making chemicals via coal gasification).
- China already has experience with CTG technology. A demonstration plant producing 2600 barrels of gasoline per day came online in 2009, built by Uhde for the Shanxi Jincheng Anthracite Coal Mining Co. Ltd. This plant uses the ExxonMobil methanol-to-gasoline process and is coupled to a fluidized bed hard coal gasifier and a plant for making methanol from coal via gasification.
- Potential demand for clean cooking fuels in China is huge. Hundreds of millions of Chinese still cook with solid fuels.
- As a large food producer, China has substantial crop residue resources that could be used for energy purposes.[17]

16 This breakeven GHG emissions price for shifting from the V to the CCS variant of the BTG-RC option is higher than the US$20/$tCO_2$-eq indicated for this pair of options in Figure 12.24 because in the present case the assumed biomass input rate is half as large.

17 Prospective crop residue supplies in China have been estimated by Li et al. (1998), who estimate that crop residue supplies potentially available for energy applications in China in 2010 were 376 million dry t/yr.

- China is a good candidate for pursuing synthetic transportation fuels derived from secure domestic coal and biomass supplies because its domestic oil supplies are scarce and its demand for liquid fuels for transportation is rapidly growing.

- The coproduction approach to CCS, which offers low energy and water penalties and low capture costs, may be perceived as an attractive approach for reducing coal-related GHG emissions in China.

The thought experiment: To illustrate the possibilities for early action for coal-based technologies, suppose that in China in the period prior to 2030 enough MTG plants are built to provide LPG sufficient to meet the needs of the 1.06 billion people that were cooking with solid fuels as of 2001.[18]

Assumptions: It is assumed that during this period the carbon policy in China becomes sufficiently stringent to warrant deployment of both CTG-PB-CCS and CBTG1-PB-CCS systems. Furthermore, it is assumed that a mix of these two technologies is deployed such that on average gasoline, LPG, and electricity are provided at one half the GHG emission rate of the CODP and PC-V electricity displaced. This implies that 62% of the capacity would be CTG-PB-CCS plants and 38% would be CBTG1-PB-CCS plants (so that, on average, biomass accounts for 3.8% of primary energy input).

Findings: The system-wide features of this combination of plants would yield 100% satisfaction of the need for clean cooking fuels and a 50% reduction in GHG emissions relative to the energy products displaced. In addition, the features would be the following:

- the required investment (Total Plant Cost (TPC)) would be US$1.1 trillion ($US_{2007}$);

- synthetic gasoline would be produced at a rate of 13.5 EJ/yr (322 Mtoe/yr or 66% of projected transportation energy demand in China in 2030 (IEA, 2009b);

- electricity would be produced at a rate of 1516 million MWh/yr (67% of projected increase in coal electricity generation in China, 2015–2030 (IEA, 2009b);

- the biomass required is 95 Mt/yr dry biomass or 25% of prospective crop residue supplies available for energy in China;[17]

- CO_2 would be stored in deep geological formations at a rate of 2.57 Gt/yr.

This coproduction approach also would offer significant advantages relative to provision of the same energy products via use of CTG-RC-CCS (a coal-only design that maximizes gasoline output) plants plus CIGCC-CCS plants to provide the electricity needed in excess of what can be provided by the CTG-RC-CCS plants. Relative to the case with production in separate facilities, the coproduction with coal/biomass coprocessing approach would involve comparable total investment, total primary input, and CO_2 storage requirements, but would generate 15% less GHG emissions. Moreover, when evaluating the coproduction system as an electricity generator, the levelized cost of electricity at crude oil and GHG emissions prices of US$90/bbl and US$65/tCO_2-eq, respectively, would be only 14% as large as for a 2028 MW_e CIGCC-CCS plant having the same primary energy input as the average coproduction unit that provides 768 MW_e of electricity. The reasons for the outstanding economic performance of coproduction plants evaluated as electricity generators compared to stand-alone power plants are discussed in Section 12.6.3.

Africa

Why Africa? The region of Africa is a good candidate for deployment of BTG-RC-CCS technology in the 2030+ time frame. There are many reasons:

- Much of Africa is biomass-rich but coal-poor (except for Botswana and South Africa).

- Much of Africa is economically poor and in need of industrial development such as that which BTG-RC-CCS technology could help provide.

- Africa has a huge population in need of clean cooking fuels, with some 710 million people (Hutton et al., 2006) dependent on solid fuels for cooking.[19]

- Much of Africa must spend precious export earnings on fuels for transportation as well as on LPG for cooking and thus stands to benefit economically from having a domestic BTG-RC-CCS synfuels industry.

- Preliminary indications are that there might be significant CO_2 storage opportunities in Africa (see Chapter 13).

- Although at low GHG emissions prices it would make more economic sense for biomass-rich/coal-poor countries to import coal and make gasoline by coprocessing coal and biomass, biomass to gasoline plants would become more cost competitive at high GHG emissions prices.[20] So, if there were a reasonable expectation of such high GHG emissions prices in the future, perhaps before 2050, such

18 Following the findings of Hutton et al., (2006) it is assumed that the average per capita LPG requirement for China is 29.3 kg/yr (43 Watts).

19 In 2006 biomass used for cooking in the developing world (assumed to be total biomass use for energy, minus biomass used for power generation, minus industrial use of biomass, and minus biomass used to make transport fuels) was 229 Mtoe (9.6 EJ) in Africa, 224 Mtoe (9.4 EJ) in China, 131 Mtoe (5.5 EJ) in India, 142 Mtoe (6.0 EJ) in other non-OECD Asia, and 32 Mtoe (1.3 EJ) in Latin America (IEA, 2008b). Thus Africa accounted for about 30% of global biomass use for cooking in 2006.

20 If the competition were between CBTG-PB-CCS and BTG-RC-CCS plants each consuming 0.5 million dry tonnes of biomass annually, the BTG-RC-CCS option would provide gasoline at a lower levelized cost of fuel when the GHG emissions price is greater than US$108/$tCO_2$-eq.

countries might be reluctant to make such coal-related infrastructure investments.

The thought experiment: A thought experiment is presented that envisions widespread deployment of BTG-RC-CCS technology in Africa in the 2030+ time frame.

Assumptions: The following conditions are assumed:

- Before 2030 all the needed technological components are established in the market somewhere in the world via earlier widespread deployment of CTG-PB-CCS and CBTG1-PB-CCS technologies (e.g., as described in the previous China thought experiment).
- The GHG emissions price is high enough (greater than US$62/tCO$_2$-eq) that BTG-RC-CCS is able to sell gasoline that is competitive with gasoline derived from US$90/bbl of crude oil (see Figure 12.30).
- There are concerted multilateral activities prior to 2030 aimed at: (i) identifying geological CO$_2$ storage opportunities in Africa's biomass-rich regions; (ii) identifying prospective biomass supplies that can be provided on a sustainable basis (avoiding supplies that involve deforestation, destruction of soil carbon stores, and competition with food production); (iii) building in currently economically poor, biomass-rich regions the physical infrastructures and human capacity needed to support rapid development of a BTG-RC-CCS industry.
- BTG-RC-CCS plants are deployed at modest scales to keep biomass supply logistics and CO$_2$ infrastructure challenges from being too daunting—producing gasoline at a scale ~2300 bbl/day, processing only 0.5 Mt/yr of dry biomass, and storing underground only 0.5 Mt/yr of CO$_2$, see Table 12.21. To get a sense of the scale of the activities, consider that Campbell et al. (2008) have estimated for tropical regions that yields for growing mixed prairie grasses on abandoned cropland in tropical regions are 7–20 dry t/yr-hectare. For these yields the amount of land required to serve a single biofuels plant is 250–714 km^2. The average biomass transport distance is 30–50 km if the biomass is available on 20% of the land around the plant and 40–70 km if the biomass is available on only 10% of the land.
- For the thought experiment it is assumed that the amount of biomass available for prospective BTG-RC-CCS plants is the same as the actual estimated amount of biomass that was used for cooking in 2006 (229 Mtoe/yr = 9.59 EJ/yr).[19] If this much biomass were grown as an energy crop at a yield of 7–20 dry t/hectare-yr, some 27–78 million hectares would be required for all of Africa. To put this into perspective, Cai et al. (2009) estimates that worldwide the amount of land available for growing biomass for energy on both abandoned and/or degraded cropland and grassland, savanna, and shrubland with marginal productivity suitable for use with low-input high diversity prairie grasses as energy crops is 1343 million ha of which one third to one half (450–670 million hectares) is in Africa.[21]

Making cooking with LPG affordable: The analysis below explores prospects for earning income that current users of biomass for cooking might pursue. They could sell their biomass to "biomass-supply-logistics" agents, who would in turn make the biomass available to operators of BTG-RC-CCS plants. And they could generate thereby enough revenue to cover both purchases of LPG for cooking and the annualized cost of purchasing an LPG stove and storage canisters.

Compare the energy requirements for cooking with these fuels. The current rate of use of biomass for cooking by 710 million people in Africa (229 Mtoe/yr, 9.6 EJ/yr),[19] corresponds to a wood consumption rate of 0.7 dry tonnes per capita/yr = 428 Watts/capita. According to Hutton et al. (2006) the average per capita consumption rate of LPG for cooking in Africa as a substitute for wood would be 14.4 kg/yr or 21 Watts. Both of these cooking rates are consistent with historical rates for cooking with wood and fluid fuels (Figure 12.28).

Energy requirements for cooking via LPG are only ~5% of the energy requirements for cooking via the direct burning of biomass. This makes LPG prospectively affordable even for very poor households. The following illustrative calculation suggests how LPG might be made affordable: Suppose that the crude oil and GHG emissions prices are US$90/bbl and US$70/tCO$_2$-eq, respectively, so that synthetic gasoline produced with carbon capture and storage would be cost-competitive with gasoline from crude oil (Figure 12.30). At these crude oil and GHG emissions prices, the estimated average retail LPG price would be US$1.39/kg in rural Africa.[22] Thus the total average cost of LPG for a family of 4.4 (the average household size in Africa) would be:

$$4.4 \times \left(\frac{\text{US\$1.38}}{\text{kg}} \right) \times \frac{14.3 \frac{\text{kg}}{\text{capita}}}{\text{yr}} = \frac{\text{US\$87}}{\text{yr}} \qquad (3)$$

The total cost of cooking also includes capital expenses for the stove and storage canisters, which are estimated to be about US$50 (IEA, 2006) or an annualized cost of US$8/yr,[23], [24] so that the total annualized

21 Of the global total Cai et al. (2009) estimate that 256–463 million hectares is abandoned and/or degraded cropland. For comparison, Campbell et al. (2008) estimate that globally the amount of land available on abandoned cropland is 385–472 million hectares.

22 Based on a wholesale LPG price of $1.07/kg for $90/bbl + a $0.31/kg markup to retail for rural Africa, as estimated in Hutton et al. (2006).

23 Assuming a 10% discount rate and a 10-year system life, the capital recovery factor is 16.3%/yr for the capital equipment.

24 Some sort of microfinancing program may be needed to overcome the expenditure "lumpiness" hurdle of the stove/canisters investment, but otherwise the required investment would not appear to be a show-stopper for poor households.

cost is US$95/yr per average African household. The price P_W (in US$/t) at which a family would have to sell biomass currently used for cooking to a biomass-supply-logistics agent of a synfuel producer in order to be able to afford the LPG without an additional income stream is given by:

$$4.4 \times \left(0.70 \frac{\text{tonnes} \frac{\text{wood}}{\text{capita}}}{\text{yr}} \right) \times P_W = \frac{\text{US\$95}}{\text{yr}} \Rightarrow P_W = \text{US\$31 per tonne} \quad (4)$$

This is a plausible selling price because it is only 30% of the assumed price of wood delivered to the conversion facility[25] – allowing a margin of revenue to the biomass-supply-logistics agent that is plausibly enough to pay for profitably getting the biomass purchased from cooking fuel consumers to the synfuel producer. (Detailed biomass supply logistics analysis is needed to ascertain the validity of this very preliminary judgment.)

Implications of the thought experiment for Africa: The biomass now used for cooking in Africa could support the operation of 1023 BTG-RC-CCS plants like those described in Table 12.21. If such a shift in biomass use were made, there would be Africa-wide implications:

- a total investment requirement for BTG-RC-CCS plants of US$528 billion;
- enough LPG to meet the cooking fuel needs of 94%[26] of the population currently cooking with biomass;
- 2.28 million bbl/day average gasoline output, equivalent to 90% of Africa's transportation fuel demand for 2030 as projected by the IEA (IEA, 2010) or 11% of world gasoline output of refineries in 2007, some 21.3 million bbl/day (47 EJ/yr) (US EIA, 2009b);
- 88 million MWh/yr of electricity, equivalent to 7% of Africa's electricity generation in 2030 as projected by the IEA; and
- annual storage in geological formations of 562 $MtCO_2$/yr.

Toward a business plan for BTG-RC-CCS technology deployment in Africa: This thought experiment suggests that widespread deployment of BTG-RC-CCS technology in Africa might not only go a long way towards meeting Africa's transportation fuel needs but also might help to catalyze widespread use of LPG for cooking, even among very poor households.

But much new thinking is needed about business strategies and public policies required to convert this thought experiment into a plausible energy projection for Africa. A list of proposed public policies for both the China thought experiment and the Africa thought experiment is presented in Section 12.5.3.2.

Although articulating appropriate business plans is beyond the scope of the current analysis, we conclude the economic analysis with a suggestion for one possible element of such business plans: involvement of industrial firms that produce and/or use crude oil-derived transportation fuel as investors in BTG-RC-CCS systems.

The reason for this suggestion is that such firms may be interested in procuring credits for the strong negative GHG emissions characterizing BTG-RC-CCS systems to offset emissions from the crude oil-derived products they produce or consume. The production of each barrel of gasoline by a BTG-RC-CCS plant provides enough negative GHG emissions to offset the emissions of 1.37 barrels of crude oil-derived gasoline.[27] Assuming that crude oil and GHG emissions prices are US$90/bbl and US$70/t, respectively, the annual cost of purchasing credits from a single BTG-RC-CCS plant would be US$34 million. The present worth of purchasing such credits over the life of the plant would be US$357 million,[28] which is about three fourth of the investment cost (TPC) for a BTG-RC-CCS plant (Table 12.21).

The industrial firms that are producers and/or users of crude oil-derived transportation fuel could either try to buy emissions credits from BTG-RC-CCS plant owners in an emissions trading market or they could instead invest in BTG-RC-CCS plants. In the former case, they would risk not being able get the full amount of credits they are seeking to obtain, while in the latter case they would have guaranteed access to these credits.

25 For all the systems presented in Figure 12.30 and involving biomass it is assumed that the delivered price of biomass at the conversion plant is $5.0GJ (HHV), which corresponds to a wood price of $103/dry tonne.

26 The cooking fuel production could be increased to 100% of the current cooking fuel needs by reducing the gasoline output of the BTG-RC-CCS plants in favor of producing some DME as a coproduct and blending this with LPG for use as a cooking fuel. So doing would be straightforward because the first step in the production of gasoline from methanol (CH_3OH) is methanol dehydration, which produces DME (CH_3OCH_3) and water. See additional discussion of DME in Section 12.5.1.

27 Alternatively, offsets might be sought from plants that make electricity via gasification of biomass with CCS, in which case a much larger fraction of the C in the biomass can be stored underground. If the negative emissions from power plants are used to offset emissions from crude oil-derived gasoline, a comparable amount of "effective" zero GHG emitting liquid fuels would be provided via the biomass to power with CO_2 capture and storage route as via the BTG-RC-CCS route (1.04 and 0.94 GJ of zero net GHG-emitting gasoline is provided per GJ of dry biomass input in the BTG-RC-CCS and power-only cases, respectively). In the power-only case, the gasoline provided is 100% crude oil-derived gasoline offsets; in the BTG-RC-CCS case, 42% of the gasoline is actually produced and 58% is in the form of crude oil-derived offsets. Thus if a biomass-rich country seeks to reduce oil imports as well as mitigate climate change, it is likely to choose the synfuel option over the power option. Another consideration that might tip the balance in favor of the synfuel option is that CO_2 storage capacity is a non-renewable resource, and the power option stores 1.6 times as much CO_2 per tonne of biomass as the synfuel option.

28 Assuming a 7% discount rate and a 20-year economic life of a BTG-RC-CCS plant.

12.5.3.2 Public Policy Issues

Despite the huge public benefits and seemingly attractive economics indicated by the China and Africa thought experiments, converting these thought experiments into projects will require new public policy initiatives. There would be many hurdles to overcome, including issues related to the viability of CO_2 storage at gigascale, CO_2 storage potential, sustainable biomass production potential, commercialization of large biomass gasifiers, new industrial collaborations, the rural lighting challenge, and physical infrastructure and human capacity for a BTG-RC-CCS industry. These public policy issues are outlined here.

Viability of CO_2 storage at gigascale: There is widespread belief in the scientific community that CCS is a viable carbon mitigation option at scales storing billions of tonnes of CO_2 annually worldwide (IPCC, 2005 and Chapter 13). Demonstration projects are needed, however, to prove and gain a high degree of confidence in CCS viability and also to provide a solid scientific and engineering basis for widespread deployment of CCS technologies post-2020. Commercial-scale integrated CCS demonstration projects worldwide are needed during the coming decade, with emphasis on CO_2 storage in deep saline formations, which account for most of the geological storage opportunity. Such projects are needed for several reasons. They could address scientific questions that can only be answered in projects that inject and store CO_2 at rates comparable to those for commercial projects. They could demonstrate to the satisfaction of a wide range of stakeholder groups that CCS is a viable major option to be included in the portfolio of carbon mitigation options. And they could provide the experience base needed for formulating practicable regulations governing CO_2 storage.

An international political framework for early CCS action has already been established. In July 2008, an agreement was reached by the G8 countries at the G8 Summit in Japan that 20 large-scale fully integrated CCS demonstration projects worldwide would be deployed by the middle of the next decade, with the aim of establishing the basis for broad commercial deployment of CCS technologies after 2020. In July 2009, the leaders of the G8 countries re-iterated their call for the projects, and in February 2010 US President Obama issued a Presidential Memorandum calling for five to ten commercial scale CCS demonstration projects to be up and running in the United States by 2016.

Much if not all of the incremental cost of CCS for the 20 projects called for by the G8 will probably have to be paid for by governments (individually or collectively) because of the likelihood that carbon prices will be lower initially than what will be needed to make pursuit of CCS a profitable activity for private companies.

If governments will have to pay for the incremental CCS cost, they will want to pursue projects in which they can maximize the learning about the gigascale prospects of CCS per dollar spent.

An important consideration is that coproduction systems based on coal or coal + biomass generate, as a natural part of the process of their manufacture, relatively pure streams of CO_2 for which the incremental cost of CO_2 capture is low. Accordingly, coproduction facilities (such as the CTG-PB-CCS and CBTG1-PB-CCS described in Table 12.21) built in coal-rich countries should be considered seriously as candidates for some of the needed CCS early action projects and supported financially jointly by the governments of several coal-intensive energy economies.

CO_2 storage potential: CO_2 storage prospects are not well known in countries where clean cooking fuels are sorely needed and where attractive economics for providing these fuels to poor households can plausibly be realized in conjunction with the building of synfuel plants with CCS. "Bottom-up" assessments of storage prospects, including the construction of supply curves (storage capacity in tonnes vs cost in US$/t), are needed on a reservoir-by-reservoir basis. These assessments should be carried out in each of the major regions requiring clean cooking fuels – with financial support from the international community.

Sustainable biomass production potential: Assessments should be carried out in biomass-rich regions to determine the prospects for biomass production for energy. Such production should be on a sustainable basis in which conflicts with food production, adverse indirect land-use impacts, and biodiversity conflicts are minimized. Emphasis should be on agricultural residues, forest residues (including mill residues, logging residues, diseased tree removals, fuel treatment thinnings, and productivity enhancement thinnings), and the growing of dedicated energy crops on abandoned croplands and other degraded lands. The growing of bioenergy crops on marginal lands should be done in ways that enhance the wellbeing of poor indigenous populations currently use such lands for their livelihoods. One way of expanding biomass production on marginal lands without forcing off the land local populations would be to encourage the local populations to grow biomass for energy by creating corporate smallholder partnerships that establish agreements for industries to purchase biomass from smallholders. Outgrower schemes such as these have been common for some time in agriculture; smallholders are now playing an increasingly important role in the establishment and management of planted forests (Cushion et al., 2010).

These assessments should be carried out in each of the major regions requiring clean cooking fuels – with financial support from the international community.

Commercialization of large biomass gasifiers: Successful demonstration projects have been carried out for biomass gasifiers at small scales (processing tens of MW of biomass). But there are no commercial biomass gasifiers capable of processing 300–600 MW of biomass – the scales for the conversion systems described here. Policies are needed to encourage commercialization of biomass gasifiers suitable for coupling to synthetic fuel production units at these scales. Such commercialization efforts should be carried out in parallel with early deployment of CBTG1-PB-CCS

systems (designed for ~10% biomass or less) that could involve instead co-gasification of biomass and coal in suitable coal gasifiers.

New industrial collaborations: New public policies are needed to facilitate industrial collaborations between companies producing transportation fuels, electricity, and clean cooking fuels and to encourage coprocessing of coal and biomass in regions having significant supplies of both (e.g., United States and China). It would be desirable to identify policy instruments that specify performance rather than technology and maximize use of market forces in meeting performance goals. Promising approaches along these lines include mandating a Low Carbon Fuel Standard (as in California); a low carbon standard for coal electricity, perhaps modeled after Renewable Portfolio Standards or green certificate markets; and a Universal Clean Cooking Fuel Standard in regions requiring major infusions of clean cooking fuels, perhaps modeled after the "obligation to serve" mandates of the rural electrification programs introduced in the United States in the 1930s. The latter could plausibly facilitate the formation of strategic industrial alliances that would be capable of guaranteeing universal access to clean cooking fuels without major subsidy.

Rural lighting challenge: Policies aimed at inducing a shift from biomass to clean cooking fuels should be complemented by policies to promote universal access to modern lighting technologies (see also Chapter 23).

Physical infrastructure and human capacity for a BTG-RC-CCS industry: Official development assistance (ODA) should be expanded for economically poor but biomass-rich and coal-poor regions. The increment should be directed to developing the physical infrastructures and human capacities needed to build and manage large BTG-RC-CCS industries. This additional ODA should aim for established infrastructures and capacities *before* GHG emission prices are high enough to launch BTG-RC-CCS technologies in the market.

12.6 Coproduction of Liquid Fuels and Electricity from Non-petroleum Feedstocks

Coproduction can enhance cost-competitiveness. The discussion of gasification-based synfuels in Section 12.4.3 was focused on recycle (RC) systems designed to maximize liquid fuel output. In RC systems, syngas unconverted in a single pass through the synthesis reactor is recycled to the reactor to maximize synfuel yield. A major study of alternative system configurations for making FTL from coal, from biomass, and from coal + biomass (Liu et al., 2011a) found that FTL can often be produced more cost-effectively in so-called "once-through" (OT) systems, in which syngas unconverted in a single pass is burned to make coproduct electricity in a gas turbine/steam turbine combined cycle power plant (See also Larson et al., 2010). OT configurations are worthwhile exploring from a synfuels production perspective for the slurry-phase synthesis reactors investigated by Liu et al. (2011a) because these reactors can yield high one-pass conversion of $CO+H_2$ to liquids – much higher than is feasible with gas-phase reactors. A major study of alternative system configurations for making gasoline via the methanol-to-gasoline process from coal, from biomass, and from coal + biomass (Liu et al., forthcoming) also found that gasoline can often be produced more cost-effectively via systems that produce electricity as a major coproduct.

Here the merits of coproduction for both FTL and MTG systems are discussed for the six systems described in Table 12.22 that involve coal (both –V and –CCS configurations) and coal + biomass (only –CCS configurations). Since detailed descriptions of RC variants of FTL and MTG systems were already made in Section 12.4.3, here only the major differences introduced by the coproduction designs are discussed.

Figure 12.31 shows several OT configurations for coal and coal/biomass FTL systems. When iron-based synthesis catalysts are used (as in the analysis in Liu et al., 2011a), CO_2 removal from synthesis gas in –CCS configurations is required downstream as well as upstream of synthesis because of the water-gas-shift activity of iron-based catalysts, and downstream CO_2 removal accounts for more than half of the total CO_2 removed. Also, a gas turbine/steam turbine combined cycle rather than a steam turbine is used to generate electricity on the power island.

The MTG designs that coproduce electricity and gasoline use a bypass of some of the syngas around the methanol synthesis reactor to directly feed a gas turbine/steam turbine combined cycle power plant in so-called partial bypass (PB) configurations (Figure 12.32).[29] An additional water gas shift reactor is introduced to convert the bypass syngas to mainly CO_2 and H_2, from which the CO_2 is captured for storage, and H_2 is the main constituent of the fuel gas delivered to the combined cycle power plant.

12.6.1 Performance Estimates

Greenhouse gas emissions are the focus of the discussion of performance estimates here. To facilitate comparisons, the coal-only plants (Figure 12.31, Table 12.22) have the same levels of coal inputs as the corresponding RC plants described in Table 12.15 that provided 50,000 bbl/day of crude oil products displaced for both FTL and MTG. As shown in Table 12.22, the OT and PB system configurations produce less liquid fuel and much more electricity from this coal than the corresponding RC systems. As in the RC cases, an important metric for comparing emissions for different system configurations is the GHGI: the ratio of the fuel cycle wide emissions of greenhouse gases from these systems are compared to emissions from a reference system.

29 A partial-bypass, rather than a "once through" (OT), process design is utilized for the MTG systems here because the assumed methanol synthesis reactor is a gas-phase design, for which the per-pass conversion of syngas is small, making it ill-suited for use in an OT process configuration. A liquid-phase methanol synthesis reactor would have much higher single-pass conversion and as a result might be better-suited for an OT application.

Table 12.22 | Performance estimates for converting coal and coal + biomass to electricity + FTL or MTG.

Process configuration >>>	CTL-OT-V	CTL-OT-CCS	CTG-PB-V	CTG-PB-CCS	CBTL-OT-CCS	CBTG-PB-CCS
Coal input, as received metric t/day	24,087	24,087	20,869	20,869	3220	5260

GHG emissions index – GHGI[b]	1.31	0.70	1.37	0.56	0.093	0.089

a COPD = crude oil products displaced.

b GHGI, the greenhouse gas emissions index, is the system wide life cycle GHG emissions for production and consumption of the energy products relative to emissions from a reference system producing the same amount of liquid fuels and electricity. For details, see Table 12.15, note (c).

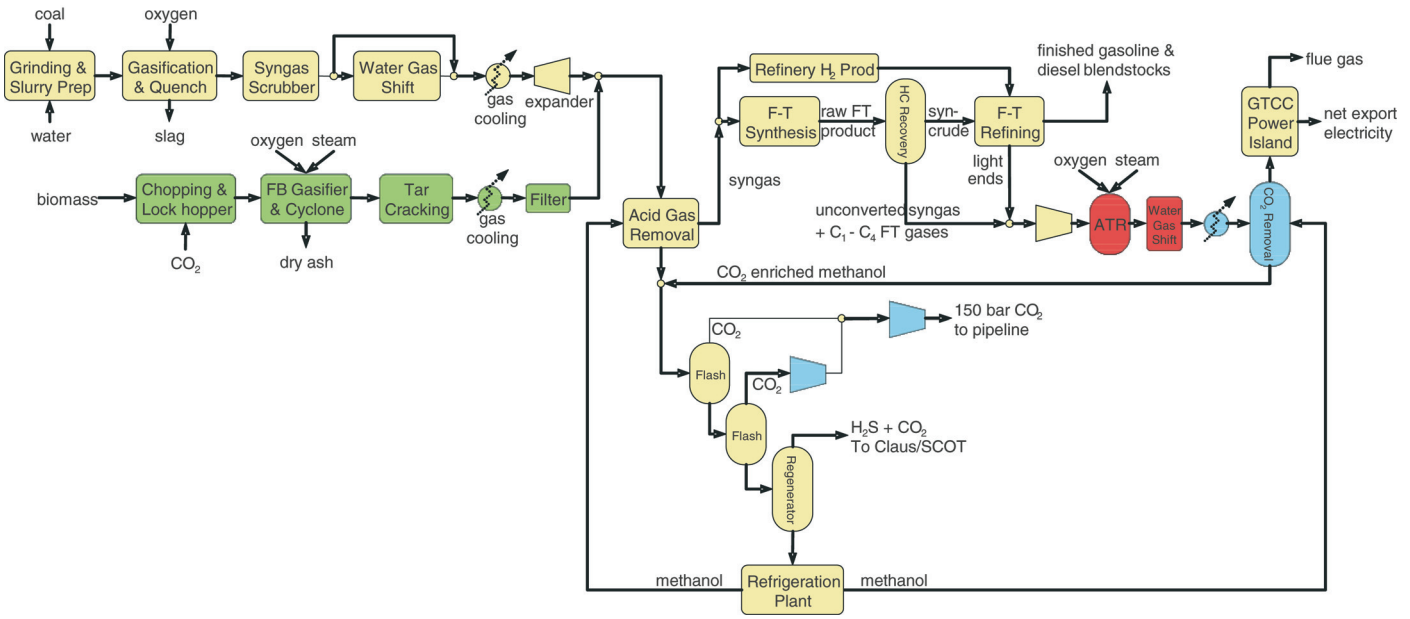

Figure 12.31 | CTL-OT-V system (including only yellow-shaded components) that provides F-T liquids + electricity from coal via gasification while venting the captured CO_2 coproduct. Upstream of the synthesis reactor CO_2 accounting for 25% of the C in the coal is captured along with H_2S using Rectisol. The H_2S is converted to elemental sulfur in a Claus plant and the CO_2 is vented.

With the addition of the blue-shaded components, the system (CTL-OT-CCS) includes capture of CO_2 both upstream of the synthesis reactor (accounting for 25% of C in the coal) and downstream of it (accounting for 27% of C in the coal). The CO_2 is compressed to 150 bar and delivered to a pipeline for transport to a geological storage site.

With the further addition of the green-shaded components, the system (CBTL-OT-CCS) co-processes biomass with coal.

And finally, the further addition of the red components creates a design (CBTL-OTA-CCS) that includes autothermal reforming (ATR) of the C_1-C_4 components in the fuel stream to the power island, followed by water gas shifting. The autothermal reforming (ATR) plus WGS creates more CO_2 for capture downstream of synthesis than is the case with the CBTL-OT-CCS system.

Both the CBTL-OT-CCS and CBTL-OTA-CCS systems have been designed with enough biomass to realize GHGI < 0.10. CBTL-OT-CCS, storing as CO_2 54% of the feedstock C, requires coprocessing 40% biomass, whereas CBTL-OTA-CCS, storing as CO_2 65% of the feedstock C, requires coprocessing only 29% biomass to realize essentially the same GHGI value.

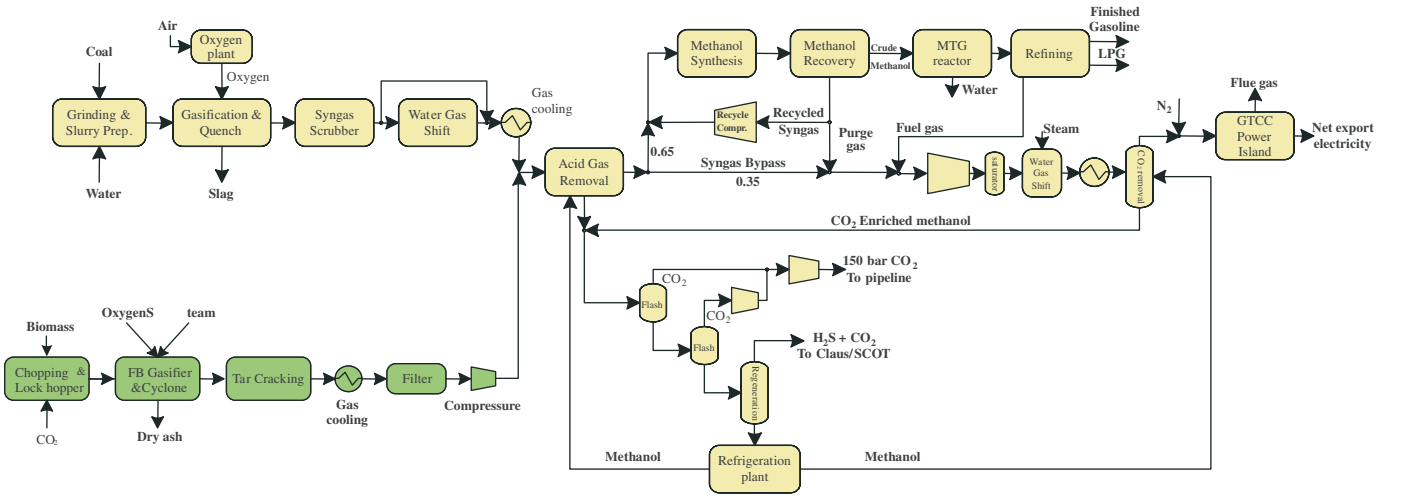

Figure 12.32 | CTG-PB-CCS system (yellow-shaded components) that provides gasoline and LPG + electricity from coal. H_2S is converted to elemental sulfur, and CO_2 is captured both upstream and downstream of synthesis (accounting for 64% of C in the coal), compressed to 150 bar, and delivered to a pipeline for transport to a geological storage site. With the addition of the green-shaded components, the system (CBTG-PB-CCS) produces gasoline and LPG + electricity from coal and biomass. CO_2 accounting for 65% of C in the feedstocks is captured and sent to geological storage.

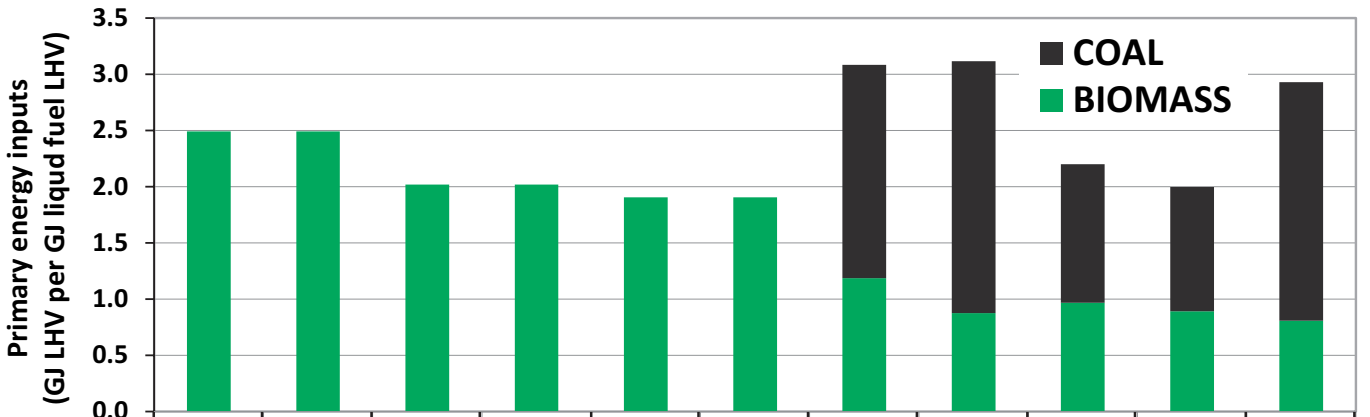

Co-products	EtOH-V	EtOH-CCS	BTG-RC-V	BTG-RC-CCS	BTL-RC-V	BTL-RC-CCS	CBTL-OT-CCS	CBTL-OTA-CCS	CBTL-RC-CCS	CBTG-RC-CCS	CBTG-PB-CCS
kWh electricity per GJ of liquid fuel	5.0	1.5	30	19	41	30	141	116	23.7	4.4	109
GJ LPG per GJ of liquid fuel	0.0	0.0	0.095	0.095						0.095	0.092

Figure 12.33 | Biomass (and coal) required to produce alternative fuels having low/zero fuel-cycle-wide GHG emissions. For this graph, all primary energy input is allocated to liquid fuels even though all systems also provide electricity. For details on the cellulosic ethanol options (EtOH-V and EtOH-CCS) see Box 12.3. Source: based on Liu et al., 2011a.

For the coal-only designs, the GHGI is 1.3–1.4 for the systems with venting of CO_2, indicating that emissions would be considerably higher than for the reference system. Adding carbon capture and storage reduces emissions relative to the reference system by 30–40% (GHGI = 0.56–0.70).

The two coal + biomass systems described in Table 12.22 are each designed for a total biomass consumption of 1 Mt/yr dry biomass, together with an amount of coal that results in a GHGI of 0.1 or less, i.e., 10% of the emissions of the reference system or less. For the FTL systems, 40% of the input feedstock energy is biomass. It is 29% for the MTG system. Unlike systems that produce liquid fuels using only biomass as a feedstock, the energy content in the near-zero GHG liquid fuels produced from coal/biomass systems is comparable to or greater than the energy contained in the input biomass (see Figure 12.33). The reason is that a large percentage of the energy input for these coal/biomass coprocessing options is provided by coal, as shown in Figure 12.33.

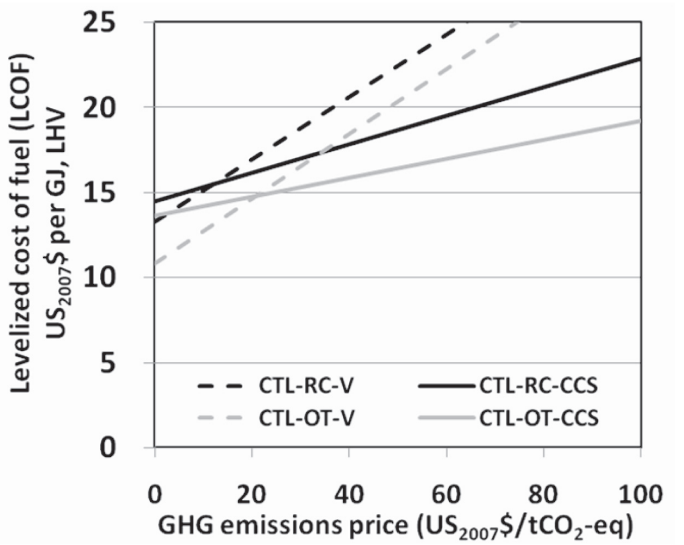

Figure 12.34 | Comparison of CTL production costs (US_{2007}): OT vs RC options, both with CO_2 vented (–V) and with carbon capture and storage (–CCS). (See Table 12.6, note (b) for financial parameter assumptions. Also, electricity sales are assumed at the US average grid price plotted in Figure 12.10.) Source: based on Liu et al., 2011a.

12.6.2 Cost estimates

When coproduction systems are evaluated from a fuels perspective, the LCOF is given by:

$$\text{LCOF} = \frac{\text{levelized system cost}\,\frac{\text{US\$}}{\text{yr}} - \text{levelized value of electricity coproduct}\,\frac{\text{US\$}}{\text{yr}}}{\text{levelized fuel production rate}\,\frac{\text{GJ}}{\text{yr}}} \quad (5)$$

In Liu et al. (2011a) and in Liu et al. (forthcoming) it is assumed that the electricity coproduct is valued at the US average grid generation price in 2007 (US$60/MWh) augmented by the value of the average grid GHG emission rate in that year (see Figure 12.10).

Figures 12.34 and 12.35 present LCOFs vs GHG emissions price for the coal only – OT and –PB systems, respectively, as well as the corresponding LCOFs for the RC alternatives.

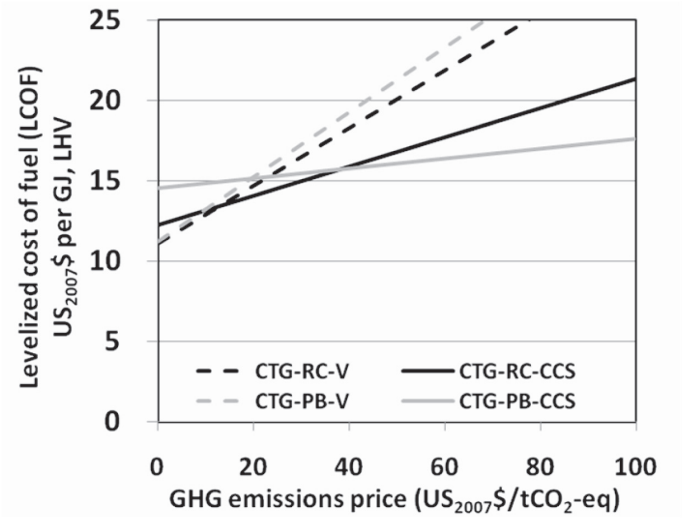

Figure 12.35 | Comparison of CTG production costs (US_{2007}): PB vs RC options, both with CO_2 vented (–V) and with carbon capture and storage (–CCS). Same financial parameter and electricity price assumptions as Figure 12.34. Source: based on Liu et al., forthcoming.

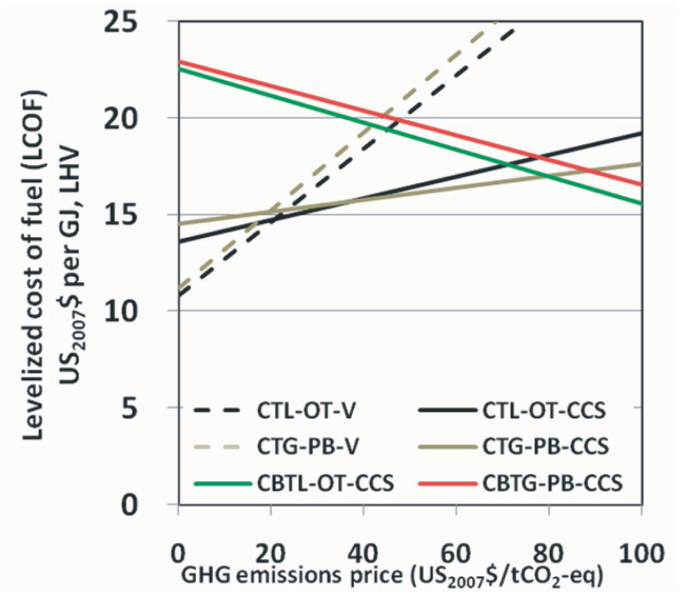

Figure 12.36 | Liquid fuel production costs (US_{2007}) for alternative FTL-OT and MTG-PB options, involving coal and coal + biomass as feedstocks. Same financial parameter and electricity price assumptions as Figure 12.34. Source: based on Liu et al., 2011a.

Figure 12.34 shows that the LCOF is 18% less for the CTL-OT-V case than for the CTL-RC-V case when the GHG emissions price is zero. This economic advantage of the OT option can be attributed in large part to the high marginal efficiency of power generation (Liu et al., 2011a): for OT and RC plants having the same FTL outputs, the difference in electricity outputs divided by the extra coal required for the OT case is 45% for the –V case and 39% for the –CCS case (HHV basis). In both instances these marginal efficiencies for power generation for OT options are much higher than for stand-alone power plants, e.g., 37.5% and 31.0% for CIGCC in –V and –CCS configurations, respectively (Table 12.7, PEI cases). For CTG systems, there are also gains in marginal efficiency, but the gains are not as pronounced as for CTL systems: the marginal efficiencies of incremental power generation are 38% for the –V case and 32% for the –CCS case.

For CTG systems (Figure 12.35) the PB option offers no cost advantage relative to the RC case when CO_2 is vented, but for GHG emissions prices greater than US$40/t there is a significant production cost advantage for systems with CCS.

One reason why the economic benefit of coproduction is less for MTG systems than for FTL systems is that in the CTL case a shift from an RC to an OT configuration involves elimination of an energy- and capital-intensive autothermal reformer, whereas neither of the MTG recycle systems use autothermal reformers. Also, MTG systems need an extra water gas shift reactor to decarbonize the syngas stream going to the power plant, which is not needed for FTL systems.

OT systems for FTL and PB systems for MTG also offer less costly approaches to decarbonizing power than stand-alone power systems. To see this consider the cost of GHG emissions avoided (US$/$tCO_2$-eq), which is the GHG emissions price at which costs are equal for the –V and –CCS system configurations, i.e., the minimum GHG emissions price needed to induce CCS by market forces. This minimum GHG emissions price for both FTL and MTG systems is ~US$20/$tCO_2$-eq (Figures 12.34 and 12.35) compared to US$45/t or more for stand-alone power systems (Figure 12.10). The reason for this large difference is that for synfuels production systems a substantial fraction of the carbon in the feedstock has to be removed from the shifted syngas upstream of synthesis as a natural part of the part of the process of making synthetic fuels. Moreover, in the FTL cases removal of the extra CO_2 downstream of synthesis is not very costly because no extra water gas shift reactors are required.

Figure 12.36 shows the LCOFs for all six OT and PB systems considered as a function of the GHG emissions price, based on the performance information presented in Table 12.22 and the additional economic information presented in Table 12.23. An important feature of the curves presented in Figure 12.36, is the rapid rate of decline in LCOF with GHG emissions price for both the CBTL-OT-CCS system and the CBTG-PB-CCS system – in stark contrast to the flat LCOF curves for the corresponding RC systems presented in Section 12.4.3. This rapid rate of cost reduction reflects the rising value of decarbonized electricity with GHG emissions price (Figure 12.10). As a result of this sharp decline the LCOFs at US$100/$tCO_2$-eq are US$15.6/GJ_{LHV} (US$1.9/gallon of gasoline equivalent) for FTL via CBTL-OT-CCS (73% of the LCOF for FTL via CBTL-RC-CCS) and US$16.6/$GJ_{LHV}$ (US$2.0/gallon of gasoline equivalent) for gasoline via CBTG-PB-CCS (80% of the LCOF for gasoline via CBTG-RC-CCS). In both instances the liquid fuels are characterized by near-zero net GHG emissions, and large quantities of decarbonized coproduct power are provided.

12.6.3 Coproduction Economics from the Electricity Production Perspective

The economics discussed in the prior section focused on estimating the cost of making liquid fuels via coproduction systems given assumed prices for the electricity coproducts. Alternatively, electricity production costs can be estimated based on assumed liquid fuel selling prices.[30] This alternative approach for evaluating the economics of

30 Here it is assumed that the synfuels are sold at the wholesale (refinery-gate) prices for the crude oil products displaced, including the valuation of the fuel cycle-wide GHG emissions for these products. The relevant GHG emissions for the crude oil products displaced are given in Table 12.15, note (c).

Table 12.24 | Alternative systems with 550 MW_e of electric power capacity.

Technology	Primary energy input, MW (HHV)	Biomass input, kt/y (%, HHV basis)	FTL output, barrels /day (kt/year)	CO_2 stored, Mt/yr (% of feedstock C stored)	TPC, million US_{2007}	GHGI[a]
Sup PC-V	1410	0	0	0	894	1.00

CBTL1-OTA-CCS	4820	370 (5)	22,800 (963)	7.58 (64)	3300	0.50

a GHGI = system wide life cycle GHG emissions for production and consumption of the energy products divided by emissions from a reference system producing the same amount of liquid fuels and electricity. Here the reference system consists of electricity from a stand-alone new supercritical pulverized coal power plant venting CO_2 and equivalent crude oil-derived liquid fuels. For details, see Table 12.15, note (c).

coproduction is of interest for three important reasons: (i) the incremental cost for carbon capture and storage is much less than for stand-alone power plants because, as already noted in Section 12.6.2, much CO_2 must be removed from syngas prior to synthesis as a natural part of fuels manufacture, so that capture costs are low; (ii) the economics of power generation are attractive at current and prospective high oil prices, resulting in a huge credit against the cost of electricity generation; and (iii) these systems can defend high capacity factors and force down capacity factors of competing technologies in economic dispatch competition. Coproduction is considered here for systems making Fischer-Tropsch liquids. First, we consider coproduction in the context of an evaluation of alternative options for new coal-using power plants (Section 12.6.3.1), with potential applications in China (Section 12.6.3.2). Second, we consider coproduction as an option for repowering old coal power plant sites (Section 12.6.3.3), with potential applications in the United States (Section 12.6.3.4).

12.6.3.1 XTL vs Stand-alone Power Options for New Plant Construction

Table 12.24 lists key system characteristics for four coproduction options and two conventional stand-alone power options – each of which is designed to have 550 MW_e of electric generating capacity. The reference technology is a new supercritical coal power plant that vents CO_2 (sup PC-V), the least costly option for new stand-alone coal power plants in the absence of a carbon constraint (see Section 12.2.2). Also listed is a coal integrated gasification combined cycle plant with carbon capture and storage (CIGCC-CCS), currently the least costly CCS option for new stand-alone bituminous coal power plants (Section 12.2.3). The CTL-OT options are identical to those considered in the previous two sub-sections except that the scales have been adjusted to 550 MW_e of electric capacity.[31] Two options are considered that involve coprocessing just enough biomass to reduce the system GHGI to 0.5. Biomass accounts for 12% of energy for one of these options, CBTL1-OT-CCS, which involves capturing only the naturally concentrated streams of CO_2 in the syngas[32] (accounting for 53% of carbon in the feedstock). Biomass accounts for 5% of energy input for the other option, CBTL1-OTA-CCS, which involves more aggressive CO_2 capture[33] (accounting for 64% of carbon in the feedstock). Thus the same GHG emissions mitigation level is realized in one case by using more biomass and in the other by capturing more CO_2.

For each of these options, curves for the levelized cost of electricity (LCOE) vs GHG emissions price is shown in Figure 12.37 for a levelized crude oil price of US$90/bbl, for US economic conditions. This is the oil price for the period 2020–2030 as projected by the IEA for a future in which the global community is then on a course aimed at stabilizing the atmospheric GHG concentration at 450 ppmv (IEA, 2009b).

Several notable observations can be made about the curves in Figure 12.37:

- A GHG emissions price of only ~US$10/t is needed to induce a transition from CTL-OT-V to CTL-OT-CCS. In contrast a GHG emissions price of more than US$50/t is needed to induce a transition in stand-alone power generation from sup PC-V to CIGCC-CCS.
- The LCOE curves for CBTL1-OT-CCS and CBTL1-OTA-CCS lie nearly atop each other, meaning the extra capital cost for the more aggressive capture option is largely compensated by the lower fuel cost.[34]

31 In adjusting plant scales it is assumed that system conversion efficiencies do not change, but capital cost scale economy effects are taken into account.

32 Both upstream and downstream of synthesis.

33 In the CBTL1-OT-CCS case, C1 to C4 gases in syngas downstream of synthesis are burned in the gas turbine combustor, thereby generating CO_2 that is vented to the atmosphere on the power island. In the CBTL1-OTA-CCS case an autothermal reformer and a water-gas-shift reactor are inserted downstream of synthesis to convert most of these C1 to C4 gases to mainly CO_2 and H_2 (see Figure 12.31). The extra CO_2 thus created is captured and stored. In this case the gas burned to make electricity is mostly H_2. For additional details regarding this "autothermal reforming" option for once-through (OT) systems, see Liu et al., 2011a.

34 The assumed (HHV) fuel prices are $2.04/GJ for coal and $5.0/GJ for biomass.

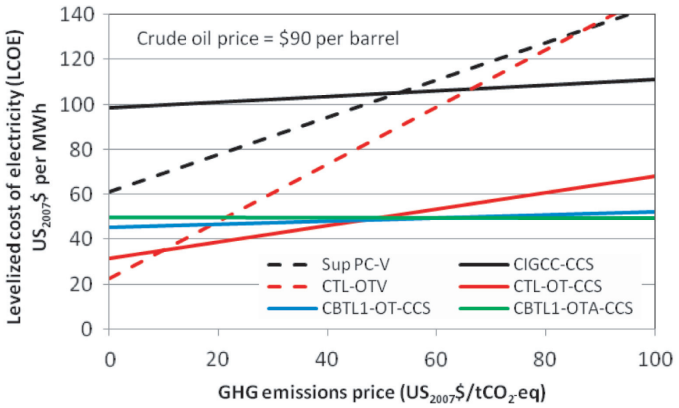

Figure 12.37 | Levelized cost of electricity (LCOE) for crude oil at $90/bbl for the electric power options described in Table 12.24. (See Table 12.6, note (b) for financial parameter values assumed.) The IEA (2009b) projects that if the global community were to pursue a GHG emissions trajectory consistent with stabilizing the atmospheric GHG concentration at 450 ppmv the world oil price would be flat at US$90/bbl, 2020–2030, considerably lower than its projection of the world oil price for its Reference Case (BAU) scenario.

- Although not shown in the figure, the LCOE for coproduction systems declines sharply with the crude oil price: for each US$10/bbl increase in the crude oil price the LCOE at a GHG emissions price of US$0/t is reduced by US$12/MWh for CTL-OT-V and by US$17/MWh for CBTL1-OTA-CCS.

- The LCOE for CBTL1-OTA-CCS is lower than for CTL-OT-CCS when the GHG emission price is US$57/t$CO_2$-eq.

The LCOE values represented by these curves are for design capacity factors of 85% for power only systems and 90% for coproduction systems. In a market economy, however, capacity factors are determined not by the design engineers but rather by economic dispatch competition. Once a power plant is built, its capital cost (*a sunk cost*) is not taken into account in the determination of the merit order dispatch on an electric grid. The dispatcher operating the grid determines, on the basis of competitive bids, the order in which plants are dispatched to meet electricity demand – with those plants being dispatched first that offer to sell electricity at the lowest price. It is worthwhile for a power generator to bid to sell electricity as long as the revenue it gets from power (in US$/MWh) is not less than its short run marginal cost of producing electricity (SRMC, which excludes sunk costs). This minimum acceptable selling price for the generator is called the minimum dispatch cost (MDC).

As power generators, the XTL-OT plants considered here were designed as "must-run" baseload units. Their MDC depends on the oil price: oil revenues reduce the revenue required from electricity. The MDC is very low for coproduction systems at sufficiently high oil prices. In the CBTL1-OTA-CCS case, with zero GHG emissions price the MDC is the same as for sup PC-V if the crude oil price is US$37/bbl, and the MDC falls to zero when the crude oil price is US$51/bbl. Thus coproduction will be able to defend high capacity factors in economic dispatch competition and force down the capacity factors of competing technologies as their deployment on the electric grid increases.

12.6.3.2 Thought Experiment for China

Coproduction technologies with CCS can be effective in addressing simultaneously climate change and energy security challenges. To illustrate these benefits of coproduction strategies, a thought experiment is constructed in which it is imagined that all new power generation in China over the period 2016–2030 is shifted from the business-as-usual path of sup PC-V to a CCS path – considering for CCS, in turn, the CIGCC-CCS, CTL-OT-CCS, and CBTL1-OTA-CCS options listed in Table 12.24. Although none of these alternatives to sup PC-V have been built, all system components for these three options are either commercial or commercially ready, so it would be technically feasible to deploy each of these options commercially beginning later in this decade.[35] The aim of the thought experiment is to gain a better understanding of the strategic implications of pursuing coproduction options for power generation.

There are several reasons for focusing on China for this power-sector oriented thought experiment that are similar to the rationale for the China clean cooking fuel thought experiment discussed in Section 12.5.3.1:

- China has powerful reasons for becoming a world leader in identifying and pursuing low-cost approaches to decarbonizing coal energy conversion such as via deployment of coproduction systems with CCS, as suggested by Figure 12.37.[36] China is the world's largest consumer of coal, the most carbon-intensive fossil fuel, accounting for 48% of world coal consumption in 2010. And the expectation is that under business-as-usual conditions coal demand will continue to grow in China (IEA, 2009b).

- China has a strong incentive to explore alternatives to oil imports. It has evolved from being a net oil exporter in the early 1990s to being the world's second largest consumer of imported oil in 2010, with the expectation of continued rapid oil import growth.

- China has more experience with coal gasification technology than any other country. Essentially all of this experience is in China's chemical process industry, which is largely based on coal because of the scarcity of China's oil and gas resources. There are nearly 400 operating and planned coal-based chemical plants in China using

35 The modeling reported above for the CBTL1-OTA-CCS option (coprocessing 5% biomass) is for a system with separate gasifiers for coal and biomass. For systems deployed in this decade, it is more likely that a single suitable coal gasifier that can cogasify modest quantities of biomass with coal would be deployed instead.

36 Of course the LCOEs shown in this figure are only suggestive for China, because they were estimated for the United States, not Chinese, economic conditions. Moreover, the LCOEs for first of a kind plants would be higher than those shown even in the US case, because the indicated costs are for Nth of a kind plants.

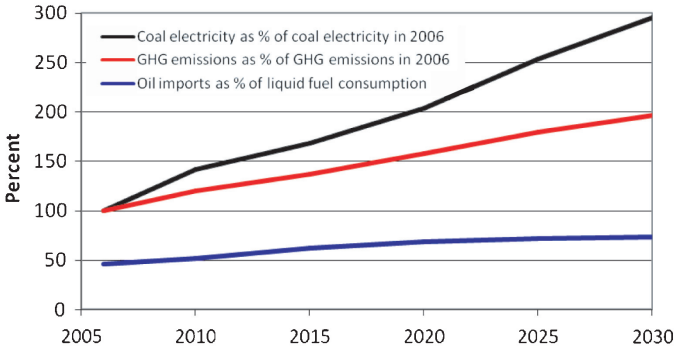

Figure 12.38 | Business-as-usual (BAU) projection by US Energy Information Administration of China's energy future, 2006–2030. Source: US EIA, 2009a.

coal gasification (Zheng et al., 2010); most are ammonia plants but there are also methanol plants, other chemical plants, and a few synthetic fuels plants. Evolving from the manufacture of chemicals and synthetic fuels in such a relatively mature gasification-based industry to the coproduction of liquid transportation fuels and electricity represents a relatively modest step forward from a technological perspective.

- China has one of the world's fastest-growing economies, and rapidly growing economies are the most favorable theatres for technological innovation.

The starting point for the thought experiment is the US Energy Information Administration's Reference Scenario for China (US EIA, 2009a), in which it is projected that between 2006 and 2030 coal power generation will almost triple, total national GHG emissions will almost double, and oil imports will increase 3.4 times from 42% to 75% of liquid fuel consumption (Figure 12.38).

Implications of the thought experiment for carbon mitigation are indicated in Figure 12.39, which shows that in 2030, China's GHG emissions would be less than for the business-as-usual case by the amounts 1.3 $GtCO_2$-eq/yr, 1.9 $GtCO_2$-eq/yr, and 2.3 $GtCO_2$-eq/yr for the CTL-OT-CCS, CIGCC-CCS, and CBTL1-OTA-CCS trajectories, respectively. That the CBTL1-OTA-CCS path leads to 20% more GHG emissions mitigation than the CIGCC-CCS path even though GHGI = 0.5 for CBTL1-OTA-CCS compared to 0.15 for CIGCC-CCS arises because the coproduction option reduces emissions for liquid fuels as well as for electricity.

Implications of the thought experiment for China's oil imports are indicated in Figure 12.40. For the business-as-usual and CIGCC-CCS trajectories, oil imports grow from 162 to 551 Mt/yr (3.3 to 11.2 million bbl/day) between 2006 and 2030 but are reduced by 2030 to + 33 and – 86 Mt/yr (+ 0.68 and – 1.74 million bbl/day) for the CTL-OT-CCS and CBTL1-OTA-CCS trajectories, respectively.

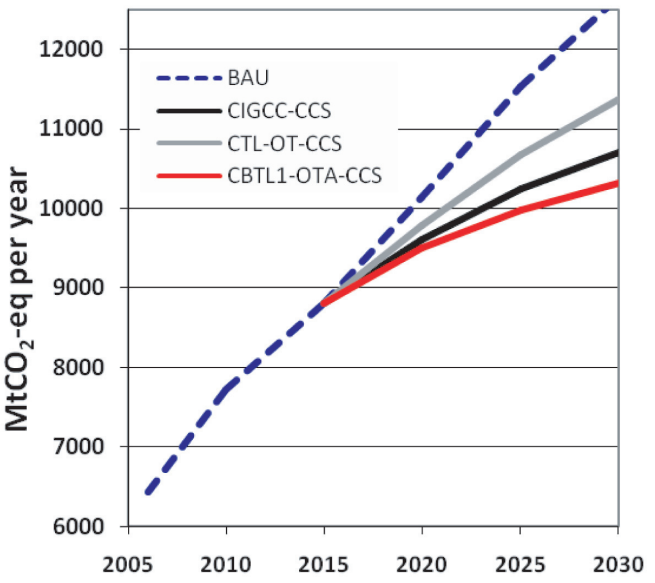

Figure 12.39 | GHG emissions for China: for the BAU scenario based on US EIA (2009a) and for the three thought experiment variants discussed in the main text.

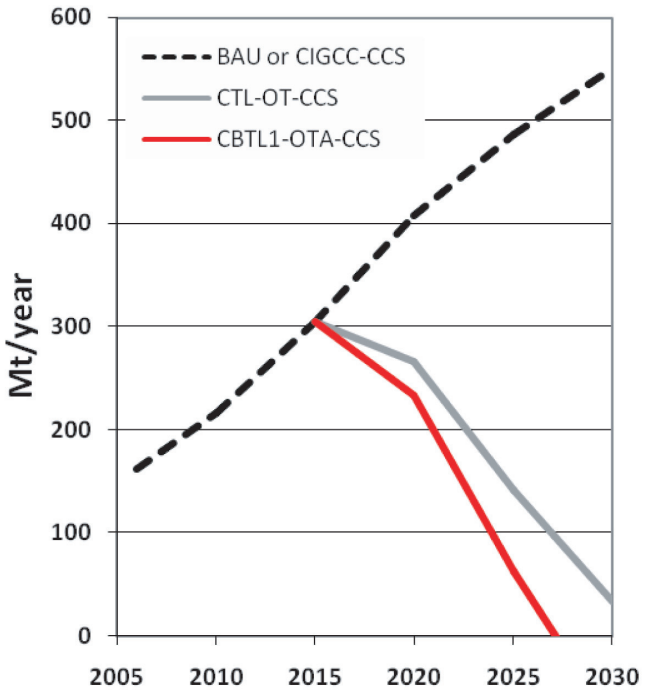

Figure 12.40 | Oil imports for China: for the BAU scenario based on US EIA (2009a) and for the three thought experiment variants discussed in the main text.

In 2030 the biomass required for the CBTL1-OTA-CCS trajectory would be 235 Mt/yr – some 62% of the crop residue supplies potentially available for energy applications in China in 2010 (Li et al., 1998).

The coproduction trajectories might well require a substantial increase in China's coal imports. However, coal imports are likely to pose less of an energy security challenge than oil imports, and the reduced oil import bill is likely to more than compensate for the increased cost of coal imports.[37]

Of course, the economics of coproduction relative to conventional power must be evaluated under China's economic conditions, and the coal/biomass supply implications of the thought experiment must be well understood before one can have a high level of confidence that this would be a cost-effective and otherwise attractive energy strategy for China. But the thought experiment suggests that investigating these issues would be worthwhile.

12.6.3.3 XTL-OT Systems as Repowering Options for Existing Coal Power Plant Sites

Decarbonization will be needed not only for new coal power plants but also for existing power plant sites. In industrialized countries such as the United States, the focus will be on existing power plant sites because overall electricity demand growth is expected to be slow. In this section, five systems providing Fischer-Tropsch liquid transportation fuels as coproducts of electricity and three stand-alone power systems are considered as repowering decarbonization options for sites of existing written-off pulverized coal plants that vent CO_2 (WO PC-V). The coproduction options include both coal-only systems and systems that coprocess coal and biomass. Each of these repowering options is compared to a CCS retrofit of the WO PC-V plant (PC-CCS retrofit), based on analyses in Williams et al. (2011) and Liu et al. (2011a). Key system characteristics for these ten systems are presented in Table 12.25. The alternative systems are compared with regard to GHG mitigation performance, CO_2 storage requirements, energy penalties for CCS, site water requirements, and economics. However, the emphasis is on GHG emissions mitigation performance and economics.

A narrow definition of repowering is scrapping an existing power plant but keeping the site and its infrastructure for use by a new facility. Not all sites can accommodate repowering. There has to be enough space to accommodate all equipment associated with repowering, there have to be suitable CO_2 storage opportunities, and (for cases in which biomass is coprocessed with coal) biomass supplies have to be available. However, the definition of repowering is broadened somewhat to include also the option of abandoning the site entirely and rebuilding at a greenfield site if the targeted site is unsuitable. The economics change only relatively modestly in a shift from building a new plant at an existing site to building a new plant at a greenfield site. The economic benefits associated with saving the infrastructure are not taken into account.

For each of the ten options in Table 12.25 the LCOE vs GHG emissions price is shown in Figure 12.41 for US economic conditions. For the options involving CCS, it is assumed that the cost of CO_2 transport and storage is US$15/t for all options – higher than would be typical for new plant construction. For coproduction systems, the LCOE is evaluated for a levelized crude oil price of US$90/bbl, the oil price for the period 2020–2030 as projected in *World Energy Outlook* 2009 (IEA, 2009b) for a future in which the global community is then on a course aimed at stabilizing the atmospheric GHG concentration at 450 ppmv.[38] As in the case of the larger-scale coproduction systems discussed in Section 12.6.3.1, LCOEs are very sensitive to the crude oil price.[39] To assess the risk from an oil price collapse, the breakeven crude oil price for the five coproduction repowering systems is shown as a function of GHG emissions price in Figure 12.42.[40]

Particular attention is given to the five options for which GHGI is less than 0.20, in light of the fact that political leaders of many industrialized countries are targeting emissions reductions of 80% or more for their countries by mid-century.

Three of the coproduction systems were evaluated earlier from a fuels production perspective, though in some cases at different plant scales: CTL-OT-V, CTL-OT-CCS, and CBTL-OT-CCS (Figure 12.31). One of the coproduction systems not discussed earlier is CBTL-OTA-CCS (also depicted in Figure 12.31), which has a GHGI below 0.1, as does CBTL-OT-CCS (0.077 vs 0.083, see Table 12.25) but realizes the low emission rate via more aggressive CO_2 capture (65% vs 54% of the C in the feedstock is captured) along with a lower biomass input percentage (29% vs 40%). The other new coproduction option considered is CBTL2-OT-CCS for which a GHGI = 0.5 is realized with about 9% biomass input. This option is included because systems involving such a modest percentage of biomass in the feed could be ready for deployment in commercial-scale demonstration projects in this decade.

37 The extra coal required for the CBTL1-OTA-CCS option amounts to 2.1 tonnes of coal equivalent (tce) per tce of Fischer-Tropsch liquid transportation fuels produced. The IEA projects for its Reference Scenario that the coal import price for OECD countries will be $100/t in 2020 and $110/t in 2030 (IEA, 2009b). For China, the cost of oil imports avoided for $90/bbl of crude oil would be 1.7 times the increased cost of coal imports if coal imported into China were to cost $110/t.

38 For this evaluation it is assumed that: i) the synthetic liquid fuel coproducts are sold at the wholesale (refinery-gate) prices of the crude oil-derived products displaced (7.90 and 8.51¢ per liter refining markups for diesel and gasoline, respectively), and ii) selling prices increase with GHG emissions price by an amount equal to the fuel-cycle-wide GHG emission rates for these crude oil-derived products times the emissions price.

39 At a GHG emissions price of $0/t, the LCOE increases by an amount ranging from $12/MWh (for CTL-OT-V) to $16/MWh (for CBTL-OTA-CCS) for each $10/bbl reduction in the levelized crude oil price.

40 The breakeven crude oil price is a metric for evaluating the economics of coproduction systems from a synfuel producer's perspective. It is the crude oil price at which the levelized costs of manufacturing the synfuel coproducts equal the wholesale (refinery-gate) prices of the crude oil products displaced. In this calculation it is assumed that the electricity coproduct is sold at the average selling price for US electricity generation in 2007 ($60/MWh) augmented by the value of the US average electric grid emission rate in 2007 (638 $kgCO_2$-eq/MWh). Figure 12.10 shows this electricity price vs GHG emissions price.

Table 12.25 | CCS retrofit and repowering options for sites of written-off PC-V plants.

	Capacities[d]				Energy penalty for CCS[e] (%)	Site raw H_2O use at full output,[f] liters/s (% of WO PC-V)	GHGI[g]	CO_2 stored, Mt/yr (% of input C stored)	TPC[h], million US_{2007}

a System characteristics as developed in Simbeck and Roekpooritat, 2009.
b Source: Williams et al., 2011 and Liu et al., 2011a.
c System characteristics as developed by Woods et al., 2007.
d Capacities for systems using coal were determined by the following algorithms: i) Coal input rates cannot exceed the coal input rate of the WO PC-V plant displaced; ii) biomass input rates cannot exceed 1.0 Mt/year; iii) CBTL2-OT-CCS has the same FTL output capacity as CBTL-OT-CCS.
e For power-only systems, penalty = 100 x (η_v/ η_c – 1), where η_v and η_c are HHV plant efficiencies for –V and –CCS options, respectively. For XTL-OT-CCS options, penalty = 100 x (extra coal energy required via CIGCC-CCS to make up for lost power in shifting from –V → –CCS)/(coal energy use by XTL-OT-V).
f Raw water usage = consumption – water recycled; estimated by authors for gasification energy systems; based on Woods et al., 2007 for combustion energy systems, as discussed in the main text.
g GHGI = greenhouse gas emissions index = system wide life cycle GHG emissions for production and consumption of the energy products relative to emissions from a reference system producing the same amount of power and liquid fuels. In this instance the reference system consists of electricity from a WO PC-V power plant (for which the GHG emission rate is 998.8 $kgCO_2$-eq/MWh_e) and equivalent crude oil-derived liquid fuels (for which the GHG emission rate is 91.6 $kgCO_2$-eq/GJ).
h This is the total plant cost (TPC), or "overnight capital cost" (which excludes interest during construction).

A CIGCC system is included as a repowering option because, among currently available technologies, this option offers the lowest LCOE among stand-alone coal power systems in new construction applications (see Section 12.2.3). The NGCC is also given close attention in light of recent bullishness about US gas supplies (MIT, 2010).

Simbeck and Roekpooritat (2009) analyzed and estimated LCOEs for several CCS retrofit options based on near-term technologies and showed that a simple CCS retrofit (without plant modification) based on an amine post-combustion scrubber offers the lowest LCOE for a retrofit, although the alternatives would be less energy-intensive. The least-costly CCS retrofit option identified in Simbeck and Roekpooritat is adopted with some of the cost assumptions adjusted to enable self-consistent comparisons in the analytical framework of Williams et al. (2011) and Liu et al. (2011a).

The findings of this analysis for various alternatives to a WO PC-V plant are as follows:

PC-CCS retrofit: The CCS retrofit option is widely thought to be the preferred option if coal use is to persist under decarbonization. This option is by far the least disruptive of the status quo. Its main attraction is that it requires the least capital investment among decarbonization options that involve coal use (see Table 12.25). However, this option involves a huge 36% energy penalty for CCS mainly because of the large amount of heat required to regenerate the amine solvent after it has absorbed the CO_2 from flue gases in which its partial pressure is only 0.14 atmospheres. This high energy penalty gives rise to a large (~33%) increase in the water requirements for the site, which will often greatly limit the viability of this option. The high energy penalty also implies a high minimum GHG emissions price ~US$70/$tCO_2$-eq to induce via market forces a shift from WO PC-V to PC-CCS retrofit (see Figure 12.41).[41]

41 The point at which the PC-CCS retrofit and WO PC-V curves cross determines the minimum GHG emissions price needed to induce CCS via market forces.

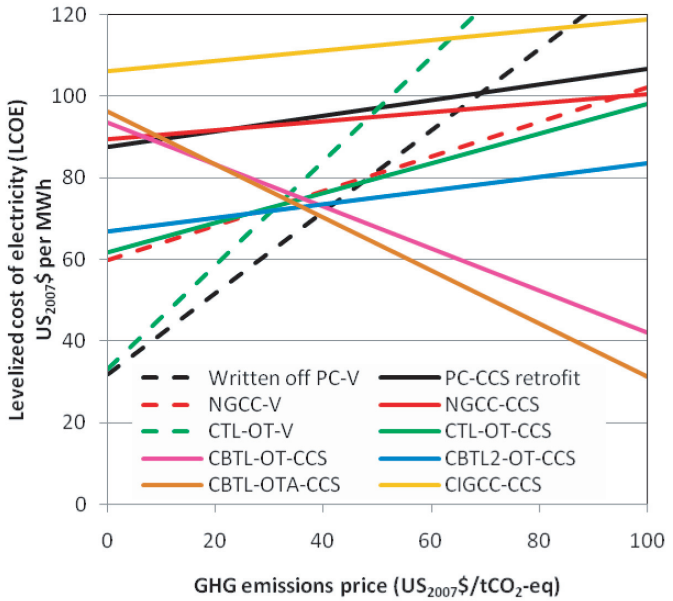

Figure 12.41 | Levelized cost of electricity (LCOE) vs GHG emissions price under US conditions for the alternative power options in Table 12.25 when the levelized crude oil price is US$90/bbl. (See Table 12.6, note (b) for financial parameter values assumed.) Source: based on Liu et al., 2011a; Williams et al., 2011.

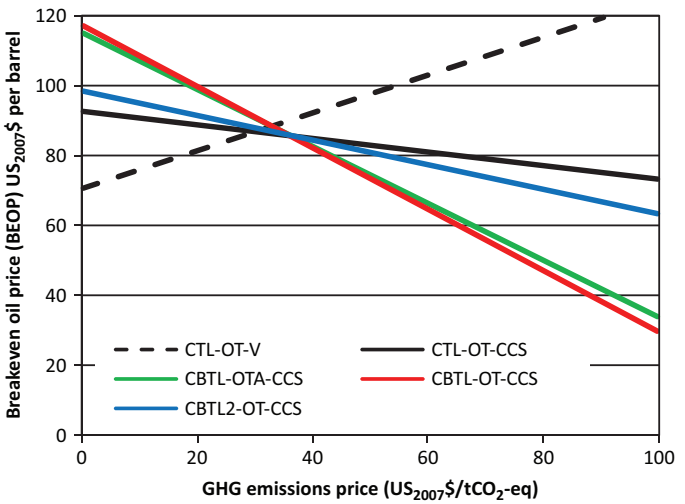

Figure 12.42 | Breakeven crude oil price (BEOP) vs GHG emissions price for the alternative coproduction systems in Table 12.25. (See Table 12.6, note (b) for financial parameter values assumed.) Source: based on Liu et al., 2011a; Williams et al., 2011.

Repowering via CIGCC-CCS: With pre-combustion capture, the energy penalty for CCS and water requirements are both reduced more than 40% relative to the PC-CCS retrofit (see Table 12.25). In part this is because the CO_2 is captured at high partial pressure from shifted syngas instead of from flue gases. But also the low water requirement reflects the fact that only ~1/3 of the power output of the combined cycle power plant is from the steam turbine, which requires the consumption of water for condenser cooling purposes (the gas turbine topping cycle does not), and cooling water dominates water requirements in all cases. These technical advantages do not imply a lower LCOE for the CIGCC-CCS repowering option compared to the PC-CCS retrofit via post-combustion capture (see Figure 12.41), in contrast to the situation for new construction. This is largely because in this application the capital investment is ~three times that for the PC-CCS retrofit (see Table 12.25) whereas in new construction, where CIGCC-CCS does offer a lower LCOE, the capital cost for CIGCC-CCS is likely to be less than for a new pulverized coal plant with post-combustion capture (see Figure 12.10).

Repowering via NGCC: The natural gas combined cycle power plant venting CO_2 (NCCC-V) is the least capital-intensive and least water-intensive of the options shown in Table 12.25. But its carbon-mitigation potential (GHGI = 0.42) is far less than what is likely to be required by mid-century to realize the US goal of more than an 80% reduction in the nation's total GHG emissions. This implies that, if NGCC-V is deployed in the near term as a repowering option at WO PC-V plant sites, the NGCC-V would have to be replaced by NGCC-CCS (as a retrofit or via repowering option) at some point during this half-century. As shown by Figure 12.41 this option would be roughly competitive with a PC-CCS retrofit, and the energy penalty for CCS and water requirements would be less than half of those for a PC-CCS retrofit.[42] One serious economic challenge posed by the NGCC-CCS option is that the minimum GHG emissions price needed to induce CCS by market forces is nearly US$100/t (see Figure 12.41). Another relates to the prospect that it will be very difficult for NGCC-CCS to defend the high assumed 85% capacity factor in economic dispatch competition if there is much coproduction capacity on the electric grid because of the technology's high minimum dispatch cost compared to coproduction options (see Figure 12.43).[43] Still another problem posed by the NGCC-CCS option is that prospective natural gas supplies in the United States are likely to fall far short of what would be required to meet fully the decarbonization challenge posed by existing coal power plants, as discussed in Section 12.6.3.4.

Repowering via XTL-OT technologies: Though not a decarbonization option (GHGI = 1.18), CTL-OT-V is included here as a repowering option because it offers the least costly electricity at low GHG emissions prices.[44] Its inclusion highlights the GHG emissions prices needed to induce a transition to coproduction systems offering significant reductions in GHG emissions. Notably, for all coproduction options the energy

42 This may seem surprising because, like the PC-CCS retrofit, CCS involves post-combustion capture and the CO_2 partial pressure in flue gases is much lower (0.04 atmospheres). The modest penalty arises in this case because the capture rate is only 0.38 t/MWh compared to 1.17 t/MWh for PC-CCS retrofit – reflecting the much lower carbon intensity of natural gas compared to coal.

43 See discussion of dispatch competition in Section 12.6.3.1.

44 At $0/t its LCOE is the same as for WO PC-V.

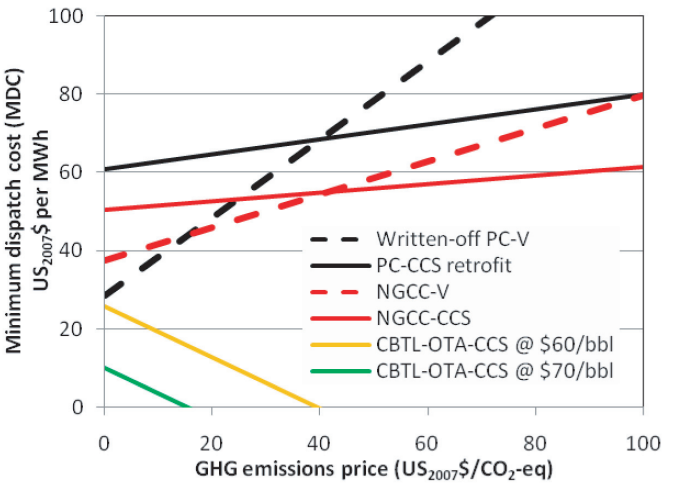

Figure 12.43 | Minimum dispatch cost (MDC) vs GHG emissions price for the alternative coproduction systems listed in Table 12.25. Source: based on Liu et al., 2011a; Williams et al., 2011.

penalty for CCS is one quarter to one half of that for the PC-CCS retrofit, and in all cases water requirements are less than two-thirds as much as for the PC-CCS retrofit. The CCS energy penalty is small largely because a substantial amount of CO_2 must be removed from syngas upstream of synthesis even in the absence of a carbon policy.[45] Water requirements are low for three reasons: (i) the low energy penalty for CO_2 capture; (ii) a significant part of the power output is from the gas turbine part of the power cycle, which does not require water for cooling (as in the NGCC and CIGCC cases); (iii) two thirds or more of the net energy output is in the form of liquid fuels, the production of which requires much less water than does electricity generation.

A notable feature of Figure 12.41 is that the coproduction options with CCS that do not offer deep reductions in emissions (CTL-OT-CCS (GHGI = 0.63) and CBTL1-OT-CCS (GHGI = 0.50)) are never the least costly electricity generation options. Rather, WO PC-V is the least costly option until the GHG emissions price reaches ~US$40/t, above which CBTL-OTA-CCS (GHGI = 0.077) is the least costly option.

It may seem counterintuitive that the more capital-intensive CBTL-OTA-CCS, which involves "aggressive" CO_2 capture, offers a lower LCOE than CBTL-OT-CCS at high GHG emissions prices. There are three reasons for this. First, the average feedstock price for CBTL-OTA-CCS (with 29% biomass) is 10% less than for CBTL-OT-CCS (with 40% biomass). Second, the capital intensity (in US$/$kW_e$) of CBTL-OTA-CCS falls from being 18% higher than for CBTL-OT-CCS when their FTL output capacities are the same to 12% higher when the CBTL-OTA-CCS output capacity is increased to the point where the biomass consumption rates are the same (1 Mt/yr) for these options. The net effect of the lower feedstock price and the higher capital intensity is that the LCOE is only 3% higher for CBTL-OTA-CCS than for CBTL-OT-CCS at US$0/t. Third, the more rapid rate of decline of LCOE with GHG emissions price for CBTL-OTA-CCS arises because its FTL/electricity output ratio (and thus the credit for GHG emissions avoided by displacing crude oil derived products) is 21% higher for CBTL-OTA-CCS than for CBTL-OT-CCS.

A single XTL-OT plant requires an investment of US$1.2–1.8 billion (see Table 12.25). Investors will worry about the risk of oil price collapse, which is a very real concern because marginal oil production costs are lower than US$90/bbl, the assumed oil price for the LCOE calculations presented in Figure 12.41. In particular, successful market establishment of coproduction technologies could plausibly drive down oil prices.

How might investors be protected against the risk of oil price collapse? To help address this question, Figure 12.42 was constructed to show the breakeven crude oil prices for the alternative coproduction technologies. This figure shows that those who invest in XTL-OT-CCS technologies that coprocess biomass at high rates (29–40%) would be protected against falling oil prices down to less than US$60/bbl if the average GHG emissions price were US$69/t, the minimum GHG emissions price needed to make a PC-CCS retrofit competitive with WO PC-V. In contrast, the XTL-OT-CCS options that coprocess no or only modest amounts of biomass offer only modest protection against the risk of oil price collapse. Thus, the combination of a strong carbon mitigation policy and a high rate of biomass coprocessing is key to simultaneously realizing deep reductions in GHG emissions and enhancing transportation fuel security.

Finally, an attractive attribute of XTL-OT systems is their low minimum dispatch costs (MDCs), which would enable them not only to defend high capacity factors in economic dispatch competition but also would make it possible for them to drive down the capacity factors of competing technologies as XTL-OT market penetration expands. Figure 12.43 illustrates the point for CBTL-OTA-CCS. At crude oil prices of US$37/bbl and US$57/bbl, respectively, this system would have MDCs that are the same as for PC-CCS retrofits and WO PC-V plants when the GHG emissions price is $0/t$CO_2$eq. For US$74/bbl crude oil the MDC = US$0/MWh for this system.

12.6.3.4 Repowering Thought Experiment for the United States

The outstanding economics at sufficiently high oil and GHG emissions prices of coproduction systems coprocessing coal and substantial amounts of biomass suggest that it would be worthwhile exploring the repowering thought experiment for the United States that follows.

The point of departure for the thought experiment is an assumption that the United States enacts public policy mandating that all coal-fired power plants be retrofitted or repowered at a linear rate over the period 2016–2050, until all existing coal power plant capacity is replaced. Since the projected level of coal capacity for 2015 is 322 GW_e (US EIA, 2010b), the coal power retrofit/repowering rate would be 9.2 GW_e/yr during

45 See caption to Figure 12.31.

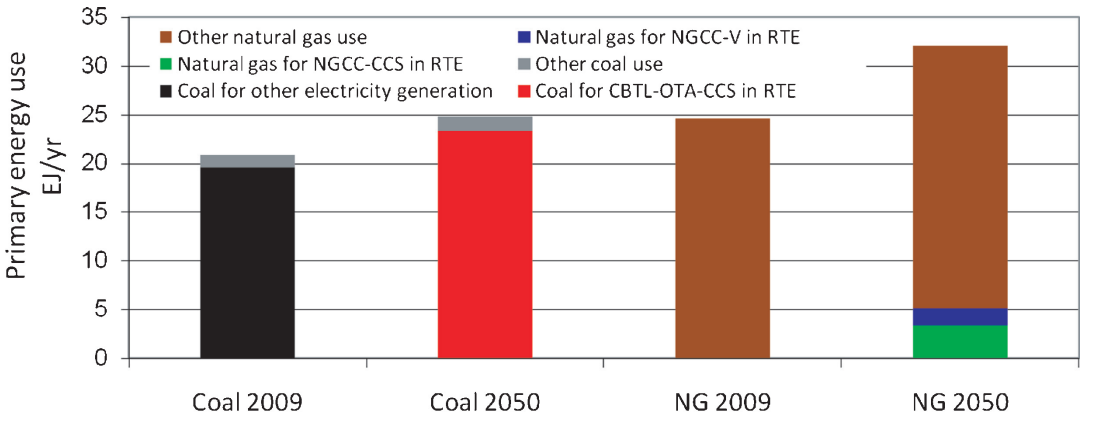

Figure 12.44 | Coal and natural gas demand implications of US repowering thought experiment (RTE).

2016–2050. It is further assumed that market forces are effective in deploying the least-costly options and that crude oil and GHG emissions prices are sufficiently high to make CBTL-OTA-CCS technology the least costly power generation option, and to make both NGCC-V and NGCC-CCS technologies less costly options than both the WO PC-V and PC-CCS retrofit options. (One set of prices for which these conditions would be met is US$90/bbl of crude oil and a GHG emissions price greater than US$50/t, see Figure 12.41.) Also it is assumed that under repowering conditions a site would not produce any electricity for a period of five years, which is the time required to bulldoze the existing site and build a new repowering unit there. Under these conditions, it would be cost-effective to retire WO PC-V plants, no PC-CCS retrofits would be deployed, and the following would be a cost-effective scenario:

- During 2016–2020, greenfield NGCC-V plants come on line at a rate of 9.2 GW_e/yr to exactly compensate for coal power plant retirements.
- During 2021–2050, each year 9.2 GW_e of coal power capacity is replaced by 4.9 GW_e of CBTL-OTA-CCS repowering capacity + 4.3 GW_e of NGCC-CCS makeup capacity built at greenfield sites to compensate for coal plant retirements.

The following are the results of this repowering thought experiment, assuming for simplicity that over the period to 2050 the US energy economy is frozen at the level of energy activities of 2015 as projected in US EIA (2010b) for all energy sectors except coal power:

- GHG emissions for 1810 TWh of electricity (all coal electricity in 2015) would be reduced in 2050 by 1.61 $GtCO_2$-eq/yr (85% reduction).
- GHG emissions for 5.4 million barrels/day of gasoline equivalent liquid transportation fuels would be reduced in 2050 by 0.84 $GtCO_2$-eq/yr (92% reduction), bringing the total GHG emissions avoided in 2050 to 2.45 $GtCO_2$-eq/yr.
- Replacement electricity generation in 2050 would be made up of 64% CBTL-OTA-CCS, 22% NGCC-CCS, and 14% NGCC-V.
- The CO_2 storage requirements in 2050 would be 2.04 $GtCO_2$ (93% via CBTL-OTA-CCS and 7% via NGCC-CCS).
- The biomass required for CBTL-OTA-CCS plants in 2050 would be 508 Mt/yr.
- US coal and natural gas use in 2050 would be, respectively, 19% and 31% higher than in 2009 (see Figure 12.44).
- The total investment required for the repowering thought experiment through 2050 is US$1.1 trillion (see Figure 12.45).

The results of the repowering thought experiment have some important strategic implications:

- The low C transportation fuels produced would be at about the level of transportation fuels produced from US domestic crude oil in 2009.[46]
- The total CO_2 storage requirements in 2050 would be about the same if PC-CCS retrofits were pursued[47] instead of this repowering strategy, even though the retrofit strategy would involving decarbonising only coal power – a startling result that reflects largely the difference in energy penalties for CCS (36% for PC-CCS retrofits vs 17% and 16% for CBTL-OTA-CCS and NGCC-CCS, respectively, see Table 12.25).
- The potentially available biomass resources converted using CBTL-OTA-CCS systems could produce much more low-GHG liquid fuel than if converted to cellulosic ethanol, because producing 1 GJ of

46 Crude oil was produced in the United States in 2009 at a rate of 5.36 million barrels per day, from which 5.18 million bbl/day of gasoline equivalent transportation fuels (gasoline, diesel, and jet fuel) were produced.

47 In the CCS retrofit strategy 73% of the system capacity and 97% of the system generation in 2050 are provided by PC-CCS retrofit plants, while 27% of system capacity and 3% of generation are provided by NGCC-CCS. The CO_2 storage rate in 2050 is 2.08 $GtCO_2$, 99% is via PC-CCS retrofit plants.

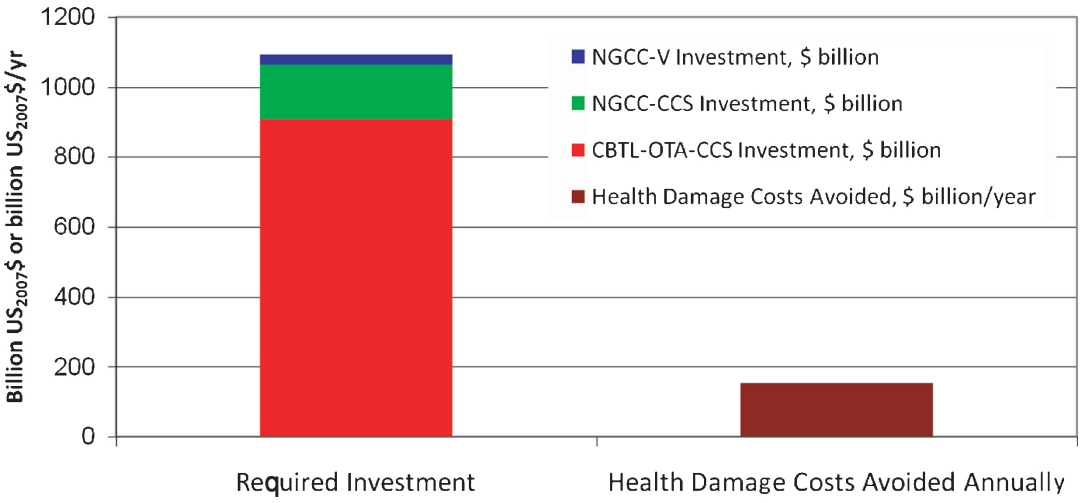

Figure 12.45 | The simple payback on the total new plant investment, 2016–2050, for the RTE would be about seven years if the sole benefit considered is the reduced public health damage costs from reduced $PM_{2.5}$ air pollution. (See Table 12.9.)

Fischer-Tropsch transportation fuels via CBTL-OTA-CCS requires only 36% as much biomass as producing 1 GJ of cellulosic ethanol (see Figure 12.33). If the same amount of synthetic low-carbon liquid fuel as would be produced in 2050 in the repowering thought experiment were instead produced as the energy equivalent amount of cellulosic ethanol, some 1400 Mt/yr of biomass would be required (see Section 12.6.4). In 2005 it was widely believed that the United States has 1300 Mt/yr of prospective biomass supplies for energy. Concerns about food/fuel competition, indirect land-use impacts, and biodiversity loss have reduced the estimate of sustainable US biomass production to ~500 Mt/y (the level for the repowering thought experiment in 2050) if growing dedicated energy crops on good cropland is not allowed – according to the *America's Energy Future* Study of the US National Research Council (AEFP, 2009).

- The incremental natural gas supply required for the RTE beyond that for 2009 is 7.5 EJ/yr by 2050 and 5.9 EJ/yr for the intermediate year 2035. The latter is much less than the 9.4 EJ/yr of incremental shale gas which the Energy Information Administration estimates will be available by 2035 (AEFP, 2009). However, US EIA also projects substantial reductions for other gas supplies in the period to 2035 (see Figure 12.46), so that the net incremental gas supply in 2035 relative to 2009 is only 3.1 EJ/yr, which is enough to satisfy only 52% of the natural gas requirements[48] for the RTE by 2035, assuming all the incremental gas is dedicated to power generation.

- Alternative renewable electricity supplies would have to grow four times between 2009 and 2035 if all of net incremental gas supply projected for 2035 were used for power generation and the shortfall in electricity generation were provided entirely instead by these renewable sources.

- The simple payback on the investment would be ~seven years (see Figure 12.45) if the only benefit considered for this repowering strategy were the reduced health damage costs from $PM_{2.5}$ air pollution (see Table 12.9).

12.6.4 Alternative Approaches for Low GHG-emitting Liquid Fuels Using Biomass

The analysis in the preceding section indicates that coproduction systems with CCS that coprocess ~30% biomass would be very competitive as repowering options for sites of old coal power plants at high oil and GHG emissions prices, while simultaneously providing synthetic liquid fuels with near zero net GHG emissions. But biomass is a scare resource. How does this biomass use option compare to other options for providing low-GHG-emitting transport fuels? This question must be addressed to understand better the extent to which biomass coprocessing with coal and CCS for coproduction systems should be given priority in public policies relating to future uses of biomass for energy.

To address this question, the CBTL-OTA-CCS option for which 29% of the feed (HHV basis) is biomass is compared to alternative ways to use biomass to provide low-C fuels. Attention is focused on six alternatives. One alternative (BIGCC-CCS) was discussed in Section 12.2.3. The negative emissions with BIGCC-CCS provide "room in the atmosphere" for emission from some petroleum-derived fuels. Three alternatives (CBTL-RC-CCS, BTL-RC-V, BTL-RC-CCS) were discussed in Section12.4.3. Two new systems not yet considered, are also introduced as alternatives: (i) a future cellulosic ethanol option (EtOH-V), which is currently a high priority for biofuels development in the United States; and (ii) a –CCS variant of this (EtOH-CCS), see Box 12.3. In total, seven options are

48 Since the natural gas demand for NGCC-V systems deployed during 2016–2020 would have to be satisfied first in the RTE, only 15% of the natural gas needed for NGCC-CCS systems by 2035 would be available from net incremental natural gas supplies.

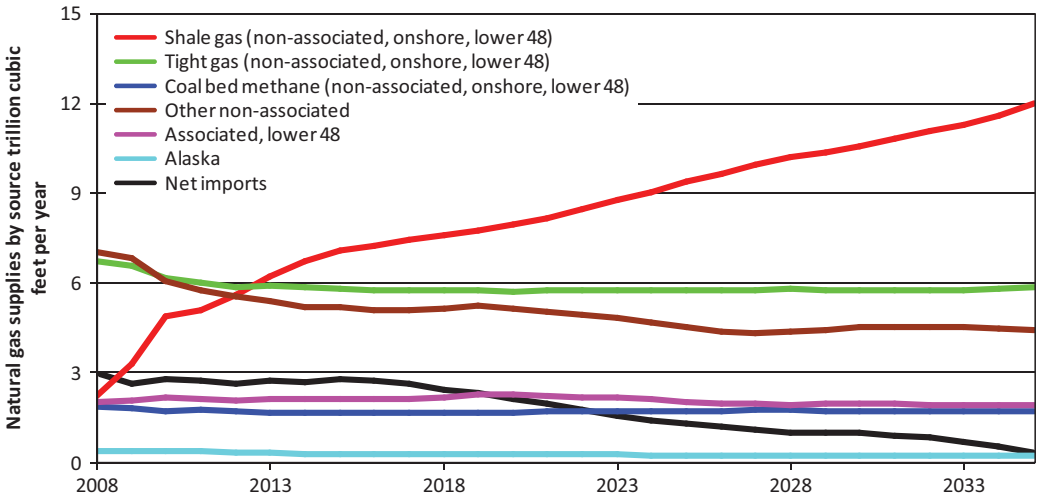

Figure 12.46 | Outlook for natural gas supplies in the United States. To convert cubic feet to cubic meters, divide by 35.3. Source: modified from US EIA, 2010a.

Box 12.3 | Prospective Cellulosic Ethanol Technologies

EtOH-V: The main cellulosic ethanol option considered here is the future switchgrass-to-ethanol option analyzed in a study by America's Energy Future Panel (AEFP, 2009), for which the estimated yield is 80 gallons of ethanol (EtOH) per dry short ton (334 L/t). For reference, the yield from switchgrass with currently understood technology is ~69 gallons per dry short ton (288 L/t). That study estimated a capital cost of US_{2007}156 million for a plant producing 40 million gallons (156 million liters) of ethanol annually (an output capacity of 1941 bbl/day, or 309,000 L/day, of gasoline equivalent).

EtOH-CCS: It is feasible to carry out CCS for EtOH production if there are adequate CO_2 storage opportunities nearby because in the fermenter 1 mol of CO_2 is generated in a pure stream for each mol of EtOH) produced. The capital cost penalty for this CCS option is modest (see Table 12.26).

presented in Table 12.26. In all cases it is assumed that the feedstock is switchgrass consumed at a rate of about 0.5 Mt/yr dry biomass – the reference scale assumed for future cellulosic ethanol plants (EtOH-V) assessed in a recent United States National Research Council report (AEFP, 2009).

Six of the plants listed in Table 12.26 involve CCS, but the CO_2 capture rates vary by a factor of 17 from the lowest (EtOH-CCS) to the highest (CBTL-OTA-CCS). To illustrate the impact of capture rate on system economics it is assumed in all CCS cases that the CO_2 is transported 100 km and stored in a saline formation 2 km underground, and that the maximum CO_2 injectivity is 2500 t/day per well. The CO_2 transport and storage cost model cited by Liu et al. (2011a) is used to estimate CO_2 transport and storage costs (in US_{2007}/t). Alternative biomass use options are compared with respect to five metrics. Three of these are defined and presented for the alternative options in Table 12.26: a biomass input index (BII), a greenhouse gas emissions index (GHGI), and a zero-emission fuels index (ZEFI). In addition, Figure 12.47 presents the LCOF for the six options that provide fuels, and Figure 12.48 presents the real internal rate of return (IRRE) for four options.

BII: This index (defined in Table 12.26, note (c)) indicates that the coprocessing options (CBTL-RC-CCS and CBTL-OTA-CCS) require much less biomass to make low-C liquid fuels than the biofuel options (e.g., 36–40% as much as is required for the EtOH options).

GHGI: All options have outstanding GHG emissions mitigation performance, with GHGI less than 0.20. Four options have negative emission rates that could offset emissions from other fossil energy systems.

ZEFI: This performance index (defined in Table 12.26, note (e)) highlights the strategic importance of storing underground a large fraction of the biomass feedstock carbon not contained in the energy products, thereby exploiting the negative GHG emissions benefit of photosynthetic CO_2 storage. It quantifies simultaneously the carbon mitigation and liquid fuel insecurity mitigation potentials of an option. The higher the value of ZEFI, the better the option. Four of the options store enough photosynthetic

Table 12.26 | Alternative low carbon fuel options – each consuming 457,000 dt/yr biomass[a].

Plant name	Capacities				BII[c]	GHGI[d]	ZEFI[e]	CO_2 stored[f], Mt/y (% of feedstock C stored)	TPC[g], million $US_{2007}$$
	Inputs		Outputs

CBTL-OTA-CCS	1041	29	131	5,395 (314)	0.90	0.086	0.92	1.70 (65)	939
BIGCC-CCS[b]	320	100	118	0	–	–0.93	0.99	0.71 (90)	398

a Based on Liu et al., 2011a. See also Box 12.3.
b Based on unpublished modeling carried out by the authors of Liu et al., 2011a in a manner that is consistent with the modeling of the systems presented here that make liquid fuels + electricity, see Table 12.7 (in which the BIGCC-CCS case here corresponds to the switchgrass case in the PEI section of the table).
c BII (biomass input index) ≡ Biomass energy (in GJ LHV dry) required to produce 1 GJ of liquid fuel (LHV).
d GHGI is the system-wide life cycle GHG emissions relative to emissions from a reference system producing the same amount of power and fuels. The reference system consists of equivalent crude oil-derived liquid fuels and electricity from a stand-alone new supercritical pulverized coal power plant venting CO_2. For details, see Table 12.15, note (c).
e ZEFI (Zero-emissions fuels index) ≡ Amount (in GJ) of equivalent zero GHG-emitting liquid fuel provided per GJ of biomass input.
f It is assumed that captured CO_2 is compressed to 150 atmospheres, transported via pipeline 100 km to a storage site, and injected into a deep saline formation 2.5 km underground.
g TPC (total plant cost) ≡ "overnight capital cost" (which excludes interest during construction).

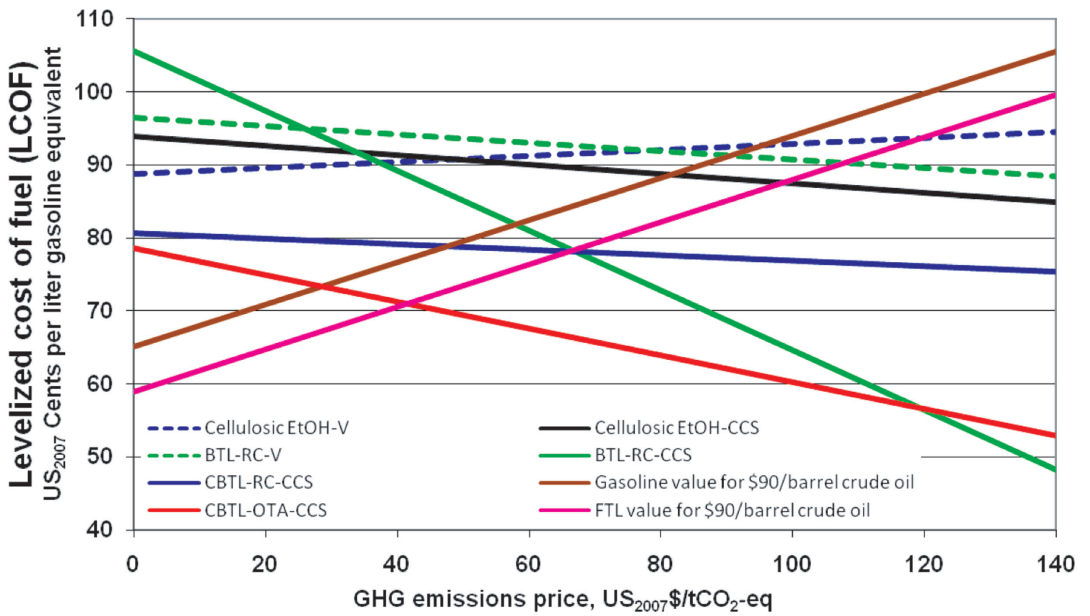

Figure 12.47 | LCOF vs GHG emissions price for the six alternative low-carbon fuel options listed in Table 12.26. Also shown are values of petroleum-derived gasoline and an average for gasoline plus diesel corresponding to the proportions of these fuels found in the FTL flues in the CBTL and BTL cases (see Table 12.15, note (a)). (See Table 12.6, note (b) for financial parameter assumptions. Also, electricity sales are assumed at the US average grid price plotted in Figure 12.10.) Based on Liu et al., 2011a.

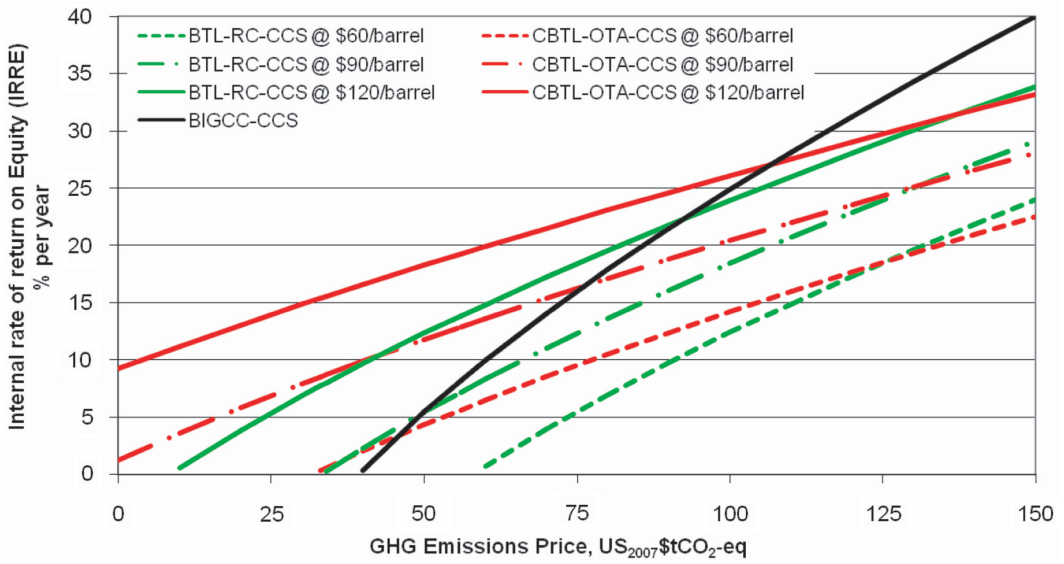

Figure 12.48 | Real internal rate of return on equity (IRRE) for BIGCC-CCS (see Table 12.26) and for the FTL options with the lowest LCOF (see Figure 12.47) for three levelized crude oil prices. Electricity sales are assumed at the US average grid price plotted in Figure 12.10. Based on Liu et al., 2011a.

CO_2 to convert (in effect) 92% or more of the biomass energy into useful zero GHG emitting transportation fuel energy. Although the BIGCC-CCS option does not provide liquid transportation fuels, the negative GHG emissions of this option enables it to offset emissions from crude oil-derived products; assuming the crude oil product displaced is gasoline, the ZEFIs for this option is high (0.99). The –V options perform poorly in terms of this metric. Notably, EtOH-CCS also has a relatively low ZEFI, reflecting the fact that only 15% of the C in the feedstock is stored underground so that the potential photosynthetic storage benefit is modest.

LCOF: Figure 12.47 shows that at all GHG emissions prices below \$120/tCO_2eq CBTL-OTA-CCS offers the least costly liquid fuel, becoming competitive with the crude oil products displaced when the GHG emissions price exceeds US\$40/tCO_2-eq and the crude oil price is US\$90/bbl. In contrast EtOH-V requires a GHG emissions price of more than US\$95/t to be competitive at this crude oil price. Notably, pursuing CCS does not markedly improve the economics of cellulosic ethanol at high GHG emissions prices – reflecting the relatively modest photosynthetic CO_2 benefit for this option (storing only 15% of the feedstock C).

Although at US\$0/t, BTL-RC-CCS is the most costly transportation fuel option, its LCOF declines rapidly with GHG emissions price as a result of its strong negative GHG rate (GHGI = –0.95). This technology cannot compete with CBTL-OTA-CCS until the GHG emissions price exceeds US\$120/t. However, in regions where coal coprocessing is not a realistic option, BTL-RC-CCS would become competitive with crude oil derived products for GHG emissions prices > US\$67/t when the oil price is US\$90/bbl. As noted earlier, *World Energy Outlook 2009* estimates that if the world community were on a path to stabilizing the atmospheric concentration of GHG gases at 450 ppmv, the world oil price would be stable during 2020–2030 at US\$90/bbl, and if, in addition, there were a single global carbon trading price, that price would be about US\$70/t by 2030 (IEA, 2009b). Thus it is plausible that in the post-2030 time period BTL-RC-CCS would be cost-competitive in biomass-rich but coal-poor regions if the world community were on this carbon mitigation path.

IRRE: The real IRRE is a good metric for comparing the economics of power-only options with liquid-fuel options. Figure 12.48 shows the IRRE for the BIGCC-CCS option and the two most promising liquid fuel options analyzed here (CBTL-OTA-CCS and BTL-RC-CCS) for three crude oil prices: US\$60, US\$90, and US\$120/bbl.[49] Several conclusions can be drawn from these curves. First, at very high GHG emissions prices, BIGCC-CCS has the highest IRRE. Second, at all three oil prices, CBTL-OTA-CCS has the highest IRRE at low GHG emission prices, and break-even with BIGCC-CCS occurs at a GHG emissions price that increases with the crude oil price: US\$46/t at US\$60/bbl, US\$76/t at US\$90/bbl, and US\$107/t at US\$120/bbl. Third, BTL-RC-CCS will become more profitable than CBTL-OTA-CCS at GHG emissions prices in the range US\$125–130/t.

12.6.5 Coal/biomass Coprocessing with CCS as a Bridge to CCS for Biofuels

Establishing in the market over the next 20 years technologies involving coal/biomass coprocessing with CCS for the coproduction of liquid fuels and electricity could plausibly serve as a bridge to widespread biofuels production with CCS in the post-2030 time frame. This is suggested by the analyses of Sections 12.6.3 and 12.6.4 considered together. This is

49 For these options it is assumed that the debt/equity ratio is 45/55 and that electricity is sold at the US average grid price indicated in Figure 12.10. For other financing assumptions relating to these IRRE calculations see Liu et al., 2011a.

an important consideration because biomass supplies in coal-rich countries are relatively limited but are abundant in many coal-poor regions of the world. In coal-poor regions, the economics of liquid fuel production via thermochemical conversion of biomass with CCS become economically attractive relative to crude oil-derived products at prospective GHG emissions prices for the post-2030 period if the global community were to pursue stabilization of the GHG concentration in the atmosphere at 450 ppmv. Moreover, the capital needed to build these plants should become available in a world with carbon trading and high GHG emissions prices. This is likely because not only would these plants be very competitive in providing liquid fuels, but they also would generate huge revenue streams from the sale of carbon credits.[50]

12.6.6 Global Coal/biomass Thought Experiment for Transportation

A global coal/biomass thought experiment for transportation is presented to illustrate the carbon mitigation potential for transportation by 2050 via widespread use of low-carbon fuels provided via coal and/or biomass with CCS in many regions. In coal-poor regions this would be accomplished via BTL-RC-CCS, and in coal-rich regions via CBTL-OTA-CCS. This thought experiment is set in the context of a world in which the growing of dedicated energy crops on cropland is off-limits (Tilman et al., 2009) because of concerns about impacts on food prices (Rosegrant, 2008) and land-use effects (Fargione et al., 2008; Searchinger et al., 2008).

It is assumed for the supply side of this thought experiment that the only biomass supplies are residues[51] and mixed prairie grasses grown with minimal inputs on abandoned agricultural lands. The estimated total global biomass supply under these conditions is approximately 6 Gt/yr dry biomass[52] – all of which is assumed to be used in the thought experiment. It is assumed that CBTL-OTA-CCS plants use 1 Gt/yr of biomass worldwide and that the rest of the biomass is used in BTL-RC-CCS plants located in coal-poor regions. Many of these plants would be located in developing regions such as sub-Saharan Africa and Latin America.

Dedicating the entire global biomass supply to BTL and CBTL plants is clearly an unrealistic assumption. However, as the preceding analysis has shown, these applications are likely to be hard to beat in terms of both the carbon mitigation per tonne of scarce biomass and economics in a world of high GHG emissions prices and high oil prices. Moreover, such a starkly defined global coal/biomass thought experiment helps to clarify the tradeoffs associated with the allocation of scarce biomass resources.

The demand for global transportation energy in 2050 in the thought experiment is assumed to be essentially that presented for the IEA's BLUE Map transportation scenario (IEA, 2009a), an update for the transport sector of its earlier projection to 2050 (IEA, 2008b).[53] A general characterization of the BLUE Map scenario is that it envisages technological change bringing emissions to 50% of the 2005 level by 2050. This includes a strong emphasis on improving energy efficiency but excludes lifestyle changes and modal shifts. It is appropriate to assume an energy-efficient future as a context for exploring the prospects for carbon mitigation via biomass and coal with CCS because, typically, energy efficiency improvement represents "the low-hanging fruit" in carbon mitigation (e.g., see Chapter 10) and thus should be given priority. Transportation is also one of the main branching points of different pathways considered in Chapter 17; Figure 17.2 shows possible final energy shares for transportation up to 2100 for different transportation system strategies (discussed further in Chapter 17, Section 17.3.3.4).

The challenge for global transportation is to reduce GHG emissions at midcentury by a factor of four relative to the IEA Baseline Projection in order to reduce global emissions by 50% relative to emissions in 2005. As shown in Figure 12.49, this baseline projection, which involves nearly a doubling of both energy demand and GHG emissions relative to 2005, illustrates the dimensions of this challenge.

In our global coal/biomass thought experiment, while transportation demand in 2050 is essentially that in the BLUE Map scenario, we modify that scenario by excluding some technologies. We are working from the assumption that no plug-in hybrid vehicles, no all-electric vehicles, and no H_2 fuel cell vehicles are included in the light-duty vehicle (LDV) mix in the period to 2050. This is in contrast to the actual BLUE Map scenario, which assumes a high penetration of these technologies in the mix by midcentury.[54] Obviously, this exclusion is not a realistic assumption, because these technologies are being heavily promoted by governments. The main reason for the exclusion is to bring to the attention of policymakers that, as shown in this chapter, deep reductions can be plausibly realized (e.g., via pursuit of CCS for coal and biomass) at attractive production costs with essentially no costly changes in transportation fuel infrastructures and with evolutionary rather than revolutionary changes

50 For example, at a GHG emissions trading price of \$70/tCO_2-eq, the present worth of the stream of revenues (over the assumed 20-year economic life of the plant) from the sale of carbon emissions credits for the BTL-RC-CCS plant described in Table 12.26 would be equivalent to 73% of the TPC for the plant.

51 Agricultural residues, forest residues, forest thinnings to reduce forest fire risk and enhance productivity for commercial species, urban wood wastes, municipal solid wastes.

52 In energy terms, the residue supply is assumed for 2050 to be 75 EJ/yr (the global residue supply for energy assumed for 2050 in IEA, 2008b). The assumed potential supply of biomass grown on abandoned agricultural lands is 32 EJ per year (average yield of 4.3 dry tonnes/yr on 429 million hectares worldwide) based on Campbell et al. (2008). The total biomass supply, 107 EJ/yr, is 2.3 times total biomass use for energy in 2005. For comparison, the global biomass supply for 2050 in the IEA Blue Map scenario is 150 EJ/yr (which includes biomass grown for energy on cropland), and the maximum biomass resource availability for 2050 is estimated in Chapter 7 to be still higher than this. For perspective, the total assumed global biomass supply (107 EJ/yr) is comparable to total US primary energy use in 2006 (97 EJ/yr).

53 For the IEA Baseline Projection the total number of light-duty vehicles (LDVs) increases three times to 2.15 billion, 2005–2050, air travel increases 3.9 times, and truck freight increases 1.9 times.

54 In 2050 the LDV fleet in the IEA BLUE Map Scenario (IEA, 2009a) includes 37% plug-in hybrids, 21% all-electric vehicles, and 25% H_2 hybrid fuel cell vehicles.

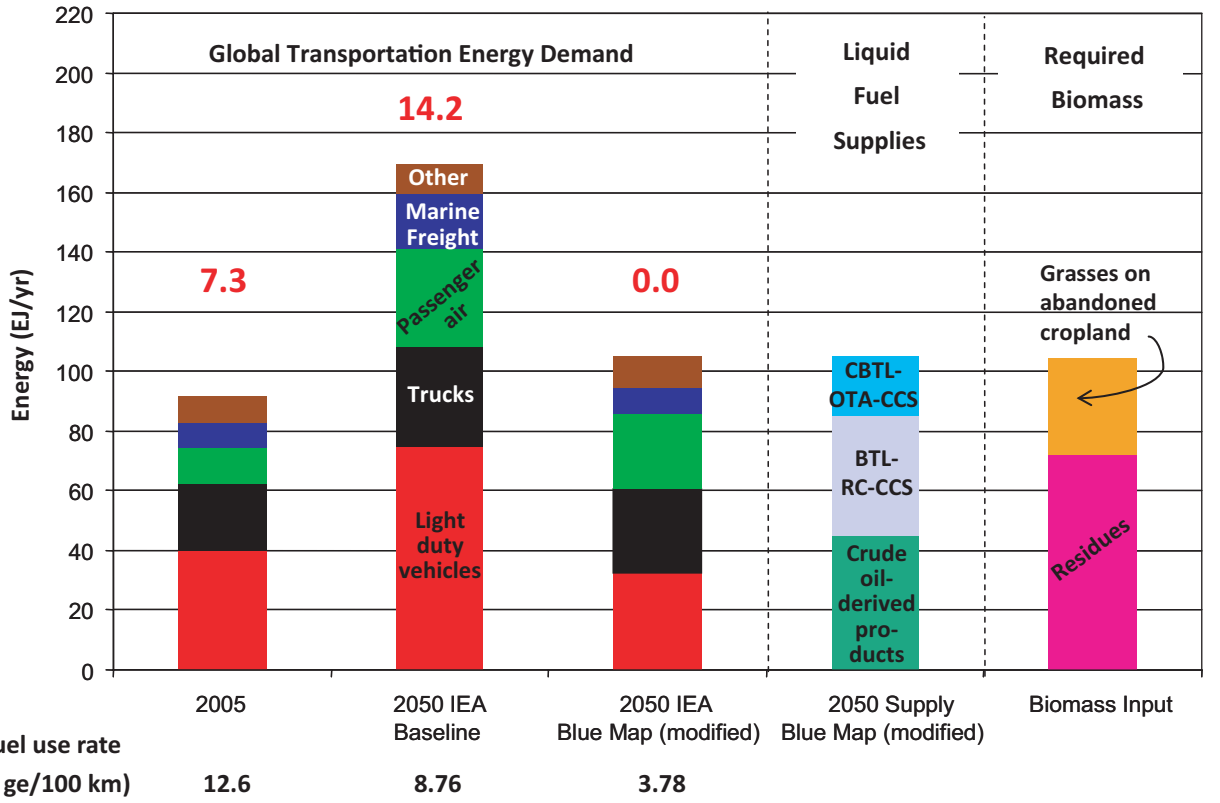

Figure 12.49 | Energy and GHG emissions for global coal/biomass thought experiment and for IEA 2050 Baseline (business-as-usual) scenario. Numbers at tops of bars are total GHG emissions in $GtCO_2$-eq/yr. LDV fuel use rate is in liters of gasoline equivalent per 100 km. Source: see discussion in text.

in automotive engine technologies. In particular, energy-efficient LDVs[55] (e.g., advanced gasoline and diesel hybrid electric vehicles) are emphasized in our modified BLUE Map scenario. Our hope is that this modified scenario will inspire policymakers to take a more balanced approach toward decarbonizing the transportation sector and to create policies that enable the low carbon transportation technology options that have been the focus of this chapter to compete alongside the technologies that are intensely promoted in current policies.

The resulting liquid fuel demand and supply for global transportation under the modified BLUE Map scenario are shown as the 3rd and 4th bars of Figure 12.49. Total net GHG emissions are zero for global transportation in 2050 under the conditions of the global coal/biomass thought experiment. The liquid fuel supply would be made up of 19% FTL via CBTL-OTA-CCS, 38% FTL via BTL-RC-CCS, and 43% crude oil–derived products. The level of crude oil-derived products used in transportation is 51% of the amount of crude oil derived products used for transportation worldwide in 2005. The projected GHG emissions are zero despite the large share of crude oil-derived products in the mix because it is assumed for the thought experiment that the negative emissions from BTL-RC-CCS systems are used to offset positive GHG emissions from both crude oil-derived products and CBTL-OTA-CCS systems.

In 2050 coal use for the modified BLUE Map scenario (with the global coal/biomass thought experiment) is 1.15 times global coal use in 2005, compared to 0.78 times for the IEA BLUE Map scenario and 3.04 times for the IEA Baseline Scenario.

Under the conditions of the thought experiment, CO_2 storage would be carried out in 2050 at rates of 3.7 Gt/yr for CBTL-OTA-CCS plants and 4.8 Gt/yr for BTL-RC-CCS plants. This finding highlights the importance of ascertaining the extent to which there are good geological CO_2 storage opportunities in biomass-rich but coal-poor regions, where consideration of CCS as a carbon mitigation option has probably not been given much thought.

Is it plausible that about ten thousand BTL-RC-CCS plants[56] might be up and running by 2050 (each processing 0.5 Mt of biomass annually)? If one imagines starting with 20 such plants by 2030 the annual average

55 In the IEA (2009a) scenarios, average fuel economies for new LDVs in 2050 are 5.9 liters of gasoline equivalent per 100 km (l_{ge}/100 km) or 40 miles per gallon of gasoline equivalent (mpg_{ge}) for the Baseline Scenario and 2.9 l_{ge}/100 km (81 mpg_{ge}) for the BLUE Map scenario. The average fuel economy assumed for the entire LDV stock in 2050 in the modified BLUE Map scenario is 2.9 l_{ge}/100 km (62 mpg_{ge}), which is consistent with the IEA assumptions for the average fuel economy for new LDVs in the actual BLUE Map scenario. There are reasonable prospects that this average fuel economy for the LDV stock could be realized without use of plug-in hybrids or fuel cell vehicles. Kromer and Heywood (2007) have estimated that by 2030 a mid-sized conventional hybrid-electric car (essentially a 2030 version of a Prius) could have a fuel economy of 3.1 l_{ge}/100 km (76 mpg_{ge}).

56 Each of which provides 2,200 bbl/day of gasoline equivalent FTL + 14 MW_e of electricity and requires an investment of US$420 million (see Table 12.26).

growth rate in plant deployment, 2030–2050, would have to be 37%/yr. This extraordinarily high growth rate would not take place without supportive public policy, but it is not inconceivable. In its heyday, nuclear power grew worldwide at a sustained average growth rate of 37%/yr from 1957–1977.

Much of this growth would take place in now-impoverished developing countries, where this technology would represent a major opportunity for industrial growth. But many such countries currently have neither the needed physical infrastructures (e.g., roads, railroads, pipelines, port facilities for managing exports, etc.) nor the human capacity to manage such industrial growth. The technology is not likely to be cost competitive until about 2030 even under strong carbon-mitigation policies worldwide, however, so there is a strategic opportunity to build those needed capacities in the interim – if the global community comes to think that there is a pressing need for this industry.

Finally, if the goal for decarbonizing global transportation were to reduce by 2050 GHG emissions for transportation worldwide not to zero but rather to half the 2005 level (in line with current long-term policy goals for carbon mitigation), the global biomass requirements for 2050 drop to a level that is only 38% higher than global biomass use in 2005 – so that considerable biomass would be available for purposes other than to satisfy the global coal/biomass thought experiment needs. Moreover, crude oil-derived products (in an amount equivalent to 69% of the level for transportation in 2005) would account for 60% of total transportation energy in 2050.

12.7 Long-term Considerations

The preceding analyses in Chapter 12 focused mainly on technologies that are near at hand. It is beyond the scope of Chapter 12 to present a comprehensive review of advanced fossil energy conversion technologies. Rather, the focus in this short section is on some advanced technologies that might be especially helpful in evolving to promising longer-term future low-GHG emitting fossil-fuel-based electricity and synfuels technologies and strategies.

12.7.1 Low-carbon Electricity Generation Technologies in the Long-term

For systems that provide only electricity, a brief review is presented of prospects for substantial cost reduction in systems with CCS. The review is restricted to gasification-based systems for three reasons. First, with current bituminous coal technologies, CIGCC systems with pre-combustion CO_2 capture outperform PC systems with post-combustion capture – as shown in Section 12.2.3. Second, synfuel/electricity coproduction systems that require gasification have astonishingly good economic prospects even with current technologies, as discussed in Section 12.6.3. Reason number three has to do with the fact that coal gasification technologies are at a much earlier stage in their technological evolution than are coal combustion technologies. Over the longer term, it is plausible that conversion efficiencies will be higher and costs for generating coal electricity with CCS will be lower with advanced gasification technologies than the costs presented in detail in earlier sections of Chapter 12.

A recent report from the US National Energy Technology Laboratory gives a sense of the possibilities: Gray et al. (2009) describe two alternative technological paths for gasification energy to provide power from coal with CCS: (i) an evolutionary change path that involves a series of incremental changes in CIGCC technology and (ii) a revolutionary change path that involves a shift from combustion energy conversion to electrochemical energy conversion via use of solid oxide fuel cells (SOFCs). Here key findings of Gray et al. (2009) are sketched out to highlight the importance of a major research and development effort in this area.

The evolutionary change approach for CIGCC involves the following incremental changes over time:

- a continuation of the historical trend toward improved gas turbine performance as a result of increasing firing temperatures and higher pressure ratios, but with emphasis in a carbon-constrained world on gas turbines burning hydrogen;
- introduction of a dry coal feed pump to reduce the energy penalty associated with evaporating water via a coal/water slurry feed system and to provide a simplified alternative to the lockhopper dry feed systems currently used;
- warm acid gas removal with CO_2 capture in Selexol instead of the current cold CO_2 capture in Selexol, to greatly reduce the energy penalty otherwise required for Selexol regeneration;
- warm acid gas removal with H_2 and CO_2 separation via a hydrogen separating membrane that delivers hydrogen in a pressurized N_2/H_2 mixture to the gas turbine combustor while enabling CO_2 recovery as a separate stream at elevated pressure, thereby reducing the CO_2 compressor load;
- use of an ion transport membrane[57] instead of a cryogenic air separation unit to provide O_2 for the gasifier – the main impact of which would be to reduce the capital cost for O_2 production;
- increased system reliability, availability, and maintainability – resulting in an increased system capacity factor.

Gray et al. (2009) carry out a systems analysis suggesting that success in all of these areas over time could plausibly lead, for US conditions, to

57 A non-porous ceramic membrane through which O_2 ions flow at high temperature (800–900°C) and are converted to O_2 molecules on the permeate side of the membrane, while electrons flow countercurrent to the retentate side of the membrane.

an eventual IGCC-CCS efficiency ~40% (HHV basis) and a capital cost (TPC) less than US$1700/kW$_e$ – values very similar to the corresponding values for new supercritical steam-electric plants in the US today (the PC-V option described in Section 12.2.2).

The revolutionary SOFC approach involves coupling a high-efficiency SOFC operating at pressure to a catalytic gasifier that produces methane-rich syngas, such as the gasifier being developed by Great Point Energy (a company in the United States) for making substitute natural gas.[58] As the syngas passes through the anode of the SOFC the methane is reformed with steam to form CO and H_2, and these gases in turn react with steam and oxygen to form CO_2 and H_2O while providing electric power for the external circuit. Part of the heat released in these reactions is manifest as a rise in the syngas temperature from 600°C to 900°C as it passes through the anode. The oxygen is provided as O_2^- ions (undiluted with nitrogen) via transport through the fuel cell's non-porous ceramic membrane electrolyte[59] from the hot air streaming through the cathode. The benefits of this approach to power generation (Grol et al., 2007) include the following:

- Making electricity directly from chemical energy without first having to burn the fuel to make heat gives rise to higher energy conversion efficiency than can be realized via fuel-powered heat engines.
- The lower gasification temperature of the catalytic gasifier means that less energy is needed to heat the gas to its operating temperature, so that the gasification efficiency is higher.
- Another benefit is energy and cost savings, given the fact that with a sufficiently high fraction of methane in the gasifier-generated syngas, the methanation reaction exotherm can provide enough heat for gasification – which implies significant energy and cost savings associated with air separation that would otherwise be needed to provide oxygen for gasification.
- The SOFC produces steam when H_2 in the syngas and pure O_2 react on the anode; the steam reacts with methane in the syngas producing CO and H_2; the CO reacts with more steam to produce H_2 and CO_2, so that what ultimately leaves the system is a stream of CO_2 and H_2O – from which CO_2 is easily separated for piping to an underground storage reservoir.
- The strong endotherm of the methane steam reforming reaction on the anode absorbs a considerable amount of heat released from the oxidation of H_2 to produce water, thereby reducing the amount of air required to cool the SOFC – one manifestation of which is a reduction of the amount of air compression that would otherwise be required to provide this cooling air.
- If the SOFC operates at an elevated pressure, the subsequent CO_2 compression required for pipeline transport to suitable storage sites would be less than if the SOFC operates at atmospheric pressure.
- The steam reforming of methane on the anode eliminates the need for a separate steam reformer when methane-rich syngas is the feed.
- The "shifting" of CO to CO_2 by reaction on the anode with water, producing H_2, eliminates the need to shift CO to CO_2 in a separate "water-gas-shift" reactor.

Gray et al. (2009) have estimated prospective efficiency, capital cost, and levelized electricity production costs for such SOFCs and compared them to the same quantities that would arise with the evolutionary strategy. They found that the system efficiency would be 40% higher (~56%), the specific capital cost (US$/kW$_e$) would be ~5% higher and the levelized cost of electricity would be about the same – although perhaps requiring a longer period of time to achieve such estimated performance and cost values. Many of the technological advances analyzed would be applicable to systems that coproduce synthetic fuels and electricity, as described for current technologies in Section 12.6. These findings suggest that both the evolutionary and the revolutionary approaches warrant comparable levels of research and development support. It does not necessarily follow, however, that these two approaches would offer comparable overall benefits when the technologies involved are fully developed.

12.7.2 Technologies and Strategies for Low-carbon Liquid Fuels in the Long-term

Maintaining the option of sustaining liquid hydrocarbon fuels as the primary energy carriers for the transportation sector even under a severe carbon policy constraint is extraordinarily important in light of the ease of transporting, storing, and using these fuels compared to the alternatives such as H_2 and electricity (e.g., see near the end of Section 12.4.4 for some discussion of the challenges for evolving a ground transportation system based on hydrogen fuel cell vehicles).

In the earlier Chapter 12 analysis of opportunities for producing synthetic fuels characterized by low greenhouse gas emission rates, some of the most important findings were the strategic importance of:

- CCS for biomass as a carbon mitigation strategy for a carbon-constrained world;
- the opportunity to get started with CCS for biomass via coal/biomass coprocessing; and

58 Based on the original Exxon process, Great Point Energy's catalytic gasifier is a relatively low-temperature gasifier that involves the production of methane as a considerable fraction of the syngas output as a result of a potassium-catalyzed methanation reactions.

59 The SOFC electrolyte permits the flow of O_2 ions (like the ceramic non-porous ion transport membrane mentioned above for O_2 production) but does not permit electrons to flow in the reverse direction.

- electricity + synfuels coproduction w/CCS as a critical path for coprocessing in realizing simultaneously:
  - Low costs for low-C electricity;
  - Low costs for low-C synfuels;
  - Energy insecurity mitigation in a manner consistent with realization of carbon-mitigation objectives.

Chapter 12 points out that first generation technologies based on these novel concepts can be deployed in the market during the current decade. Much can be done to improve such systems using advanced technologies. Although a systematic review of advanced concepts is beyond the scope of the present analysis, what is discussed here is of possible strategic importance:

- a new approach to chemical synthesis in the context of a carbon constrained world;
- shale gas for a carbon-constrained world; and
- extension of the coproduction concept from the present focus on coal/biomass coprocessing to include as well natural gas/biomass coprocessing.

12.7.2.1 Synthesis chemistry for a carbon-constrained world

The chemical process industry and the embryonic synfuels industry are based on making synthesis gas (mainly CO and H_2) from a fossil fuel and/or biomass and then combining the synthesis gas molecules CO and H_2 to make chemicals and/or fuels. A recent paper (Hildebrandt et al., 2009a) points out that there are potentially significant gains in energy conversion efficiency to be exploited by shifting both the gasification process from the production of mainly CO and H_2 to the production of instead mainly H_2 and CO_2 and basing the subsequent chemical synthesis on combining H_2 and CO_2 instead of H_2 and CO. Applying the idea to the production of F-T liquids from coal via gasification, those authors point to an 18% theoretical potential reduction in the amount of net work required for the overall process and a 15% reduction in the amount of coproduct CO_2 generated in the process.[60]

This idea might be helpful in the context of a carbon mitigation policy, for evolving from the present situation where energy is based mainly on fossil fuels, to an energy future in the very long term when synthetic liquid hydrocarbon fuels might be made mainly by combining H_2 derived from water using a non-carbon primary energy source[61] such as solar energy or thermonuclear fusion, and CO_2 extracted directly from the air[62] to make liquid fuels – a process that might start with methanol production:

$$CO_2 + 3\ H_2 \rightarrow CH_3OH + H_2O, \quad (6)$$

followed by conversion of the methanol to hydrocarbon liquid fuels such as gasoline via the already commercial MTG processes (see Sections 12.4.1.2 and 12.4.3.1) or via future processes that would produce middle distillates as well as gasoline (Keil, 1999).

Though seemingly different in the case of methanol production from the present approach that involves making methanol from syngas via:

$$CO + 2H_2 \rightarrow CH_3OH, \quad (7)$$

it is now well known (Hansen, 1997) that what really happens in making methanol from syngas is that CO first reacts with H_2O to form CO_2 and H_2 via the water gas shift reaction followed by the hydrogenation of CO_2 on the catalyst surface. Moreover, making methanol from CO_2 and H_2 is actually not a novel approach.[63]

At present H_2 produced from non-carbon energy sources is far more costly than making H_2 with ultra-low GHG emissions from coal or natural gas with CCS (Williams, 2002), and direct extraction of CO_2 from the air is far from being economic.[64] Nevertheless, the concept of making chemicals and synfuels from CO_2 + H_2 could potentially be of strategic importance even in the near term in fossil fuel and fossil/biomass systems that make synfuels (or synfuels + electricity) and produce CO_2 as a major coproduct. Under a serious carbon policy constraint, the excess CO_2 has to be captured and stored underground in any case; a key insight implicit in the Hildebrandt analysis (Hildebrandt et al., 2009a; Hildebrandt et al., 2009b) is that there may be strategic advantages of using this readily available CO_2 to improve overall energy system performance before delivering the excess to underground storage.

This discussion ends with a word of caution. The importance of potentially improving system efficiencies by exploring gasification and synthesis

60 An e-letter comment on the Hildebrandt et al. (2009a) paper by Desmond and Gibson (2009) points out that at the high gasification temperature considered it is not practical to design a gasifier that produces mainly H_2 and CO_2 unless an enormous amount of water is added to promote the water-gas-shift reaction, but the energy penalty of heating that water would eliminate potential energy savings. Hildebrandt et al. (2009b) responded that it would be practical to produce mainly H_2 and CO_2 if one considers not a single piece of equipment but rather a gasifier followed by a water-gas-shift reactor operated at a much lower temperature than the gasifier. But if that were done it is not clear how one could realize energy savings for the gasification part of the system, although there would still be significant savings by basing synthesis on CO_2 + H_2. Moreover, the GHG emissions associated with the water heating referred to in the Desmond and Gibson (2009) criticism could be mitigated by heating the water with solar energy instead of burning fossil fuel.

61 See, for example, Lewis and Nocera (2006) and OSL (2003).

62 See, for example, Section 2.1.4: Carbon dioxide capture from ambient air, in The Royal Society (2009).

63 Olah et al. (2009) point out that the very first methanol plants operating in the 1920s and 1930s were commonly using CO_2 and H_2 from other processes to make methanol.

64 In a recent report of the American Physical Society, it is estimated that with current technology direct air capture of CO_2 would cost $600 or more per tonne of CO_2, under optimistic assumptions (APS, 2011).

based on CO_2 chemistry should not be construed as suggesting that CO_2 reuse to make synthetic fuels is a viable alternative to CCS.

There is widespread interest in CO_2 reuse for making industrial products as an alternative to CCS. For example, the US Department of Energy has dedicated more than US$107 million to the exploration of twelve approaches to reuse (DOE, 2010). Of these concepts, the most numerous and globally significant are systems that use microalgae to capture CO_2 from power plant flue gas and convert it (via sunlight, water, and nutrients) into natural oils that are readily processed into liquid transportation fuels such as biodiesel. The concept is tantalizing when one considers, as an example, that the United States in 2008 consumed fossil fuel carbon in the amounts of 500 Mt in the form of transportation fuels while simultaneously emitting 540 Mt from pulverized coal steam electric power plants. If the CO_2 in flue gases were captured and reused by being converted into carbonaceous liquid fuels using solar energy or another non-carbon energy source to provide the needed process energy, enormous quantities of transportation fuels could be provided without increasing GHG emissions. But this example contains the essence of the shortcomings of reuse to make transportation fuels: If, hypothetically, 100% of the CO_2 from flue gases of US coal power plants were converted via carbon-free energy sources into transportation fuels, the carbon emissions for the system of making both transportation fuels and electricity from coal would be reduced by only 50% from the level of the current system that makes electricity from coal with CO_2 venting and transportation fuels from crude oil.

Kreutz (2011) examines two cases to estimate the potential for GHG emissions reduction via reuse of coal power plant CO_2 to make liquid transportation fuels: the growing of algae in algal ponds to make biodiesel and the use of concentrated sunlight to reduce CO_2 to CO and O_2 and/or H_2O to H_2 and O_2 to make liquid fuels via Fischer-Tropsch synthesis. He shows that the carbon mitigation potential of reuse strategies to make synthetic transportation fuels is at best very modest in a world where the carbon price is high enough to induce decarbonization of coal power plants either by shifting to a carbon-free or low-carbon power source or by making CCS more economical than venting CO_2 (in which case the CO_2 would be captured and available mainly in pipelines to underground storage sites so that its diversion from this purpose would be equivalent to extracting CO_2 from underground).[65] According to Kreutz: "Using the carbon twice fails to meet the objective of deep GHG emission reductions across the entire energy economy; only one sector (either power or transportation) – but not both – can claim the benefit of carbon neutrality." Thus CO_2 reuse strategies to make synthetic fuels would not enable the deep (over 80%) reductions in GHG emissions that leaders of industrialized countries are targeting for their countries by midcentury.

65 This is in contrast to the case at low carbon prices, when using CO_2 from flue gases is equivalent to extracting CO_2 from the atmosphere, because a profit-motivated power generator would rather vent the CO_2 to the atmosphere and pay the emissions fine than invest in CCS.

12.7.2.2 Implications of Abundant and Ubiquitous Shale Gas

It is truly remarkable how fast views of the fossil fuel energy future change. In its 2003 report to the US Secretary of Energy, the National Petroleum Council (NPC, 2003) predicted that future North American natural gas supplies would be flat or declining. In sharp contrast, there is currently much bullishness about the future prospects of shale gas, largely as a result of applications of new effective, economic hydraulic fracturing and horizontal drilling technologies.[66] It is now thought that natural gas extracted from shale in sedimentary basins might turn out to be abundant and ubiquitous, with reasonable production costs. Although most empirical data are from the United States, there is much optimism that the judgments that are now being formed about US shale gas prospects might be more or less valid for sedimentary basins throughout the world (see Chapter 7).

If this bullishness about shale gas proves to be sound, and growing environmental concerns associated with extraction of shale gas (Rahm, 2011) can be addressed, it has potentially far-reaching implications for the future of fossil fuel energy in a carbon-constrained world.

To begin, CCS would need to be pursued for NG energy conversion systems based on shale gas in order to meet carbon mitigation obligations over the longer term. Consider first use of shale gas for making electricity in NGCC-CCS plants. One advantage offered relative to CIGCC-CCS plants is that less than half as much CO_2 would have to be stored per MWh. Moreover, the capital investment required to generate electricity via NGCC-CCS is likely to be less than half that for a CIGCC-CCS plant having the same output capacity, and the LCOE for such a plant is likely to be less than for a CIGCC-CCS plant at the GHG emissions price needed to make a CIGCC-CCS plant cost competitive with a PC-V plant for natural gas prices up to four times the coal price.[67] The downside for the NGCC-CCS system is that the GHG emissions price required to induce a shift from NGCC-V to NGCC-CCS is very high (see Figure 12.10).

12.7.2.3 Gas/biomass to Liquids and Electricity with CCS

Should shale gas prove to be as abundant and ubiquitous as some believe, it will be of interest to consider the merits of using shale gas for liquid fuels production. The high breakeven GHG emissions price required to induce CCS for gas-based power generation could be greatly reduced while simultaneously making it possible to realize deep reductions in GHG emissions for synthetic liquid fuels if natural gas were coprocessed

66 There are fundamental differences in the production of gas from shale and from other unconventional sources such as tight sands (Frantz Jr. and Jochen, 2005). The latter yield a tremendous amount of gas for the first few months, but then production declines significantly and often becomes uneconomic after a relatively short time. In contrast, shale gas wells do not come on as strong as gas from tight sands but, once production stabilizes, the wells will produce consistently for 30 years or more.

67 For a coal price of US$2.0/GJ.

with biomass to make liquid fuels + electricity with CCS – analogous to the CBTL-OT-CCS and CBTL-OTA-CCS systems discussed in Section 12.6.

Liu et al. (2011b) present analysis of systems coproducing FTL and electricity from natural gas and from natural gas + biomass (switchgrass). Two of the systems analyzed are described in Table 12.27. The GBTL-OT-CCS option (see Figure 12.50), which provides 300 MW_e of net electricity + 9750 bbl/day of FTL transportation fuels, was designed to coprocess enough biomass (34%) to reduce GHGI to 0.10. The output capacities of the system were determined by the design criterion that the system consumes 1 Mt/year dry biomass. Its system features are compared to the same system without CCS (GBTL-OT-V) and two coal based systems that also coprocess 1 Mt of biomass annually: CBTL-OTA-CCS, which coprocesses 29% biomass to realize GHGI = 0.0855 (discussed in Section 12.6.3.3 (see Figure 12.31)), and a variant without CCS.

Notable differences between the natural gas-based and coal-based coproduction systems can be gleaned from Table 12.27:

- The natural gas-based systems convert 34.5% of the feedstock C to FTL compared to 24.2% for the coal-based systems – a consequence of the much lower H/C ratio for coal compared to natural gas (0.8 vs 4.0);
- The FTL output amounts to 34.4% of input energy for natural gas-based systems compared to 32.5% for coal-based systems, showing that the low rate of carbon conversion in the coal case is largely compensated for by the water gas shift reaction, which entails a relatively minor energy penalty;
- The CO_2 storage rate for GBTL-OT-CCS is only half that for CBTL-OTA-CCS, reflecting both the lower H/C ratio for coal and the fact that the latter option vents as CO_2 only 6.6% of the C in the feedstock compared to 12.4% in the GBTL-OT-CCS; and
- The GBTL-OT-CCS option is much less capital intensive than the CBTL-OTA-CCS option.

Figure 12.51 presents the levelized cost of electricity (LCOE) vs GHG emissions price for these four options along with the LCOEs for four stand-alone power plants (discussed in Section 12.2.2), assuming for all cases that: (i) the levelized fuel prices are US\$2.04/GJ_{HHV}, US\$5.1/GJ_{HHV}, and US\$5.0/GJ_{HHV} for coal, natural gas, and biomass, respectively (see note (b) of Table 12.6 for additional financial parameter assumptions), (ii) a US\$90/bbl crude oil price, and (iii) the captured CO_2 that is pressurized to 150 atmospheres is transported via pipeline 100 km and stored in a deep saline formation 2 km below ground with a maximum injectivity per well of 2500 t/day. The important results from this set of curves are:

- Compared to other stand-alone power plants, the GBTL-OT-CCS option has outstanding performance under a carbon policy constraint, having breakeven GHG emission prices of: US\$25/t in competing with sup PC-V, US\$28/t in competing with NGCC-CCS, and US\$47/t in competing with NGCC-V; moreover, GBTL-OT-CCS would be able to compete with CIGCC-CCS even at \$0/t. For comparison the breakeven GHG emissions price for NGCC-CCS competing with NGCC-V is about US\$83/t.
- At the assumed reference feedstock prices GBTL-OT-CCS is not competitive with CBTL-OTA-CCS.
- However, the relative competitiveness between the natural gas-based and coal-based coproduction systems depends sensitively on the relative coal and natural gas prices. For example, at a GHG emissions price of US\$0/t the LCOEs for these two coproduction options with CCS would be equal with a modest decrease of 8% in the assumed natural gas price (to US\$4.7/GJ_{HHV}) and a modest increase of 8% in the assumed coal price (to US\$2.19/GJ_{HHV}).

Finally, a global gas/biomass thought experiment for transportation is constructed in the same spirit as the global coal/biomass thought experiment for transportation presented in Section 12.6.6 to illustrate how zero net GHG emissions for transportation in 2050 might be realized via widespread deployment of a combination of GBTL-OT-CCS + BTL-RC-CCS systems instead of CBTL-OTA-CCS + BTL-RC-CCS systems, assuming the same demand levels as in the global coal/biomass thought experiment presented in Figure 12.49.

A comparison of some attributes of the two global thought experiments is presented in Table 12.28. This table shows that overall production rates for FTL fuels, the amounts of crude oil products used, the total GHG emissions avoided in displacing conventional fossil fuels, and electricity generation rates are comparable for the two thought experiments. The amount of coal used in the coal/biomass thought experiment (which produces a larger fraction of FTL via coproduction) is 25% more than the amount of gas used in the gas/biomass thought experiment. The amount of CO_2 storage required with natural gas is only 80% of that for coal, reflecting in large part the lower carbon content of natural gas compared to coal.

The relative roles of coal-based and natural-gas based systems will vary from region to region depending on relative coal and natural gas prices. Despite the bullishness about shale gas in the United States, total US domestic gas supplies are not likely to be adequate to support a substantial role for GBTL-OT-CCS. This conclusion is suggested by the analysis in Section 12.6.3.4. However, the finding presented in Table 12.28 that total worldwide natural gas use in the modified BLUE Map scenario (which includes the natural gas used for the global gas/biomass thought experiment) is only 0.81 times the projected worldwide natural gas use in the IEA Baseline Scenario – suggests that at the global level gas supplies might be adequate for realization of the global gas/biomass thought experiment. In any case, the potential benefits of the gas/biomass coproduction option as indicated in

Table 12.27 | Performance and capital cost (US_{2007}) estimates for coproduction systems with biomass/fossil fuel coprocessing.

b GHGI is the system-wide life cycle GHG emissions relative to emissions from a reference system producing the same amount of power and fuels. The reference system consists of electricity from a stand-alone new supercritical pulverized coal power plant venting CO_2 plus equivalent crude oil-derived liquid fuels. See Table 12.15, note (c), for details.

Table 12.28 suggest the importance of exploring further gas/biomass coproduction systems – which might offer a key to exploiting abundant and ubiquitous shale gas in a carbon-friendly manner. However, environmental concerns about "fracking" technologies used for shale gas recovery with respect to protection of water (Osborn et al., 2011) and soil (Jones, 2011), as well as concerns about life cycle GHG balances for shale gas (Howarth et al., 2011), need to be addressed effectively.

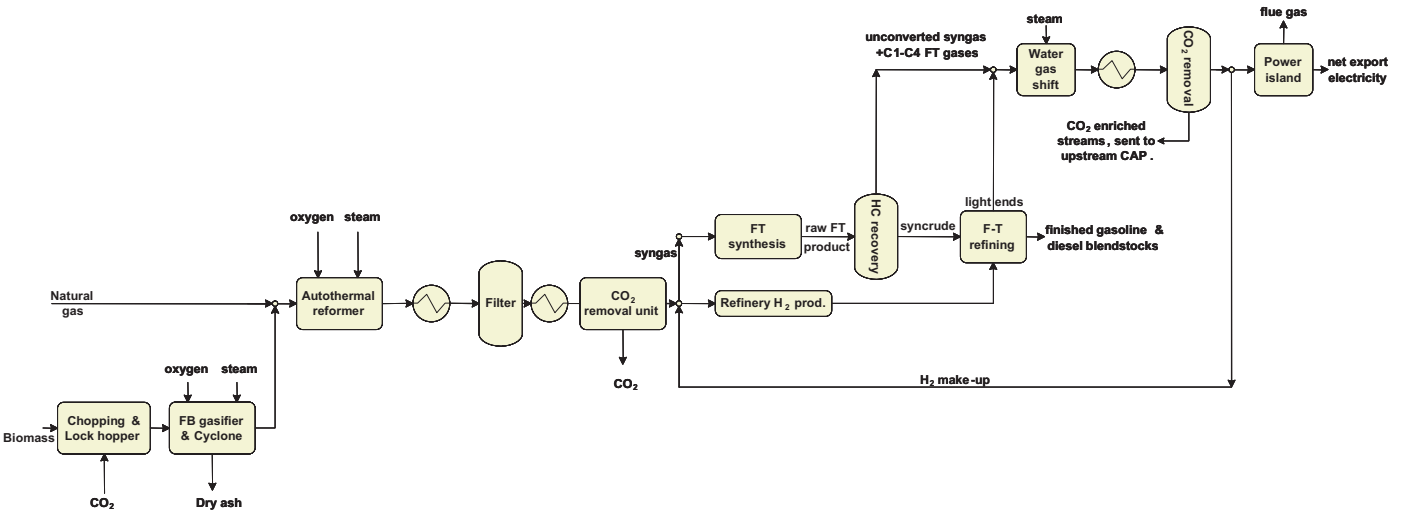

Figure 12.50 | GBTL-OT-CCS system that provides electricity + FTL (via use of a cobalt catalyst) from natural gas and biomass. Natural gas is converted to syngas in an autothermal reformer. Syngas is generated from biomass in a fluidized bed gasifier. The autothermal reformer is also used to crack (i.e., eliminate) the tars from the biomass-derived syngas. 52% of C in the feedstocks is captured, compressed to 150 bar, and sent via pipeline to a geological storage site. The system was designed with enough biomass coprocessing (34%) to realize GHGI = 0.10. Source: based on Liu et al., 2011b.

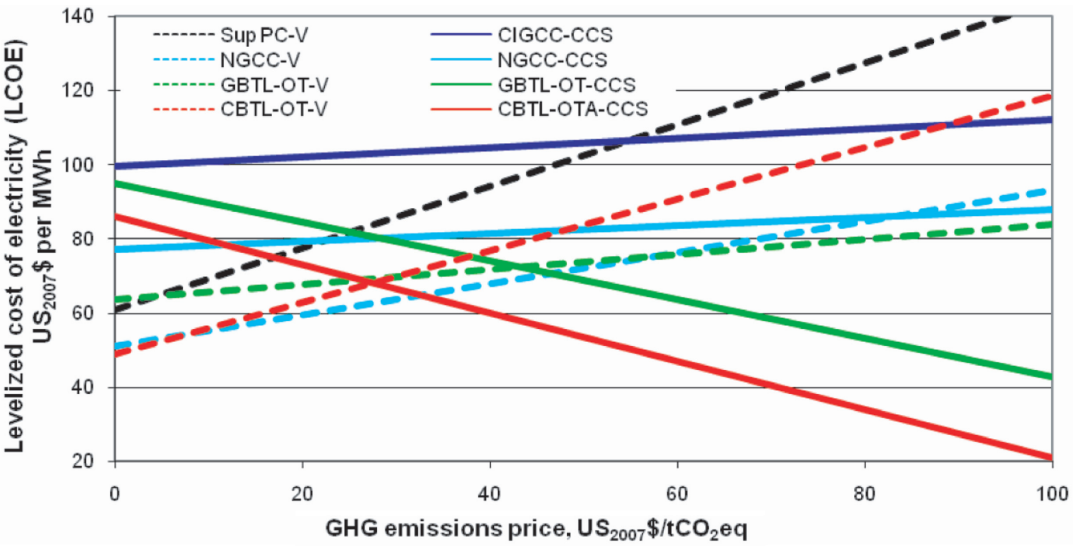

Figure 12.51 | Levelized cost of electricity vs GHG emissions price for the coproduction technologies in Table 12.27 and stand-alone power options – assuming a US$90/bbl of crude oil price and reference case coal and natural gas pricing (US$2.04/GJ and US$5.1/GJ, respectively). (See Table 12.6, note (b) for financial parameter assumptions.) Source: based on Liu et al., 2011b.

12.8 Strategies and Policies for Radically Transforming the Fossil Energy Landscape

The analysis in this chapter shows that a radical transformation of the fossil energy landscape is feasible for simultaneously meeting the multiple societal objectives of wider access to modern energy carriers, reduced air pollution health risks, enhanced energy security, and major GHG emissions reductions.

12.8.1 Strategies for a Radical Transformation

Developing countries have quite different economic circumstances at present and hence different energy priorities from industrialized countries. The strategies for fossil energy development in developing and industrialized countries will, accordingly, be different in the short term, but necessarily must be convergent in the long term.

Table 12.28 | Thought experiments with zero GHG emissions for global transportation in 2050.

	Global C/B TE	Global G/B TE
Decarbonized synfuels produced for transportation in 2050, EJ/yr LHV	59.8	59.0
FTL via coproduction, %	32.7	29.8
FTL via BTL-RC-CCS, %	67.3	70.2
Decarbonized net electricity generation in 2050, million MWh/yr	3,484	3,621
Crude oil-derived products used in transportation in 2050, EJ/yr LHV	45.0	45.2
Fossil fuel feedstock for making FTL in thought experiment, EJ/yr HHV	45.7	36.3
Biomass for making FTL in thought experiment, EJ/yr HHV (a)	111.7	114.4
Fossil fuel feedstock (coal or NG) needed for Modified Blue Map Scenario relative to use of that feedstock in IEA Blue Map Scenario in 2050	1.46	1.26
Fossil fuel feedstock (coal or NG) needed for Modified Blue Map Scenario relative to use of that feedstock in IEA Baseline Scenario in 2050	0.38	0.81
Fossil fuel feedstock (coal or NG) needed for Modified Blue Map Scenario relative to use of that feedstock in 2005	1.15	1.59
Overall GHG emissions avoided in displacing conventional energy, $GtCO_2$-eq/yr	12.8	12.6
CO_2 storage rate, $GtCO_2$/yr	8.47	6.75

a Estimates of sustainable biomass resource potentials are subject to discussion (e.g., see Chapters 7, 20).

The key for developing countries is to lay a sound foundation for further evolution to low carbon energy systems. In high economic growth developing countries like China and India, reducing conventional pollution is still the most urgent energy challenge. The priority of economic development of these societies tends to lead to increasing emissions of CO_2. Accordingly, carbon emissions for such countries will increase in the near term as they complete their industrialization and will subsequently decrease under appropriate sustainable development policies. In the poorest developing countries, economic poverty and associated lack of access to modern forms of energy are the major problems, and growing conventional pollution is a risk as these countries develop. In order to minimize overall carbon emissions from the use of fossil fuels in developing countries, efforts should concentrate on building manufacturing and infrastructure for the most efficient use of hydrocarbon energy resources and flexibility for incorporation of low carbon energy and feedstocks into the energy mix. Technology leapfrogging in energy-using technologies is another essential component of radical transformation strategies.

Although industrialized countries have made major advances in controlling conventional pollution, much more needs to be done in this regard—especially for old coal power plants. Moreover, their energy systems have not been designed for minimal CO_2 emissions. At the same time, the energy infrastructure is well established and much of it is several decades old and ready for replacement or upgrade. Thus, the emphasis going forward in industrialized countries should be on replacing or upgrading obsolete infrastructure, e.g., via repowering sites of old fossil fuel power plants with technologies offering additional capabilities (such as coproduction of electricity and fuels, as discussed in this chapter) and pursuing CCS retrofits.

While different strategies are needed regionally, this chapter has identified four key technology-related requirements as essential for transforming the fossil energy landscape: (i) continued enhancement of energy conversion efficiencies, (ii) carbon capture and storage (CCS), (iii) co-utilization of fossil fuel and biomass in the same facilities, and (iv) coproduction of multiple energy carriers at the same facilities.

Fossil fuel/biomass coprocessing with CCS to coproduce clean liquid fuels and electricity with low greenhouse gas emissions is a technically and economically feasible strategy that can make significant contributions in addressing all the major challenges posed by present energy systems, although additional strategies are also needed to solve all the problems posed by fossil fuels in the electric power and transportation sectors. Moreover, coproduction via fossil fuel/biomass coprocessing with CCS also represents a promising approach for launching CCS technologies in the market early on (facilitating as a result of early experience CCS for power-only systems in both greenfield and brownfield applications). Also, it offers a promising route for gaining early experience using lignocellulosic biomass to make liquid fuels thermochemically at attractive costs. And it can serve as a bridge to enabling CCS as a routine activity for biomass energy (with corresponding negative greenhouse gas emissions) in the post-2030 era. The latter could plausibly become a major industrial development opportunity for economically poor and fossil fuel-poor but biomass-rich regions, while making major contributions to decarbonization of the transport sector worldwide.

No technological breakthroughs are needed to get started with coproduction technologies and strategies that involve fossil fuel/biomass coprocessing with CCS. Most of the technical challenges are engineering issues best addressed via commercial-scale experience (learning by doing).

Despite the multiple attractions of coproduction systems, the concept faces formidable institutional hurdles because of complexities at the systems level. Success requires managing two disparate feedstocks (a fossil fuel and biomass) to provide simultaneously three commodity products (liquid fuels, electricity, and CO_2) that would serve three very different markets.

With fossil fuel/biomass coproduction systems, fossil fuel consumers for power generation would have to become consumers of biomass as well. There has been some experience cofiring existing coal power plants with biomass but that has been at biomass levels far more modest than the levels envisioned for the coproduction technologies described here.

Moreover, there is little reason to expect that electricity generators will want to take on the risks of producing and marketing liquid fuels. The oil industry, which could do that, has shown little interest in producing either synfuels from coal or electricity for sale to the electric grid, which offers much lower profit margins than what the oil industry has been accustomed to in exploration and production (E & P).

Yet these obstacles might be surmountable. Coal power generators are coming to realize they will have to embrace CCS in order to survive in a carbon-constrained world and will have to give priority in industrialized countries to CCS for existing coal power plant sites. Coal suppliers who are eager to see coal use expand into synfuels production are coming to realize that this cannot be done without both CCS and coprocessing of biomass under a stringent carbon policy constraint. Biomass suppliers might become interested in the concept once they recognize the potential for greater profits selling biomass to operators of such systems rather than to producers of "pure" biofuels, such as cellulosic ethanol. The coproduction concepts described in this chapter offer the potential for meeting these obligations in a more profitable manner than other routes. And some multinational oil companies might come to embrace synfuels production both because they are running out of E & P investment opportunities as a result of being denied adequate access to the oil resources controlled by national oil companies, and because at high oil and GHG emissions prices, profit margins with coproduction systems can approach historical norms for E & P investments.

Strategic corporate alliances involving partnerships across industries could facilitate deployment of coproduction systems. Encouraging power industry/oil industry partnerships is likely to be especially important. Power companies could, of course, manage the power side of the business but may be uncomfortable with gasification technology – which doesn't resemble the "boiler technology" that they are accustomed to managing. Moreover, the power industry has no experience with either CO_2 capture or management of the geological structures needed for CO_2 storage. The oil industry could, of course, manage liquid fuels production and marketing quite well. It has extensive experience with CO_2 capture (at refineries and chemical process plants for purposes unrelated to CO_2 storage), with CO_2 transport (for enhanced oil recovery), with management of geological structures similar to those that will be used for CO_2 storage, and with gasification of petroleum residuals at both refineries and chemical process plants that could facilitate their becoming comfortable with coal and biomass gasification. Moreover, oil companies that also sell natural gas might become interested in natural gas/biomass coprocessing systems that make fuels and electricity with CCS.

12.8.2 New Policies for a Radical Transformation

A radical transformation of the fossil energy landscape is unlikely to occur without new facilitating public policies. Needed critical broad cross-cutting policies include:

- Carbon mitigation policies in the near term for which implicit GHG emission prices are high enough to make CCS competitive as a routine commercial activity, and which are implemented soon in the context of the expressed G8 support for a global effort to limit the increase in average global temperature due to climate change to 2°C above the pre-industrial level. This goal is written into the Copenhagen Accord and reconfirmed during COP16 in Cancun. The G8 statement in July 2009 noted that this formidable goal will require a global reduction in emissions by at least 50% by 2050 (relative to the 1990 level), and they supported the goal for industrialized countries to achieve 80% reductions by 2050 to help meet the global 50% reduction.

- New air pollution control policies are needed, with highest priority given to pollution from existing coal power plants in industrialized countries and indoor air pollution in developing countries. The analysis in Chapter 12 shows the value of crafting new air pollution control policies and GHG mitigation policies together because of the helpful synergisms that would arise with "co-control" approaches.

- Technological innovation policies in support of the plausible radical transformation described in this chapter should include both support for R&D on promising technological options and incentives for early deployment, including incentives that would encourage needed new inter-industry partnerships. First-of-a-kind projects are always risky, both technologically and financially. Despite the attractive economic features of coprocessing, coproduction, and other technologies discussed in this chapter, without incentives for first-of-a-kind and early deployment projects that offer major public benefits, such technologies will enter the market only slowly or not at all.

High priority should be given to encouraging early CCS action, especially for coal, because if coal is to be widely used in a future carbon-constrained world (via coproduction and coprocessing with biomass or via any other means), so doing will be viable only if the option is available to safely store CO_2 in geological media. For geologic storage, there appear to be neither technical issues that cannot be managed nor economic show-stoppers (see Chapter 13). Nevertheless, there is a pressing need to carry out a significant number of integrated commercial-scale CCS projects worldwide (each involving the annual storage of at least one $MtCO_2$/yr) with an emphasis on storage in deep saline formations, to: (i) address scientific and engineering issues at scale for storage; (ii) provide a sound empirical basis for developing the regulatory and political framework for site selection, permitting, operation, monitoring, and closure of storage sites for routine commercial CCS projects; and (iii) satisfy a wide range of stakeholders as to the viability of CCS as a "gigascale" carbon mitigation option.

The international political framework for early CCS action has already been established. As noted earlier, the G8 Summit in 2008 produced an agreement to sponsor at least twenty commercial-scale, fully integrated CCS demonstration projects worldwide that would be committed by 2010 with the aim of establishing the basis for broad commercial

deployment of CCS technologies after 2020. The G8 reiterated its call for these CCS projects in 2009. In August 2010, a high-level task force in the U.S. created by President Obama issued its report on a comprehensive CCS strategy for the United States that includes bringing five to ten commercial demonstration projects online by 2016.

Much if not all of the incremental cost of CCS for the 20 projects called for by the G8 will probably have to be paid for by governments (individually or collectively). It is likely that carbon prices will be lower initially than what will be needed to make pursuit of CCS a profitable activity for private companies in many, if not most, parts of the world. To minimize spending, governments should aim to pursue projects in which they can maximize the learning about the gigascale prospects of CCS per dollar spent. In this context, the coproduction systems described in this chapter are good candidates for CCS early action projects because they have much lower capture costs than power only systems. If these projects are allowed to compete for government awards for CCS demonstrations, the cost to government might be significantly less than for CCS demonstration projects based on power-only systems. Accordingly, coproduction facilities coprocessing fossil fuel and biomass with CCS, especially those built in coal-rich countries, should be considered seriously as candidates for some of the needed CCS early action projects and supported financially jointly by the governments of several coal-intensive energy economies.

Since it will require at least a decade of demonstration efforts before CCS systems can begin to be routinely deployed, the deployment of CCS systems in conjunction with fossil energy conversion would need to proceed very rapidly thereafter to achieve deep reductions in global GHG emissions from fossil fuel burning by 2050.

Analysis in this chapter indicates that biomass conversion with CCS could play an essential role in enabling continued fossil fuel use. This would be accomplished by off-setting GHG emissions from fossil fuels via the strongly negative emissions of biomass/CCS systems. Two new initiatives needed in this area are:

- New policies should encourage demonstration and commercialization of large biomass gasifiers (300–600 MW biomass input) because these represent a key technology for economically attractive biomass/CCS systems. To date, biomass gasifiers have only been successfully demonstrated at the scale of tens of MW biomass input.

- Detailed assessments should be carried out of the prospects for biomass production for energy on a sustainable basis in ways that minimize conflicts with food production, adverse indirect land-use impacts, and biodiversity. Emphasis should be on agricultural residues, forest residues (including mill residues, logging residues, diseased tree removals, fuel treatment thinnings, and productivity enhancement thinnings), and the growing of dedicated energy crops on abandoned cropland and other degraded lands. These assessments should be carried out in each of the major world regions.

New policies are also needed to promote universal access to clean cooking fuels (as discussed in detail in Chapter 19, Section 19.2.2) derived from coal and/or biomass systems with CCS (Section 12.5):

- As a basis for new policy, CO_2 storage assessments should be carried out in each of the major regions requiring clean cooking fuels – with financial support from the international community. CO_2 storage prospects are not well known in countries where clean cooking fuels are sorely needed. This is especially true in biomass-rich but coal-poor regions – where consideration of CCS as a carbon mitigation option has probably not been given much thought. Accordingly, "bottom-up" assessments of storage prospects, including the construction of supply curves (storage capacity in tonnes vs cost in US$/t), are needed on a reservoir-by-reservoir basis.

- For regions where there are good prospects for biomass energy with CCS, official development assistance should be expanded to help develop the physical infrastructures and human capacities needed to build and manage large industries based on modern biomass conversion technologies with CCS. This additional ODA should aim to establish this industry so that it can take off as GHG emission prices approach levels high enough that market forces are sufficient to support commercial biomass/CCS activities.

Finally, new public policies are needed to facilitate in the near term industrial collaborations between companies that would produce simultaneously fuels (clean cooking fuels as well as transportation fuels) and electricity from fossil fuels and biomass in regions having significant supplies of both. It would be desirable to identify policy instruments that specify performance rather than technology and maximize use of market forces in meeting performance goals. Promising approaches along these lines include: (i) mandating a Low Carbon Standard for Fuels (Andress et al., 2010; Sperling and Yeh, 2010), (ii) a low carbon standard for electricity generation, perhaps modeled after Renewable Portfolio Standards or green certificate markets; (iii) feed-in tariffs for environmentally-qualified electricity, and (iv) a Universal Clean Cooking Fuel Standard in regions requiring major infusions of clean cooking fuels, perhaps modeled after the "obligation to serve" mandates of the rural electrification programs introduced in the United States in the 1930s. The latter could plausibly facilitate the formation of strategic industrial alliances that would be capable of guaranteeing universal access to clean cooking fuels without major subsidy.

Executive Summary

Emissions of carbon dioxide, the most important long-lived anthropogenic greenhouse gas, can be reduced by Carbon Capture and Storage (CCS). CCS involves the integration of four elements: CO_2 capture, compression of the CO_2 from a gas to a liquid or a denser gas, transportation of pressurized CO_2 from the point of capture to the storage location, and isolation from the atmosphere by storage in deep underground rock formations. Considering full life-cycle emissions, CCS technology can reduce 65–85% of CO_2 emissions from fossil fuel combustion from stationary sources, although greater reductions may be possible if low emission technologies are applied to activities beyond the plant boundary, such as fuel transportation.

CCS is applicable to many stationary CO_2 sources, including the power generation, refining, building materials, and the industrial sector. The recent emphasis on the use of CCS primarily to reduce emissions from coal-fired electricity production is too narrow a vision for CCS.

Interest in CCS is growing rapidly around the world. Over the past decade there has been a remarkable increase in interest and investment in CCS. Whereas a decade ago, there was only one operating CCS project and little industry or government investment in R&D, and no financial incentives to promote CCS. In 2010, numerous projects of various sizes are active, including at least five large-scale full CCS projects. In 2015, it is expected that 15 large-scale, full-chain CCS projects will be running. Governments and industry have committed over USD 26 billion for R&D, scale-up and deployment.

The technology for CCS is available today, but significant improvements are needed to support widespread deployment. Technology advances are needed primarily to reduce the cost of capture and increase confidence in storage security. Demonstration projects are needed to address issues of process integration between CO_2 capture and product generation, for instance in power, cement and steel production, obtain cost and performance data, and for industry where capture is more mature to gain needed operational experience. Large-scale storage projects in saline aquifers are needed to address issues of site characterization and site selection, capacity assessment, risk management and monitoring.

Successful experiences from five ongoing projects demonstrate that, at least on this limited scale, CCS can be safe and effective for reducing emissions. Five commercial-scale CCS projects are operational today with over 35 million tonnes of CO_2 captured and stored since 1996. Observations from commercial storage projects, commercial enhanced oil recovery projects, engineered and natural analogues as well as theoretical considerations, models, and laboratory experiments suggest that appropriately selected and managed geological storage reservoirs are very likely to retain nearly all the injected CO_2 for very long times, more than long enough to provide benefits for the intended purpose of CCS.

Significant scale-up compared to existing CCS activities will be needed to achieve large reductions in CO_2 emissions. A 5- to 10-fold scale-up in the size of individual projects is needed to capture and store emissions from a typical coal-fired power plant (500 to 1000 MW). A thousand fold scale-up in size of today's CCS enterprise would be needed to reduce emissions by billions of tonnes per year (Gt/yr).

The technical potential of CCS on a global level is promising, but on a regional level is differentiated. The primary technical limitation for CCS is storage capacity. Much more work needs to be done to realistically assess storage capacity on a worldwide, regional basis and sub-regional basis.

Worldwide storage capacity estimation is improving but more experience is needed. Estimates for oil and gas reservoirs are about 1000 $GtCO_2$, saline aquifers are estimated to have a capacity ranging from about 4000 to 23,000 $GtCO_2$. However, there is still considerable debate about how much storage capacity actually exists, particularly in saline

aquifers. Research, geological assessments and, most importantly, commercial-scale demonstration projects will be needed to improve confidence in capacity estimates.

Costs and energy requirements for capture are high. Estimated costs for CCS vary widely, depending on the application (e.g. gas clean-up vs. electricity generation), the type of fuel, capture technology, and assumptions about the baseline technology. For example, with today's technology, CCS would increase cost of generating electricity by 50–100%. In this case, capital costs and parasitic energy requirements of 15–30% are the major cost drivers. Research is underway to lower costs and energy requirements. Early demonstration projects are likely to cost more.

The combination of high cost and low or absent incentives for large-scale deployment are a major factor limiting the widespread use of CCS. Due to high costs, CCS will not take place without strong incentives to limit CO_2 emissions. Certainty about the policy and regulatory regimes will be crucial for obtaining access to capital to build these multi-billion dollar projects.

Environmental risks of CCS appear manageable, but regulations are needed. Regulation needs to ensure due diligence over the lifecycle of the project, but should, most importantly, also govern site selection, operating guidelines, monitoring and closure of a storage facility.

Experience so far has shown that local resistance to CO_2 storage projects may appear and can lead to cancellation of planned CCS projects. Inhabitants of the areas around geological storage sites often have concerns about the safety and effectiveness of CCS. More CCS projects are needed to establish a convincing safety record. Early engagement of communities in project design and site selection as well as credible communication can help ease resistance. Environmental organisations sometimes see CCS as a distraction from a sustainable energy future.

Social, economic, policy and political factors may limit deployment of CCS if not adequately addressed. Critical issues include ownership of underground pore space (primarily an issue in the US); long-term liability and stewardship; GHG accounting approaches and **ve**rification; and regulatory oversight regimes. Governments and the private sector are making significant progress on all of these issues. Government support to lower barriers for early deployments is needed to encourage private sector adoption. Developing countries will need support for technology access, lowering the cost of CCS, developing workforce capacity and training regulators for permitting, monitoring and oversight.

CCS combined with biomass can lead to negative emissions. Such technologies are likely to be needed to achieve atmospheric stabilization of CO_2 and may provide an additional incentive for CCS adoption.

13.1 Introduction: The Need for Carbon Capture and Storage

13.1.1 Introduction to Carbon Capture and Storage (CCS)

In 2008 fossil fuels provided over 85% of our energy supply and emitted over 30 Gt (billion tonnes) of carbon dioxide (CO_2) into the atmosphere. Stabilizing greenhouse gas (GHG) concentrations in the atmosphere at levels that avoid dangerous interference with the climate system will require reducing emissions by an estimated 50–80% by 2050 (IPCC, 2007). Fossil fuel use continues to grow worldwide, especially in countries with rapidly developing economies. Heavy reliance on fossil fuels for all aspects of our energy system makes the transformation to a sustainable future with lower GHG emissions very challenging. The principal benefit of CCS is that it reduces emissions from fossil fuel use, especially from power generation and industrial processes, thus enabling reducing or slowing growth of emissions while other lower GHG emission energy technologies mature and deploy more widely. In addition, over the longer term, CCS could be used to reduce emissions from sources that are difficult to eliminate in any other way, such as energy-intensive industrial processes, natural gas cleanup, hydrogen production, fossil fuel refining, petrochemical industries, and steel and cement manufacturing. The availability of scalable CCS technology by 2020 to 2030 would be most beneficial to lessen the disruption of this transformation by providing low-emission energy services from fossil fuels while alternatives are still developed and scaled-up to meet current and growing energy demands.

For heavily coal-dependent and coal-rich counties such Australia, Canada, China, India, the United States, and Russia, it will be difficult to provide adequate energy supplies while rapidly reducing emissions if CCS is not possible. Figure 13.1 illustrates the current reliance on coal and rate of capacity growth for new coal-fired plants for several of the world's largest economies. Among these heavily coal-reliant economies, those with the most rapid economic growth continue to install new plants at a rapid rate. Large new coal plants will each emit over 100 $MtCO_2$ over their 30- to 40-year lifetime, unless they can be retrofit with capture in the future.

CCS involves the integration of four elements: CO_2 capture, compression of the CO_2 from a gas to a liquid or a denser gas, transportation of pressurized CO_2 from the point of capture to the storage location, and isolation from the atmosphere by storage (see Figure 13.2). Technologies are available to carry out each of these elements, but today, implementation of CCS is challenging because the cost for capture is high, integration of CCS with electricity production or industrial processes is not demonstrated at a large scale, and more confidence is needed that storage can be safe and effective over time periods of 1000 years or longer. While in principle CCS could be deployed on a much wider basis today, the challenge of doing so should not be underestimated. Integrating CCS into existing power generation

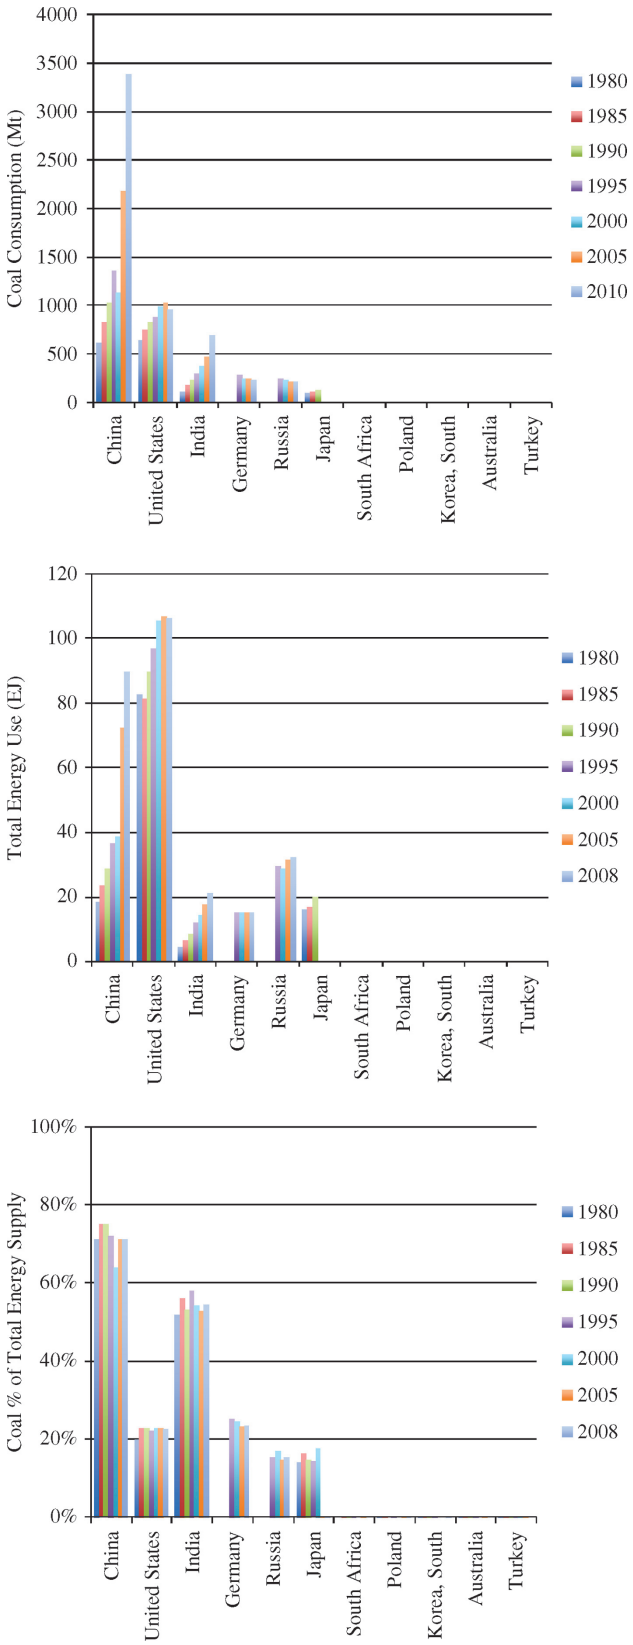

Figure 13.1 | Analysis of trends in the 11 largest coal consuming countries: (a) coal consumption from 1980 to 2010 (Mt), (b) total energy use (Exajoules), (c) percentage of total energy from coal.

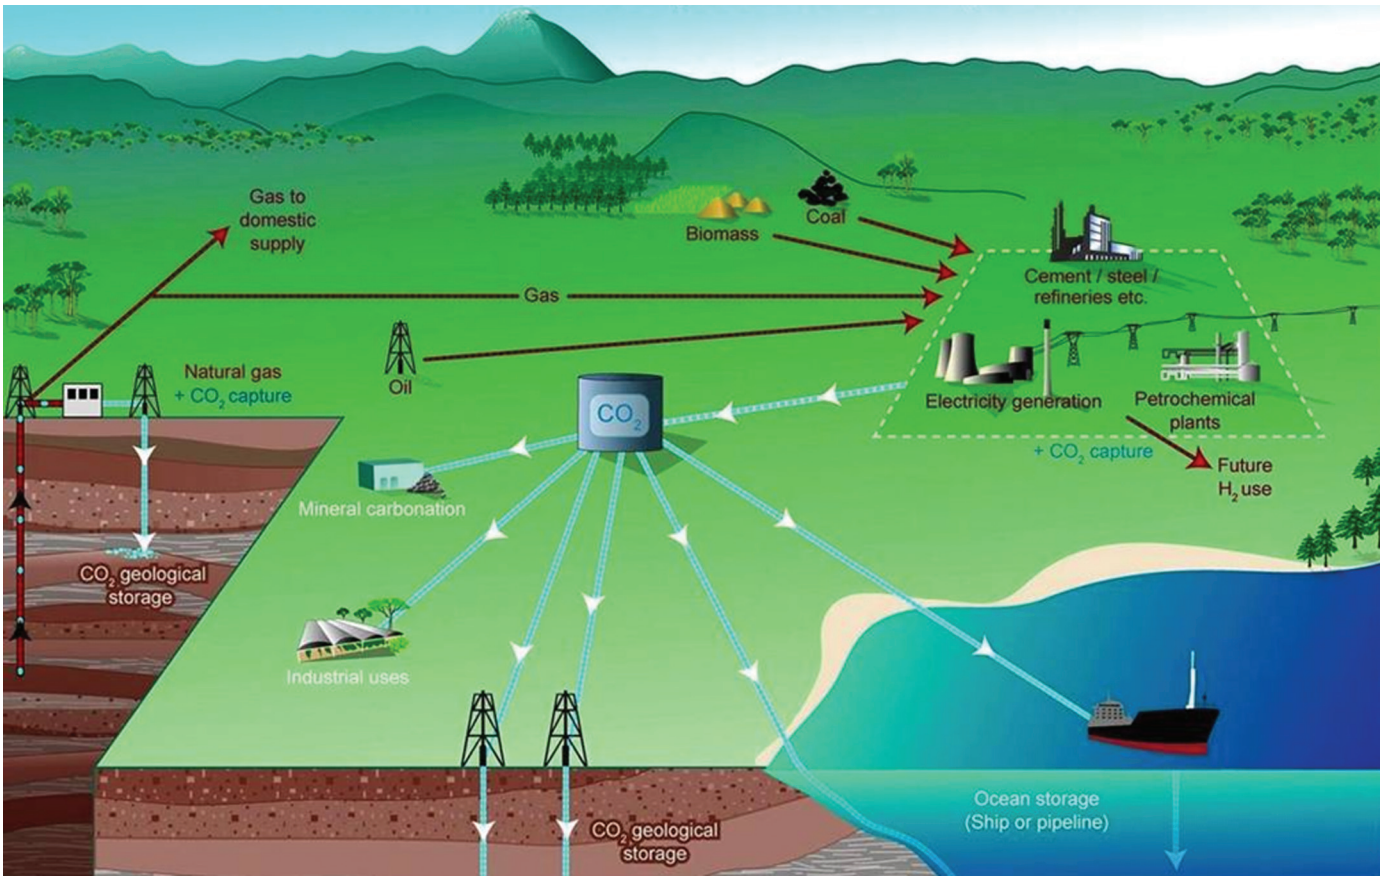

Figure 13.2 | Schematic of a fossil fuel-based energy system using carbon capture and storage to reduce CO_2 emissions. The red lines in the figure illustrate the extraction of oil, gas, and coal from natural resources and transport to facilities used for power generation, refining, and industrial applications. Carbon dioxide capture is integrated with the facilities for burning fossil fuels. After the CO_2 is captured, it is compressed to a dense gas, or more typically a liquid. From the compressor, CO_2 is put into pipelines for transport as shown by the blue lines. The CO_2 is transported to the storage sites, whereas shown, it could be injected into deep underground geological formations, converted to minerals, used to increase biological productivity in greenhouse and algae, or perhaps injected into the deep ocean. With today's technology, storage in deep geological formations is the most advanced of these storage options and could be applied on the scale needed to significantly reduce emissions. Source: IPCC, 2005.

facilities and other industrial operations that demand highly reliable performance is fraught with technological challenges, on top of the large capital investment and significant operating costs required for CO_2 capture. Moreover, with today's capture technology, from 10 to 30% of the output of the power plant may be consumed by the capture unit, depending on the capture technology, the vintage and type of power plant, and the degree of systems integration. Advances not only in capture technology, but ongoing improvements in the efficiency of power generation will be needed to offset the energy penalty for CO_2 capture.

An enormous effort is now devoted to advancing this technology with over 234 active or planned projects (GCCSI, 2011a). While many of these are small-scale pilot projects, 77 are large-scale integrated projects in various stages of the asset life cycle, nine large-scale projects are operating with two more under construction, and an additional 65 potential projects are at various stages of planning (GCCSI, 2011a). The vast majority of these projects have not yet made a final investment decision to go ahead with the construction and operation phases of these projects. Consequently, it is far too early to tell what will be the outcome of the large amount of activity in this area. As of April 2010, this represented US$26 billion of government investment.

Today, five CCS projects capture 0.5–2 $MtCO_2$/yr from industrial sources and store it in deep geological formations and have been operating for years to a decade or more, demonstrating that, at least on this limited scale, CCS can be safe and effective for reducing emissions. For four of these projects, CO_2 is captured from natural gas cleanup operations while in the fifth, CO_2 is captured from a coal to synthetic natural gas plant. Relevant experience from nearly 40 years of CO_2 enhanced oil recovery (EOR) also shows that CO_2 can safely be injected underground. While most of the CO_2 used for EOR is from natural CO_2 reservoirs, a small fraction is produced from industrial sources such as natural gas cleanup, hydrogen production, and ammonia production. A five- to ten-fold scale-up in the size of individual projects would be needed to capture and store emissions from a single large coal-fired power plant (e.g. current CCS projects store about 1 Mt/yr, while a 500–1000 MW power plant with capture would need to store from 5–10 $MtCO_2$/yr). Globally, a thousand-fold scale-up from current CCS operations would be needed to achieve a

contribution to emissions reductions on the order of 20% of current fossil fuel derived emissions over the next century (IEA, 2008a).

13.1.2 The Potential Role of CCS in Climate Change Mitigation

The goal of CCS is to reduce CO_2 emissions from large stationary sources such as power generation, natural gas processing, hydrogen (H_2) production from coal or gas, cement manufacturing, or steel making. Considering full life cycle emissions, using CCS technology on an individual facility can reduce about 65–85% of CO_2 emissions from fossil fuel, although greater reductions may be possible if low emission technologies are applied to activities beyond the plant boundary, such as fuel transportation. In reality, the optimal degree of emission reduction will depend on the tradeoffs between the amount of emission reduction and the cost of capture and age of the facility on which it is deployed. Partial capture may in some cases be more advantageous than striving for the largest emissions reductions possible from a particular facility. For example, a low cost and widely deployed retrofit technology that captures 50% of the emissions from existing coal-fired power plants in China may be one of the most cost effective ways for near-term emission reductions. On the other hand, for a newly built power plant with integrated capture, emissions reductions of 90% may be preferable.

Worldwide assessments suggest that under a range of stabilization scenarios, the contribution of CCS is anticipated to be about 20% of needed emission reductions over the next century, on par with the contributions from renewable energy supplies and end-use efficiency gains (IPCC, 2005; 2007; IEA, 2008c). While the early focus of CCS has been on reducing emissions from coal and natural gas electricity generation, it is estimated that by 2050 about 2–3 $GtCO_2$/yr from industrial sources will need to be captured and stored (IEA, 2009). In the future, CCS may also contribute significantly to emission reductions from the transportation sector via hydrogen production and use for light- and heavy-duty vehicles, electrification of vehicles, production of synthetic fuels using captured CO_2, or the manufacturing of other products such as cement or polymers from captured CO_2 (see also Chapter 12). The importance of CCS will vary by region, depending on the mix of primary energy supply and storage options. Key determinants of the extent to which CCS is likely to be deployed include:

- capacity for storage in appropriate sites in suitable geological formations;
- policy frameworks to encourage emissions reductions, likely to include incentives for early deployments for capacity building;
- lack of lower cost opportunities for reducing emissions such as the increased use of renewable energy resources or nuclear power;
- pace of technological progress to lower the cost and increase confidence in the safety and permanence of geological storage;
- interest in widespread deployment of CO_2-EOR;
- public acceptance of CCS in the local communities where projects are deployed; and
- access to the large capital investment needed for CCS projects, on the order of several billion US$ for a 500 MW power generation plant, particularly for first-of-a-kind facilities (Al-Juaied and Whitmore, 2009; US DOE, 2010).

Today it is difficult to predict the extent to which CCS will be deployed, given the rapidly evolving energy technology and policy landscape.

In the long run, CCS combined with biomass gasification/combustion could be used to create net negative emissions. Net negative emissions are possible when CO_2 is captured from the atmosphere by plants and then used as an energy source with CCS. However, the extent to which this is possible will depend on a number of factors, which are described below (see Section 12.2.3.2 for additional discussion).

Co-location of Geological Storage Opportunities, Energy Services Demands, and Woody Biomass Resources: Rock formations suitable for geological storage are not distributed equally around the world. Additionally, pipeline transportation of CO_2 over distances longer than several hundred kilometers can become costly and impractical, especially in urbanized areas. A quantitative assessment of the co-location of biomass resources, sequestration capacity, and electricity/heat demand is needed to provide a realistic assessment of negative emissions potential.

Flue Gas Composition from Biomass Combustion: Technology options, energy requirements, and cost for capture depend on flue gas composition, which could range from about 15% CO_2 for fully combusted biomass to less than 5% for partially oxidized biomass. Alternatively, combustion in pure oxygen could be used to achieve very high concentrations of CO_2 that would need little post-combustion processing, but this would come at the cost of reduced efficiency caused by the energy needed to separate oxygen from air. A systematic study to evaluate technology options, energy requirements, and cost of capture of CO_2 from woody biomass is needed – with an overlay of the practicality of various technology options depending on the scale of the woody biomass resource, technology access in different parts of the world, and desired balance between CO_2 and biochar production.

Scalability of Negative Emissions from Capture and Storage of Woody Biomass: Today's paradigm for the capture and storage of CO_2 emissions is based on deployment at very large central station facilities (greater than 1 $MtCO_2$/yr emissions). CCS is a complex technological endeavor embedded in a policy framework regulated by numerous local, national, and potentially international laws. Depending on the size and continued availability of these biomass resources, this large-scale approach to deployment using stationary facilities may not be appropriate. The technological and socioeconomic requirements for scaling down this technology and operating storage facilities in a far more distributed manner must be assessed.

13.1.3 Consequences of Excluding CCS from the Mitigation Portfolio

The consequences of excluding CCS from the emission reduction options fall into three broad categories.

First, the cost of the overall emission reduction actions will be greater if CCS is excluded. Integrated assessment studies indicate that the overall cost of cutting emissions will be significantly higher if CCS technology is not included in the portfolio of emissions reductions opportunities (e.g., EPRI, 2008; IEA, 2008c).

Second, sufficiently large emissions reductions may not be possible without CCS. Maintaining a reliable supply of electricity that meets needs for both base-load and peak-load power may not be possible in the 2050 timeframe without CCS. Renewable energy sources are intermittent and of limited geographic distribution. Firming these supplies either by having large-scale energy storage or an extremely extensive electrical grid and needed storage may not be practical in the 2050 timeframe. Additionally, while rapid advances in demand-side energy management are promising, the extent to which these can be aggregated and used to balance supply and demand remain unproven. Nuclear power may provide more of the energy services currently provided by fossil fuels, but to displace them entirely may require an unrealistically rapid scale-up of the nuclear power industry. Additionally, nuclear power plants are not well suited to providing the variable, low-load factor generation currently provided by fossil fuel plants.

Third, political support for reducing emissions may not be sufficient if CCS is excluded from the portfolio of emission reduction options. In many parts of the world, including China, North America, and the Middle East, coal and natural gas provide the major source of electricity. Emission mitigation strategies that do not enable continued use of these domestic and plentiful resources are likely to meet with insurmountable political opposition. Furthermore, some geographic areas lack alternative options for providing reasonably priced electricity with lower emissions. Hence, CCS would be favored under these conditions. Excluding CCS as an option would hinder international negotiations seeking global solutions to the climate change problem.

13.1.4 Key Conditions for CCS to Contribute to Climate Change Mitigation

There are a number of conditions that must be met if CCS is to contribute to climate change mitigation at a significant scale. First, if CCS is implemented as a major part of this transformation, large volumes of CO_2 will need to be captured and stored, on the order of several Gt/yr, with cumulative totals over the next century on the order of hundreds to thousands of Gt. The pathways described in Chapter 17 indicate that a maximum of 400 Gt of CO_2 storage will be needed over the range of decarbonization pathways examined. In addition, these pathways indicate this will require large storage capacities broadly distributed over the globe within several hundred kilometers of large emission sources. Second, unless the technology reaches maturity sometime in the next several decades and wide-scale deployment begins shortly thereafter, other options for reducing emissions may emerge and displace CCS in the carbon mitigation portfolio. Technical maturity will require demonstrating that:

- CCS is a cost-competitive way to reduce emissions;
- storage sites can be selected effectively and managed during and after operations are complete;
- populations living near storage sites feel safe and that storage does not unreasonably compromise property values;
- policies are established to reduce emissions;
- regulations are developed and effectively implemented for managing a CCS project over its entire life cycle, including the post-injection period where long-term stewardship of stored CO_2 is required; and
- methods are available for integrating power generation with CCS in the evolving electricity generation, transmission, and distribution system.

All of these issues are addressed in the following sections.

13.2 Carbon Dioxide Capture and Compression Technology

The objective of this section is to present a brief status of CO_2 capture (separation) and compression technology, focusing on the updates since the *IPCC Special Report on Carbon Dioxide Capture and Storage* (IPCC, 2005). This includes CO_2 capture for energy-intensive industrial applications and electricity production with fossil fuel and biomass feedstocks. The focus is on the new developments in the three CO_2 capture technology process options (pre-combustion, post-combustion, and oxyfuel combustion), as well as CO_2 compression technology.

Costs of CCS are addressed by first developing CO_2 avoidance costs (see Section 13.5.2.1 for a precise definition of CO_2 avoidance cost) for both new and existing coal power plant baselines. The CO_2 avoidance costs are then applied as a CO_2 tax to determine the "triple-point" where product cost (i.e., electricity) is the same for coal with and without CCS and natural gas combined cycle (NGCC) without CCS based on varying the price of natural gas (NG). Learning curves and prospects for technology improvements to reduce CCS costs are also addressed.

In the seven years since the *IPCC Special Report on Carbon Dioxide Capture and Storage* there have been significant technology developments in CO_2 capture and transport. This brief section is an update of only the CO_2 capture technology and costs. A brief description of next-generation capture research and development is also provided in Section 13.3.2.9.

13.2.1 Applications and Feedstocks for CO_2 Capture

The greatest focus of CCS is on coal-based electric power generation. This focus is logical because close to 40% of total human-made fossil fuel CO_2 emissions are from this one application and feedstock. Coal-based power plants also dominate the lists as the biggest stationary CO_2 point sources. Nevertheless, there are other applications and feedstocks for CCS. For example, all of the large commercial-scale CCS projects currently in operation are for industrial applications such as natural gas clean-up, biofuels production, and production of synthetic natural gas from coal. Only one of the five commercial scale projects operating today uses coal.

13.2.1.1 Industrial CO_2 Capture

Examples of CCS projects of approximately 1 Mt/yr or greater of CO_2 storage that have been successfully operated for over five years (listed from the oldest) include:

- Statoil's Sliepner offshore gas platform in the North Sea between Scotland and Norway, with CO_2 from associated natural gas purification injected into an undersea deep saline formation;
- Dakota Gasification in North Dakota, United States, with brown coal (lignite) gasification via synthetic natural gas (SNG) purification into a CO_2 pipeline to Weyburn, Saskatchewan, Canada, for use in enhanced oil recovery (CO_2-EOR);
- ExxonMobil's LaBarge facility in Wyoming, United States, with CO_2 from natural gas purification into a CO_2 pipeline for CO_2-EOR in the Powder River Basin of Wyoming;
- BP's In Salah facility in Algeria, with CO_2 from natural gas purification with injection into the same formation, but at a distance from the production well; and
- Statoil's Snøhvit Project, which sequesters CO_2 from a liquefied natural gas facility in a saline formation underneath the Barents Sea.

Most of these successful commercial-scale CCS projects have the economic advantage of producing a large pure CO_2 vent from raw natural gas purification. Natural gas produced from these fields contains from about 2% to over 15% CO_2 or more. Carbon dioxide removal or capture is required to meet natural gas pipeline energy content specifications, regardless of the CO_2 mitigation issue. CO_2-EOR projects have the added economic advantage of a small market value credit for the CO_2 after its compression and CO_2 pipeline delivery expenses to nearby oil fields (EPRI, 1999). Thus, the overall costs of these CCS projects have significantly lower CCS costs than those discussed later in this section.

There has been some debate about whether CO_2 used for EOR should be considered as CO_2 storage. While the amount remaining underground varies from place to place and well to well, about 50% of the injected CO_2 never returns to the surface (Stevens et al., 2003). Moreover, in almost all cases, the CO_2 produced with the oil is separated and injected back into the reservoir, primarily because it is a valuable commodity and avoids the need to purchase more CO_2. Beyond this, some argue that the CO_2 emitted into the atmosphere when the oil is used negates the benefits of storage. However, at least on the margin, if this CO_2 was not geologically stored in EOR, the alternative replacement oil from other sources would not have reduced the CO_2 in the atmosphere at all. In the United States, where most of the CO_2-EOR is carried out, CO_2 utilization credits for EOR are only about US$10/t (or US$0.53 per thousand standard cubic foot (scf) in common EOR terms). That is significantly less than the total cost of CCS unless the CO_2 is being captured regardless of the CO_2 mitigation issue.

There are several important industrial applications that produce large, nearly pure CO_2 vents. These include raw natural gas and synthesis gas (H_2 and CO from gasification) purification, plus the production of high-value products like ammonia and sometimes other synthesis gas products such as hydrogen, synthetic natural gas (SNG), coal-to-liquids, or methanol. It should be noted that most hydrogen is made from natural gas via steam methane reforming (SMR), which normally does not produce a pure CO_2 stream (Shah et al., 2006). However, hydrogen made from heavy oil, petcoke, or coal via gasification does produce large, pure CO_2 streams.

Industries with moderately large point sources of CO_2 include cement kilns, iron/steel making, oil refining, and bulk chemicals. Large industrial CO_2 point sources have typically less than 1 $MtCO_2$/yr. These CO_2 sources for CCS are relatively small compared to the big coal power plants. Nevertheless, the pure industrial CO_2 vent sources for CCS should not be overlooked due to their lower CCS costs. Nations, such as China with over 65 coal gasification plants and 20 GWt of synthesis gas capacity for ammonia, methanol, and hydrogen, have these pure CO_2 vents for lower cost CCS (Simbeck, 2009a).

13.2.1.2 Electric Power Generation

As already discussed, electric power generation and large industrial operations are the focus of CCS efforts due to their large overall CO_2 emissions and large point sources. Typical central coal power plants (resulting in 40% of total worldwide fossil fuel CO_2 emissions) emit 0.8–1.0 tCO_2/TWh of net electricity generated. A 1000 MWe coal power plant at a 75% annual load factor emits about 6 $MtCO_2$/yr. An equivalent baseload 1000 MWe NGCC power plant emits about 3 $MtCO_2$/yr. There are very few industrial point sources that match the size of fossil fuel power plants.

Fossil fuel power plants in wealthy nations are the most susceptible to CO_2 reduction mandates and thus CCS may be strategic to their future CO_2 mitigation options. Furthermore, unlike other energy-intensive industries, with few exceptions, power plants cannot move to nations

with fewer CO_2 restrictions. CO_2 taxes on energy-intensive industries are only effective if the imported products are taxed based on their manufacturing and shipping direct and indirect CO_2 emissions (Davis and Caldeira, 2010). Otherwise, the movement of industries to countries with fewer CO_2 restrictions would hurt the economies of countries with high CO_2 restrictions while failing to reduce total world CO_2 emissions.

13.2.1.3 CCS Feedstocks

Feedstocks for CCS reflect the industry, applications, and fuel availability. More importantly, CCS also requires large point sources located near good geologic CO_2 storage sites. This key issue favors large coal uses for CCS, which are dominated by central coal-fired power plants but also large coal-based integrated steel mills and cement kilns.

Most industries are natural gas-based, except for nations where it is not readily available, such as China, where coal is widely used by energy-intensive industries. Industrial natural gas applications tend to be relatively small CO_2 point sources, thus generally not attractive for potential CCS. Industrial exceptions are the large oil refineries, cement kilns, and iron/steel making and ethanol fermentation facilities.

Oil refinery CO_2 emissions are generally from processing raw crude oil into usable oil products. The heavier the crude oil feed and the lighter the products, the higher the CO_2 emissions. If available, oil refineries prefer using natural gas for hydrogen production and fuel gas, thus reducing the need for more expensive oil for their internal use. CO_2 emissions from the process of oil refining are only about 9% of the carbon in the raw crude oil feed. Also, the extensive use of residual oil coking for heavy oil conversion avoids a significant amount of CO_2 emissions by oil refiners. Most CO_2 emissions from crude oil are emitted by the end user of the oil refinery products, both premium distillate fuels and low-value petcoke. Emissions from the end user of petroleum products are widely distributed and are often from small and mobile sources such as cars, trucks, and airplanes, which are, of course, difficult to capture.

Cement kilns are large CO_2 producers due to both the fuel requirement and the conversion of limestone to lime. It should be noted that cement kilns have the highest CO_2 emissions per unit value (or per million dollars) of product. Cement kilns are also ideal for the utilization of waste fuels. If waste fuels are not available, coal or petcoke are commonly used.

Integrated steel mills are traditionally coal-based and make mostly virgin iron from iron ore via coke ovens and blast furnaces. This should not be confused with mini-mills recycling scrap steel via electric furnaces. Integrated steel mills have very high CO_2 emissions per unit value of product. Mini-mills have much lower overall energy use, and most of their CO_2 emissions are indirect, e.g., located at the electric generation facilities.

A potentially interesting and often overlooked CCS CO_2 source could be the high purity CO_2 vent of ethanol fermentation from biomass (US DOE, 2010). Ethanol plants are extensive and growing for gasoline replacement in the United States and Brazil due to government mandates and subsidies. Currently, US ethanol production is about 54.27 billion liters/yr (13.3 billion gallons/year) and almost all of it comes from corn fermentation. The high purity CO_2 vented from corn ethanol fermentation in the United States alone is about 30 Mt/yr. However, a challenge is the small size of the CO_2 ethanol fermentation vents. With about 150 ethanol plants operating in the United States, the average point source is about 0.2 $MtCO_2$/yr per plant. Nevertheless, many of these US corn ethanol facilities are concentrated in the corn belt of the upper Midwest, from Indiana to eastern South Dakota, with the major capacity located in Iowa, Illinois, and Nebraska.

Electric power generation is traditionally focused on coal feedstocks for "baseload" (60–80% annual load factor) power generation due to its low and stable fuel costs (US EIA, 2009). Natural gas is more commonly utilized for cycling and peaking power generation unless the local grid does not have enough coal or nuclear available for baseload. The demand for natural gas-based cycling and peaking generation increases with mandates for more intermittent wind and solar renewable power. Therefore, CCS for electric power generation logically focuses first on coal-based power. However, this could change in the future due to the heightened interest in natural gas-based power. If stable long-term supplies of lower natural gas prices are available, and gas is used in high-efficiency cogeneration (COGEN) or baseload power with high annual load factors, natural gas power generation may become the focus of CCS.

The focus on large coal power plants for CCS creates an interesting longer-term opportunity for biomass, as discussed in Section 13.1.2 and Chapter 12. The CCS infrastructure would likely begin with coal due to its low delivered fuel cost. However, as CO_2 avoidance values grow, the economics begin to favor blending waste biomass (whenever available) with coal to increase CO_2 reductions using biomass with CCS.

13.2.2 CO_2 Capture Status

CCS has several important decision steps and process choices. The following discussion simply and briefly explains these choices so the CO_2 capture and compression technology status can be discussed.

13.2.3 The Basics of CO_2 Capture

CCS requires large CO_2 stationary point sources within reasonable distances of good geologic storage locations. CO_2 can be from an existing source considering CO_2 capture retrofit or rebuild or from a potential new CO_2 source. It should be noted that a new CO_2 source adding CCS would only avoid increasing CO_2 emissions unless it were based on biomass or if it displaced an existing source without CCS. CO_2 emissions reductions based on fossil fuels require existing CO_2 sources to have retrofits, rebuilds, or new unit replacements, all with CCS.

Existing CO_2 sources adding CCS are subject to net capacity and efficiency losses (Simbeck and Roekpooritat, 2009a; 2009b). It may be useful to also consider rebuilding existing CO_2 sources for CCS to avoid efficiency losses, particularly in the case of older, inefficient coal plants. Rebuilding old power plants increases the total capital but can also avoid the net capacity and efficiency losses of adding CCS (relative to the older existing power plant). Existing CO_2 sources may also consider moving new replacement units with CCS to be co-located with CO_2 storage sites, thus avoiding CO_2 pipeline costs and permitting issues at the expense of permitting and the capital outlay of an entire new replacement plant.

The first step of CO_2 concentration, recovery, or capture to a high purity CO_2 stream is the most expensive and has the most options. This step is normally subdivided into three general process options (IPCC, 2005):

- pre-combustion,
- post-combustion, and
- oxyfuel combustion.

A schematic illustrating the major process steps and material flows for each of these options is provided in Figure 13.3. The choice of CO_2 capture process is complicated by the many different process technologies being developed as well as their state of their development.

13.2.3.1 CO_2 Capture and Storage Ready

The concept of making plants "CO_2 capture and storage ready" is to enable plants to be retrofitted with CCS when the necessary economic and policy drivers are in place, which in most countries currently are not. The term "CO_2 capture and storage ready" means different things to different people. The Global Carbon Capture and Storage Institute (GCCSI), in collaboration with the International Energy Agency (IEA) and Carbon Sequestration Leadership Forum (CSLF), has produced a definition of CCS ready (GCCSI, 2010), which states that in order for a facility to be considered capture and storage ready the project developer should:

- carry out a site-specific study in sufficient detail to ensure that the facility is technically capable of being fully retrofitted with CO_2 capture using one or more choices of technology that are proven or whose performance can be reliably estimated as being suitable;
- demonstrate that retrofitted capture equipment can be connected to the existing equipment effectively and without an excessive outage period and there will be sufficient space to construct and safely operate additional capture and compression facilities;
- identify realistic pipeline or other routes to storage of CO_2;
- identify one or more potential storage areas that have been appropriately assessed, and found suitable for safe geological storage of the projected full lifetime volumes and rates of captured CO_2;

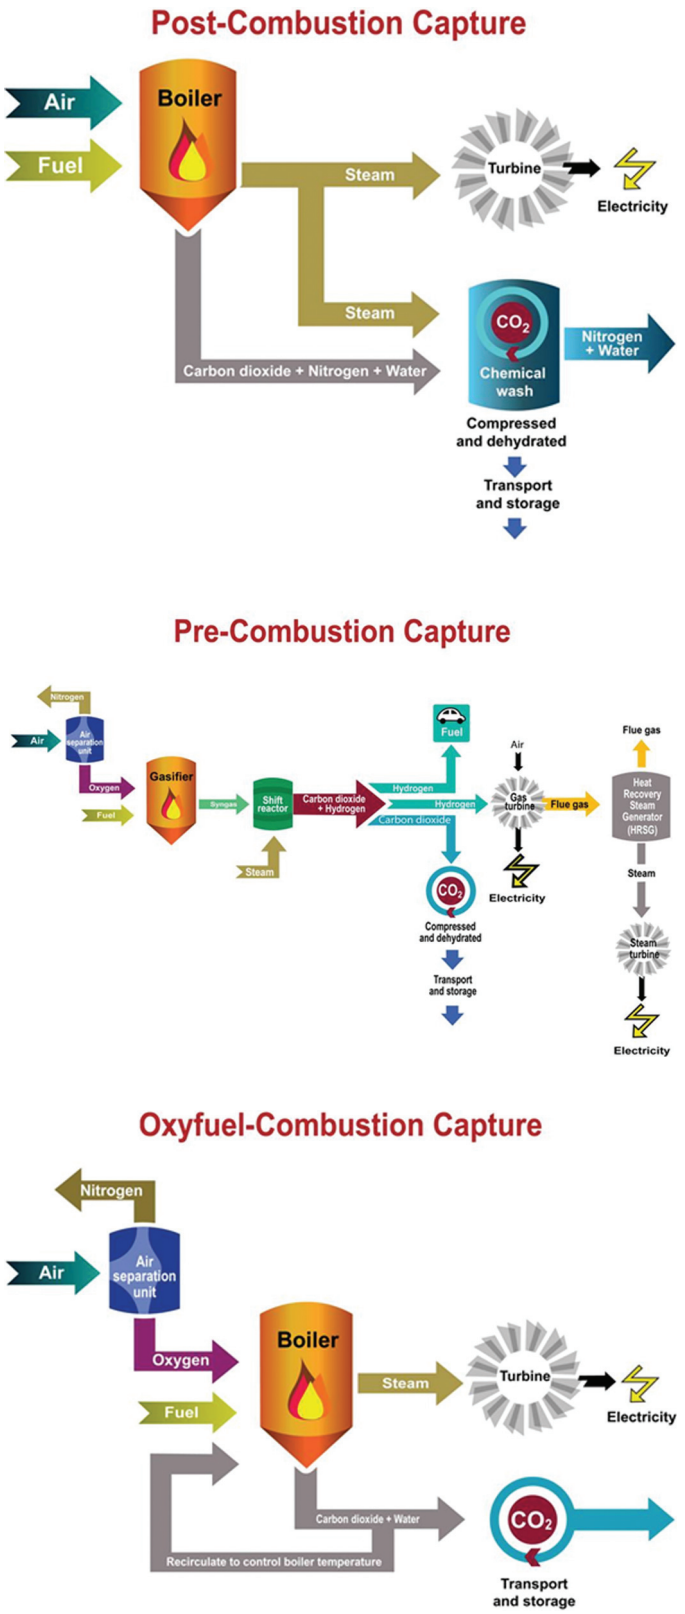

Figure 13.3a-c | Schematic showing the major steps and materials flows associated with the (a) post-combustion capture, (b) pre-combustion capture, and (c) oxy-combustion. Source: courtesy of ZEP, 2011.

- identify other known factors that could prevent the installation and operation of CCS and identify credible ways in which they could be overcome;
- estimate the likely costs of retrofitting CCS;
- engage in appropriate public engagement and consideration of health, safety, and environmental issues; and
- review CCS status and report on it periodically.

A much more dubious meaning of "CO_2 capture ready" is that processes or plants simply claim that space has been left for the addition of retrofitting CO_2 capture at a later date. This usually occurs for new natural gas or coal power plants. In these cases, there is no large pure CO_2 vent, just a normal natural gas or coal power plant with some extra space. However, once the investment is made, the economics of CCS greatly change. Sunk capital cost (paid-off or not) power plants that are considering adding CCS require much higher CO_2 avoidance costs in order to economically justify adding retrofit CCS than if the investment had been made before the original large power plant was built. This is shown in the later cost sections.

Additionally, the concept of "CCS ready" applies to processes or plants removing (capturing) CO_2 in their normal operation and venting it as a large, high-purity CO_2 stream. These sources provide good opportunities for low-cost CCS when compression and storage are added to the existing operations. Examples include most industrial synthesis gas gasification plants, some natural gas-based hydrogen plants, and some natural gas purification plants that remove high concentrations of CO_2.

13.2.4 Tracking Real and Proposed CCS Developments

There are numerous groups and organizations developing and promoting potential CCS technologies as well as bench scale research and development (R&D), pilot, demonstration, and commercial-scale projects. These include governments (at all levels), national laboratories, academics, and private organizations ranging for one-person government grant recipients to venture capital start-ups to major international corporations. A recent report by GCCSI lists hundreds of organizations working on CCS (GCCSI, 2009a).

Keeping up-to-date with the many developments and promotions of CCS projects is very time-consuming. Nevertheless, there are some excellent websites and organizations that are tracking the real and numerous proposed CCS projects. Some of these organizations are also attempting to document worldwide CO_2 point sources for potential CCS, as well as potential geologic CO_2 storage locations.

Some of the organizations tracking real and proposed CCS developments include:

- Bellona: www.bellona.org/ccs
- IEA GHG R&D: www.ieaghg.org
- MIT: sequestration.mit.edu/index.html
- NETL: www.netl.doe.gov/technologies/carbon_seq/global/database/index.html
- Scottish CCS: www.geos.ed.ac.uk/sccs/

In addition to the numerous government organizations funding CCS technologies and R&D, there are some important joint ventures and institutes actively involved in CCS:

- CO_2 Capture Project (CCP): www.co2captureproject.org
- Cooperative Research Centre for Greenhouse Gas Technologies (CO2CRC): www.co2crc.com.au
- Electric Power Research Institute: www.epri.com
- Global CCS Institute (GCCSI): www.globalccsinstitute.com
- Global Climate & Energy Project (GCEP): gcep.stanford.edu
- Zero Emissions Platform: www.zeroemissionsplatform.eu

13.2.4.1 Pre-combustion – Industrial

Pre-combustion CO_2 capture has the most commercial experience. However, all of this large-scale use has been in industrial applications, and not in electric power generation. All five of the large successful CCS projects discussed in the application subsection involve pre-combustion CO_2 capture in industrial oil and gas applications.

There are natural gas purification- and gasification-based synthesis gas (H_2 + CO) purification plants that remove (or capture) CO_2 at amounts greater than 1 Mt/yr. However, that high purity CO_2 is normally just vented. The CO_2 is simply removed to meet product gas (usually natural gas or H_2) specifications. The feed gas is at high pressure without any oxygen, making the CO_2 capture relatively easy. This CO_2 removal or capture is usually accomplished by scrubbing the high-pressure feed gas and then, with low-pressure steam use, stripping the CO_2 from highly loaded tertiary amine chemical solvents, or just high-pressure drop flashing the CO_2 from highly loaded physical solvents for even lower energy requirements.

Of the 50 GWt (synthesis gas) capacity of operating gasification plants around the world, most include large CO_2 capture. The exception is the 8 GWt of synthesis gas converted into 4 GWe of IGCC electric generation. This industrial CO_2 capture is due to the raw synthesis gas having a lower H_2/CO ratio, whereas the higher value uses are for a high H_2/CO ratio such as for hydrogen, ammonia, and methanol production. Therefore, H_2O is added to the CO-rich synthesis gas that reacts over catalysis into H_2 and CO_2 and the CO_2 is then removed. Examples of industrial gasification plants with pure CO_2 vents with CCS include the Dakota Gasification SNG plant in the United States, the Shell Oil Pernis refinery in the Netherlands, and the Shenhua Group coal liquefaction plant in China (CO_2 from the Shell coal gasifiers supplying the hydrogen). The Shenhua Group CCS plant is a smaller first stage demonstration of only 0.1 $MtCO_2$/yr, and it is still under construction. However, it will be the first CCS plant operating in China in 2011, and it may be expanded to a 3 Mt/yr CCS operation.

There has also been prior extensive experience with the combustion of H_2-rich fuel gas in oil refineries when there was excess hydrogen used as a fuel in refinery gas. However, this experience is for older and smaller gas turbines operating at relatively low firing temperatures, and it is only useful today for COGEN when the low gas turbine firing temperature does not hurt the overall efficiency.

Pre-combustion industrial CCS development tends to get much less publicity than electric generation. Nevertheless, industrial CCS costs can be much lower if the industrial process makes a large, pure CO_2 vent regardless of the CO_2 mitigation issue. This is commonly the case for the production of hydrogen (via gasification), ammonia, synthesis gas (for chemicals), and natural gas (when significant amounts of CO_2 are in the raw natural gas).

There is increasing interest in developing hydrogen units for oil refineries via steam-methane reforming (SMR) of natural gas that produce a pure CO_2 vent, as is already the case when making hydrogen via the gasification of heavy feedstocks. Most modern SMR units do not make a pure CO_2 vent because of the use of high-pressure swing absorbers (PSA). With the improvement of natural gas supplies and increase in hydrogen demand due to upcoming heavy fuel oil upgrading and desulfurization mandates for maritime fuel, an SMR unit with a pure CO_2 vent could be an excellent opportunity for low-cost CCS.

Research on vacuum pressure swing absorbers (VPSA), along with staged PSAs by the major industrial gas companies for integration into SMR to produce a pure CO_2 vent, is underway. Interestingly, this is already commercially applicable but not for SMR hydrogen units. A Linde VPSA system is used for synthesis gas recycle purification as part of a Corex/Midrex iron making unit in South Africa (Linde, 2009). However, VPSAs would have about half of the total SMR CO_2 emissions unless a portion of the product H_2 is used to fire the reforming furnace, which would greatly increase the overall cost. There are also commercially proven heat exchange reformers by several vendors that recover all of the CO_2 as a pure vent in making H_2 from natural gas. However, these designs require oxygen, whereas traditional SMR does not.

ExxonMobil is developing a cryogenic process for removing CO_2 from high pressure raw natural gas that is high in CO_2. It is called the Controlled Freeze Zone process and it is being demonstrated in a US$100 million unit at its LaBarge NG facility in Wyoming, United States (Mart, 2009). One of the advantages of this process is the production of liquid CO_2 at pressure, thus greatly reducing the CO_2 compression costs for CCS.

Due to high CO_2 emissions from iron/steel production, there is increased interest in advanced iron making processes that produce CO_2 in a pure stream for potential CCS. An option is to convert the air-blown blast furnaces to an oxygen-blown operation (plus adding CO_2/CO top gas for recycle). More advanced options are the utilization, integration, or advanced versions of synthesis gas-based direct reduced iron (DRI) processes, such as Corex or Midrex (ULCOS, 2008). The synthesis gas conversion pre-pass over the iron ore is low, and thus the top gas is recycled after removal of H_2O and CO_2 (products of iron oxide reduction to iron). As mentioned above, this is already commercially done with VPSA on a Corex/Midrex plant in South Africa. In addition, several coal-based DRI steel mills are under construction in India. The mills are based on separate coal gasification that will increase the H_2/CO ratio before feeding into the Midrex DRI units; thus, a second large pure CO_2 vent is produced (Jindal, 2009).

The ammonia solvent CCS process is usually associated with post-combustion CO_2 capture. However, it has some of the same benefits for use in pre-combustion CO_2 capture of stripping at pressure to reduce CO_2 compression costs. It has the added benefits of high solvent loading, fewer side reactions, no refrigeration, and fewer ammonia leakage issues when operated on high-pressure synthesis gas. Testing is currently being done at SRI International for application with SNG for coal with CCS.

13.2.4.2 Pre-combustion – Electric Generation (See also Chapter 12)

Pre-combustion CO_2 capture in electric generation is mostly focused on coal via integrated gasification combined cycle (IGCC) and not for NGCC. NGCC CO_2 capture is more focused on post-combustion CCS, as this avoids major modification to the standard NGCC design. Plus, the CO_2 capture can be by-passed when needed for additional peaking power.

Even before the CO_2 capture issue, the electric power industry had been slow to accept the IGCC option relative to conventional direct combustion pulverized coal (PC) boiler steam systems. This was due to the high capital cost, low availability plus complex chemical processing, and the integration requirements of IGCC. There is also an ongoing debate about the lack of expertise in the electric power industry because gasification is a very complex chemical process. There was a similar slow acceptance and learning curve by electric generators of wet limestone scrubber flue gas desulfurization and selective catalysis reduction nitrogen oxide (NO_x) controls, which are very simple chemical processes.

The addition of CO_2 capture to pre-combustion IGCC has some challenges. First, the hot raw synthesis gas cooling heat recovery is lost due to the large excess steam (H_2O) requirements of the CO conversion to H_2 and CO_2. More important are the special challenges of firing H_2-rich gas in high temperature gas turbines. This is generally due to the negative impact of the much higher heat transfer coefficient of H_2O vapor (after combustion of the H_2-rich fuel) on the critical hot gas path metal parts associated with the hottest initial stages of the gas turbine exhaust gas expansion. The options for addressing this issue include: reducing the firing temperature (lower capacity and efficiency) or shorter hot gas path metal parts life (i.e., higher maintenance), adding large amounts of high pressure nitrogen to the H_2 fuel (reducing net efficiency or most

expensive air-blown gasification), or developing a special and challenging gas turbine pre-mix air and H_2 combustor. Reducing the firing temperature would be the worst choice, unless utilized in the industrial COGEN of combined heat and power (CHP).

Perhaps the biggest challenge facing pre-combustion CCS is the high capital cost of the few IGCC projects actually being built at this time. For example, the latest capital cost of Duke Energy's Edwardsport, Indiana IGCC project (currently under construction) has increased to US$3.3 billion for 618 MWe (net), or US$5593/kW, with no capture and storage. However, this very high capital cost does include "as spent" current and future dollars, some infrastructure for a potential second unit, allowance for funds during construction, and other owners' costs. While this high unit capital cost is reducing interest in IGCC, at the same time it is going unnoticed that the few conventional coal boiler power plants under construction in the United States have unit capital costs almost as high. A good example is Duke Energy's Cliffside project in North Carolina, at a cost of about US$3000/kW with no capture or storage. The few US nuclear plants currently under construction have also increased to significantly higher unit capital costs.

The positive activity in pre-combustion CO_2 capture for electricity is associated with increasing competition and innovative designs. This is likely a result of the many studies showing the incremental costs plus net power and efficiency losses of converting IGCC to CCS as being lower than for post- and oxyfuel combustion (US DOE, 2007; EPRI, 2008). However, the issue is higher power plant costs and the lower availability of IGCC compared to more commercially proven PC boilers before considering CCS.

There are more than 10 IGCC with CCS projects being promoted based on at least six different coal gasification technologies. Also, many pre-combustion power projects are being proposed by independent power producers (IPP), some having innovative designs based on "polygeneration" versus just stand-alone central power plant IGCC. The use of high H_2/CO ratio synthesis gas with CCS for various high-value products such as hydrogen, SNG, methanol, olefins, and plastics, as well as COGEN CHP, is involved. As previously explained, COGEN avoids the added challenges and costs of high-temperature gas turbine-fired H_2-rich fuel gas while also greatly increasing overall efficiency and reducing water demands (Simbeck, 2009a; 2009b). The combination of this added competition, especially from the more aggressive and innovative IPPs, will reduce overall costs and improve performance. In fact, the key potential advantage of pre-combustion CO_2 capture for electricity is that hydrogen has more uses and flexibility than just steam from boilers.

13.2.4.3 Post-combustion – Industrial

Globally, there are over 2500 industrial sources with CO_2 emissions over 0.1 Mt/yr. These emissions sources tend to be smaller than for coal-fired power generating stations, averaging about 1 Mt/yr (IPCC, 2005). Carbon dioxide concentrations in flue gas vary widely, from 7–10% for gas-fired boilers to 14–33% for cement kilns (IPCC, 2005). Post-combustion CCS for industry has been successfully demonstrated at a relatively small scale. The largest operating unit is only about 0.1 Mt/yr. There are few commercial post-combustion CO_2 capture (without special circumstances) units but MHI (Mitsubishi Heavy Industries) has for example built around 10 of the largest units, which handle flue gas from NG-SMR ammonia plant reforming furnaces to capture CO_2 to make urea from the ammonia.

The low pressure and low CO_2 concentration in flue gas after combustion requires large absorbers, high CO_2 removal solvent circulation rates, and high stripping steam use. The presence of oxygen in flue gas also eliminates many potential solvents and leads to a small amount of waste from the reaction with the solvents. However, for boiler systems it is possible to add flue gas catalysis combustion via the use of a small amount of NG to consume the few percent of oxygen in the flue gas and then use better solvents. This was commercially done in the early days of CO_2 EOR before large CO_2 pipeline sources of cheaper CO_2 became available.

Perhaps the greatest attribute of post-combustion CO_2 capture is the ability to retrofit any flue gas steam with little impact on the original process other than the added utility demands (which reduce net capacity and efficiency) and space requirements. The added utility demand, and consequently added energy demand, can be met by adding a small boiler with a steam turbine or gas turbine in a COGEN system for the CO_2 compressor power and low pressure CO_2 stripping steam. The CO_2 scrubber could be located in the base of a new wet stack, as has been done for a retrofit flue gas desulfurization (FGD) unit with space limitations. Back-end CO_2 capture also means the CO_2 capture process can be by-passed at any time, thus assuring higher availability than pre-combustion or oxyfuel combustion and the ability to meet any peak demands if CO_2 emissions are allowed.

Most of the effort on post-combustion CO_2 capture is focused on electric power generation applications. One exception is Statoil's current demonstration of chilled ammonia post-combustion CO_2 capture on flue gas from the fluid catalytic cracker (FCC) at its Mongstad refinery in Norway (Alstom, 2007).

13.2.4.4 Post-combustion – Electric Generation

Post-combustion CO_2 capture for electric generation has gained greater interest in the last five years. This increasing post-combustion CO_2 capture interest is due to many factors, including the following:

- a decreased interest in pre-combustion CO_2 capture, likely due to the high capital costs and slow commercial acceptance of IGCC (with or without CCS). Current reported capital costs for IGCC plants average about US$6400/kW normalized to a 460 MW plant with 90% capture (Al-Juaied and Whitmore, 2009);

- the number and scale of emissions from existing and planned PC power plants;
- improved designs for post-combustion CO_2 capture with more vendor competition and choices of chemical solvents;
- minimal impact to the traditional NGCC or PC power plant process other than the large need for low pressure steam for CO_2 stripping and for CO_2 compressor power;
- the ability to easily by-pass the back-end flue gas scrubber process when problems with the CO_2 system occur or when there is a need for additional peaking power; and
- lower total capital outlay (not to be confused with CO_2 avoidance costs) and ease of retrofit to the existing power plant, except for accounting for the moderately high net capacity and efficiency losses plus additional space requirement.

As already discussed, most interest in natural gas-based electric generation CCS is with post-combustion CO_2 capture for the CO_2 emission avoidance reasons. Lower natural gas prices and improved supplies are making NGCC more competitive with coal-based electric generation for baseload power. However, NGCC without CCS replacing coal is generally more economical than coal with CCS until there are very high CO_2 avoidance values or high NG prices. Also, with high natural gas prices, CCS economics can favor coal with CCS over natural gas with CCS.

There are at least five quality vendors offering improved amine CO_2 capture systems via advanced amines and/or innovative integration. There are also at least two quality vendors claiming even better performance based on less developed ammonia solvent in the place of amines (Black, 2006; McLarnon and Duncan, 2008).

The advantages of ammonia over amine CO_2 capture are higher solvent loading (units of CO_2 captured per unit of total solution recirculation), significantly lower stripping steam requirements, and sizable CO_2 compression power plus capital savings. However, ammonia to ammonium bicarbonate flue gas chemical scrubbing system is still in the early stages of demonstration. Nevertheless, ammonia for both pre-combustion and especially post-combustion CCS is likely the most significant development in CO_2 capture technology in the last five years.

The current small (0.1 $MtCO_2$/yr) "Chilled Ammonia" demonstration plants on coal boilers in North America and on NGCC and oil refinery FCC fuel gas in Europe are being followed closely (Alstom, 2009; Spitznogle, 2009). These demonstration plants should resolve concerns about potential ammonia leakage in the stack gas, solid ammonia bicarbonate buildups, the impact of higher quality steam to strip the CO_2 at pressure, expensive refrigeration, and extensive heat exchange requirements.

The Powerspan ammonia CO_2 capture process claims it can avoid the ammonia leakage concern and refrigeration requirements. However, they have only begun testing a very small CO_2 pilot plant. Powerspan also has the added challenge of integrating this process to its only demonstrated SO_2 and NO_x control process that utilizes high-cost ammonia for conversion into lower grade and less utilized ammonia sulfate fertilizer that may saturate local markets.

There is increasing fundamental R&D interest in more advanced chemical *ab*sorption and *ad*sorption of CO_2, especially with solid sorbents and strong bases that could adsorb CO_2 more effectively (Rhudy, 2009). However, these ideas are at the very early stage of development and not close to the minimal small pilot plant stage or successful development. Solid sorbents range from non-volatile amine polymers to sodium carbonate to metal organics to lithium silicates. Adsorption and regeneration configurations, energy requirements, and sweep gas issues are yet to be resolved. Also under consideration is oxyfuel combustion for the regeneration to make the higher purity CO_2 stream. CO_2 flue gas capture into advanced cement and building materials are discussed separately in Section 13.2.4.7 due to their close association with reducing the large cement making CO_2 emissions.

13.2.4.5 Oxyfuel Combustion – Industrial

Oxyfuel combustion replaces air with oxygen, thus generating a CO_2-rich flue gas. Oxyfuel CO_2 capture is the least developed of the three CO_2 capture processes. However, it continues to gain interest and development. This is likely due to its potential advantage of greatly simplifying the overall CO_2 capture process plus avoiding most of the chemical processing associated with pre-combustion and post-combustion capture. Oxyfuel combustion also has the interesting potential to increase existing process efficiency in retrofit applications. This is due to its much lower gas volume of oxygen with recycle CO_2-rich flue gas replacing high N_2-content air with a much higher total gas volume per tonne of oxygen. However, the challenge here is the massive oxygen requirement at about 60% more oxygen needed than for pre-combustion CO_2 capture. The benefits of higher combustion efficiency with oxygen combustion is lost once the large energy demands of producing oxygen plus smaller energy demands of CO_2 recycle are considered. Also, oxygen from external sources or from air separation units using grid electricity will usually have large indirect or off-site CO_2 emissions.

The oxyfuel CO_2 capture is being seriously considered for CCS demonstrations by the CO_2 Capture Project (CCP) for oil refinery-fired heaters and FCCs as well as steam boilers. Petrobras is already testing oxyfuel in its FCC pilot plant in Brazil and Suncor is working with the provincial government of Alberta (Canada) on a potential oxyfuel retrofit of an existing NG-fired field steam boiler for steam generation in oil sands production via steam-assisted gravity drainage (de Mello et al., 2008).

Advanced oxygen production looping cycles are being developed at a small scale by numerous groups and companies. This involves the oxidation and reduction cycling of metals on ceramic particles at moderate temperatures. The high solid flow recycle rates per tonne of oxygen and

contacting requirements of solids and gases generally favor the use of modified circulating fluid beds with long-term particle attrition being a key issue. Looping cycle oxyfuel CCS is being developed for both natural gas and coal as well as at atmospheric pressure and pressurized. Oxygen looping with natural gas is easier, as it avoids the added challenge of solids and coal ash. Oxygen looping cycles also apply to pre-combustion CCS while reducing the oxygen demands by about 60%.

13.2.4.6 Oxyfuel Combustion – Electric Generation

Despite being the least developed of the CO_2 capture options, oxyfuel combustion is perhaps the CO_2 capture option that the traditional electric power industry likes best. This is most likely due to the lack of chemical processing compared to the simple chemical processing of post-combustion and especially the complex chemical processing of pre-combustion CO_2 capture. There is hope that raw CO_2 from the oxygen combustion flue gas might be directly compressed for CO_2 storage, thus avoiding additional SO_2 and NO_x controls as well as 100% CO_2 capture and no stack or emissions. Oxyfuel combustion at moderate pressures could also noticeably reduce the CO_2 compression capital costs and power requirements relative to the added power/costs of making or compressing the oxygen at moderate pressure.

Oxyfuel combustion has several challenges, such as the large net capacity and efficiency losses associated with making the massive amounts of oxygen, which are 60% larger than required for pre-combustion. There are also challenging CO_2 compression, pipeline, and injection issues on purity relative to the raw CO_2 coming from oxyfuel combustion. Specifically, trace amounts of SO_2 and NO_x are likely to react and even a 1% residual amount of oxygen (from oxyfuel combustion) is generally not acceptable in a traditional CO_2 pipeline (White et al., 2008; Darde et al., 2008), so CO_2 purification using low temperature separation of other means will be required. Finally, N_2 that remains in the oxygen from the air separation requires higher pressure CO_2 to avoid a two-phase flow and can increase the injection well back-pressure.

Oxyfuel combustion for electric generation CCS has been under development by Vattenfall for its large Eastern European brown coal power plants for many years. There is now a small demonstration scale unit of 0.1 $MtCO_2$/yr at its large brown coal power plant at Schwarze Pumpe in Germany. FutureGen 2.0 in the United States will demonstrate retrofit of an old coal plant with oxyfuel combustion.

All of the major air separation vendors are working with most of the major boiler vendors on oxyfuel combustion. Larger oxyfuel combustion CO_2 capture demonstration projects are being promoted for several power plants. The projects are still smaller in size, and there are fewer proposed projects than for pre-combustion and significantly less than for post-combustion. A large oxyfuel demonstration proposed in Western Canada was abandoned due to its high capital costs. Most proposals are for PC boilers, both new and retrofits, where the mass of recycled CO_2-rich flue gas mixed with oxygen matches the mass flow and heat exchanges similar to conventional air and coal combustion boilers.

Praxair and Foster Wheeler have proposed a new circulating fluidized bed combustion boiler steam cycle oxyfuel CCS demonstration power plant in Western New York, United States. Circulating fluidized bed combustion boilers have the advantage over PC boilers of a much greater feed fuel flexibility to co-process larger amounts of waste biomass for double CO_2 reductions in CCS.

Oxyfuel combustion for CO_2 capture has revitalized renewed R&D in the magnetohydrodynamics (MHD) process for the advanced electric generation process from fossil fuels. The original MHD development suffered a big loss in performance because of the N_2 in its air combustion.

Most of the interest in oxyfuel for NG-based power generation CCS has been based on a modified steam turbine used like a gas turbine without the big air compressor. Large amounts of water injected with NG-oxygen combustion generate a high pressure of mostly hot steam working in the fluid for expansion as in the modified steam turbine. This produces a high steam temperature with direct NG-oxygen combustion plus high temperature double reheats with smaller oxyfuel combustors and then steam condensing. This is the basis for the Clean Energy System under development in both North America and Europe. It is also being proposed for integration with coal gasification.

For some, the potential of 100% CO_2 capture, avoiding separate SO_2 and NO_x capture, and totally avoiding a stack via oxyfuel CCS, is a great incentive to investigate sequestering "dirty CO_2." The only significant impurity in large commercial CO_2 operations is the H_2S from pre-combustion CCS. Specifically, Dakota Gasification's CCS project in Weyburn, Canada leaves all of the coal gasification H_2S in the CO_2. This is also common in EOR field CO_2 recycles as the oil production often has associated gas with H_2S. However, transporting H_2S-rich CO_2 gas through long pipelines carries greater risks and costs, thus negating some of the benefits of this approach.

Researchers are investigating innovative ways to integrate, convert, and/or process dirty CO_2. The trade-off of CO_2 compressors and pipelines versus varying the CO_2 purity has not been fully addressed. Traditional commercial EOR operations pipeline CO_2 purity specifications (except for the water content) have been developed based on the natural CO_2 dome sources, not CCS. Other options for dirty CO_2 include the reaction and recovery of SO_2 and NO_x before or during CO_2 compression and low temperature catalysis combustion with a small amount of natural gas to react all of the residual oxygen in the raw oxyfuel combustion flue gas.

13.2.4.7 CO_2 Capture via Advanced Building Materials

A growing area of interest is the development of advanced building materials that utilize CO_2, perhaps directly from fossil fuel stacks. This

can be a "win-win" situation if CO_2 captured materials can be effectively utilized in place of traditional cement, thereby replacing limestone-based cement kilns, which are the second largest source of human-made stationary CO_2 emissions (after power plants).

Most of the focus appears to be based on the utilization of naturally occurring magnesium silicates to replace limestone in cement making. The magnesium silicate reacts to MgO by adding CO_2 to make cement that thereby reduces the CO_2 that is generated from current limestone cement kilns. The challenges are many, including traditional building material standards that have been based on chemical composition instead of performance required for the building material application. There are at least five developers of this general type of process. Somewhat related applications are the use of carbon-rich building materials to replace limestone-based cement and coal-based steel. Possibilities are a more carbon-rich asphalt replacing cement for road construction and a carbon fiber or CO-based hard plastic replacing steel.

All building material applications for CO_2 reduction have the challenge of the much larger mass of CO_2 emissions versus the order of magnitude smaller building material markets. In addition, large amounts of naturally occurring oxides of silica, alumina, and iron aggregate added to building materials are used because they are inexpensive and also because they have no impact on CO_2 emissions.

13.2.4.8 CO_2 Capture from the Air

A small group of mostly advanced research physicists have been promoting the idea of CO_2 capture from the air for some time (APS, 2011). If practical, this would be an elegant solution, as it would completely separate the CO_2 capture locations from the CO_2 emission sources and would indirectly solve the CO_2 reduction issue for mobile transportation fuels from mostly oil.

However, practical and economically competitive CO_2 capture from air is a major challenge due to its very low pressure and concentration in air of only about 390 ppmv of CO_2. The ultra-low CO_2 partial pressure in air (at just 0.0004 atmospheric pressure) would likely require strong bases to capture most of that CO_2 from the air as well as a very large adsorber or absorber contactor. This also could mean large energy requirements to regenerate the CO_2 from the strong basic sorbent into a high purity CO_2 stream for compression. Conversely, if a practical CO_2 capture system from the air is possible, it could be much cheaper with better performance if first used at higher pressure and much higher concentration CO_2 sources. CO_2 capture from the air is in the very early stages of development. A recently completed study suggests that direct air capture using chemicals will cost more than \$600/tCO_2 and will therefore not be competitive with capture from higher concentration sources (APS, 2011).

Basic R&D is also being done using biological processes for CO_2 capture from air. This could also be applied to higher concentration and pressure CO_2 sources (like fossil power plants). However, like microalgae for CCS, the annual load factors of CO_2 capture could be very low if it only works during warm, sunny daylight hours. The economics of CCS generally favor processes with high annual load factors due to the high capital costs.

13.2.4.9 Prospects for Advanced Capture Technology and Capture Research

Over the past five years or so, there has been a growing interest by governments, a new community of academic scientists, and industry in developing new materials and separations techniques that could dramatically improve the efficiency and lower the cost of CO_2 capture. While these new approaches are a long way from commercial implementation, in principle, they hold significant promise. Among these new methods are (e.g., US DOE, 2010):

- metal-organic frameworks, a new class of nano-structured hybrid materials with exceptionally high surface area that can improve the efficiency of absorption of traditional and novel organic solvents;
- ionic liquids with higher absorption rates and comparatively smaller energy penalties for regenerating the solvent;
- Si-based solvents requiring much less water for CO_2 capture;
- biologically motivated approaches that utilize nature-inspired catalysts such as carbonic anhydrase to capture and convert gaseous CO_2 to liquid or solid forms;
- membranes coated with CO_2 affinity materials to improve the selectivity and permeance to CO_2;
- hydrogen-conducting membranes for pre-combustion capture;
- catalytic membranes to simultaneously separate CO_2 and carry out the water-gas shift reaction;
- oxygen separation membranes to lower the cost of oxygen production; and
- solid adsorbents such as activated carbon, carbon nanotubes, or other nano-structured solids.

As these new approaches reach maturity, they will need to compete based on cost and performance with existing approaches for CO_2 capture as described above. These existing technologies are, of course, expected to improve as they become more widely deployed. For this reason, it is difficult to anticipate which of the existing and new technologies will emerge as market leaders.

13.2.5 CO_2 Compression

CO_2 compressors are commercially well proven from their use in EOR over the last 30 years. In 2010, 50 MtCO_2 were compressed and transported

through over 4800 km of CO_2 pipelines. Nevertheless, there are some development opportunities in this area. The impact on overall CCS cost and performance improvements, however, is likely much smaller than in the development of better CO_2 capture processes.

Current CO_2 compressors have high capital costs of over US$1000/kW, and the power requirements are significant at 100–150 kWe per t/hr of CO_2 (McCollum and Ogden, 2006). The best and easiest improvement is doing the CO_2 capture at high pressure. An operating pressure of 3–5 atmospheres will begin to significantly reduce CO_2 compression costs.

Development is occurring on an advanced CO_2 compressor via shock wave compression. This might reduce the total installed unit capital cost ($/kWe) by a large amount, as this type of compressor may require only two stages of compression compared to current CO_2 compressors that require 8–12 stages plus more intercoolers. The developer, Ramgen Power Systems, is working with Dresser-Rand on commercialization (see Ramgen, 2011).

As discussed in the oxyfuel CO_2 capture subsection, there is ongoing development for advanced compressors and pipeline standards for handling dirty CO_2. The raw flue gas from oxygen combustion emits mostly CO_2, but also significant amounts of H_2O, N_2, and O_2, as well as lesser amounts of SO_2 and NO_x. H_2O and O_2 may require removal or conversion, respectively. Current CO_2 compressors may unintentionally convert the SO_2 and NO_x into ammonia sulfate and plug the compressor.

13.2.6 CO_2 Capture Costs (See also Chapter 12)

There are numerous reports documenting current and future estimates for the cost of capture for power generation and industrial emission sources (e.g., IPCC, 2005; MIT, 2007; Al-Juaried and Whitmore, 2009; US DOE, 2010). Costs of capture for the n^{th}-of-a-kind plant range from about US$30–100/t$CO_2$ avoided. First-of-a-kind plants are expected to cost significantly more with estimates in the range of US$100–150/t$CO_2$ avoided. Costs of capture for first generation CCS power plants available in the early 2020s are estimated to be about $45/t$CO_2$ avoided for coal and $115/t$CO_2$ avoided for natural gas (ZEP, 2011). Estimates vary widely, in part because they use a variety of different assumptions about baseline technology, capture technology, discount rates, material and labor inflation, regional indices, first-of-a-kind plants versus n^{th}-of-a-kind plants, etc. We do not repeat these here, but provide an overview that describes not only the complexity of these estimates, but the underlying drivers as well. Examples providing costs are provided for a variety of illustrative scenarios. CO_2 capture cost estimating for CCS is extremely challenging for several reasons, including:

- Costs are application specific. Therefore, while it is necessary to analyze the CCS costs for coal-based power plants, the use of natural gas or biomass with CCS for a double CO_2 reduction needs to be considered, as well as other applications especially those for industrial applications with existing large, pure CO_2 vents, regardless of the CO_2 mitigation issue.
- Costs will also be site specific, depending on labor rates, material costs, construction codes, safety codes, local construction constraints, etc.
- Comparison of costs with and without capture needs to also consider baseline costs in a broad context. Fuel type, fuel switching, and future fuel price impacts – especially as a carbon-constrained world develops – will have a significant effect on costs. Coal energy prices are currently low and stable and may even go down slightly as a carbon-constrained world develops and coal use declines. However, natural gas energy prices are significantly higher than coal and are highly volatile with few, if any, long-term fixed price contracts, except for take-or-pay Liquefied Natural Gas (LNG) contracts. Furthermore, natural gas prices will almost certainly go up as a carbon-constrained world develops. Natural gas supplies will be stressed as natural gas begins replacing some of the large coal use applications long before economics warrant serious consideration of coal or natural gas with CCS. Also at high natural gas prices, the cost of NGCC with CCS quickly becomes higher than coal with CCS.
- Costs can be assessed based on a variety of metrics, such as the increase in product cost (i.e., $/MWh for electricity) with CCS versus without CCS or the CO_2 costs of CCS as CO_2 capture costs or CO_2 avoidance costs.
- Existing CO_2 sources considering retrofit CCS have much different costs than those for a proposed new CO_2 source considering CCS. There are also issues that a new CO_2 source with CCS would only minimize CO_2 emissions growth unless it replaces an old existing CO_2 source that is shut down. Also to be considered is the large impact of CO_2 avoidance costs based on the baseline fuel with coal having about twice the baseline CO_2 emissions as natural gas.
- Basic capital cost estimates have changed due to the large run-up in construction costs (materials, labor shortages, and equipment) from 2005–2008, but since then there has been moderate construction cost decline. There is also the issue of site-specific cost factors such as contingencies, capitalization of allocation of funds during construction (common for regulated US electric utilities), and cost of capital or project capital return rates due to mainly the debt/equity ratio, but also due to local taxes, depreciation rates, and the design basis (e.g., extreme weather conditions or earthquake rating). For example, recent all-in capital costs estimates by SaskPower for the commercial-scale oxyfuel and post-combustion capture demonstrations for coal boiler power plants are over CAN$12,000/kW (US$12,453/kW).
- CCS costs are traditionally estimated based on the assumption of proven commercial operating experience, sometimes called the "n^{th}" plant design, which signifies that the cost estimate is not for the 1^{st}, 2^{nd}, or 3^{rd} commercial unit. In other words, there are much lower cost estimates than for the first large-scale demonstration or first commercial plant using a specific CCS technology because it has already progressed down the learning curve.

- Estimating cost for developmental technology without any large-scale operating demonstration plant experience is difficult. In this case, it is common to excessively overestimate performance and underestimate costs.

This section attempts to reduce these complexities to simple economics. More importantly, the economics are presented in a logical and transparent way with an emphasis on the key variables and relative consistency. Learning curves and impact of the state of development are also addressed, as the less developed CCS systems are more likely to have their performance overestimated and costs grossly underestimated.

13.2.6.1 What Does CO_2 Avoidance Cost Mean?

Most economics of CCS are stated in terms of CO_2 avoidance cost. Therefore, it is essential to fully understand what the CO_2 avoidance cost matrix means as well as what the key inputs, sensitivities, and other options are to CCS.

It is also essential to understand the key difference between CO_2 capture and CO_2 avoidance costs, especially with CCS. This is because CCS usually reduces net capacity and efficiency. CO_2 capture cost is calculated based on the CO_2 captured per unit net product. Thus, larger the efficiency losses can erroneously appear to lower CO_2 capture costs. However, CO_2 avoidance is calculated based on the CO_2 reduction or avoidance to the atmosphere per unit net product. Thus, the larger the efficiency losses, the higher the CO_2 avoidance costs, especially when the fuel costs are high. The goal of CCS is reducing CO_2 emissions into the atmosphere; thus, it is almost always best to work with and estimate just CO_2 avoidance costs.

It is typically assumed that CO_2 avoidance cost is the likely minimal CO_2 tax required for a major human-made CO_2 emissions source to start seriously considering CCS. Using a coal-fired power plant as a simple example, the CO_2 avoidance cost is the $/t$CO_2$ emissions tax at which the $/MWh electric "loaded" (capital charges, fuel, and operations and maintenance) price is the same as paying the CO_2 tax or adding CCS to avoid paying most of the CO_2 tax. In reality, the CO_2 tax (or CO_2 avoidance costs) must be even higher to justify the added capital and much higher risks of adding CCS versus simply paying the CO_2 tax.

The formula for CO_2 avoidance cost is relatively simple. As shown below, the formula estimates the product costs (in $/MWh) and CO_2 emissions per unit of product (tCO_2/MWh) for a traditional plant (called "b" for baseline case) and then estimates the higher product costs but with lower CO_2 emissions (called "c" for carbon reduction cases). The lower CO_2 emissions case can simply be a higher efficiency or lower carbon fuel with or without CCS. The CCS added option is the most common comparison option due to the larger potential CO_2 reduction. Nevertheless, conversion without CCS to higher efficiency or lower carbon fuel switching cannot be overlooked or ignored, due to its higher efficiency and much lower capital and avoiding CO_2 storage liability risks.

The formula is as follows:

$$\$/tCO_2 \text{ avoidance cost} = (\$/MWh_c - \$/MWh_b) \div (tCO_2/MWh_b - tCO_2/MWh_c) \quad (1)$$

This simple formula makes it easy to understand the conditions where the CO_2 avoidance cost estimates can be high or low. Low CO_2 avoidance costs occur when small increases in power costs give large CO_2 reductions. High CO_2 avoidance costs occur when there are large increases in power costs and small reductions in CO_2 emissions. The following three simple examples show the fluctuation of CO_2 avoidance costs depending on the baseline and choice of CO_2 reduction option. All three examples are for a coal power plant baseline and assume baseload (high annual load factor) power prices at the plant gate, without added transmission or distribution costs.

- First, consider the CO_2 avoidance cost of an old, dirty, and inefficient, but paid-off coal power plant that is replaced with a new, clean, state-of-the-art coal plant without CCS. The electricity price increase would be about US$40/$MWh_c$, assuming US$80/MWh_c for the new, efficient coal power (with all of the capital charges) up from only US$40/$MWh_b$ for the old paid-off baseline plant (with no capital charges and just operating costs). The CO_2 reduction would be only about 0.2 t/MWh, assuming 1.0 t/MWh_b for the old subcritical coal plant baseline, and reduced to 0.8 t/MWh_c for the new efficiency supercritical plant. Thus, the CO_2 avoidance cost would be very high at US$200/$tCO_2$ based on a US$40/MWh power increase divided by 0.2 t/MWh of CO_2 reduction.

- Second, consider the CO_2 avoidance cost for a proposed new coal power plant contemplating the addition of CCS. The electricity price would increase about US$40/$MWh_c$, assuming US$120/MWh_c for the new coal power with CCS, up from only about US$80/$MWh_b$ for the normal new state-of-the-art coal unit. The CO_2 reduction would be large at about 0.7 t/MWh, assuming 0.8 t/MWh_b for the new state-of-the-art coal plant baseline reduced to only 0.1 t/MWh for the similar new coal unit but now having CCS. Thus, the CO_2 avoidance cost would be US$57/$tCO_2$ based on a US$40/MWh power increase divided by 0.7 t/MWh of CO_2 reduction.

- Third, consider the CO_2 avoidance for replacing the old coal power plant in the first example with the new coal plant with CCS in the second example. The CO_2 avoidance would now be US$89/$tCO_2$ based on a US$80/MWh power increase divided by 0.9 t/MWh of CO_2 reduction.

In general, CO_2 avoidance costs are usually high if the baseline is a paid-off existing facility with low cost fuel or if the CO_2 reduction is relatively low. Conversely, CO_2 avoidance costs are the lowest when the baseline is for a new proposed CO_2 source and the CO_2 reduction are high.

A CO_2 avoidance cost involving natural gas can be more complex due to the large potential variation of prices and the relatively low CO_2 emissions of natural gas. Over the long term, as a carbon-constrained world develops, natural gas prices will likely increase and supplies may be stressed as coal is replaced with natural gas long before it becomes economical to consider CCS.

13.2.7 Triple CCS Point Economics

Due to the above complexity of CCS CO_2 avoidance costs with coal versus a similar scenario with natural gas, it is useful to develop "triple point economics" from a coal baseline that also includes natural gas. This would avoid the suggestion that a CO_2 tax or CO_2 avoidance cost where coal with CCS could become competitive while ignoring the simple use of natural gas without CCS to replace coal. Three simple steps define the CO_2 tax triple point economics where the power price is the same for natural gas without CCS versus coal with or without CCS.[1]

The following examples of triple point economics are estimated for two recent projects. As discussed, the baseline choice of existing versus proposed new CO_2 sources greatly impact the economics of coal-based CCS and natural gas price where it would be less expensive to simply replace coal with natural gas and avoid CCS.

13.2.7.1 Triple Point CCS Economics for an Old Existing Coal Power Plant Baseline

Existing coal-fired power plants represent most of the current large CO_2 point sources that are good prospects for CCS. For example, in the United States there are over 300 GW of existing coal power plants with a MWe-weighted average age of almost 40 years old. Recent estimates for this option have been made assuming US$2.00/MMBtu of coal and all costs in constant $US_{2008}$$ (Simbeck and Roekpooritat, 2009a; 2009b). The lowest CO_2 avoided cost for continued coal use was a simple add-on retrofit post-combustion CCS to the old existing boiler at a CO_2 avoided cost of US$74/$MtCO_2$. This reduced the old existing power plant net capacity by about 27% and dropped the net efficiency (HHV) from 34% to only 25%. A rebuilt new supercritical steam coal plant with CCS would avoid the net capacity loss and decrease most of the net efficiency loss of CCS relative to the old subcritical steam coal power plant without CCS (US DOE, 2010). The new rebuilt coal units with CCS had higher CO_2 avoidance costs, however, due to the significantly higher total capital investment associated with the new power plant.

Existing paid-off power plant baselines generally force higher CO_2 avoidance costs due to the inexpensive baseline power costs. In this case, the existing steam coal power cost was estimated at only US$37/MWh (plant gate). At this relatively high US$74/$tCO_2$ avoided, the triple point electricity price was US$108/MWh. At this price for power generation, by converting to natural gas via repowering with a new NGCC unit without CCS, the same cost per tonne of CO_2 avoided could be obtained at US$8.31/MMBtu for natural gas. Consequently, repowering an aging steam coal power plant with new NGCC without CCS could be an attractive option if the natural gas industry and electric power generators become willing to agree to amenable long-term supply/price contracts.

13.2.7.2 Triple Point CCS Economics for a New Proposed Coal Power Plant Baseline

The more traditional CCS economics are based on proposed new coal and NG power plants. However, this would only minimize CO_2 emissions growth from the new power plant capacity addition unless an equivalent-size old fossil fuel power plant is shut down and replaced by the new power plant with CCS.

This scenario was evaluated in 2009. The lowest CO_2 avoided cost for a new coal power plant with CCS was the pre-combustion option at a CO_2 avoided cost of US$48/$MtCO_2$. However, the post-combustion and oxyfuel combustion CCS option costs and performance were relatively close. In comparison to the new supercritical steam coal plant baseline, the addition of CCS reduced the power plant net capacity by about 20% and dropped its net efficiency (HHV) from 39% to 32%.

As previously explained, setting a proposed new fossil power plant as the baseline reduces the CO_2 avoidance costs, as the new power plant baseline will have relative power costs even before the additional cost of CCS. At a moderate US$48/$tCO_2$ tax, the triple point electricity price would be US$113/MWh for the new coal unit with or without CCS or, if converting to a new NGCC without CCS, it would be US$11.15/MMBtu for natural gas.

Both the new and old coal power plant baseline estimates required about the same US$110/MWh power price for CCS. However, the electric costs increased by about 300% for the CCS addition to the old paid-off power plants, whereas the electric costs only increased by about 50% for CCS added to a new proposed power plant. The CO_2 avoidance cost and natural gas alternative prices (without CCS at the given CO_2 tax) were also much different for the two coal power plant baselines. Existing coal power plants would find it cheaper and a much lower risk to simply pay the CO_2 tax than to significantly reduce CO_2 emissions until the CO_2 tax is very high. Another option is to mandate

1 Start with estimating CO_2 avoidance costs for a coal plant baseline without CCS versus adding CCS. This is the most logical baseline due to the high CO_2 emissions per unit of coal energy, which is the dominant use in large central power plants having large point sources and a likely stable coal price even as a carbon-constrained world develops. The only major issue would be if the baseline is an existing PC power plant or a new state-of-the-art PC power plant. The CCS case can be retrofitted, rebuilt, or a new plant, and can include any or all of the CCS process options (pre-, post-, or oxyfuel combustion). Next, enter the CO_2 avoidance cost estimated in Step 1 for the same coal baseline estimate and CCS option with the lowest cost. The power cost should now be the same for the coal baseline without CCS (paying the CO_2 tax) and the best coal CCS option (avoiding most of the CO_2 tax). Finally, the third key alternative of natural gas without CCS is simply replacing coal. The natural gas replacement option is estimated by varying the natural gas price until this option (without CCS) has the same electricity price as the Step 2 coal cases (with and without CCS).

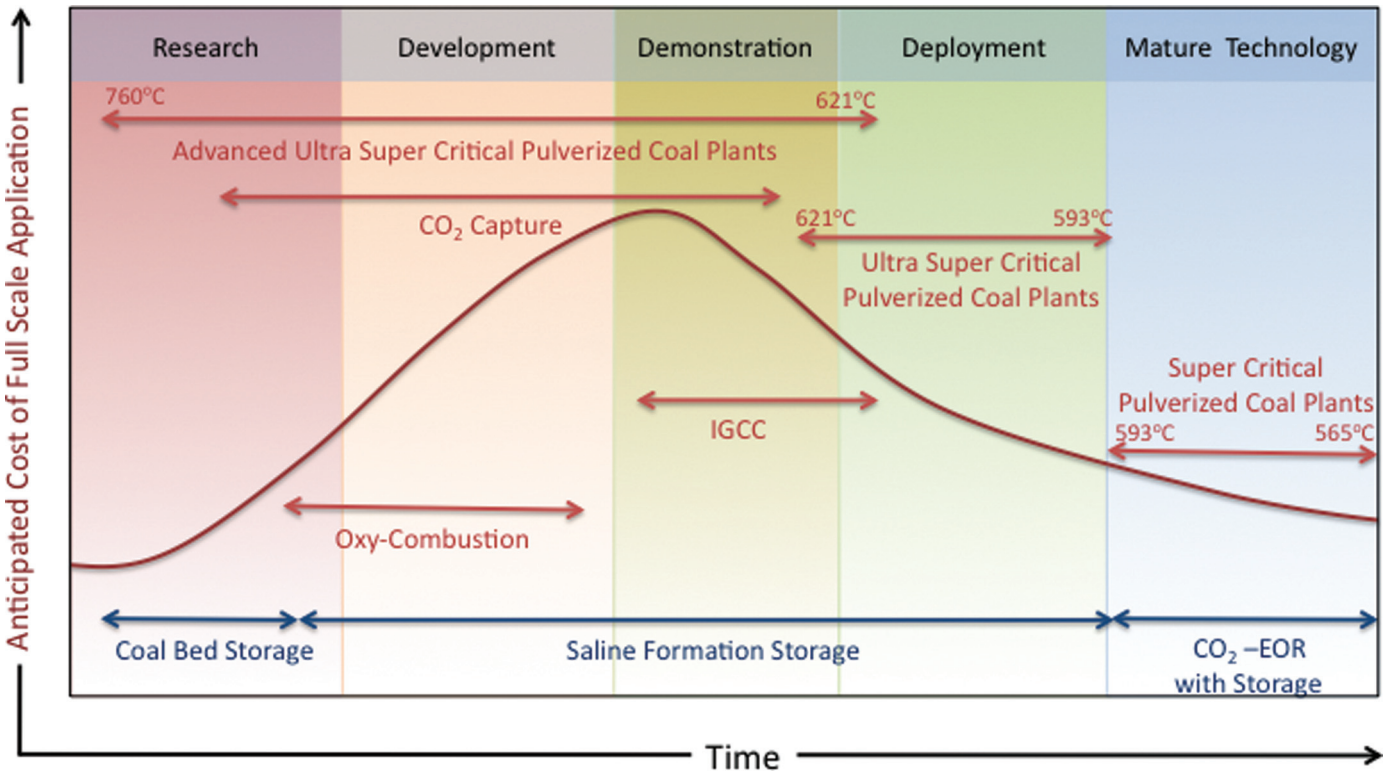

Figure 13.4 | Utility and petroleum industry perspective on CCS and advanced power generation technology for coal. Source: modified from Booras, 2009.

that old coal power plants shut down after 45 years of service, as is currently being proposed in Canada. In the meantime, ongoing talk about CO_2 mitigation encourages the life extension of existing old coal power plants with high emissions. However, life-extending old coal units maximize CO_2 emissions before potential CO_2 reduction mandates take place and increase the quantity of inexpensive CO_2 cap and trade allocations that existing coal unit owners will likely receive. This also keeps electric power prices relatively low in nations such as the United States, which have large fleets of aging coal power plants.

13.2.7.3 CCS Cost Estimating Learning Curves

There are very real learning curves associated with the increasing use of specific technologies in industries where the unit costs go down as the total installed capacity increases. This is sometimes referred to as "learning by doing." In the electric generation industry, these cost improvement "learning curves" are well documented for the growth in the use of flue gas desulfurization (FGD) SO_2 controls and selective catalytic reduction (SCR) NO_x controls (Yeh and Rubin, 2007). However, this is not always the case, as exemplified by the large cost increases for nuclear power plants (Grubler, 2010).

Learning curves are sometimes applied to CCS technologies. Only time will tell the accuracy of the estimates. Nevertheless, it is essential to realize that learning curves almost always start to reduce unit costs after the respective technology is established in commercial service and the total commercial capacity is growing at a high rate with time. From pilot to demonstration to the first commercial unit, the unit costs almost always increase before decreasing via the learning curve. This is illustrated in Figure 13.4, which shows cost versus stated development for coal technologies and CCS options (Booras, 2009). In the early stages of development, advanced technologies often overestimate performance and underestimate costs. The less developed the CCS technology, the more uncertain the estimates.

All CO_2 mitigation options performance and cost estimates are highly questionable until successfully demonstrated in large commercial-scale operations. The time and cost to progress from research to development is long and expensive for advanced energy and environmental technologies. It is even longer and more expensive for the electric power industry. This is because highly regulated industries do not reward risks, and traditional electric power generation, especially for CCS, is more economical in very large and expensive power plants. Innovative policies and incentives will be required to change this.

13.2.8 Air Pollution from Power Plants with CCS

Contrary to CO_2, where emission levels are mainly dependent on the fuel type, non-CO_2 emissions are mainly influenced by parameters related to specific conditions such as fuel composition, type of technology, combustion, operating and maintenance conditions, size and age,

Table 13.1 | Average minimum and maximum emission factors for energy conversion concepts with and without CO_2 capture as reported in the literature. The ranges, in brackets, report the minimum and maximum values found in 171 studies.

Capture Technology	Conversion Technology	CO_2 g/kWh	NO_x	SO_2	NH3	VOC	PM
			mg/kWh

and emission control policy (EMEP, 2009). Table 13.1 shows an overview of emission factors reported in the literature for power plants with and without CO_2 capture. General trends can be summarized as follows.

13.2.8.1 Sulfur Dioxide – SO_2

SO_2 emissions are expected to be very low for power plants with CO_2 capture. This will mainly be due to plants using fossil fuels with very low sulfur content (e.g., NGCC or GCs), a limitation in SO_2 content in the flue gas to avoid solvent degradation (post-combustion with amine-based solvents), or to a high level of recovery of sulfur compounds from the syngas in IGCC plants.

13.2.8.2 Nitrogen Oxides – NO_x

In post-combustion capture concepts, NO_2 needs to be removed since it can react with amine-based solvents and cause degradation. NO_2 accounts, however, for only ~10% of the NO_x, making the net impact of its removal limited. A major factor will be the increased use of fuel due to the efficiency penalty. Such an increase may result in higher levels of NO_x (/kWh) for the whole power sector (Tzimas et al., 2007; Koornneef et al., 2010). Studies in the literature of pre-combustion concepts report both lower and higher NO_x values, compared to similar plants without CO_2 capture (e.g., IEA GHG, 2006; Davison, 2007; US DOE/NETL, 2007a). The levels of NO_x reported are dependent on the performance of the gas turbines and the efficiency penalties. NO_x emissions in oxyfuel concepts are expected to be very low, due to a reduction of fuel NO_x and inhibition of thermal NO_x (Croiset and Thambimuthu, 2001; Tan et al., 2006) and removal of NO_x during CO_2 purification (White et al., 2008).

13.2.8.3 Ammonia – NH_3

Changes in NH_3 levels are only relevant for post-combustion capture. Formation of NH_3 is the result of reactions between flue gases and monoethanolamine (MEA)-based solvents as a consequence of oxidation or elevated temperatures.

13.2.8.4 Particulate Matter – PM

The emission of particulate matter from natural gas-fired cycles in general can be considered negligible. In the case of coal-fired plants, significant reductions are expected for the post-combustion capture process

since low levels of PM are necessary to assure a stable capture process. However, in terms of emissions/kWh, there may be an overall increase in PM emissions as a result of increased use of fossil fuel due to the efficiency penalty. PM in IGCC plant cycles without CO_2 capture is already low due to high removal efficiencies in the gas cleaning section. Preliminary estimates indicate that the application of pre-combustion capture may lower further PM emissions (US DOE/NETL, 2007a). Also, for coal-fired oxyfuel concepts, PM emissions are estimated in the literature to be lower per kWh, compared to conventional pulverized coal-fired power plants.

13.2.8.5 Volatile Organic Carbon – NMVOC

Quantitative estimates for the impact of CO_2 capture on the level of NMVOC emissions are absent in the (open) literature. It is therefore not possible to indicate whether and to what extent CO_2 capture technology will affect the net level of these emissions.

13.2.9 Water Consumption

Water consumption will increase as a consequence of additional fuel use to make up for the energy penalty and the demand of the CO_2 capture system itself. For instance, coal-fired power plants with post-combustion capture (MEA-based) have large cooling water make up requirements, while increased water demand in IGCCs with pre-combustion capture is mainly driven by the increased cooling load required to further cool the syngas and steam for the water gas shift reactor and the increase auxiliary load (US DOE/NETL, 2009a). The impact on water use appears larger for PCs and NGCCs than for IGCCs and oxyfuel. Ranges reported in the literature indicate relative increases in water use, compared to similar plants without capture, between 50–95% for PC with post-combustion capture, 30–50% for IGCC with pre-combustion capture, and 30–35% for oxyfuel with CO_2 removal (US DOE/NETL, 2007a; US DOE/NETL, 2007b; RECCS, 2008). Water use could be reduced by using dry cooling instead of wet cooling, even to levels below those of wet cooled plants without CCS. However, operating power for a given heat load in a dry cool-based system can be four to six times larger than that for an optimized wet system (Maulbetsch, 2002) and this could result in an increase in the energy penalty in the power plant.

13.2.9.1 Waste and By-products from CCS

As a consequence of increased fuel consumption, it is expected that waste streams such as bottom ash, fly ash, boiler slag, and reclaimer waste will increase with the implementation of CO_2 capture. Relative increases reported in the literature for power plants are between 20–40% (bottom ash/fly ash); 18–29% (slag); 18–25% (sulfur); and 31–47% (gypsum) (US DOE/NETL, 2007a; Davison, 2007; Rubin et al., 2007). Depending on market conditions, gypsum (from PC plants) and sulfur (from IGCC plants) may be considered sub-products instead of waste.

Reclaimer waste generated in post-combustion capture processes may become a point of concern. This waste, containing heat stable salts, heavy metal corrosion inhibitors, and absorption solvents among others, is considered hazardous. Amounts of reclaimer waste for post-combustion with amine-based solvents are reported in the range of 1.6–4.5 g/kWh (Rubin et al., 2007; Koornneff et al., 2008; Schreiber et al., 2009; Korre et al., 2010). This amount could be even higher, depending on the rate of solvent slip stream. Thitakamol et al. (2007) have indicated that an increase of 0.5–2% in the slip stream could result in a factor four increase in the amount of reclaimer waste.

13.2.10 Capture Conclusions

To make a large contribution to CO_2 emissions reductions, capture technologies are needed both for new sources and existing sources. The same technology is unlikely to be optimal for both situations. Four approaches are available for capture from the power and industrial sources. Three of them – the so-called post-combustion capture, pre-combustion capture, and oxy-combustion capture approaches – produce CO_2 gas with a relatively small concentration of contaminants. This needs to be compressed for transport to a storage location. All have been separately demonstrated; some are used routinely today for other applications, but little experience is available for integration and optimization with power production or most industrial applications. The fourth approach, mineralization, produces solids whose composition depends on the specific process. Mineralization is much less mature than the other capture technologies. Mineralization of CO_2 is an attractive option because the end product is a carbonate rock, thus avoiding the need to store large amounts of CO_2. However, mineralization requires large volumes of rocks to provide a source of magnesium (or other cations) and is more expensive and energy intensive than other options. If a use for these minerals is not found, they will become a waste that must be managed.

Today's capture and compression technology has a parasitic energy requirement of 15–30% of the electricity generated from combustion sources. This increases the cost of capture, the use of valuable energy resources, and the upstream impacts of energy supply. Progress is being made on reducing electricity requirements for capture and compression, but more progress is needed to make CCS less energy intensive.

Impacts of CO_2 capture on other air pollutants are highly dependent in the capture approach used. SO_2 emissions are expected to be very low for power plants with CO_2 capture. In the post-combustion concepts, NO_x emissions are believed to be largely unaffected by the capture process while for oxyfuel capture these emissions are expected to be very low. For pre-combustion, consensus on the possible effects seems to be absent. Only post-combustion capture NH_3 emissions are estimated to significantly increase (with more than a factor of 20 for conventional amine solvents). This aspect will have to be addressed by the facilities and, while technology already exists which could abate these emissions, it will have an impact on the investment costs. PM emissions are

expected to increase per kWh as a result of the efficiency penalty. There is little experience in the power generation sector with operating capture facilities. Capture facilities are large chemical processing plants. Operating these facilities requires different expertise than operating steam boilers and turbine generators. Building the expertise and experience to integrate power production and CCS to provide electricity with the high reliability expected today will require significant capacity building in the power generation sector.

The capture of CO_2 directly from air has also been proposed. Air capture is appealing for a number of reasons, namely: capture facilities could be co-located with ideal storage locations; emissions from nonpoint sources could be captured; and emissions from noncompliant parties could be offset. However, the low concentration of CO_2 in the air makes capture with today's technology expensive and energy intensive. The high cost of direct air capture compared to capture from concentrated point sources makes it unlikely that air capture will play a role in CO_2 emission reduction until far into the future.

The cost of capture is challenging to determine, but is estimated to range from US$50 to over US$150/tCO_2 avoided, depending on the type of fuel, capture technology, assumptions about the baseline technology, and whether it is the first plant or the n^{th} of a kind. Costs of capture for first generation CCS power plants available in the early 2020s are estimated to be about $45/t$CO_2$ avoided for coal and $115/t$CO_2$ avoided for natural gas. The combined cost of capture and compression would increase the cost of power production by about 50% to over 100%. The costs of early demonstration projects are likely to be significantly higher. Worldwide, large investments in improving capture technologies are being made by governments and the private sector. It remains to be seen whether these investments are sufficiently large to quickly reduce costs and energy requirements for capture and compression, particularly those investments in fundamental research, which could produce technological breakthroughs with dramatic improvements.

13.3 Carbon Dioxide Transport

13.3.1 Introduction

One common requirement for all CCS schemes is the need to transport CO_2 from the capture to storage sites. CO_2 can be transported by land via pipelines, motor carriers, or railway, or by water via ships or barges. Each of the individual possibilities can be considered mature, but their integration at large-scale will be complex; in fact, the scale and the speed at which transport networks will be needed are regarded as the main challenges for CO_2 transport (IPCC, 2005; IEA, 2008a).

Experiences in CO_2 transport by truck or ship are mainly found in the food and brewery industry. CO_2 is generally transported as a compressed liquid (e.g., -50°C, 0.7–0.8 MPa). The transport of CO_2 by ship or train will require the development of loading and unloading infrastructures and temporary CO_2 storage in steel tanks or rock caverns, which make the options costly. R&D is being carried out to increase the cost-effectiveness of the option, for instance by using integrated tug barges instead of ships. Although this concept has not been demonstrated, it could theoretically eliminate the need for intermediate storage, reducing cost and logistic complexity (Haugen et al., 2009). Though transport of CO_2 via ships or trains is not regarded as the preferred option for large-scale systems (e.g., IPCC 2005; MIT, 2009), it may prove to be cost effective during a transition phase (when pipeline networks are not yet available) and on a case-specific basis (specific combinations of pipeline, ships, and/or trucks).

CO_2 transport by pipeline is currently considered the most mature transport option. There are currently some 5800 km of CO_2 pipelines in operation in the United States (Parfomak and Folger, 2008). These pipelines transport CO_2 in the liquid or dense phase (CO_2 pressure above 7.38 MPa), are land-based and sectioned (typically less than 30 km), are generally made out of carbon steel, transport relatively clean CO_2, do not use internal coating, and mainly transport CO_2 for EOR purposes (Oosterkamp, 2008). The IEA estimates that about 150,000 km of dedicated CO_2 pipelines will be needed in the European Union. In the United States, up to 37,000 km of CO_2 pipelines will be needed between 2010 and 2050 (Dooley et al., 2009). Given its importance, the focus of this section is on pipeline transport.

Gas compression is well developed around the globe and uses mature technologies, as described in Section 13.2.4. CO_2 needs to be compressed generally from atmospheric pressure, at which point it exist as a gas, up to a pressure suitable for pipeline pressure in either the liquid or "dense" phase regions, depending on the temperature. In the gas phase, a compressor is required, while in the liquid/dense phase, a pump can be used to boost the pressure. It is generally assumed that the cut-off pressure for switching from compressor to pump is 7.38 MPa (McCollum and Ogden, 2006). At this pressure and at temperatures lower than 20°C, CO_2 would have a density of between 800–1200 kg/m^3. At these conditions, larger mass per unit volume can be transported, since CO_2 would behave as a liquid and have liquid-like density while having the compressibility and viscosity of CO_2 in the gas phase. As an example, a 30-inch pipeline could transport about 5 MtCO_2/yr in gas phase. In the liquid or dense phase, the same pipeline could transport about 20 Mt/yr.

13.3.2 Transportation Operational Issues

13.3.2.1 Pressure Drop

As CO_2 flows through a pipeline, there is frictional loss. For single phase flow, the pressure drop (ΔP) depends on the pipe's inner diameter, CO_2 flow velocity, viscosity, and density, and the pipe's roughness factor. At constant temperature, pressure drop in a typical 20-inch pipeline transporting CO_2 in dense phase is about 30 kPa/km (Essandoh-Yeddu and

Gulen, 2008). In order to maintain the inlet pressure to the pipeline, it is necessary either to increase the pipeline inlet pressure to levels that secure that after losses CO_2 would still have at least 7.38 MPa or to install boosters every 100–200 km to make up the pressure losses.

13.3.2.2 Corrosion

CO_2 and components such as SO_2, NO, and H_2S may form acid compounds in the presence of water that are highly corrosive. Furthermore, H_2S could react with carbon steel to form thin films of iron sulphide (FeS). FeS may dislodge at times and coat the inside surface, decreasing heat transfer efficiency and potentially causing operational problems in the compression units. Control of water content by dehydration is therefore essential for safe and cost-effective pipeline operation. Other possibilities to minimize corrosion are material selection (e.g., stainless steel instead of carbon steel), use of corrosion inhibitors, use of protective coating, and cathodic protection. These possibilities will increase pipeline costs.

13.3.2.3 Hydrate Formation

In the presence of water, CO_2 and H_2S may form hydrate compounds, which can block the line and plug and damage equipment. Hydrate formation can largely be stopped by drying the CO_2 and removing the "free water" that is present. Maximum allowable water content recommended in the literature is in the range of 50–500 ppm (Visser et al., 2007).

13.3.2.4 Operating Temperatures

CO_2 pipelines' operating temperatures are generally dictated by the temperature of the surrounding soil or water. In northern latitudes, the soil temperature could reach below zero in winter and to 6–8°C in summer, while in tropical locations, soil temperatures of 20°C are common. At the discharge of compression stations, after-cooling of compressed CO_2 may be required to ensure that the temperature of CO_2 does not exceed the allowable limits for either the pipeline coating or the flange temperature (McCoy, 2008). CO_2 cools dramatically during decompression, so pressure and temperature must be controlled during routine maintenance (Gale and Davison, 2003).

13.3.2.5 Impurities

Depending on the source of the flue gas and the type of CO_2 capture process, CO_2 streams may contain trace concentrations such as H_2S, SO_2, NO_x, O_2, CO, HF, Hg, N_2, and Ar. These impurities might have an impact on (Visser et al., 2007; McCoy, 2008; Oosterkamp, 2008):

- *the physical state of the CO_2 stream*, affecting the operation of the compressors, pipelines and storage fields;
- *CO_2 compressibility*, which is non-linear in the range of pressures common for pipeline transport and is highly sensitive to any impurities such as H_2S or CH_4. Changes in compressibility may result in the reduction of the CO_2 volume that can be transported;
- *CO_2 density*, since impurities such as N_2, O_2, H_2, Ar, and CH_4 reduce the density of the flow, which in turn reduces the CO_2 volume that can be transported;
- *pipeline integrity*, for instance, by producing hydrogen of sulphide-induced stress cracking;
- *safe exposure limits* required for the pipeline; and
- *minimum miscibility pressure* of the CO_2 in oil, which could affect the possibilities to use CO_2 for EOR.

13.3.3 Cost of Transportation

CO_2 transport costs are a function of pipeline length, diameter, material, route of the pipeline, and safety requirements, among other things. Figure 13.5 shows relations between capital costs, levelized cost, and CO_2 flows outlined in the literature.

The transport of CO_2 by pipeline benefits from economies of scale: i.e., average costs decrease as scale increases. The amount of fluid that can flow through a pipeline increases non-linearly with diameter, so larger diameters are preferred to smaller ones. Pressure drop, ΔP, is inversely related to the diameter. Lower pressure drops translate to lower costs, since costs to compress or pressurize a fluid are linearly related to ΔP. Finally, the marginal cost of constructing a pipeline decreases with diameter (Bielicki, 2008; MIT, 2009). Economies of scale regarding the transport of large amounts of CO_2 by pipeline indicate that it may be more efficient to encourage hub-and-spoke transport systems than point-to-point systems. Returns to scale are, however, not constant; i.e., they do not continually increase as the system expands (Figure 13.5b). The point at which economies of scale are reached is case dependent. Some studies found that economies of scale are reached with annual CO_2 flow rates in excess of 60 Mt/yr (e.g., van den Broek et al., 2010), while other studies report lower values, e.g., 10 Mt/yr (Heddle et al., 2003). The increase in costs with scale is partly due to the increase in material costs. McCoy (2008) reports that doubling pipeline diameter would result in a three-fold material costs increase. This is a concern for most investors, due to the high price fluctuations of steel in recent years (Parformak and Folger, 2008). For example, in late 2001, steel prices were about US$600/t. By late 2007, it was US$1400/t. Studies in the literature have also shown a high variability in pipeline costs depending on the length assumed (e.g., McCollum and Ogden, 2006; Perfomak and Folger 2008). In this regard, CO_2 pipeline costs may present the costs component in integrated CCS schemes with the greatest potential variability (IPCC 2005; MIT, 2007).

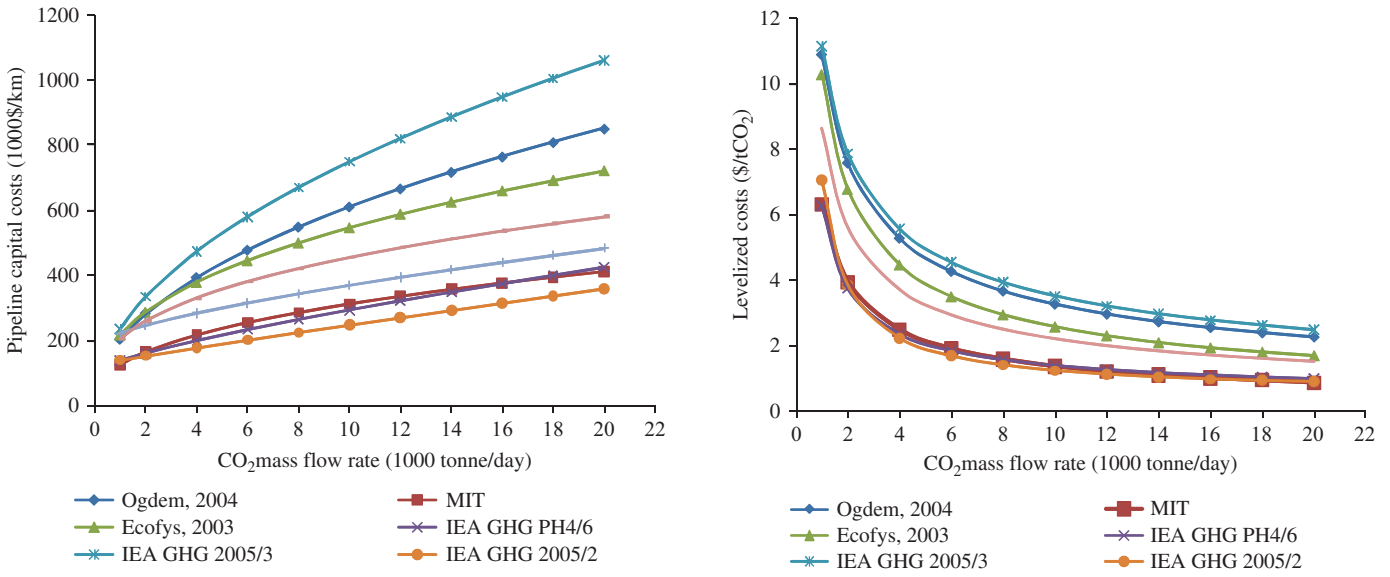

Figure 13.5 | Comparison of pipeline costs (a) and levelized costs (b) for a pipeline with a length of 100 km. Costs are reported in $US_{2005}$$. Source: McCollum and Ogden, 2006.

13.3.4 Transportation Safety

Several studies indicate that CO_2 transport by pipeline does not pose a higher risk than is already tolerated for transporting hydrocarbons (e.g., Heinrich et al., 2004; Hooper et al., 2005; Damen et al., 2006). For instance, cumulative failure rates reported in the literature for CO_2 pipelines range from 0.7–6.1 per 10,000 km/yr, which is in the same range of failure rates reported for hydrocarbon pipelines (Koornneef et al., 2009). Currently there are no minimum standards for pipeline quality CO_2 for CCS purpose. Such standards could depart from those already used in existing CO_2 pipelines. However, since most of those pipelines (e.g., EOR in the United States) predominantly run through sparsely populated areas, the impact of a potential incident is limited. Existing standards and risk assessment models will have to be modified to take into account the vicinity to densely populated areas. Additional measures can include (Skovholt, 1993; Koornneef et al., 2009):

- appropriate monitoring facilities and safety systems, e.g., sectioning valves to reduce the quantity of CO_2 that could leak out and shorter distances between valves near populated areas;
- safety zones on both sides of the pipeline. Ranges recommended in the literature vary between less than 1 m and 7 km;
- increased pipe wall thickness near populated areas; and
- protection from damage (e.g., burying the line).

13.3.5 Conclusions

From a technical point of view, transport of CO_2 by pipeline and ship has successfully been conducted for many years, indicating that issues associated with the design and operation of CO_2 transport can be addressed. Nevertheless, the transport of CO_2 for geological storage also has challenges that need to be addressed. Factors of concern for the appropriate and safe management of CO_2 pipelines include water content, hydrate formation, corrosion, two-phase flow, and toxic components. Benefits of scale indicate the development of pipeline networks as an optimal strategy for the medium and long term. The challenge remains with the scale and speed at which transport networks will need to be constructed, often through densely populated areas. Further development and validation of models that deal with the operation of CO_2 pipeline networks and the management of external safety is therefore necessary.

13.4 Carbon Dioxide Storage Science and Technology

13.4.1 Introduction

Carbon dioxide storage in deep geological formations has emerged over the past 15 years as a feasible component in the portfolio of options for reducing GHG emissions. Five commercial projects now operating provide valuable experience for assessing the efficacy of carbon storage. These projects, in addition to more than 100 CO_2-EOR located primarily in North America, provide a growing experience base for assessing the potential for geological storage. However, if CCS is implemented on the scale needed for large reductions in CO_2 emissions, one Gt or more of CO_2 will be sequestered annually – a 250-fold increase over the amount sequestered annually today. Effectively sequestering these large volumes requires building a strong scientific foundation for predicting the coupled hydrological-geochemical-geomechanical processes that govern the long-term fate of CO_2 in the subsurface. In addition, methods to

characterize and select storage sites, subsurface engineering to optimize performance and cost, safe operations, monitoring technology, remediation methods, regulatory oversight, and country-specific institutional approaches for managing long-term liability will all be needed.

13.4.1.1 Options for the Storage of CO_2

Geological formations are not the only option considered for CO_2 storage. Beginning in the early 1990s, there was a great deal of interest in storing CO_2 in the ocean. Two different approaches were pursued: biological sequestration via ocean fertilization and direct injection of a concentrated stream of CO_2.

Scientific experiments have been conducted to evaluate whether adding iron to the ocean could increase biological productivity, thus increasing the rate of ocean uptake CO_2. In 2001, the Southern Ocean Iron Experiment was conducted in the southern Pacific (Buesseler et al., 2004). Results from this and similar experiments showed rapid increases in biological productivity, but many questions remain regarding long-term ecosystem impacts and the effectiveness of this technique for lowering atmospheric CO_2 concentrations. Consequently, at the present time, ocean fertilization is not under serious consideration for large-scale CCS.

CO_2 can also be injected into the mid-depth ocean (1000–3000 m deep), which enables storage for hundreds to thousands of years before returning to the atmosphere via ocean circulation. The injected CO_2 would dissolve and be transported with ocean currents. Alternatively, it could be injected near the ocean bottom, to create stationary "pools" of CO_2. The potential capacity for ocean storage is large – on the order of a trillion tonnes of CO_2 (IPCC, 2005). Little ocean storage research is still being actively pursued. Concerns about unknown biological impacts, high costs, impermanence of ocean storage, and concerns regarding public acceptance have decreased interest and investment in this technology over the past five years.

Hybrid storage schemes that rely on a combination of ocean storage and geological storage have also been proposed recently (Schrag, 2009). For a sufficiently cold ocean, at water depths of greater than 3000 m CO_2 transitions from being lighter than water to heavier than water. Under these conditions, CO_2 would remain on the ocean bottom; however, over time the CO_2 would dissolve into the ocean water, leading to ocean acidification and gradual release back into the atmosphere. To prevent dissolution of CO_2, it is proposed to inject the CO_2 under a thin layer of ocean bottom sediments, thus combining aspects of geological and ocean storage. This relatively new idea is the subject of research and is much less well developed than conventional geological storage.

It has also been suggested that CO_2 storage could be combined with subsea production of methane hydrates (Ohgaki et al., 1996). As methane is being released from the hydrate structure, CO_2 could replace it. In principle not only would this provide a secure storage option, but it would increase hydrate production as well. This idea is in the early stages of conceptual development.

Due to its comparative maturity, geological storage will be the focus of the remainder of this section.

13.4.2 Geological Storage in Deep Underground Formations

13.4.2.1 Technology Description

Under a thin veneer of soils or sediments, the earth's crust is made up primarily of three types of rocks: igneous rocks, formed by cooling magma from either volcanic eruptions or magmatic intrusions far beneath the land surface; sedimentary rocks, formed as thick accumulations of sand, clay, salts, and carbonates over millions of years; and metamorphic rocks of either origin that have undergone deep burial with accompanying pressure and thermal alteration.

To date, sedimentary rocks, located in so-called sedimentary basins, have been the primary focus for geological storage of CO_2 because the storage on geological timescales has already been proven through the presence of oil and gas accumulations in them. Sedimentary basins underlie much of the continents and are co-located with many major large CO_2 emission sources (see Figure 13.6). Until recently, storage in sedimentary basins has been the exclusive focus of geological storage technology and capacity assessments. However, in the past five years there has been a significant effort to understand the potential of volcanic rocks, primarily basalt, for the storage of CO_2 (McGrail et al., 2006; Kumar et al., 2007). Experiments testing the feasibility of storage in basalt are underway in Iceland, India, and two locations in the United States. Motivation for evaluating storage in basalt is two-fold: first, some countries with large CO_2 emissions, such as India, Brazil, and the United States, are underlain primarily by basaltic rocks, and second, it is hypothesized that a large fraction of the stored CO_2 would be converted to stable minerals, assuring permanent storage.

Sedimentary basins often contain many thousand meters of sediments where the tiny pore spaces (10^{-3}–10^{2} μm) in the rocks are filled with saltwater (saline aquifers) and where oil and gas reservoirs are found. An example of a cross section through a sedimentary basin is shown in Figure 13.7. Sedimentary basins consist of many layers of sand, silt, clay, carbonate, and evaporite (rock formations composed of salt deposited from evaporating water). The sand layers provide storage space for oil, water, and natural gas. The silt, clay, and evaporite layers provide the seal that can trap these fluids underground for millions of years and longer. Geologic storage of CO_2 would take place deep in sedimentary basins trapped below silt and clay layers, much in the same way that oil and natural gas are trapped today (Holloway, 1996; Gunter et al., 2004). Within sedimentary basins, possible storage formations include oil reservoirs, gas reservoirs, saline aquifers, and even coalbeds (see Figure 13.8).

Figure 13.6 | Geographical relationship between CO_2 emission sources and prospective geological storage sites. The dots indicate CO_2 emission sources of 0.1–50 $MtCO_2$/yr. Prospectivity is a qualitative assessment of the likelihood that a suitable storage location is present in a given area based on the available information. This figure should be taken as a guide only, because it is based on partial data, the quality of which may vary from region to region, and which may change over time and with new information. Source: IPCC, 2005.

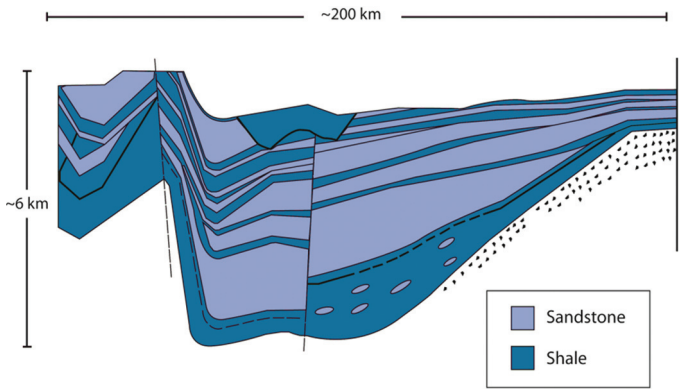

Figure 13.7 | Cross-section of the San Joaquin Valley, California, showing alternating layers of sand and shale. Sand layers provide storage reservoirs; shale layers provide seals.

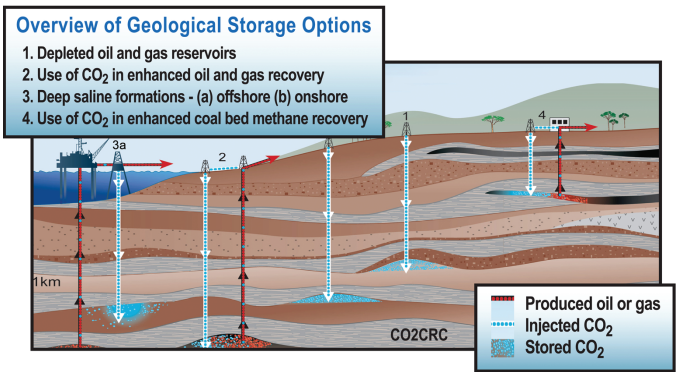

Figure 13.8 | Options for geological storage within a sedimentary basin, including oil and gas formations, saline aquifers, and coalbeds. Source: modified from IPCC, 2005.

The presence of an overlying, thick, and continuous layer of shale, silt, clay, or evaporite is the single most important feature of a geologic formation that is suitable for geological storage of CO_2. These fine-textured rocks physically prevent the upward migration of CO_2 by a combination of viscous and capillary forces. Oil and gas reservoirs are found under such fine-textured rocks and the mere presence of the oil and gas demonstrates the presence of a suitable reservoir seal. In saline aquifers, where the pore space is initially filled with water, after the CO_2 has been underground for hundreds to thousands of years, chemical reactions will dissolve some or all of the CO_2 in the saltwater and eventually some fraction of the CO_2 will be converted to carbonate minerals, thus becoming a part of the rock itself (Gunter et al., 2004). These so-called secondary trapping mechanisms that continue to increase storage security as time goes on have been the subject of significant scientific research over the past five years, with hundreds of relevant publications (Benson and Cole, 2008).

Capillary trapping, sometimes referred to as residual gas trapping, occurs primarily after injection stops and water begins to imbibe into the CO_2 plume. The mechanism immobilizes CO_2, slowing migration towards the surface as the trailing edge of the plume is immobilized. This mechanism is particularly important for storage in dipping formations that do not have structural closure. Studies by Ide et al. (2007) and Hesse et al. (2008) suggest that eventually all the CO_2 in a plume can be

immobilized by this mechanism and develop analytical approaches for predicting how quickly this happens and how far the leading edge of the plume moves before it is immobilized.

The dissolution of CO_2 (and other flue gas contaminants) in saline aquifers can lead to the mechanism known as "solubility trapping." The solubility depends on several factors, most notably pressure, temperature, and salinity of the brine (see e.g., Spycher et al., 2003; Lagneau et al., 2005; Oldenburg, 2005; Koschel et al., 2006). For typical storage conditions, the solubility of CO_2 in brine ranges from about 2–5% by mass. Bench-scale experiments have shown that the dissolution of CO_2 is rapid at high pressure when the water and CO_2 share the same pore space (Czernichowski-Lauriol et al., 1996). However, in a real injection system, dissolution of CO_2 may be limited due to the variability of the contact area between the CO_2 and the fluid phase. The principal benefit of solubility trapping is that once the CO_2 is dissolved, it decreases the amount of CO_2 subject to the buoyant forces that drive it upwards. The amount of solubility trapping is expected to increase over periods of hundreds to thousands of years because the density of CO_2-saturated brine is several percentage points higher than the *in situ* brine, leading to convectively enhanced mixing and dissolution.

The third type of secondary trapping is known as "mineral trapping," which occurs when acidic brines enriched in dissolved CO_2 react directly or indirectly with minerals in the geologic formation, leading to the precipitation of stable secondary carbonate minerals (Gunter et al., 2004). This mechanism is potentially attractive because it could immobilize CO_2 permanently. However, a significant degree of mineral trapping could take thousands of years due to sluggish rates of silicate mineral dissolution and carbonate mineral precipitation, so the overall impact may not be realized until far into the future. Moreover, the amount of mineral trapping depends heavily on the mineralogical makeup of the storage reservoir rock. Rocks with large fractions of feldspar minerals are expected to have a significant amount of mineral trapping, while quartz-dominated reservoirs may have little to no mineral trapping.

Schematics illustrating the relative contribution of each of these mechanisms and the consequent increase in storage security over time are shown in Figures 13.9 and 13.10. The range of trapping contributions from each of these processes is highly site specific.

One of the key questions for geologic storage is: how long will the CO_2 remain trapped underground? There are a number of lines of evidence that suggest that for well-selected and -managed storage formations, retention rates will be very high and more than sufficient for the purpose of avoiding CO_2 emissions into the atmosphere (IPCC, 2005). Specifically:

- Natural oil, gas, and CO_2 reservoirs demonstrate that buoyant fluids such as CO_2 can be trapped underground for millions of years.
- Industrial analogues such as natural gas storage, CO_2-EOR, acid gas injection, and liquid-waste-disposal operations have developed methods for injecting and storing fluids without compromising the integrity of the caprock or the storage formation.

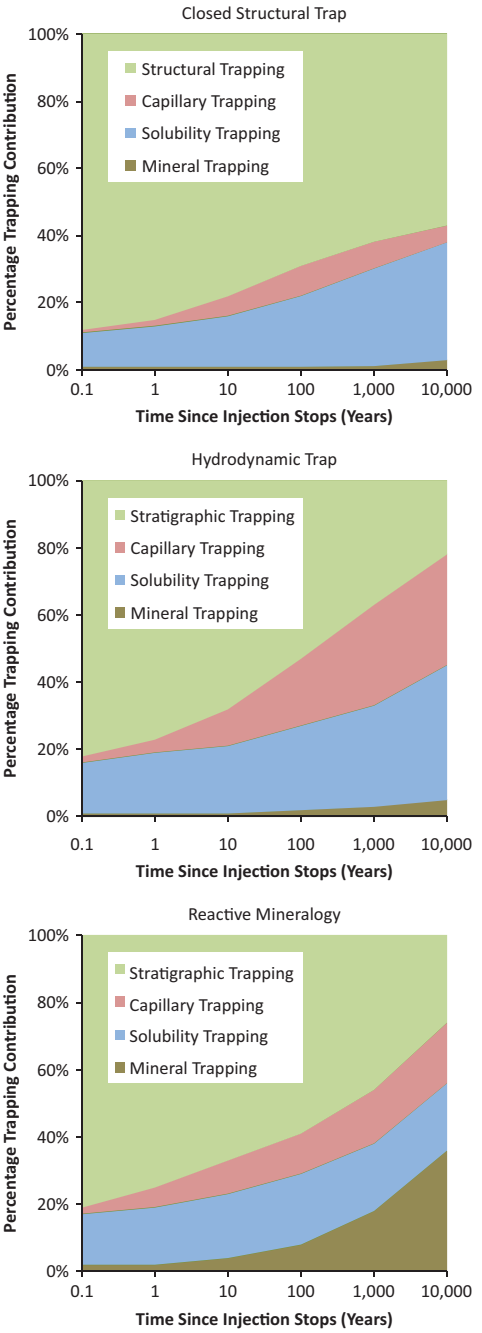

Figure 13.9 | Conceptual schematic showing trapping mechanisms and their evolution over a 10 thousand year period, as expressed as a percentage of the total trapping contribution (modified from IPCC, 2005). The relative importance of each trapping mechanism will be different depending on the attributes of the formation. For example, in a closed structural trap, which provides excellent containment beneath a dome-shaped seal, the secondary trapping mechanisms are comparatively small. In a formation with a dipping seal where the CO_2 moves upgradient due to buoyancy effects, the CO_2 will dissolve more quickly and a large fraction be subject to capillary trapping. For geological formations with a large fraction of reactive minerals such as feldspar or olivine, a significant fraction of the CO_2 may be converted to minerals.

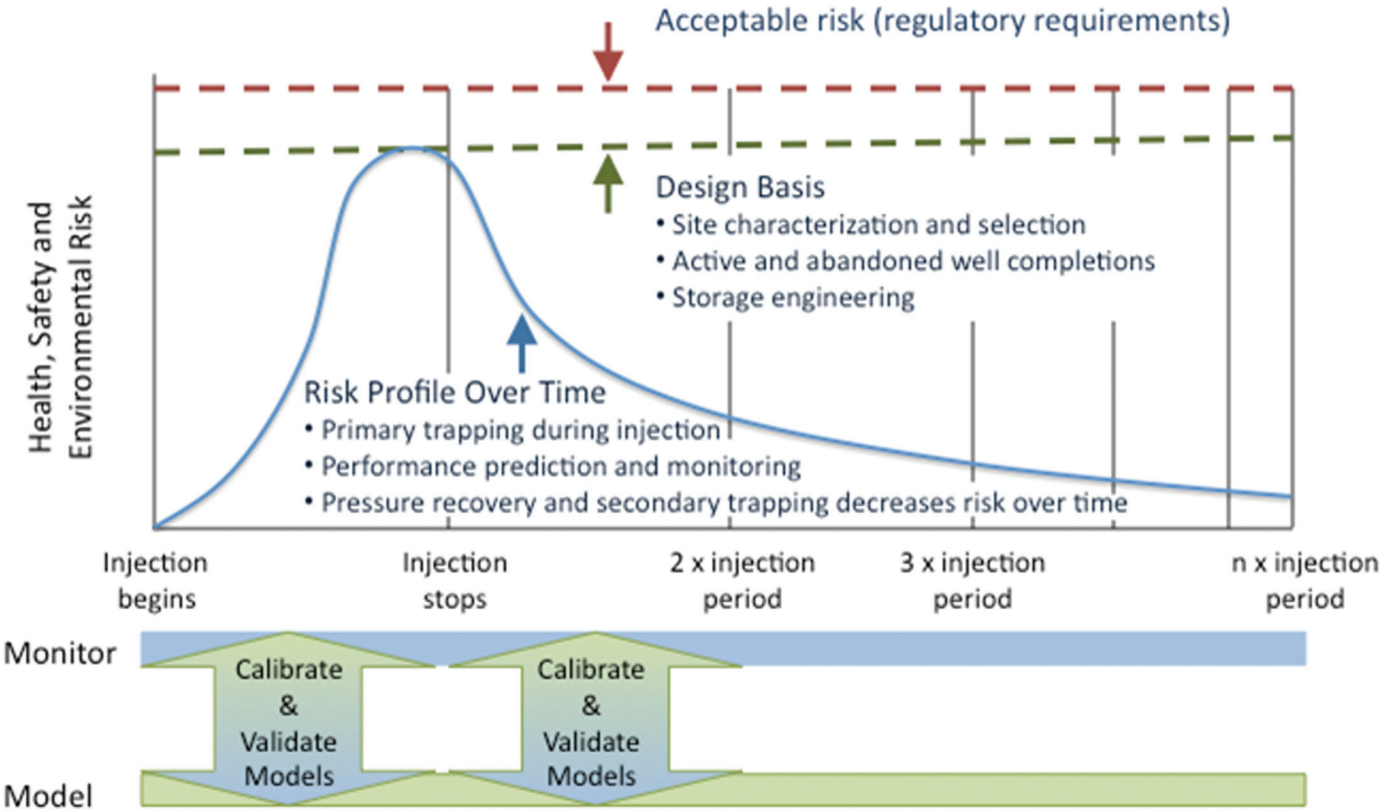

Figure 13.10 | Conceptual schematic illustrating the anticipated magnitude of health, safety and environmental risks over the lifetime of a typical geological storage project. Performance specifications, or acceptable risks, will be set by regulatory authorities. Projects will be designed to conform to regulatory requirements – or even lower depending in the design specifications. Primary risk management tools include site characterization and selection, identification and assessment of abandoned wells (including potential remediation), and storage engineering to ensure CO_2 containment and management of injection pressures. Actual risks will change over time, with growing risks during the early stages of the project, as CO_2 is first injected into the storage reservoir. Eventually, information gained from the combination of performance modeling and acquisition of monitoring data will provide assurance that the project is conforming to the design specifications – or remediation measures will be taken to address unforeseen risks. After injection stops, the pressure in the storage reservoir will begin to decrease, lessening the risk of CO_2 leakage or brine migration. Over time, as indicated in Figures 13.9a-c, secondary trapping mechanisms will further reduce the risks of health, safety and environmental impacts.

- Multiple processes contribute to long-term retention of CO_2, including physical trapping beneath low permeability rocks, dissolution of CO_2 in brine, capillary trapping of CO_2, adsorption on coal, and mineral trapping. Together, these trapping mechanisms increase the security of storage over time, thus further diminishing the possibility of potential leakage and surface release.

- Experiences with projects having large amounts of monitoring data, such as the Sleipner Project in the North Sea and the Weyburn Project in Saskatchewan, Canada, have demonstrated a high degree of containment.

The technology for storing CO_2 in deep underground formations is adapted from oil and gas exploration and production technology. For example, technologies to drill and monitor wells that can safely inject CO_2 into the storage formation are available. Methods to characterize sites are fairly well developed. Models are available to predict where the CO_2 moves when it is pumped underground, although more work is needed to further develop and test these models, particularly over the long timeframes and large spatial scales envisioned for CO_2 storage. Monitoring of the subsurface movement of CO_2 is currently being successfully conducted at several sites, although again, more work is needed to refine and test monitoring methods.

13.4.2.2 Existing and Planned CO_2 Storage Projects

Maps showing the location of current and planned CO_2 storage projects are shown in Figures 13.11a and 13.11b. Many of these are pilot tests or small-scale demonstrations. Today, each of five commercial projects store from about 1–3 $MtCO_2$/yr in deep geological formations at Sleipner, Weyburn, In Salah, Powder River Basin, Wyoming and Snøhvit (Torp and Gale, 2003; Riddiford et al., 2003; Moberg et al., 2003). The Sleipner, In Salah, and Snøhvit projects were designed with CCS as their primary purpose. The Weyburn and Wyoming projects designed initially as an enhanced oil recovery project but has evolved into a project that combines enhanced oil recovery with CO_2 storage. Today,

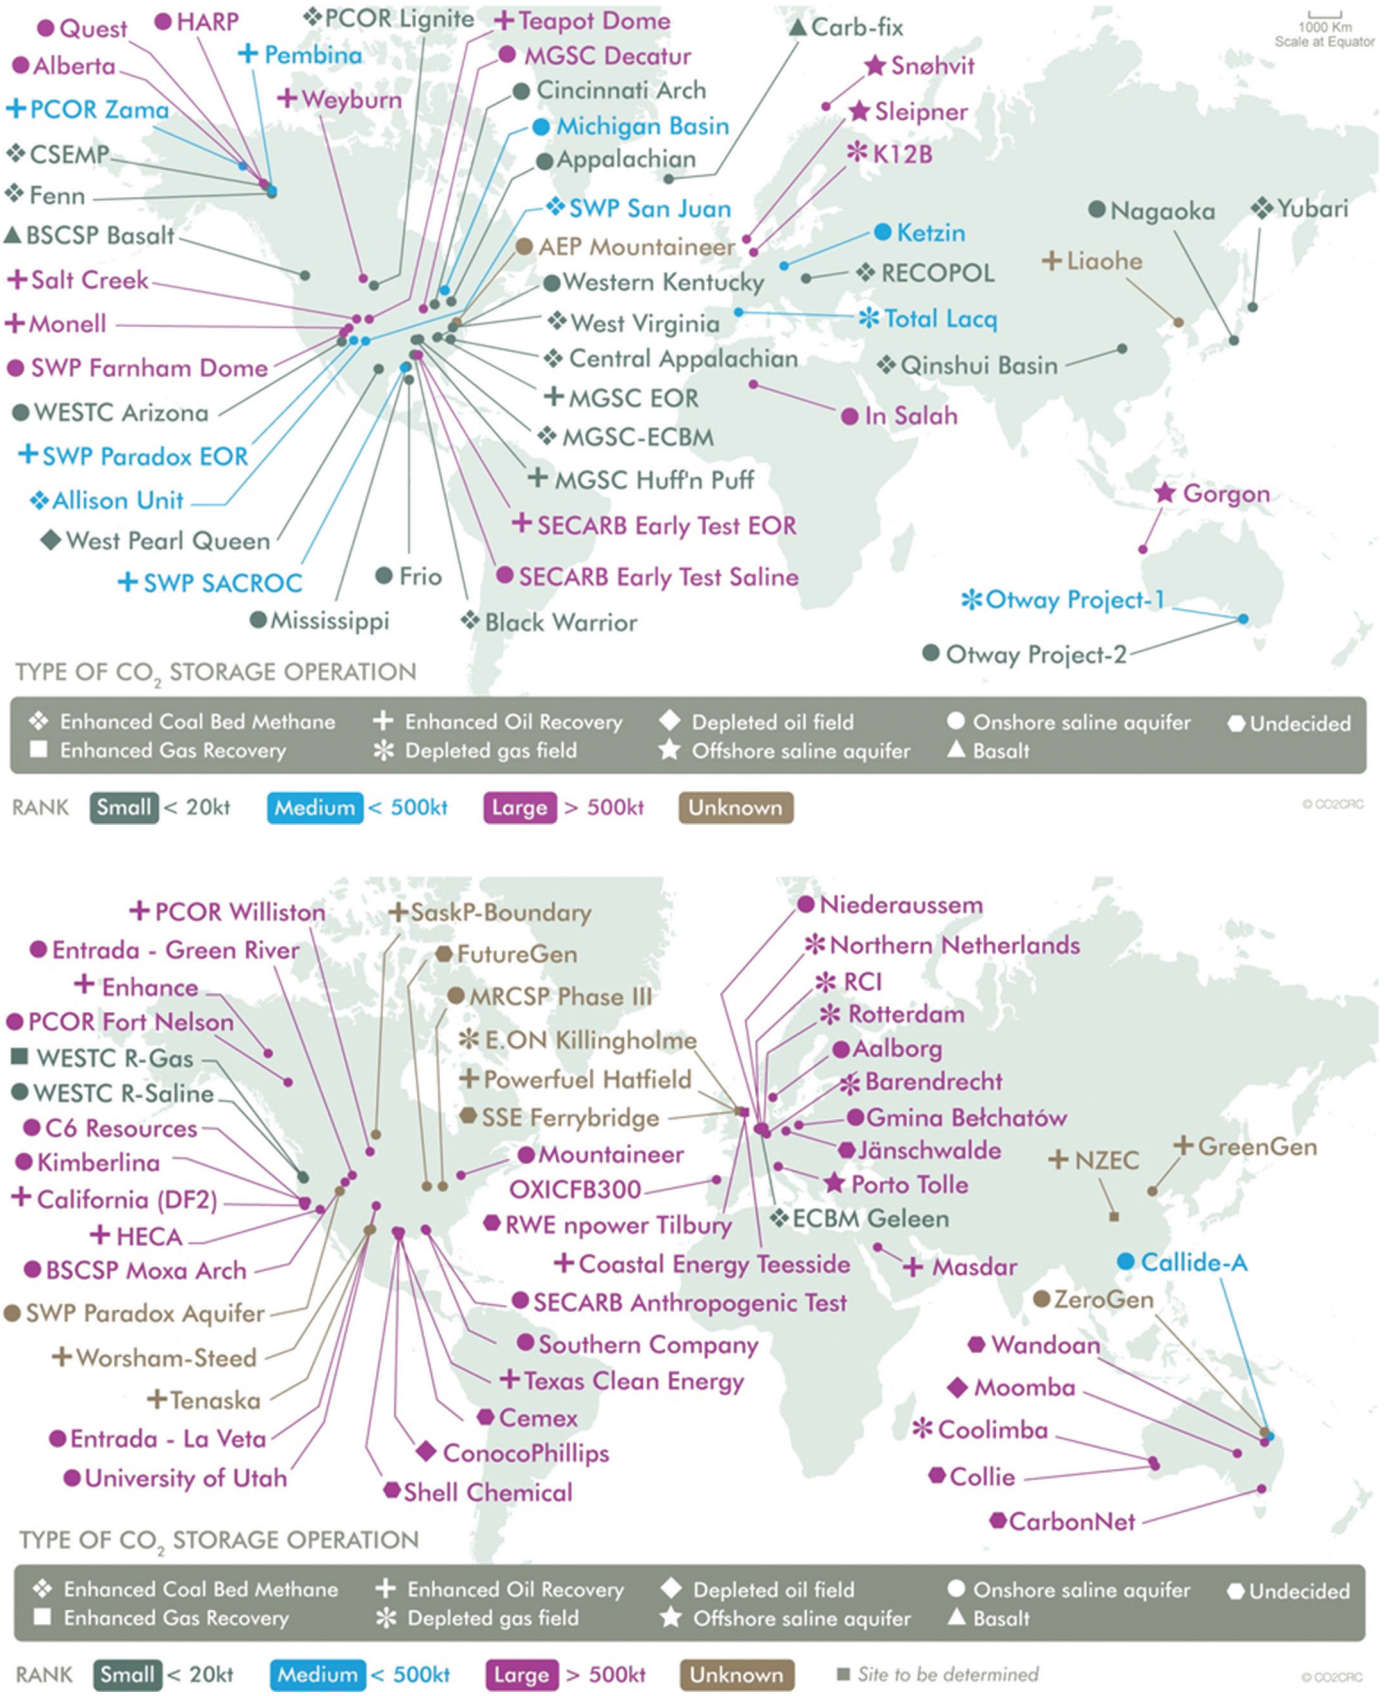

Figure 13.11 | (a) Location of existing CCS projects, including commercial projects, pilot tests, and demonstration projects. (b) Location of planned CCS projects, including commercial projects, pilot tests and demonstration projects (ES1). Source: courtesy of CO2CRC, 2011.

over 30 years of cumulative experience have been gained from these projects.

Sleipner Project, Norway

Beginning in 1996, Statoil initiated storage of approximately 1 $MtCO_2$/yr in a saline aquifer underneath the North Sea. Injection is carried through a single well screened near the base of the 200 m thick Utsira sandstone, at a depth of about 1 km beneath the sea level. The formation is highly permeable and porous, with a number of thin layers of shale distributed over the thickness of the formation. Injection has taken place with few difficulties. A comprehensive seismic monitoring program has provided invaluable information about the movement of CO_2 in the subsurface, demonstrating that CO_2 is securely trapped beneath a thick shale bed (Arts et al., 2010). After 16 years of injection, the plume covers an extent of about 15 km^2 and is moving slowly below the base of the seal. Numerous studies have compared predictions from computer models to observed migration, with reasonably good results as long as the geological complexity of the storage reservoir is included in the model (Bickle et al., 2007). Overall, the Sleipner Saline Aquifer Storage Project has done a great deal to generate confidence in the geological storage of CO_2.

Weyburn Project, Canada

The Weyburn Project in Saskatchewan, Canada combines CO_2-EOR and storage in a carbonate oil reservoir located north of the United States-Canada border. Beginning in 2000, PanCanadian Oil Company, and later Encana, initiated injection of a total of 2–3 $MtCO_2$/yr containing about 2% H_2S from the Dakota Gasification Plant into an array of wells designed to optimize oil recovery. The IEA Greenhouse Gas Program coordinates an extensive monitoring effort, including seismic imaging, geochemical sampling of produced brine, and soil gas sampling. The oil field is situated under a thick seal of anhydrite (salt formation), which is expected to provide an excellent seal. Results from the monitoring program document the movement of CO_2 in the reservoir (White el al., 2009), geochemical interactions between CO_2 and the carbonate rocks (Emberly et al., 2005), and the lack of detectable changes in soil gas composition associated with injection (Wilson and Monea, 2004). Overall, the Weyburn Project demonstrates effective retention of CO_2 in the oil field.

In Salah Project, Algeria

The In Salah Project in Algeria, initiated by BP, Sonatrech, and Statoil, is the most technologically complex storage project undertaken to date. CO_2 separated from natural gas is pumped back into the flanks of the gas reservoir from which the CO_2 is produced. Due to the low permeability of the reservoir rocks, three horizontal wells (with open intervals of 1000–1500 m) are used to inject CO_2 into the 20-meter thick reservoir at a depth of about 1800 m. Since 2004, about 0.7 $MtCO_2$/yr have been injected into the reservoir. In 2008, satellite-based land surface deformation monitoring enabled mapping of the region where pressure buildup was occurring, as documented by uplift on the order of 2 cm/yr. This discovery, confirmed now by many research groups, provides a new method for monitoring CO_2 storage projects (Vasco et al., 2008). These observations, combined with the detection of a small leak up an exploratory well, suggested that the flow of CO_2 is in part controlled by fractures in the reservoir (Iding and Ringrose, 2010). After the leak was detected, injection in the closest well was stopped while the exploratory well was plugged with cement and abandoned properly. Injection was started again after the well was plugged. The In Salah Project provides an interesting case study regarding the ability to detect and stop leaks, as well as illustrating how subsurface complexity controls CO_2 movement in the storage reservoir. Seismic data has been collected and is now being interpreted with regard to CO_2 movement.

Snøhvit Project, Norway

The Snøhvit Project, located in the Barents Sea north of Norway, is the most recently initiated project, with injection starting in 2008. Approximately 0.7 $MtCO_2$/yr is injected into a sub-sea saline aquifer situated underneath the producing gas reservoir. The storage facility is associated with a large liquefied natural gas project. The injectivity was initially lower than expected. The large pressure buildup leading to low injectivity was attributed to compartmentalization of the storage reservoir and a remedy has been implemented (Eiken et al., 2011).

CO_2 EOR Projects

Vast experience pumping CO_2 into oil reservoirs also comes from nearly 30 years of CO_2-EOR, with nearly 50 Mt injected in 2010. About 100 projects are underway worldwide, with the vast majority in North America. When CO_2 is pumped into an oil reservoir, it mixes with the oil, lowering the viscosity and density the oil. Under optimal conditions, oil and CO_2 are miscible, which results in the efficient displacement of oil from the pore spaces in the rock. An estimated increase in oil recovery of 10–15% of the initial volume of oil-in-place is expected for successful CO_2-EOR projects. Not all of the injected CO_2 stays underground, as 30–60% is typically produced back with the oil. On the surface, the produced CO_2 is separated from the oil and re-injected into the reservoir. If CO_2 is left in the reservoir after oil production stops, most of the CO_2 injected over the project lifetime remains stored underground. The majority of CO_2-EOR projects today uses CO_2 from naturally occurring CO_2 reservoirs. The high cost and limited availability of CO_2 has restricted the deployment of CO_2-EOR to those areas with favorable geological conditions and a readily available source of CO_2. A few projects use CO_2 captured from industrial sources, notably the Weyburn Project discussed above and the Salt Creek Project in Wyoming, which is injecting several million tonnes per year.

The recent high oil prices have spurred interest in expanding the application of CO_2-EOR. This possibility, together with prospects for obtaining tradable credits for storing CO_2, has attracted considerable interest by the oil and gas industry.

Other Planned Projects, Pilot Tests, and Small-Scale Demonstrations

As shown in Figure 13.11, there are more than 280 pilot tests, demonstration projects, and commercial projects that are underway or in the planning stages. Most of these are small-scale pilot tests, supported by government-industry partnerships and designed primarily to gain experience with site selection and monitoring and to increase our understanding of the behavior of CO_2 in the subsurface. Launching a commercial scale storage project takes many years and in some cases a decade or more, as a result of the need to characterize the site, obtain injection permits, secure financing, drill wells, and manage all of the other components of these large-scale engineering endeavors. Several large projects, notably the Gorgon Project in Australia (3–4 $MtCO_2$/yr), are under construction and are expected to begin operations in the next five years.

13.4.3 Storage Capacity Estimation

The distribution and capacity of storage reservoirs are two of the most important parameters with regard to the widespread deployment of CCS technology. If storage capacity is not sufficient or it is not co-located with large emission sources, CCS is unlikely to play a major role in reducing CO_2 emissions. The IPCC (2005) gathered worldwide capacity estimates and concluded that there is sufficient capacity to meet at least one hundred years (technical potential ranging from 200–2000 Gt) of needed storage capacity, but that the distribution was variable and not all nations or regions had equally good potential for storage. The storage capacity in oil and gas formations ranged from 675–900 Gt, in coalbeds from 3–200 Gt, and in saline aquifers from 1000–10,000 Gt (IPCC, 2005).

In 2005, the quality of information about storage capacity was highly variable, with only a few regions having undertaken systematic capacity assessments. Moreover, the IPCC report also highlighted the uncertainties with respect to the storage capacity of saline aquifers. No generally accepted methodology for saline aquifer capacity assessment was available (Bachu et al., 2007). Since that time, many nations have undertaken systematic capacity assessments, using more clearly documented methods (e.g., US DOE, 2010). Specifically, the majority of saline aquifer capacity assessments are carried out by identifying locations where the following criteria are met:

- deep sedimentary basins where permeable strata are present;
- depths are greater than 800–1000 m;
- seals are present above the storage reservoir;
- salinity exceeds specific standards (e.g. 10,000 ppm in the United States); and
- access is not otherwise precluded due to other beneficial uses (e.g., military bases, parks, etc.)

After these screening criteria are applied, the mass of CO_2 that can be stored is calculated by equations of the following type:

$$\begin{aligned} &Capacity = \rho_{CO_2} \cdot A \cdot T \cdot \Phi \cdot E \\ &where: \\ &\quad \rho_{CO_2} = density\ of\ CO_2\ (kg/m^3) \\ &\quad A = Area\ (m^2) \\ &\quad T = net\ sand\ thickness\ (m) \\ &\quad \Phi = porosity \\ &\quad E = Efficiency\ Factor \end{aligned} \tag{2}$$

The efficiency factor typically ranges from 0.01–0.05, or from 1–5% of the pore space of the rocks (NETL, 2010a). The efficiency factor is estimated based on the numerical simulation of a wide range of storage scenarios. Variations on these kinds of volumetric capacity estimation methods that account for a number of other factors are also being developed and applied. These factors include considering those areas where there is a structural closure that limits the migration of CO_2 (European method; USGS, 2010); multiphase flow dynamics (Juanes et al., 2010); and the amount of CO_2 dissolved in the saline aquifer. Capacity estimates using these different methods can vary significantly, particularly when accounting for only those regions with structural closure. Consequently, while much progress has been made with regard to capacity estimation, many uncertainties remain.

One of the largest questions regarding storage capacity is the extent to which saline aquifers without structural closure can be used for storage. Structural closure refers to the presence of a typically domed-shaped seal where buoyant fluids can accumulate. Arguments in favor of using these formations without closure rely on scientific theories indicating that CO_2 will be immobilized by a combination of capillary trapping, solubility trapping, and mineral trapping (IPCC, 2005). These processes gradually reduce the fraction of CO_2 that is free to continue moving after injection has stopped (Ide et al., 2007; Hesse et al., 2008; MacMinn and Juanes, 2009). In theory, once CO_2 stops moving, structural closure is not needed to securely trap CO_2 over geological time periods. Arguments against using portions of saline aquifers without structural closure focus on uncertainties about the extent and timing of these secondary trapping mechanisms. If these processes do not effectively immobilize the CO_2 quickly enough, CO_2 could migrate into drinking water aquifers or be released to the atmosphere. Additional understanding of these trapping processes through a combination of theoretical, laboratory, and field research is needed. The monitoring of existing projects described in Section 13.4.2.2 will also provide crucial insights into the long-term mobility of CO_2 in the subsurface.

Over the past several years, another issue has arisen with regard to capacity estimation. Several authors have suggested that pressure buildup in the storage reservoir will limit storage capacity (van der Meer and van Wees, 2006; Economides and Ehlig-Economides, 2009; Birkholzer and Zhou, 2009). For small- to moderate-size reservoirs that are completely sealed above, below, and on all sides, pressure buildups

can be very large if even a small fraction of the pore space (~1% or more) is filled with CO_2, resulting from the extremely low compressibility of water. Overly large pressure buildup can lead to hydraulic fracturing of the reservoir and seal, thus limiting the maximum pressure buildup in the storage reservoir. For completely sealed reservoirs, pressure buildup would indeed limit storage capacity. The importance of pressure buildup constraints on capacity will depend on the degree to which completely sealed reservoirs are used for storage and how many such reservoirs exist. Most reservoirs are not completely sealed and only a top seal is absolutely essential and, perhaps, desirable. Additionally, several authors have also shown it is possible to extract water while storing CO_2 to control the extent of pressure buildup (e.g., Guénan and Rohmer, 2011). Consequently, the extent to which pressure buildup will limit storage capacity remains to be seen. Importantly, pressure limits on storage capacity should not be confused with pressure limits on injectivity, which is a very real constraint on the rate that CO_2 can be injected into a well.

13.4.3.1 Regional and Global Geological Storage Capacity Estimates

Table 13.2 summarizes the results from regional and national capacity assessments. Capacity estimates for oil and gas formations range from 996–1150 $GtCO_2$, coalbeds from 93–150 $GtCO_2$, and saline aquifers from 3963–23,171 $GtCO_2$. Current estimates suggest that global capacity will be at the high end of the range estimated in IPCC (2005).

Table 13.2 | Compilation of current storage capacity estimates. (Note this is not a complete accounting because capacity assessments have not been completed in many areas of the world. Additionally, common methods are not used and significant uncertainties in capacity assessment methodology remain. Different methodologies and assumptions have been used and comparisons between capacities for different regions should be viewed with caution.)

Region	Estimated Storage Capacity ($GtCO_2$)				Source	Note
	Depleted Oil and Gas Reservoirs	Saline Formations	Coal Seams	TOTAL		
North America	143	1653–20,213	60–117	1856–20,473	1

(a) All countries in Central and South America, including Brazil.

(b) The storage capacities are only in Australia. There is no storage capacity assessment in New Zealand.

(c) The numbers correspond to the storage capacity in China only. The numbers are not additive since they come from different references.

(d) The numbers correspond to the storage capacity in Indonesia only. No information was available for other countries.

(e) The numbers correspond to the storage capacity in India, Pakistan, and Bangladesh. The same report states that significant storage capacity exists in saline formations, but it has not been quantified yet.

(f) Does not include Estonia, Latvia, and Lithuania, even though they are former Soviet states. The capacity in the aforementioned states is considered in the European Union region.

(g) Includes Eastern, Western, and Southern Africa (not Northern Africa)

(h) Not all European countries are included in the Geocapacity Study. The countries that are NOT included in the Geocapacity study (specifically Finland, Ireland, Portugal, Switzerland, and Sweden) were individually studied, and no information was found about their CO_2 storage capacity.

(i) Equal to the sum of the values in Table 13.2 for oil and gas field, coalbeds and saline formations.

13.4.4 Risks of Geological Storage of CO_2

Risks of CO_2 storage are typically separated into two broad categories: 1) risks associated with the release of CO_2 back into the atmosphere, and 2) health, safety, and environmental risks associated with the local impacts of the storage operations and potential leakage out of the storage reservoir.

The consequences of releases of CO_2 back into the atmosphere are that CCS would be less effective as a mitigation measure than anticipated and there would be financial liabilities associated buying credits or otherwise assuming responsibility for those emissions. Ultimately, these kinds of risks are associated with the duration and security of storage, which are addressed in Section 13.4.4.1. A particular complexity of CCS is that these financial liabilities are perceived to persist over periods of up to several hundred years or longer, but, as discussed in Section 13.4.4.1, the risk of releases to the atmosphere are greatest during the period of CO_2 injection, which for any particular project are limited to decades. Additionally, as discussed in Section 13.4.5, legal and administrative mechanisms for managing long term liabilities, well beyond the period of operation and post-injection assurance monitoring are being developed by governments worldwide.

The local health, safety, and environmental concerns of a CO_2 storage project are similar to those typically associated with producing oil and gas fields, such as road traffic, noise, habitat fragmentation, and infrequent uncontrolled releases from wells. In addition, if CO_2 or brine leaks out of the storage reservoir it may affect groundwater quality, and result in locally hazardous concentrations of CO_2 in the air and microseismicity if injection pressures are very high. The local health, safety, and environmental concerns for CO_2 storage projects are discussed in Section 13.4.4.2.

Because of the operational and technological similarities, the probability and consequences of risks from geological storage are generally assumed to be similar to those of existing activities such as oil and gas production, natural gas storage, and acid gas injection (IPCC, 2005). The risks are managed on a routine basis through a combination of operational controls, management oversight, monitoring, maintenance, regulatory oversight, and insurance. Similar practices are needed to manage the risks of geological storage. In fact, each of the five active projects described in Section 13.4.1 have successfully managed these risks.

Based on analogous experience from the natural gas storage industry, the three largest sources of risk for geological storage projects are inadequate site selection due to inadequate seal characterization, leakage up active or abandoned wells, and leakage through undetected faults or fractures in the storage reservoir seal.

With experience, site selection for the natural gas storage industry has improved to the point where these risks are relatively small. For natural gas storage projects, if a sufficiently thick seal with structural closure, low permeability, and high capillary entry pressure covers the entire extent of the storage project, the risks of leakage are small. However, in comparison, a typical underground plume of CO_2 may grow to extend over hundreds of km^2, far larger than the size of a typical natural gas storage project; this suggests that time and experience will be needed to perfect the site selection process.

Leakage up active and abandoned wells remains the largest concern from natural gas storage projects and indeed has resulted in a small amount of leakage from the In Salah Project (Mathleson et al., 2011). The potential for wellbore leakage from CO_2 storage reservoirs has been the subject of a large amount of experimental and theoretical research over the past five years (Gasda et al., 2004; Carey et al., 2007; Nordbotten et al., 2009; Duguid and Scherer, 2009). Clearly, if CO_2 encounters a wellbore that is not cemented to the rock, CO_2 can migrate up the annulus and, if left unchecked, can reach the surface. More problematical is the influence of CO_2 on a cemented well. Laboratory and theoretical studies suggest that chemical reactions with water and CO_2 can degrade cement, creating leakage pathways through a largely intact cement seal. On the other hand, several wellbores in active CO_2 reservoirs have been tested and suggest that cement degradation is minimal. Additional studies are needed to resolve this issue.

Leakage through undetected faults and fracture is another source of leakage risk. Usually a combination of well drilling, logging, pressure testing, and seismic imaging is used to assess the quality of the reservoir and seal. Under certain circumstances, particularly where the offset across a fracture or fault is small, a fault may go undetected. Site characterization methods are getting better all the time, decreasing the risk that this could occur. Nevertheless, this risk is usually minimized by avoiding storage projects in areas with known faulting or at least with no active faults. Over time, as the best storage sites are used, greater efforts will be needed to assure that undetected faults and fractures do not compromise the storage site.

13.4.4.1 Duration and Security of Storage

Based on our best scientific understanding of the processes controlling CO_2 migration in the subsurface, CO_2 should remain securely stored in the subsurface for geological time periods (thousands of years and longer) if the following conditions are met:

- The seal has a low enough permeability and high enough capillary pressure to prevent migration into the seal.
- CO_2 cannot migrate around the edge of the seal or through breaches in the seal caused by leaking wells, faults, or fractures.
- The injection pressure is low enough to avoid fracturing the seal.

While in principle these are straightforward enough to understand, the bigger challenge is to identify sites that meet these conditions. Subsurface geology is by nature complex and geological storage sites

are by necessity large, with CO_2 plumes potentially covering hundreds of km^2. For this reason, it is not easy to provide an unqualified answer about the duration and security of storage. The IPCC (2005) dealt with this issue by making qualified statements about the retention of CO_2:

> "Observations from engineered and natural analogues as well as models suggest that the fraction retained in appropriately selected and managed geological reservoirs is very likely to exceed 99% over 100 years and is likely to exceed 99% over 1000 years" (IPCC, 2005).

This statement was unsatisfying to many people for several reasons. First, the statement was based on expert opinion as opposed to actual experience. Second, the quantitative measures appear to be somewhat arbitrary, using terms like "likely" and "very likely," which perhaps imply a greater degree of precision than is possible. Finally, the statement is somewhat circular, implying that a good outcome will be achieved if the "the job is done right" but without prescribing exactly how to do the job right. The question then becomes, what have we learned in the intervening five years that could shed further light on the issue of storage permanence, especially considering the tremendous amount of research carried out over the past five years, numerous pilot tests, and demonstration and commercial projects?

From the five existing commercial scale projects, available information indicates that overall, they have performed as expected, with little or no leakage, and leakage that did occur was caused by abandoned wells. Once identified, the leaking wells can be sealed. This suggests that it is possible to find sites that meet the conditions needed for secure storage. Monitoring methods have shown to be effective for tracking CO_2 and the pressure buildup caused by CO_2 injection. Calibrated models also reasonably replicate CO_2 plume movement. All of these build confidence in the security of storage and our ability to "do the job right." But, it is still early in the lifetime of the projects and more will be learned as time goes on.

From the vast amount of research and pilot projects, much has been learned about how CO_2 migrates through the subsurface and how CO_2 geochemically interacts with rocks and cement. Understanding and confidence are growing in the secondary trapping mechanisms' ability to immobilize CO_2 and increase storage security in the post-injection period. Many new and improved methods for monitoring are being developed and tested, improving our ability to detect even small amounts of leakage. Methodologies for characterizing sites have been proposed and are being tested in numerous demonstration projects around the world (WRI, 2009, NETL, 2010b, DNV, 2010). Leakage up abandoned wellbore remains the biggest vulnerability for otherwise high-quality sites.

In light of the progress made over the past five years, what new can be said about storage duration and security? Observations from *commercial storage projects*, engineered and natural analogues, as well as *theoretical considerations*, models, and *laboratory experiments*, suggest that appropriately selected and managed geological storage *reservoirs are very likely to retain nearly all the injected CO_2 for very long times, more than long enough to provide benefits for the intended purpose of CCS.*

13.4.4.2 Local Health, Safety, and Environmental Concerns for CO_2 Storage

CO_2 is used in a wide variety of industries, from chemical manufacture to beverage carbonation and brewing, from enhanced oil recovery to refrigeration, and from fire suppression to inert atmosphere food preservation. Because of its extensive use and production, the hazards of CO_2 are well known and routinely managed. Engineering and procedural controls are well established for dealing with the hazards of compressed and cryogenic CO_2.

While CO_2 is generally regarded as a non-toxic inert gas, exposure to concentrations in excess of several percent can lead to adverse consequences. In particular, since CO_2 is denser than air, hazardous situations arise when large amounts of CO_2 accumulate in low-lying, confined, or poorly ventilated spaces. While the chances of this occurring are very low, if a large amount of injected CO_2 were to escape from a storage site, it could present risks to health and the local environment. However, hazardous conditions would only persist several hundred meters from the site of the release, even for the largest possible leakage rates (Aines et al., 2009). Such releases could be associated with surface facilities, injection wells, or leakage from the storage formation itself. There may be small-scale diffuse leaks or leaks concentrated near the injection facilities. Leakage, if unchecked, could harm groundwater and ecosystems. Persistent leaks could suppress respiration in the root zone or result in soil acidification and eventually lead to tree-kills such as those associated with soil gas concentrations in the range of 20–30% CO_2 which have been observed at Mammoth Mountain, California, where volcanic out gassing of CO_2 has been occurring for several decades (Martini and Silver, 2002).

CO_2 storage projects are designed with the goal of avoiding these potential hazards. It is important, however, to have a comprehensive understanding of what could go wrong. Potential local health, safety, and environmental concerns from geological storage include the following. This list is approximately ordered with the largest to smallest risks, based on analogous experience from existing commercial operations:

- Occupational risks associated with well field operations. These risks are well understood both in terms of the nature of the risks and the frequency of occurrence. Overall, the injury rate for oil and gas field projects in the United States are lower than for many industries, but the severity is on the higher side, caused mainly by vehicle accidents (US Bureau of Labor Statistics (BLS, 2011), on-line database). For example, from the

2 The TRC is defined as the number of recordable injury and illness cases per 100 full-time workers.

period 2004–2007, the TRC (Total Recordable Case Rate) for the oil and gas production workers ranged from 1.4–1.7, as compared to 4.3–5.4 for all or the goods-producing industries.[2] For the same period, injuries or illnesses involving days away from work were 0.4–1.0 for oil and gas workers compared to 1.2–1.5 for all goods-producing industries.

- While CO_2 storage projects are expected to take place in storage reservoirs far deeper than drinking water aquifers, if CO_2 or brine leaks out of the storage reservoir it could migrate into drinking water aquifers. Risks of groundwater contamination include CO_2 intrusion into a fresh water aquifer, secondary contamination resulting from geochemical reactions between CO_2 and the aquifer rocks, from displaced saline brines, or in the case of storage in oil and gas fields (and potentially coalbeds), organic contaminants transported with the CO_2. In addition, risks will be site specific, depending on the hydrogeological environment and mineralogy of the rocks (Wilkin and DiGiulio, 2010). Of particular emphasis is the potential for brine migration even if no CO_2 leaks from the storage reservoir, which could increase the salinity and potentially the trace element content of drinking water sources (Nicot, 2008; Birkholzer et al., 2009). A significant concern is the large region over which the pressure will increase in the storage formation, a region far larger than the extent of the CO_2 plume. If abandoned wells or faults provide a conduit to short-circuit the seal, brine could invade a drinking water aquifer and degrade water quality. However, an extensive field study above one of the largest CO_2-EOR projects did not find any evidence of groundwater degradation due to CO_2 intrusion or brine migration (Romanak et al., 2010).

- Resource damage to nearby oil and gas fields or coalbeds, due to unwanted CO_2 migration into nearby mineral resources. The probability of these risks is low unless the storage reservoir is close to an oil or gas field.

- Ecosystem impacts in the event that CO_2 is released into soil, wetlands, or surface waters. If CO_2 is released to the surface, some local impacts to ecosystem productivity and function would be expected.

- Public safety risks from exposure to elevated CO_2 concentrations if CO_2 is released at the surface. The risks to the public will always be small compared to worker risk. Additionally, around the world there are many known sites of CO_2 releases into the atmosphere that pose little to no hazard, such as the Crystal Geyser site in Utah (Aines et al., 2009) and many sites in Europe (Beaubien et al., 2004; Voltattorni et al., 2006). However, if CO_2 leaks to the surface and accumulates in a low-lying area, exposure to even fatal concentrations of CO_2 is possible such as occurred at Mammoth Mountain, CA (Martini, and Silver, 2002). Risks from areas of known leakage can and are controlled by limiting access to the hazardous areas through signage and fences (Beaubien et al., 2004).

- Structural damage associated with land surface deformation or microseismicity. These risks are relatively well understood and should be managed by controlling the injection pressure to avoid unacceptable levels of microseimicity or land surface deformation. High-resolution remote sensing maps depicting subsurface faults, fractures, and fracture density patterns of geological storage sites may be prepared to understand the structure and associated risks. Regulatory oversight is needed to ensure the project is managed with proper controls.

Importantly, the five existing projects have experienced none of these environmental impacts. Even though an abandoned well that intersected the storage reservoir at In Salah was found to be leaking through a routine monitoring program, no health safety or environmental impacts resulted from this event (Mathleson et al., 2011).

Extensive industrial experience with injection of CO_2 and gases in general indicates that risks from geologic storage facilities are manageable by using standard engineering controls and procedures. Loss of well control, probably the highest risk event that could occur in a CO_2 storage project, is infrequent. For example, one study focused on the largest oil and gas producing region in California indicated an overall rate of one blowout/12,000 wells/yr (Jordan and Benson, 2008). Furthermore, this study showed that property damage and human health impacts were small from blowouts that did occur (Jordan and Benson, 2008). Regulatory oversight and institutional controls further enhance the safety of these operations, and ensure that the site selection and monitoring strategy are robust. Employed on a scale comparable to existing industrial analogues, the risks associated with CCS are comparable to those of today's oil and gas operations. Eventually, if CCS were to be deployed on the grand-scale needed to significantly reduce CO_2 emissions (billions of tonnes annually), the scale of operations would increase to become as large as or larger than existing oil and gas operations (Burruss, 2004). In this eventuality, experience gained in the early years of CCS would be critical for assessing and managing the risks of the very large-scale geological storage projects.

13.4.4.3 Monitoring and Risk Management

In the 2005 *IPCC Special Report on Carbon Dioxide Capture and Storage*, the authors concluded that "the local health, safety and environment risks of geological storage would be comparable to risks of current activities such as natural gas storage, EOR, and deep underground disposal of acid gas." To achieve this high level of performance, a comprehensive approach is needed to manage environmental, health, and safety risks throughout the life cycle of a storage project, from site selection past the operational lifetime of the storage project. Monitoring must play a key role to observe the behavior of the injected CO_2, calibrate and validate predictive models, and provide any early warning that leakage may be imminent. In the event of imminent or actual leakage, remediation measures such as plugging abandoned wells will be needed. A regulatory oversight capacity is needed to ensure due diligence for siting, engineering, operating, monitoring, and remediating storage projects. Finally, private

and/or public sector mechanisms are needed to ensure financial responsibility for any short- and long-term liabilities created by the project.

Every storage project is likely to use a combination of monitoring techniques (e.g., geophysics, hydrology, geochemistry) that will, at a minimum, track migration of the CO_2 plume, detect leakage out of the storage reservoir, monitor injection rates and pressure, and detect microseismic activity. Technology for monitoring geologic storage of CO_2 is available from a variety of other applications, including the oil and gas industry, natural gas storage, disposal of liquid and hazardous waste in deep geologic formations, groundwater monitoring, food preservation and beverage industries, fire suppression, and ecosystem research. Many of these techniques have also been demonstrated at the five existing storage projects and many smaller-scale pilot tests around the world (e.g., Arts et al., 2004; Hovorka et al., 2006). Specific regulatory requirements for monitoring have yet to be established. The principle methods of monitoring are described below.

Geophysical Monitoring

Several geophysical monitoring methods can be used to monitor the location of the CO_2 plume. Seismic imaging can detect changes in compressional wave velocity and attenuation caused by the presence of separate phase CO_2. Electromagnetic imaging can detect decreases in electrical conductivity caused by the presence of CO_2 in the pore spaces of the rock. Gravity measurements are sensitive to the decrease in bulk density of the rock caused by the presence of CO_2. Seismic methods for monitoring have been used successfully at Sleipner, Weyburn, the Frio Brine Pilot, and the Otway Basin Pilot Project, as well as others (Arts et al., 2009; Hovorka et al., 2006; White, 2009; Pevzner et al., 2010).

Geochemical Monitoring

Two types of geochemical measurements can be deployed to monitor CO_2 injection. The first involves the use of direct techniques including measurements of brine chemistry and introduced or natural tracers in samples obtained from injection horizons in observation wells. The second involves monitoring the near-surface for possible CO_2 leakage in the immediate vicinity of injection and observation wells, as well as from soils and shallow wells within the injection area.

To date, geochemical methods have been used primarily for the pilot scale tests because of the important insights they provide about the geochemical interactions between CO_2 and the storage reservoir rocks (Kharaka et al., 2006a; 2006b). They have also been used extensively at the Weyburn Project (Emberly et al., 2005). The simplest monitoring systems include pH, alkalinity, and gas-compositions. Of these, pH is probably the most diagnostic indicator of brine-CO_2 interactions and typically exhibits marked decreases that correlate closely with the breakthrough of CO_2 to monitoring wells. Major, minor, trace elemental chemistry and stable isotope geochemistry are used to assess the extent of water-CO_2-rock interactions. Enrichments of constituents such as Fe, Mn, and Sr compared to pre-injection fluid concentrations have been shown to be indicative of mineral dissolution reactions occurring at depth during brine-CO_2-rock interactions (Emberly et al., 2005; Kharaka et al., 2006a; 2006b).

Monitoring of surface fluxes can also directly detect and measure leakage. Surface CO_2 fluxes may be measured directly with eddy covariance towers, flux accumulation chambers, and by techniques such as a field-portable, high-resolution infrared (IR) gas analyzers (Klusman, 2003; Miles et al., 2005; Lewicki et al., 2007; Lewicki et al., 2009; Spangler et al., 2010). A great deal of progress has been made to quantify detection levels, compare various surface monitoring approaches, and increase the number of options for monitoring CO_2 leakage at the surface (Spangler et al., 2010; Krevor et al., 2010).

13.4.5 Legal and Regulatory Issues for CO_2 Storage

There are a number of legal and regulatory issues that must be addressed before widespread deployment of CCS is adopted (IEA, 2007). If these issues are not addressed, they could become impediments to the deployment of CCS.

13.4.5.1 CCS Policy Context Related to Other Environmental Laws

From a regulatory and institutional perspective, any laws, regulations, and institutional changes that may affect CCS must be viewed within a larger regulatory framework. While not the emphasis here, it is important to note these other regulatory and legal requirements may impact CCS. For example, in the United States, these include, but are not limited to: Source Emission Regulations and Emerging Requirements; Clean Air Act after *Mass v. USEPA*; Tailoring Rule; USEPA policy guidance on BACT; USEPA GHG Reporting Rules; USEPA Conditional Exemption for CCS Under RCRA; DOT Regulations that May Impact Carbon Dioxide Pipelines; Safety (Department of Transportation); Siting (primarily state-based permitting); Rate Regulation; Safe Drinking Water Act under USEPA; and USEPA Underground Injection Control (UIC) Class II, V, and VI Rule (publication of Class VI rule will be specific to CCS). Solutions to the current institutional and legal issues facing CCS cannot be developed without considering the myriad of related laws and regulations and their intent.

13.4.5.2 CCS Regulatory and Legal Issues and their Current Status

The most pressing issues facing CCS include long-term stewardship and related liability concerns; pore space (subsurface) ownership; monitoring, measurement, and verification protocols for accounting purposes and health, safety, and environmental oversight; and regulatory oversight. These issues are discussed in turn below.

Long-Term Stewardship and Liability

Liability associated with long-term management and/or ownership of a carbon storage facility is of great concern to the private sector. Two

types of liabilities can be distinguished: the health and safety related liability of releases of CO_2 on the long term potentially harming people or ecosystems, and the climate-related liability of releases of CO_2on the long term, contributing to climate change. For most phases of any geologic storage project, the risks and attendant insurability of the project phases are well known. However, although many models and analyses conclude that the long-term probability, post-closure, of a significant release of gas is low and major existing projects have proven to be very effective in storing CO_2, the long timeframes associated with storage extend beyond existing institutional experience.

The rationale for a government role in addressing (and possibly indemnifying) long-term liability is due to the belief that CCS is in the public interest and that long-term liability issues should not, at this early stage in the development of the industry, be a barrier to further development. For example, in the case of the FutureGen project in the US, the acceptance of long-term liability became a competitive tool for Illinois and Texas and was deemed beneficial to those competing states.

CO_2 must remain underground for a long period – thousands of years and longer – to meet the goals of atmospheric climate change amelioration. This is well beyond the historic lifespan of companies and most governments. This will require institutional, administrative, and regulatory approaches for long-term stewardship to protect the public and to properly assess the efficacy of the removal of CO_2 from the atmosphere. As a result, the major barrier for industry and its supporting financial community to undertaking CCS projects is the undefined and open-ended liability for any CCS project. Any organization accepting liability will likely (without the development of institutional initiatives) be held responsible for the expenses of continuing monitoring and verification activities, any mitigation or remediation required, and compensation for any damages if leakage occurs.

One option is to create an industry-supported fund managed by the goverment. Such an approach is under discussion in the United States. For example, bills have been introduced in the US Congress that would establish a carbon storage stewardship trust fund financed by fees from operators to ensure compensation for potential damages. Long-term liability schemes have been adopted for other industries, including bond provisions by the UIC program, trust accounts funded through fees to operators that are administered by state or industry organizations such as the Acute Orphan Well Account, the Price-Anderson indemnity program that pools risk for the nuclear industry, and the National Flood Insurance Program.

The most common option is for government agencies to take on the long-term responsibility for CCS sites. This approach has been agreed to in the member states of the European Union, Australia and Norway. In addition, some states in the United States have adopted legislation to accept limited liability, but there has been little consistency in the time frames or agreement as to where the liability should ultimately reside. States, including oil-producing states like Texas and Louisiana and coal-producing states like Wyoming and Montana, have enacted laws relating to CCS development. There are some common elements in these statutes:

- state policy declaration that CO_2 is a valuable commodity and that CO_2 storage provides a public benefit by reducing GHG emissions;
- a fee-based structure to cover the state's responsibility for administering long-term monitoring and oversight of CO_2 injection and storage;
- post-closure monitoring by the drilling or reservoir operator for a period of 10 years or longer;
- a certificate of completion to be issued by a designated state or federal agency, following permanent closure; and
- in some cases, a transfer of the state's responsibility for long-term (post-closure) monitoring and verification to the federal government after a designated period of years (e.g., 10 years or longer).

There are examples of governmental support for accepting CCS liability for the long-term in other countries. These include the Norwegian government acceptance of long-term liability from Statoil for the Sleipner project. Australian federal and state governments jointly accepted long-term liability for the Gorgon facility. In 2009, the European Parliament issued Directive 2009/31/EC on the geological storage of CO_2. Provisions in this directive are similar to those issued by other governments; particularly that financial security must be established for the operations and an anticipated post-injection phase of a minimum of 30 years. Liability may be transferred to a "competent authority" after a minimum of 20 years. "Competent authority," however, is not defined.

In summary, liability and the related long-term stewardship issues are potentially the most significant impediments to creating a global CCS industry. While some governments have taken a number of tentative steps toward solving this problem, it is currently unclear how the issue will be successfully resolved.

13.4.5.3 Pore Space (Subsurface) Ownership Issue Status

Specifically in the United States, there are a number of legal issues surrounding pore space ownership. In some other parts of the world, this is not an issue as the deep pore space is not owned by private individuals but by government.

There are a number of legal issues surrounding pore space ownership in the United States. While there is some interest in applying the same subsurface rules currently used for CO_2 ownership when it is considered a commercially-recoverable resource, most pore space laws and regulations are much more complicated in terms of federal or state ownership, mineral rights, and other subsurface regulation (CIEE, 2010). These rules and requirements can become complicated, but the key issues can be simply stated as:

- Who owns the pore space and can authorize CO_2 storage in them?
- How are ownership rights between surface and subsurface resolved?
- When does plume migration constitute trespass?
- How can rights to pore space be aggregated to enable large-scale projects, particularly in saline aquifers?

The answer to these questions varies from country to country, as discussed in Section 13.6, "Regional Outlook." However, regardless of the approach taken by a country, these issues need to be resolved before large-scale deployment of CCS is likely. In some regions like Europe and China, the State is the owner of the pore space. In this case, the resolution of these issues is comparably simple. These laws and requirements are either poorly developed or not developed at all in emerging economies, as will be addressed in the following section. In other regions, like North America, the situation is quite different.

In the United States, there is a body of statutory and case law that provides guidelines to resolving any issues associated with injecting CO_2 into deep subsurface saline formations. Original case law suggested that mineral rights ownership was to "the center of the earth." However, recent case law suggests that the answer is not as clear. This is based on a number of CCS-analog court cases that have legal, as well as scientific and technological, precedent. This includes natural gas storage, hazardous waste injection (under UIC regulations), fresh water storage in aquifers, and EOR. Much of current case law addresses "trespass," or the migration of materials from injection sites to the subsurface areas whose rights are owned by someone else. In some cases, under common tort law, the verdict has been that these trespasses interfered with possible future use of the subsurface formation. Thus, fines and penalties were assessed. In other instances, seemingly for the same type of trespass, it was judicially determined that there were no damages to the subsurface formation and, therefore, no fines or damages were assessed. For cases involving EOR or fresh water storage, these are deemed to be in the public interest and no fines were assessed. In cases where there are no mineral rights owners for the pore space, ownership devolves to the state. It is clear that new, more straightforward, laws will need to be enacted to clarify ownership, operation in the public interest, and legal recourse for CCS. Some states, such as Montana, Wyoming, and North Dakota, have taken the initiative to develop laws that clarify pore space ownership and liability with respect to CCS. In particular, these laws must clarify CCS's impact on saline formations and how the state will chose to regulate these resources and operations.

13.4.5.4 Monitoring, Verification, and Accounting (MVA) Protocols

There has been considerable discussion of Monitoring, Verification, and Accounting (MVA) at international level and national levels. This work is driven by three major public concerns. First, monitoring needs to be established to ensure public health and safety are maintained and not compromised by CO_2 releases. Second, national emissions are reported using uniform and documented protocols. The IPCC (2006) developed guidelines for inventory verification that included how to treat CCS projects. Third, as laws emerge mandating emission reductions (e.g., carbon taxes, cap-and-trade legislation, and performance standards), there will be verification and accounting protocols that determine that the volume of CO_2 that an organization is taking credit for is, in fact, staying underground.

Many international and national agencies have focused on this issue and a considerable body of information has been developed. A recent summary of these activities has been developed as part of a supporting background document for the Carbon Capture and Storage Blue Ribbon Panel in California (CIEE, 2010). However, these findings and data need to be translated into laws. The legal requirements are to ensure that human health and safety and other living systems (flora and fauna) will be protected. Thus, MVA protocols will have two purposes. The primary purpose will be measurement to allow for the proper crediting of CO_2 that is sequestered. However, monitoring protocols must also be developed to ensure that public health, safety, and the environment are properly protected. This will lead to emissions requirements for CCS projects.

Most importantly, there must be protocols developed that will allow for crediting organizations that sequester CO_2. These protocols will have value to the organizations, as they can take credit for CO_2 removed from emission streams as a means for capturing financial credits, either through cap-and-trade rules (similar to current sulfur dioxide rules) or minimizing taxes under a tax system. Until CO_2 is regulated and treated as a commodity, there will be no reason to inject it into saline formations. To treat it as a commodity, rules and regulations need to be developed under international MVA guidelines that allow for the crediting of CO_2 removal from emission streams. Similarly, when CCS is deployed under the clean development mechanism (CDM), MVA protocols will be needed to ensure that expected emission reductions are in fact achieved.

13.4.5.5 Regulatory Oversight

All of the requirements for regulation will eventually fall on regulatory agencies for enforcement and verification. There are several issues facing these agencies at this time.

Laws covering CCS implementation on a large commercial scale are under development worldwide. In the United States, the most important law appears to be the Underground Injection Control (UIC) Law. The US Environmental Protection Agency has developed regulations under the UIC for underground injection of CO_2 for the purposes of long-term storage. However, additional focused legislation to appropriately regulate and validate CCS activities is likely to be required.

The second issue facing any developer of CCS projects is the overlapping authorities for many of the phases of operations that define a CCS project (Tsang et al., 2002). For example, a thorough analysis of either the lack of jurisdiction or the existence of overlapping authorities has been done in California (CIEE, 2010). As stated above, many of the rules and regulations that CCS projects must operate under have not been promulgated. However, as noted in Section 13.1, many projects will face multiple jurisdictions and legal requirements, each of which will have different metrics for permitting. The nature of this issue could cause a developer to not move forward on a project, simply because the timeline associated with obtaining all regulatory approvals from multiple state and federal agencies is too long from a financing perspective.

An additional issue is the capability of regulatory agencies to meet the needs of new types of industrial projects such as CCS. Most agencies are significantly understaffed. Further, the rapid scientific and technical changes require agency staff to be better equipped to address new regulatory requirements. In fact, most agencies are becoming less adept at keeping staff that can stay abreast of these changes. In countries without existing regulatory authorities, the situation is even more challenging, as the regulatory infrastructure will need to be established. These issues are addressed in the "Regional Outlook," Section 13.6.

An additional issue related to those described earlier in this section is the need to develop regulations and institutional requirements that can address some of the issues described in the previous subsections. Continued lack of clarity on pore space ownership and trespass, post-closure liability, the extent of long-term stewardship, and MMV precision and accuracy requirements will preclude any large-scale development until resolved.

13.4.5.6 Summary of Regulatory and Legal Issues

Currently, many international, federal, and state legislative bodies understand the nature of these issues and are trying to develop legislation that can allow CCS to move forward. It will be critical over the early part of this decade to see if institutional and regulatory solutions can be developed to address legal and regulatory issues. Failure to do so could have a bigger impact on CCS than issues of carbon dioxide capture costs and the low, but uncertain, risks associated with CCS.

13.4.6 Cost of Storage

Costs for geological CO_2 storage consist of four elements: site characterization costs; project capital costs (e.g., costs for surface equipment for each well, cost of drilling, costs of additional CO_2 compression if required); operating and maintenance (O&M) costs; and monitoring, verification, and closure costs. Site characterization costs are lower for storage in oil and gas formations (compared to saline formations and deep coal seams), since the main characterization of these types of fields has already occurred during their exploration. Site characterization costs will be dependent on the area of review (aerial extent of plume spread in CO_2), which will be determined by regulatory regimes in place (Rubin et al., 2007). Drilling costs are mainly dependent on the number of wells (including water production wells if necessary), the injectivity of the field, and the allowed overpressure. O&M costs for CO_2 injection are assumed to be comparable to the costs of water injection for secondary oil recovery (Bock et al., 2003; Rubin et al., 2007).

Storage costs vary depending on numerous factors, including type of reservoir, existing information/infrastructure for the site, onshore versus offshore storage, extent of monitoring, and regional factors. Cost estimates found in the literature are limited to capital and operational costs, and do not include potential costs associated with long-term liability. Table 13.3 shows an overview of these costs by field type. A first assessment of global investment needed for CO_2 storage alone, under a stabilization scenario of 450 ppmv, indicate a range between US_{2009}0.8–5.6 billion in 2020, and US_{2009}88–650 billion in 2050 (IEA, 2009).

Table 13.3 | Overview of indicative geological storage costs published in the literature. The figures represent average data; when available, ranges are provided between brackets. Data is presented in US_{2008}/tCO_2 stored.

	Ecless et al., 2009	Heddle et al., 2003	Hendriks et al., 2004	IEA, 2008	IPCC, 2005	Kober and Blesl, 2010	McKinsey, 2008	Ramírez et al., 2010
Depleted gas and oil fields		(2–24)[a]	(1–11)	(10–25)	(1–14)	(1–21)		(1–20)
-onshore			3 (1–5)		(1–14)	5 (1–21)	6	(1–9)
-offshore			8 (5–11)		(4–9)	6 (4–12)	16	(4–20)
Aquifer	(2–7)	(1–15)	(3–14)	(10–20)	(0.2–33)	(2–35)		>25
-onshore			4 (3–8)		(0.2–7)	3 (2–15)	7	
-offshore			9 (7–14)		(1–33)	6 (3–35)	18	

[a] average value for depleted gas fields is \$6/tCO_2 and for depleted oil fields \$5/tCO_2

Estimates of storage costs derived from current commercial-scale projects are in the order of US$11–17/tCO$_2$ (Sleipner); US$20/tCO$_2$ (Weyburn) and US$6/tCO$_2$ (In Salah) (ITFCCS, 2010). CO$_2$ storage costs for EOR projects could be offset by the revenues provided by the additional gas or oil produced. In these cases, storage costs are determined by the marginal value of oil, the underlying production costs, and the potential cost of supply of CO$_2$. Currently, the largest single cost component in EOR projects is the purchase of CO$_2$ (IPCC, 2005; Kuuskraa and Ferguson, 2008). CO$_2$ purchase prices found in the literature are in the order of US$38–49/tCO$_2$. The large variability in the economics of EOR makes it difficult to provide representative levelized annual costs of CO$_2$ stored, and therefore large cost ranges are reported in the literature. For instance, Haddle et al. (2003) reported a range of –91–74 US$_{2008}$/tCO$_2$, while Hendriks et al. (2004) reported a range of –12–24 US$_{2008}$/tCO$_2$.

13.4.7 CO$_2$ Storage Conclusions

Storage in deep underground formations is the most mature storage option because it uses technology developed from over a century of oil and gas exploration and production. Ocean storage has also been studied; however, due to lack of permanence and potential environmental impacts, ocean storage is not being considered at this time. Stimulating the primary productivity of the oceans by adding trace nutrients (e.g., iron), so-called ocean fertilization, has also been proposed as a means of extracting CO$_2$ from the atmosphere. The long-term effectiveness of this method of removing CO$_2$ from the atmosphere is uncertain. Impacts to ocean ecosystems are unknown and potentially large.

Cumulative learning from over 30 years of experience is available from five active storage projects. Deep underground formations suitable for CO$_2$ storage are located in sedimentary basins and include depleted or depleting oil and gas fields, saline aquifers, and deep, unminable coalbeds. Other options for geological storage, such as storage in volcanic rocks, which rely on in situ mineralization for long-term storage, may be developed over time. Rapid in situ mineralization, a comparatively new idea, is the subject of fundamental research investigations that will take many years to mature. Ocean bottom sediments in very deep and cold water may provide an attractive option for emission sources near coasts or where other options are not available. However, this approach has not been tested and considerable research and demonstration will be needed before this option becomes available.

The permanence of storage in deep geological formations in sedimentary basins will depend on a number of factors, the most important one being the presence of a high-quality seal at the top of the storage reservoir. A very high degree of permanence (defined as retention of greater than 99% of the injected CO$_2$ over a period of 1000 years) is likely for sites that have good seals, are characterized and selected carefully, are operated to stay within a safety envelop to protect the seal and prevent well leakage, and are routinely monitored and regulated to ensure due diligence in all of the aforementioned activities.

The biggest health, safety, and environmental risks from geological storage are groundwater pollution, short-duration well failures, and leakage through undetected faults or fractures in the reservoir seal. These risks should be manageable, as they are similar to the risks that are routinely managed in the oil and gas industry. Some failures are, however, to be expected, especially in the early projects as experience in geological storage is growing. Worst-case environment, health, and safety impacts are likely to be less than the worst case accidents that occur in the oil and gas exploration and production industry because CO$_2$ is not explosive and it does not accumulate in ecosystems like oil does.

The cost of storage is highly variable, depending on the location of the project, the number of wells needed, whether the project is onshore or offshore, and if the project is in a hydrocarbon reservoir or saline aquifer. Costs from three of the existing projects are in the range of US$6–20/tCO$_2$.

13.5 Energy Systems Synergies and Tradeoffs Influencing CCS Deployment

13.5.1 Life Cycle Analysis of CCS

Life Cycle Assessment (LCA) is one of the most frequently used tools for evaluating the potential environmental impact of products and materials, since it allows upstream and downstream elements to be included in the analysis. For CCS, this implies that besides CO$_2$ capture, CO$_2$ transport, and CO$_2$ storage, the acquisition of the fuel (e.g., coal mining), its transport, and the materials and energy required for the capital equipment and the infrastructure throughout the complete chain are also included.

The most common categories examined in LCA-CCS studies are global warming potential (GWP), increase energy use, acidification potential, and eutrophication. Impact categories such as land use, habitat alteration, impacts on biodiversity, human toxicity and ecotoxicity, and photo-oxidant formation are not addressed by most studies. This, however, is not a unique feature for LCAs of CCS systems. It has already been reported that these impact categories are not (formally) addressed by most published LCAs and due to significant data gaps (e.g., Finnveden, 2000).

A comparison of key results recently published for different CCS technologies is shown in Table 13.4. The results indicate that CCS decreases the global warming potential (GWP) of fossil fuel-fired power plants by 65–85% depending on the technology selected. Indirect emissions are responsible for between 15–46% of the GWP and are mainly originated

Table 13.4 | Key results of selected LCAs for CCS chains.

1: In this study the authors compare an average PC plant of 2005 with a PC using best available technologies (BAT) and a PC with post combustion capture.
2: In this study, two other solvents were analyzed besides MEA: a hindered amine (KS-1) and a promoted potassium carbonate (K^+/PZ).

in the fuel supply chain. Contributions due to capital equipment and infrastructure are estimated to be below 5%. Due to the energy penalty induced by CO_2 capture, there is a relative increase in total primary energy demand in the order of 20–40%, with up and down streams accounting for 15–30% of this increase. Impacts on the acidification and eutrophication potentials differ and are highly dependent on the type of technology examined. Gas and oxyfuel concepts tend to show better performances than coal-based systems, especially post-combustion concepts. However, the type of solvent selected appears as the main determinant on the environmental performance of post-combustion capture.

13.5.2 Potential Impacts of CCS on Reducing Vehicle Emissions (See also Chapter 12.4)

Several studies have been undertaken on well-to-wheels emissions of GHGs from vehicles (see Chapter 12). The IEA Greenhouse Gas R&D Programme undertook a study to assess the addition of CCS to transport fuel production, which was based on a well-to-wheels study undertaken by JEC, CONCAWE, and EUCAR (IEA GHG, 2005). The costs and CO_2-eq emissions of various transport fuel options are summarized in Table 13.5. The base case for calculation of the costs of GHG abatement is a typical European car, such as a Volkswagen Golf, with a gasoline port injection spark ignition engine (PISI). A study looking at just hydrogen options undertaken by the European HySociety project (Mulder et al., 2007) resulted in somewhat more optimistic results for CCS.

Production of Fischer-Tropsch (F-T) diesel and dimethyl ether (DME) from natural gas with CCS results in modest (22–31%) reductions in emissions compared to the gasoline base case. The percentage emissions reduction from the use of hydrogen produced from fossil fuels with CCS is 60–78%, depending on whether the fuel is coal or natural and whether fuel cells or an IC engine is used. Without CCS, some of the hydrogen production options would have emissions greater than the reference case. The fossil-fuel electricity cases with CCS result in the greatest emissions reduction (79–88%). The biomass-based cases result in negative net emissions, assuming the biomass is produced from sustainable sources, but the results should be viewed cautiously due to a

Table 13.5 | Potential impacts of CCS on reducing vehicle emissions

Pathway, Fuel	Vehicle	Emissions gCO_2-eq/km (mean)	Avoided cost relative to the gasoline base case €/tCO_2 avoided
Gasoline (base case)	PISI	165	0

whole range of factors, from indirect land use change to differing engine efficiencies with biofuels.

The costs of CO_2 abatement are in all cases substantially greater than the costs of abatement by use of CCS in fossil fuel power generation. For the cases where there are comparable data, the use of CCS reduces the overall costs per tCO_2 abated. The costs depend strongly on plant construction costs and fuel prices, which have been highly volatile in recent times, and in some cases the costs of technologies that have not yet been widely used, such as fuel cells and hydrogen storage in vehicles.

13.6 Regional Outlook for CCS

13.6.1 Methodology

This section discusses in four parts the activities in various regions in the field of CCS. Technical potential and source-sink matching comprise the presence of CO_2 sources amenable to capture, what is known about the storage capacity, and its proximity to CO_2 sources. The local aspects of economic viability of CCS in the region will be discussed under the section on factors influencing regional CCS costs. The economic activities that relate to CCS, such as oil and gas operations, related human capacity and education, and CCS-related R&D in the region, are addressed in the third part. Fourth, the developments related to legislation and policy are discussed. Last, there is a general discussion of politics and, where data is available, public perception.

13.6.2 Europe

13.6.2.1 Technical Potential and Source-Sink Matching

From 2006–2009, a Europe-wide consortium of research institutes conducted a geological storage capacity estimate and mapped CO_2 point sources and prospective storage reservoirs over the 27 Member States, Norway, and several states in former Yugoslavia and the Balkans (Geocapacity, 2009). An overall estimate of prospective reservoirs yielded 360 $GtCO_2$ storage capacity, the majority in saline aquifers, and more than half in saline aquifers off the coast of Norway. Much of

this storage capacity may not have trapping structures, making storage integrity less certain (see the discussion in Section 13.4.2.2). A more conservative estimate yields a storage potential of 96 $GtCO_2$ in saline aquifers, around 20 Gt in hydrocarbon reservoirs and another one Gt in coalbeds all over Europe.

In 2008, the European Union emitted 4.9 $GtCO_2$-eq, of which around 2.6 $GtCO_2$ are stationary CO_2 sources that could be amenable to capture, and 1.3 $GtCO_2$ is electricity production. The sources of CO_2 are widely distributed over Europe, although there is a concentration in the German Ruhr area, the Netherlands, the United Kingdom, and southern Poland (Geocapacity, 2009).

13.6.2.2 Factors Influencing Regional CCS Costs

Costs of CCS are built from capture and compression, transport, and storage costs. Capture and compression costs can be affected by the type of CO_2 sources – if there is a significant amount of high-purity, storage-ready CO_2 sources, capture costs can be kept low. If transport distances can be kept short and in sparsely populated, flat areas, this positively affects the transport costs. And if storage can be done in EOR, or in onshore fields where injection facilities are still usable, this reduces CCS costs as well. Other indirect factors that impact the siting, and therefore the costs, of CCS operations include population density and public perception, types of industrial activities, and access to resources.

In terms of the cost curve for CCS in Europe, there are a number of relevant factors. First, much of the storage potential in Europe seems to be located offshore and in saline aquifers. Therefore, storage costs may be higher, as saline aquifers are often not characterized well and offshore drilling adds to the costs. Second, the population and industrial density as well as the landscape in much of Europe make transport a relatively costly matter. Third, with relatively high consumer electricity prices, the cost increase of CCS compared to current electricity prices are relatively low compared to other countries: incremental cost of CCS for a typical residential consumer is estimated to be about 20%.

13.6.2.3 Technical and Human Capacity

Most countries in Europe are developed countries with a highly educated workforce. Several European countries have a significant oil and gas industry, with ensuing human and technical capacity on the underground. Many universities and research institutes in Europe conduct research and education related to various technical, economic, and social aspects of CCS. Although the capacity in Europe is considered high, in order to enable broad application of CCS, a larger base of CCS experts and practitioners will need to be developed over the years to come.

In terms of R&D, the European Union indicates that through 2009, €115 million was spent on CCS-related R&D activities through its major program.[3] In addition, member states invest significant sums in CCS R&D; the Netherlands, for example, has since 2003 spent and planned roughly €50 million on CCS research, which was matched by industry.[4] The Zero Emissions Platform (ZEP), a European platform for stakeholders of CCS, indicates that its industry members' investment in CCS-related R&D have amounted €635 million over 2003–2008.[5]

13.6.2.4 CCS Legal and Policy Initiatives

In December 2008, the European Parliament passed the "Climate and Energy package," a collection of new EU Directives including a commitment for the European Union to, by 2020, reduce GHG emission by 20% compared to 1990, use 20% renewable energy, and improve energy efficiency by 2% annually. Part of the package was legislation to enable CCS in the European Union. It consisted of a "Directive on geological CO_2 storage" and a series of modifications to other Directives that took away obstacles to CCS in, for instance, directives on landfills and on large combustion plants.[6] The geological storage directive outlines the legal conditions that any CO_2 storage project has to meet. The provisions are further detailed and implemented by the Member States.

The Climate and Energy package also modified the directive regulating the EU Emissions Trading Scheme (ETS), providing a carbon price incentive for CCS projects. However, due to various factors, carbon prices, steady at around $US_{2010}$$14.64 halfway through 2010, remained too low to enable CCS (Sijm, 2009). In addition to the inclusion in the ETS, the European Union decided to reserve 300 million emission allowances, corresponding to the value of 300 million not emitted tCO2, from the "New Entrants Reserve" for demonstration of innovative energy technologies, which is widely considered to go mainly to CCS demonstration. In 2009, the European Union decided to grant around €1 billion to six demonstration projects as part of its economic recovery package in response to the 2009 economic crisis. Later, it was decided in addition to the economic recovery package to make available 300 million emission allowances from the New Entrants Reserve in the EU Emissions Trading Scheme for demonstration of innovative renewable and CCS projects. At a price of roughly 10 EUR/tCO2, this amounts to another EUR 3 billion in total. Combined, the EU hopes to enable up to 12 large-scale demonstrations of CCS by 2015. Most of these demonstrations are expected to be in the power sector, but some are intended to take place in industry.

3 CCS EII Implementation Plan 2010–2012. ec.europa.eu/energy/technology/initiatives/doc/ccs_implementation_plan_final.pdf.

4 www.co2-cato.nl/cato-2/program-overview.

5 CCS EII Implementation Plan, 2010. See ec.europa.eu/energy/technology/initiatives/doc/ccs_implementation_plan_final.pdf. It is unclear what is included in this number; it may include investments of European companies in CCS projects elsewhere, for instance BP's investment in the In Salah project.

6 Directive 2009/31/EC on the geological storage of carbon dioxide: eur-lex.europa.eu/LexUriServ/LexUriServ.do?uri=OJ:L:2009:140:0114:0135:EN:PDF.

13.6.2.5 Discussion of CCS in the European Union

CCS is considered a political reality in the European Union. Many policy documents indicate the importance of the option to achieving the European Union's ambitious climate goals and steps have been undertaken to stimulate demonstration of CCS, establish a legal framework, and develop human and business capacity and knowledge. On the other hand, CCS in Europe experiences some of the strongest resistance. Although several environmental organizations support or tolerate CCS, others are vehemently opposed. In addition, companies and governments in Denmark, Germany, and the Netherlands have experienced strong public opposition to CCS demonstration projects by local inhabitants resulting in the cancellation of several projects.

CCS is not expected to become a reality all over the continent. R&D and policy activities are concentrated in a few active countries, including Norway, the Netherlands, Germany, Denmark, and the United Kingdom. Those countries are characterized by a strong fossil fuel tradition, high industrialization levels, a coastline on the prospective North Sea, a relatively high per capita national income, and a relatively well-developed environmental awareness. In addition, countries like France, Poland, Italy, and Spain have shown interest and have worked on the option. But CCS is not considered to be an option in countries with low storage potential, a small fossil fuel industry, and low incomes.

13.6.3 North America

13.6.3.1 Technical Potential and Source-Sink Matching

In 2008, the CO_2 emissions in the United States and Canada reached 5921.2 and 574 Mt, respectively. The Regional Carbon Sequestration Partnerships (RCSP), initiated by the US Department of Energy (US DOE), have been leading the efforts to determine the most suitable technologies, regulations, and infrastructure needed for CCS in different areas in North America. The *2010 Carbon Sequestration Atlas of the United States and Canada,* released by the US DOE and National Energy Technology Lab (NETL, 2010a), provides information about the currently estimated CO_2 emissions in 42 US states and four Canadian provinces, divided into the seven main partnership regions. The Atlas documents more than 4700 stationary CO_2 sources with total annual emissions of over 3200 Mt. Most of these emissions come from power generation (83%), followed by refining and chemical processes (6%), industrial processes (4%), petroleum and natural gas processing (3%), cement production (3%), and ethanol plants (1%) (NETL, 2010a).

Significant storage capacity has been documented in depleted and depleting oil and gas reservoirs, saline aquifers, and unminable coal seams throughout the seven partnership regions. The RCSPs document the location of almost 143 Gt of geologic CO_2 storage potential in 9667 oil and gas reservoirs distributed over 27 American states and three Canadian provinces. Similarly, the CO_2 geologic storage potential in unminable coal seams is estimated at 187–217 Gt, distributed over 24 states and three provinces. Finally, 3600–13,000 Gt is the estimated CO_2 storage potential in saline formations. The capacity estimation range in the case of coal seams and saline aquifers is primarily due to the uncertainty inherent in the calculation methodology (NETL, 2010a).

The National Carbon Explorer (NATCARB) is another initiative by the US DOE that aims to link CO_2 geological storage and emissions sites databases across several regional centers. NATCARB interactive maps show close proximity between CO_2 sources and sinks throughout North America where many CO_2 sources are located on or near CO_2 storage sites. Nevertheless, exceptions exist and source-sink matching is not very good, including parts of the US upper mid-west and northeast.

13.6.3.2 Technological Maturity

North America is among the leading regions in CCS activities. Today, many pilot projects exist, and commercial-scale projects are in the early stages of planning, the majority of which are in the United States. This includes pre-combustion, post-combustion, and oxy-combustion capture facilities, as well as geologic storage projects at the R&D, demonstration, and industrial/commercial scales (BRGM, 2009). In addition to CCS-related endeavors, a well-developed CO_2 infrastructure exists in North America, which facilitates the early deployment and testing of CCS. In this regard, EOR through CO_2 injection (CO_2-EOR) is implemented widely in the United States and Canada. The 2008 World EOR Survey issued by the Oil and Gas Journal lists 100 ongoing CO_2-EOR projects in the United States and seven projects in Canada (Koottungal, 2008).

13.6.3.3 Factors Influencing Regional CCS Costs

As mentioned before, the geographical distribution of sources and sinks plays a major role in determining the economic competitiveness and feasibility of CCS deployment. To start, most of the currently implemented and proposed CCS-related projects in North America are onshore, and, as noted previously, many CO_2 point sources are located either on or close to potential geologic storage formations. Both factors favor economic implementation of CCS. Equally important, both the United States and Canada have conducted several studies to investigate the effect of population density, environmental factors, and topography on the cost of CCS implementation. In 2010, NETL published *Site Screening, Selection, and Initial Characterization for Storage of CO_2 in Deep Geologic Formations*, which aims to provide a framework and an overview of processes for selecting suitable sites for geologic storage. The proposed framework discusses several aspects related to site screening, site selection, and initial characterization. Among other important topics, the document investigates the effect of protected and sensitive areas (wetlands, source water protection areas, protected areas, and protected species); population centers; existing resources development; and pipeline right-of-way on the feasibility of CCS deployment (NETL, 2010b). Similarly, *Carbon*

Dioxide Capture and Storage: A Compendium of Canada's Participation (Natural Resources Canada, 2006) lists several studies and R&D projects that aim to optimize the economic aspects of CO_2 transportation network and infrastructure design, including: *Optimisation of integrated CO_2 capture, transportation, and storage in Canada (Waterloo),* and *Integrated economic model for CO_2 capture and storage (ARC and others).*

In 2009, more than 80% of US energy use was fossil fuel based, and almost 60% was from oil and coal (US EIA, 2010a). Similarly, more than 77% of Canada's energy use in 2008 was fossil fuel based. As of 2010, Canada's oil reserves are the second largest in the world after Saudi Arabia, and a significant portion of these reserves is unconventional CO_2-intensive oil shale (US EIA, 2009). As such, both countries are highly dependent on fossil fuels, which, in the absence of earlier, cheaper, low-carbon alternatives, improves the economic attractiveness of CCS as an effective climate change mitigation option.

13.6.3.4 Human Capacity, Research and Development

Several governmental agencies, academic institutes, and industrial/commercial businesses in the United States and Canada are actively involved in CCS and are conducting CCS-related R&D locally and internationally. In the United States, the Department of Energy, specifically the Office of Fossil Energy (FE) and NETL, are guiding local and international research initiatives on CO_2 geologic sequestration. FE/NETL is directly supporting more than 75 research projects across the United States and internationally. The CCS R&D network database of the Global CCS Institute (GCCSI) shows that a total of 209 organizations in the United States are involved in CCS R&D, the majority of which is related to CCS technologies (GCCSI, 2011b). Canada is actively involved in CCS R&D through 25 CCS research centers (including eight universities with substantial engagement); 23 companies that are developing, testing, using, or analyzing the effects of CCS technologies; and 13 governmental programs supporting CCS projects. In that regard, 59 CCS-related projects in Canada are led by universities, 42 are led by government research agencies (including provincial research organizations), 23 are led by industry (a category that includes any for-profit company) and two are led by nongovernment organizations (Natural Resources Canada, 2006). Similar to the United States, the CCS R&D network database of the GCCSI shows that a total of 58 organizations in Canada are involved in CCS R&D, the majority of which is related to CCS technologies (GCCSI, 2011b).

In addition, the United States and Canada take part in international collaboration on CCS. Both countries are members of the Carbon Sequestration Leadership Forum (CSLF), GCCSI, and the *IEA Greenhouse Gas* R&D Programme (IEAGHG). Both countries are also engaged in bilateral and multilateral agreements promoting CCS, including the US-China Fossil Energy Cooperation Protocol; the National Energy Technology Laboratory-Korea Institute of Energy Research Memorandum of Understanding (Smouse, 2007) the CO_2 Capture Project; and Weyburn-Midale Monitoring Organizations (Natural Resources Canada, 2006). All aforementioned research endeavors, as well as the pilot CCS projects and the well-developed industrial and energy infrastructure discussed in the section above, contribute significantly to building a skilled human capital that is competently educated about CCS and would be expected to play a major role in advancing this technology. In that regard, both the United States and Canada are also investing in developing, supporting, and initiating educational opportunities (conferences, workshops, publications) that guide various stakeholders on how to engage the public and raise awareness and support for CCS-related activities. (Natural Resources Canada, 2006; The ECO ENERGY Carbon Capture and Storage Task Force, 2008; US DOE/NETL, 2009b).

13.6.3.5 CCS Legal and Policy Initiatives

Several regulatory frameworks contribute to the deployment of CCS. Regulations governing the deployment of CCS-related activities have been proposed and are currently considered in both the United States and Canada. In July 2008, the US EPA published the Federal Requirements under the Underground Injection Control (UIC) Program for Carbon Dioxide (CO_2) Geologic Sequestration (GS) Wells Proposed Rule. This proposal, which applies to owners or operators of CO_2 injection wells, establishes a new class of wells, as well as minimum technical criteria for the geologic site characterization, fluid movement, area of review and corrective action, well construction, operation, mechanical integrity testing, monitoring, well plugging, post-injection site care, and site closure, to ultimately protect underground sources of drinking water (USEPA, 2010). More recently, in March 2010, a bill titled the Carbon Capture and Sequestration Deployment Act of 2010 was introduced in the US Congress. The bill aims to "provide financial incentives and a regulatory framework to facilitate the development and early deployment of CCS technologies, and for other purposes. (IIIth US Congress, 2010)" On the other hand, even though no comprehensive national legislation specifically addressing CCS has been proposed yet in Canada, several of the Canadian CCS activities are adequately regulated under the oil and gas legislation (IEA, 2010b). In 2009, the Government of Alberta introduced the Carbon Capture and Storage Funding Act, which aims to "encourage and expedite the design, construction and operation of carbon capture and storage projects in Alberta." (Province of Alberta, 2009a).

In March 2012 the EPA issued the first Clean Air Act performance standand for carbon pollution from future power plants (epa.gov/carbonpollutionstandanrd). The Standard limits emissions to 1000 lbs CO_2/MWh (454.4 kg CO_2/MWh), which is about one-half of the typical emissions from a coal-fired power plant and about equal to typical emissions from a combined cycle natural gas power plant. The Standard applies to all power plants that will be constructed beginning 12 months hence. In the short term this will encourage the deployment of natural gas power generation over coal-fired generation. Over the long run, if natural gas power generation over coal-fired generation. Over the long run, if natural gas prices rise above the level where coal generation plus 50% CCS is economically competitive, the Standard will encourage the deployment of CCS.

These CCS-specific legal frameworks are part of both countries' efforts to manage carbon emissions, and in their national policies that promote CCS as a major contributor to climate change mitigation. While there is no nationwide commitment to reduce emissions in the United States, both the American Power Act (2010) and the American Clean Energy and Security Act (2009) propose forming a nationwide cap-and-trade program and creating other incentives and standards for increasing energy efficiency and low-carbon energy use (US EPA, 2010). In Canada, even though no national legislative framework addressing CO_2 emissions reduction has been officially proposed, get several provinces have adopted legislation that tax or cap CO_2 emissions. In 2003, Alberta introduced the Climate Change and Emissions Management Act, requiring companies to reduce the intensity of their GHG emissions by 12% and providing funding for CCS-relates activities (Province of Alberta, 2009b). Ontario introduced regulations for a cap and trade system in 2009. Similarly, in 2009, Quebec introduced a bill that provides a framework for a provincial GHG emissions cap-and-trade scheme (Quebec National Assembly, 2009), and British Columbia introduced a carbon tax in 2008 (Legislative Assembly of British Columbia, 2008).

Another important legislative aspect that affects the deployment of CCS is subsurface resources ownership and mineral rights. In the United States, no national legislation exists to regulate subsurface and pore space ownership, especially for the purpose of CO_2 geologic storage. Nevertheless, taking into account that property rights are generally regulated at the state rather than the federal level, some states have taken the initiative to address the issue of pore space ownership. In 2008, Wyoming enacted legislation that gives the ownership of subsurface pore space in the state to the owners of the surface (Duncan et al., 2009). In Canada, no specific legislation regulates subsurface rights and pore space ownership. Nevertheless, the Canadian Mineral Resources Act gives the Crown (and thus the federal government) ownership over "all minerals existing or which may be found within, upon or under lands in the province. (Government Canada, 2009)."

Equally important, both the United States and Canada have devoted large amounts of federal funds to promote the deployment of CCS. In 2009, the United States announced US$2.4 billion funding for CCS projects (USDOE, 2008). Similarly, Canada committed to more than US_{2009}48 million funding for CCS R&D initiatives and around US_{2009}2 billion for large-scale demonstrations. Here is it important to note that the Government of Alberta announced a US_{2010}1.9 billion fund to encourage the large-scale deployment of CCS (Mourits, 2009). Along with budget allocations, both countries have taken the effort to raise public awareness and analyze the community's perspectives on CCS through focus groups and interviews. In the US, some studies found that factors such as past experience with government, existing low socioeconomic status, desire for compensation, and/or perceived benefit to the community contribute to shaping, along with the risks associated with CCS technology, the public opinion on CCS deployment (Bradbury et al., 2009). In Canada, several studies have been conducted and several initiatives have been taken to enhance public engagement in discussions about CCS deployment in Canada (Natural Resources Canada, 2006).

13.6.4 China

13.6.4.1 Technical Potential and Source-Sink Matching

In 2007, China ranked first in global CO_2 emissions with 6538 Mt (IEA, 2008a). Electricity and heat production, as well as industrial manufacturing, contribute to the majority of these emissions, followed by residential use, transportation, and others. In 2000, the IEA estimated China's CO_2 emissions from stationary sources to be almost 3000 Mt, projected to increase up to 4600 Mt in 2010. The power sector contributes more than 90% of stationary CO_2 emissions, and 73% of these emissions come from coal-fired power stations. In 2005, the six largest CO_2 point sources existed in China, all of which are power stations emitting a total of 227 $MtCO_2$ annually. Other CO_2 point sources include iron, steel, ammonia, cement, ethylene, and ethylene oxide facilities as well as refineries. Until 2005, 77 pure CO_2 sources existed in China, forming attractive early opportunities for low-cost CO_2 capture (APEC, 2005).

Significant storage capacity has been documented in depleted and depleting oil and gas reservoirs, saline aquifers, and unminable coal seams. The *CO_2 Storage Prospectivity of Selected Sedimentary Basins in the Region of China and South East Asia* report, issued by Asia Pacific Economic Cooperation in 2005, identifies several potential storage basins with high, intermediate, and low prospectivity (APEC, 2005). An overall storage capacity of 1445 $GtCO_2$ has been reported in China by APEC, and more recent investigations indicate the capacity may be as high as 3080 $GtCO_2$ (Dahowski et al., 2009). In more detailed studies, depleted and depleting oil and gas fields storage potential has been estimated to be 9.7–21 Gt, which makes it a short-term sink for a small fraction of China's CO_2 emissions from stationary sources (approximately 3–7 years of storage capacity based on 2007 emissions level) (Wang, 2010). Geological storage potential in unmineable coal seams is estimated to be approximately 10 $GtCO_2$, including 4 $GtCO_2$ in Ordos, 2 $GtCO_2$ in Turpankumul, and more than 1 $GtCO_2$ in Dzungaria (Wang, 2010). In fact, one study reports that CO_2 storage capacity by enhanced coalbed methane (ECBM) can be up to 12.08 $GtCO_2$ (Petra China Company Limited, 2007). Finally, 110–360 $GtCO_2$ is the estimated CO_2 storage potential in saline formations (Wang, 2010; 240, 2008). A more recent assessment suggests there is a capacity of about 3080 $GtCO_2$ in China, with all but 780 $GtCO_2$ available on shore (Dahowski et al., 2009).

The aforementioned APEC report shows that most large CO_2 point sources (10–55Mt/yr) are located either on or close to high- and intermediate-prospectivity storage basins. Thus, the distribution of major CO_2 stationary point sources and analyzed storage basins throughout China shows reasonable proximity between sources and sinks and some potential for source-sink matching.

13.6.4.2 Technological Maturity

China continues to develop the technological infrastructure required for CCS deployment. The NETL reports eight CCS projects in the country, many

of which are currently active. This includes pre-combustion capture, EOR, and ECBM, at the R&D, demonstration, and industrial/commercial scales (Wang, 2010; BRGN, 2009). In this regard, CO_2-EOR is being actively developed, and more than 10 pilot projects have been implemented. In addition to increasing oil production, some of these projects aim to test permanent storage of injected CO_2, such as the Research on Exploitation of Natural Gas with Higher CO_2 Concentration, CO_2 Storage and Comprehensive Utilization of Resources in Jilin Oil Field project, which was initiated in August 2007. This rapid development of pilot projects enhances China's capability of early deployment and testing of CCS (Luo, 2008).

According to the US Energy Information Administration (US EIA), China's total oil and gas production in 2007 reached 192.2 t/yr (4.0 million bbl/day) and 69.2 billion m^3/yr (2,446 bcf), respectively. Since 1987, oil production and consumption in China increased by almost 25% and 350%, respectively, and both gas production and consumption increased by almost 500% (US EIA, 2010b). As such, it would be reasonable to argue that China's experience in oil and gas exploration and production and rapidly developing energy infrastructure help in the early deployment of CCS.

13.6.4.3 Factors Influencing Regional CCS Costs

As mentioned before, many of the currently proposed CO_2 storage sinks in China are onshore, and many CO_2 point sources are located either on or close to potential geologic storage formations (APEC, 2005). Both factors favor economic implementation of CCS. Nevertheless, even though several CCS pilot projects are currently implemented, the design and layout of the potential CO_2 infrastructure and transportation network in the country are not fully investigated yet. Accordingly, little information exists on the effect of population density, landscape topography, and environmental factors on the construction of the CCS infrastructure.

Still, China's significant dependence on coal in fueling its economy and energy sector favors the country's adoption of CCS as an economically attractive option to reduce CO_2 emissions. According to the IEA *World Energy Outlook* in 2007, coal accounts for approximately two-thirds of China's energy needs, 80% of its electricity fuel mix, 50% of its industrial fuel use, and 60% of its chemical fuel use. In addition, oil and coal account for 81.6% of the country's overall energy demand in 2005; renewable energy (including nuclear) accounts for less that 14% of the energy demand. In terms of future projections of energy use, China generated around 622 GW of electricity in 2006, with additional installed capacity of 100 GW since 2005. Over 90% of this capacity increase was coal-fired. By 2030, the electricity generation capacity is expected to increase up to 1755 GW, Taking into account that China's domestic coal reserves are the second largest in the world, and given the coal's relatively low price, some studies suggest that even with strong policy incentives for energy efficiency, renewables, and other low carbon technologies, coal will remain a major contributor to China's energy fuel mix for the coming two decades. Thus, CCS is expected to be a major, option for reducing China's CO_2 emissions as part of its efforts to combat climate change (FIndlay et al., 2009).

13.6.4.4 Human Capacity, Research and Development

Several Chinese governmental agencies, academic institutes, and industrial/commercial businesses are actively involved in many aspects of CCS both locally and internationally. CCS-related research initiatives have been authorized, initiated, and supported by governmental agencies, including: Research for Utilizing Greenhouse Gas as Resource in EOR and Storing It Underground (Project 973), supported by the Major State Basic Research Development Program of the People's Republic of China, and Carbon Capture and Storage Techniques (Project 863), supported by the National High Technology Research and Development Program of China (Wang 2010). In addition, many aspects of the CCS technology are investigated by Chinese academic institutions, including: CO_2 absorption, CO_2 adsorption, membrane separation, membrane adsorption, CO_2 storage, and others (Wang, 2010). China National Offshore Oil Corporation and PetroChina are also active participants in CCS research (Wang 2010). China National Offshore Oil Corporation supports a project investigating the utilization techniques of CO_2 on large-scale. PetroChina is involved in several projects promoting CCS, including: the aforementioned Project 973, Pilot Test of CO_2 EOR and Storage in Jilin Oil Field, and Research on Phase Theory of Multiphase and Multi-component during CO_2 Flooding Process (Shen and Jiang, n.d.) In this regard, the CCS R&D network database of GCCSI shows that a total of 18 organizations in China are involved in CCS R&D, the majority of which is related to CCS technologies (GCCSI, 2011b).

In addition to the local efforts, China is actively engaging in international collaboration on CCS initiatives. For example, China is a member of the Carbon Sequestration Leadership Forum (CSLF), GCCSI, and the Asia Pacific Partnership on Clean Development and Climate Change. In addition, China is collaborating with the European Union through the Cooperation Action within CCS China-EU, Geo-Capacity, and Support to Regulatory Activities for Carbon Capture and Storage. Similar collaboration efforts exist between China and the United Kingdom through Near Zero Emissions Coal, Australia through the China-Australia Geological Storage, and the United States through some projects supported by the US EPA (Findlay et al., 2009). All aforementioned research efforts, as well as the vigorously developing energy sector, discussed in the section above, contribute to building a competently educated human capital that would be expected to play a major role in advancing CCS development. In that regard, China have both hosted and participated in several conferences and workshops that educate and train on CCS topics and guide various stakeholders on how to engage the public in CCS activities.

13.6.4.5 CCS Legal and Policy Initiatives

Although no specific mandates currently exist to regulate CCS activities in the country, China's national policies promote CCS as a major climate change mitigation option. *China's National Climate Change Programme* report, issued in 2007 by the National Development and Research Commission, states that strengthening the development of advanced and suitable technologies such as carbon dioxide capture, utilization,

and storage is one key area to combat climate change (CNDRC, 2007). However, China Roundtable Meeting Notes from the IEA CCS Roadmap shows that the CCS profile in the Chinese climate and energy policy is currently low, due to its high cost and perceived status as an emerging option for GHG mitigation that requires more R&D (OECD/IEA, 2009). In terms of subsurface resources, pore-space ownership, and mineral rights, the Chinese constitution and the Mineral Resources Law of China explicitly state that the "mineral resources are owned by the state." The State Council exercises the state ownership over the mineral resources. In 1996, the National Mineral Resources Commission was established to strengthen the central government's control over mineral resources and protect its mineral rights (Chinese Government, 2003).

Another important aspect affecting the deployment of CCS is governmental funding. Currently, only a modest funding is provided by the Chinese Ministry of Science and Technology on CCS R&D. The government is not providing support to CCS due to its high cost and energy penalty. In that regard, some suggest that it would be valuable to develop a roadmap for China's development of CCS, which would particularly focus on early opportunities for profitable CO_2-EOR and explain the costs and benefits of a progressive expansion of the Chinese CCS industry from early demonstration. In addition, the Chinese government can be expected to increase expenditure on CCS if international funding resources become available (OECD/IEA, 2009). Still, money alone cannot ensure a wide deployment of CCS; public support is an essential element too. Some studies have been conducted to raise public awareness and analyze the community's perspectives on carbon capture and storage. The results showed that the awareness of CCS was low among the surveyed public in China, compared to other clean and renewable energy options. Further analysis of the results shows that the community's understanding of the characteristics, risks, and potential regulations of CCS are all important in predicting and promoting CCS public acceptance (DUAN, 2010).

13.6.5 Sub-Saharan Africa

13.6.5.1 Technical Potential and Source-Sink Matching

The short-term technical potential for CCS is generally considered low as the amount of CO_2 point sources amenable to capture are limited. With the exception of South Africa, many sub-Saharan countries lack large, energy-intensive industries, coal- or gas-fired power production and other stationary CO_2 sources. Most countries have very low or even negative GHG emissions. According to the 2006 version of the IEA GHG database on CO_2 point sources, sub-Saharan Africa has a total of 155 point sources, 79 of which are power and 76 cement, iron and steel, ethylene and ammonia, amounting to some 241 $MtCO_2$ emissions from power and some 46 $MtCO_2$ industrial emissions (IEA, 2008c). Of both, around half of the emissions originates in South Africa.

In the future, CO_2 emissions in Africa are projected to rise. IEA (2009) projects CCS activities in Africa from around 2030 onwards. Several African countries have an abundance of coal and plan to use it.

Geological storage potential for CO_2 in sub-Saharan Africa is generally not known, as no comprehensive assessments have been carried out. However, various countries have known sedimentary basins or have done underground exploration for other economic reasons, such as hydrocarbon exploration or searching for underground drinkable water reservoirs in arid areas. For instance, it is likely that oil-exporting countries along the west coast of Africa, such as Nigeria, Angola, and Gabon, have areas of high geological storage prospectivity (IPCC, 2005) but also a country like Mozambique with oil and gas exploration (ECN, 2010).

South Africa has done a focused geological storage atlas. Although the atlas was not public at the time, some early results can be conveyed (Cloete, 2010). South Africa does not appear to have an abundance of suitable sedimentary basins, and early results suggest that the coal fields in the northeast (northern Karoo), where most of the large-scale emission sources are, also do not appear prospective.

13.6.5.2 Factors Influencing Regional CCS Costs

Literature around costs of CCS in sub-Saharan Africa is sparse. What is remarkable is the presence, however, of the largest single high-purity source of CO_2 in the world: around 30 $MtCO_2$ from a Sasol-operated coal gasification plant in South Africa (Cloete, 2010; Surridge, 2010). This could be an early opportunity if suitable storage capacity can be found nearby.

In oil-producing countries, in the longer term, potential for EOR might exist but such suggestions are highly hypothetical at the moment and not supported by literature.

13.6.5.3 Technical and Human Capacity

South Africa has an unofficial target of realizing one demonstration plant for CCS by 2020 and developing the technical and human capacity for this demonstration along the way. The main instrument for developing human capacity is the South African Centre of Excellence on CCS, founded in 2009 during a conference on CCS, which was also attended by representatives from surrounding countries. The Centre, however, still needs to gain critical mass. In addition, there is capacity on CCS within South African companies such as Sasol and Eskom. Additionally, South African industry representatives support the CO2CRC in Australia.

In Africa broadly, a few capacity building activities have taken place. In 2007, two regional workshops were held on CCS and CDM, one aimed at West Africa in Dakar, Senegal and the second focusing on Southern Africa in Gaborone, Botswana (ECN, 2010). In 2010, country workshops were held in Botswana, Mozambique, and Namibia. There is no R&D on CCS taking place in sub-Saharan Africa.

13.6.5.4 CCS Legal and Policy Initiatives

There are no sub-Saharan countries with any developments toward legislation on CCS. The only potential incentive for CCS might have come through the CDM. Botswana and South Africa are the only sub-Saharan countries that have mentioned CCS in their submissions to the UNFCCC for the Copenhagen Accord. The World Bank is interested in providing financing for feasibility studies on CCS in Botswana. Capacity for regulatory permitting of CCS projects in sub-Saharan Africa is currently largely absent, and apart from capacity building efforts mentioned above, little is being undertaken now to change this.

13.6.5.5 Discussion of CCS in Sub-Saharan Africa

CCS in sub-Saharan Africa is an option for the longer term, given the presence of coal in southern Africa that is projected to be used to fulfill the continent's growing energy and development needs. Before CCS can be realized, human and technical capacity needs to increase, regulation and policy need to be developed, and better insight in geological storage capacity is needed. South Africa is most progressed with a demonstration plant anticipated for 2020 and a pathway toward it. Also in South Africa, short-term, low-cost CCS potential may exist in the form a large coal gasification plant if suitable storage reservoirs can be found within a reasonable distance.

13.6.6 Former Soviet Union

13.6.6.1 Technical Potential and Source-Sink Matching

CO_2 emissions related to fuel combustion in the Former Soviet Union (FSU) region decreased by 34% from 1990 to 2008, reaching 2427 Mt, while population grew by 8%. Russia's emissions declined by 27% to 1594 Mt and Ukraine by as much as 55% to 310 Mt. Energy supply decreased by 27% over the same period in the FSU, with a first period of decline from 1990 to 2000, followed by an expansion from 2000 onwards. Electricity and heat production contributed in 2008 to 50% of the emissions from fuel combustion, followed by manufacturing (17%) and transport (14%). Gas represented 50% of the emissions, declining by only 7%, to be compared with coal (-42%) and oil (-57%). Given the abundance of natural gas resources in the region, applications of CCS would be mostly limited to storage from fuel transformation and natural gas-fueled power plants. A number of gas fields in the Caspian region have relatively high CO_2 and/or H_2S content, and some of the field developments have been delayed due to the issue of sour gas handling.

An assessment of sources and sinks matching in the Baltic States has been made within the EU-funded Geocapacity and CO2NET East projects (Shogenova et al., 2008). There are 24 large sources of CO_2 emissions (greater than 0.1 Mt/yr), with Estonia's upstream production (associated with the extraction and use of oil shales) amongst the largest. While there are no suitable storage areas in Estonia, several prospective formations exist in the Baltic sedimentary basin, with solubility trapping capacities in the range of 13 Gt.

Russia is the country with the single highest storage potential after the United States, with more than 2000 Gt; the capacity of depleted oil and gas fields in the Western Siberian Basin alone is in the order of 150–200 Gt. However, given the distribution of CO_2 emissions (mostly located in the European part of Russia) and the potential storage sites, distances for pipeline transport of 2000–4000 km have to be considered, significantly increasing the cost for the CCS chain.

13.6.6.2 Technological Maturity

The Russian oil and gas and petrochemical industries have a long experience with CO_2 capture, transport, and storage. Use of CO_2 from anthropogenic sources has been investigated since the early 1980s in Russia (Kuvshinov, 2006). Large-scale pilot tests have been carried out to inject CO_2 and other flue gas for enhanced oil recovery. Areas that have promising source and sink matching include the onshore Black Sea area (oil fields near Krasnadar), the Baskortostan (near Ufa), Tatarstan (near Samara), and Perm oil fields. Enhanced coalbed methane potential also exists in the coal fields in the southern part of Russia, but given the current levels of oversupply in gas markets, the application of technology in those prospects is unlikely.

13.6.6.3 Factors Influencing Regional CCS Costs

The cost of CO_2 transport and subsurface injection is well-documented in the FSU, given the volume of oil and gas operations in the region.

13.6.6.4 Human Capacity, Research and Development

In addition to the EU FP6-funded projects for CCS potential in the Baltic States, a call for proposals for clean coal applications has been made in 2010 by the European Commission to explore the potential for some of the Caspian states, including Kazakhstan. In Russia, several technological institutes related to oil and gas production have in-house capabilities for CO_2-EOR, as well as subsurface knowledge. The oilfield service sector has also developed the capabilities to use the building blocks of site assessment for CO_2 storage.

13.6.6.5 CCS Legal and Policy Initiatives

Emission levels decreased significantly during the economic collapse that followed the separation of the FSU states. Therefore, there are no incentives for Russia to use CCS, except if appropriate international mechanisms allowed a monetization of storage. While the current efforts are directed toward gas flaring reduction as a priority, political willingness

exists for promoting CCS. The 2006 G8 Summit in St. Petersburg included a joint statement from the Russian Academies of Science promoting research, development, and demonstration in the areas of carbon dioxide storage for energy sustainability.

13.6.7 Australia

13.6.7.1 Technical Potential and Source Sink Matching

CO_2 emissions related to fuel combustion in Australia increased by 56% from 1990 to 2009, reaching 417 Mt, while population grew by 25% (EIA on-line data base). The single largest contributor is stationary sources (particularly coal-fired power station), with 2006 total stationary emissions around 280 $MtCO_2$.

Like most countries, Australia is pursuing a broad portfolio approach to GHG mitigation, although it currently excludes nuclear power from the portfolio. It has in place a Mandatory Renewable Energy Target (MRET) of 20% of electricity from renewables by 2020 and a longer-term goal to reduce emissions by 60% from 2000 levels by 2050. It also has a range of mitigation options under consideration, such as biomass, enhancement of soil carbon, fuel switching (coal to natural gas), and greater energy efficiency. Important though all these measures are, the reality is that at present the rate at which they are being implemented is not keeping pace with the rise in demand for electricity, with most of that increase in demand being met from increased use of coal.

Australia has abundant gas reserves, but currently coal-fired power generation is cheaper than gas in the absence of a price on carbon. In 2011 the Australian governments announced a carbon tax for the 500 top emitters of $US_{2011}$$24. However, a carbon price in the range US$20–30/$tCO_2$ is unlikely to produce a marked change in consumer behavior or significant deployment of CCS in Australia in the short term. At the same time, there is widespread recognition that given Australia's high level of economic dependency on inexpensive coal for power generation (and its coal exports), it potentially has more to gain than most countries from the successful deployment of CCS. In the short term there is scope for replacing some coal-based power generation with gas, with a commensurate decrease in GHG emissions, and almost certainly this will happen to some extent. In addition, given Australia's move to 20% renewable power, there is likely to be increased use of gas to handle the intermittency of wind power. Gas substitution may provide some reprieve from ever-increasing emissions in the next decade, but in the longer term gas, like coal, becomes part of the greenhouse problem, as gas-related CO_2 emissions rise. There may also be some increase in the use of biomass, particularly for COGEN. However, whether it is coal-, gas-, or even biomass-based power generation, the likelihood is that CCS will play a future role. With this in mind, Australia has taken a number of recent CCS initiatives, including an update of its storage potential through the Carbon Storage Taskforce (CST, 2009).

The major sources of CO_2 are located primarily in eastern Australia, where the major population centers are located, although it is anticipated that the emissions will grow significantly in northwestern Australia as new LNG production comes on stream along with other industrial developments. The Carbon Storage Taskforce (CST, 2009) has identified 10 concentrations of stationary emitters, with sources sufficiently close together that a "hub approach" to CCS may be feasible. There is, or will be, some storage potential in depleted oil and gas fields, estimated by the Taskforce (CST, 2009) at 16.5 $GtCO_2$, most of which is offshore. The depleted fields of the Bowen-Surat Basin in southeast Queensland are the most prospective onshore, with the Gippsland Basin the most prospective offshore region. However, many of the fields are still some years away from being depleted, and therefore overall, the potential for storage in depleted oil or gas fields is quite modest in the short to medium term. CO_2-EOR is regarded as having only very limited potential because of the light nature of Australian crude oil.

The major CO_2 storage opportunities for Australia lie in saline aquifers. The Taskforce (CST, 2009) has determined the technical storage capacity (at 90% confidence level) as 10.9–87.5 $GtCO_2$ for eastern Australia, using storage efficiencies of 0.5% and 4%, respectively, and for western Australia the capacities are 12.3 $GtCO_2$ (0.5% efficiency) and 98.5 $GtCO_2$ (4% efficiency). Total storage capacity is estimated at between 33 and 226 $GtCO_2$, suggesting adequate storage capacity for at least this century and possibly for several centuries, assuming a storage rate of 2–300 $MtCO_2$/yr. It is important to treat these figures with caution, as knowledge of many saline formation systems is still quite limited. Nonetheless, the values do provide confidence that Australia has sufficient storage potential to meet its CCS needs for many years to come.

13.6.7.2 Factors Influencing Regional CCS Costs

Most of Australia is quite sparsely populated with widely dispersed CO_2 sources, which adds significantly to the cost of CCS infrastructure. However, as pointed out earlier, there are a number of emission hubs, where a coordinated approach could be taken to CCS in order to bring down costs. The most extensively investigated hub is that of the Latrobe Valley in eastern Victoria, where brown coal-fired power stations collectively produce one of the largest regional sources of CO_2 in the country. The Gippsland Basin, located only 150 km away, is an excellent prospect for large-scale CO_2 storage with a technical storage capacity of 4–5 $GtCO_2$ at the P90 level, assuming a conservative storage efficiency of 0.5%. Therefore, it is highly likely that a Latrobe-Gippsland source-sink could function very effectively for the remainder of this century. South Central Queensland may also offer similar opportunities, using the Bowen-Surat Basin. Other source-sink matches are also possible with some of the natural gas/LNG-related sources offering effective CCS options for the future. Some of the other emission nodes are less favorably located for nearby large-scale storage, with transport distances in excess of 500 km being contemplated in some instances, such as New

South Wales. Therefore, in some areas, the need for large-scale long distance pipelines will add considerably to the cost of CCS. Those costs will be increased by the need for recompression over long distances with substantial power requirements.

The possible impact of CO_2 storage on other resources could also add to the cost of CCS and result in delays in implementation. For example, while the Latrobe-Gippsland source-sink hub is the highest ranked in terms of storage capacity and cost, it is also a major oil and gas producing basin and will be for quite some years to come. Careful management of CO_2 storage would obviously be necessary to ensure that there is no adverse impact on oil or gas production. In the case of some of the Queensland storage options, the major concern is to ensure that any CO_2 storage does not adversely impact on the significant fresh water resources of the Great Artesian Basin.

The Taskforce (CST, 2009) summarizes the main factors affecting the economics of CO_2 storage as "location (the distance from the CO_2 source to the storage location determines pipeline costs), reservoir depth (influencing well costs) and injectivity parameters (notably permeability and differential pressure, which determine the number of wells needed)." As a result of these factors, CCS costs vary considerably throughout Australia, ranging (for transport plus storage only) from less than US\$10/tCO_2 avoided for the Victorian Latrobe-Gippsland option to more than US\$100/tCO_2 avoided for the proposed New South Wales Sydney-Cooper proposal.

The further challenge to deployment in Australia and elsewhere is to establish the appropriate business model for taking the hub concept forward. Several models are under consideration at the moment, including as a government-owned utility, as a public-private partnership, and as a privately-owned utility. There is general agreement on the need for any pipeline network to have excess capacity to handle future growth in emissions, but at the same time, there are no agreed mechanisms to pay for that upfront investment to provide the excess capacity. Finally, in many parts of Australia, as in many parts of the world, there is a lack of knowledge of the deep geology of many sedimentary basins, which in turn makes it difficult to provide a confident assessment of storage capacity. Paucity of geological information represents a significant investment risk in many areas. The Taskforce (CST, 2009) has proposed a national program of precompetitive storage assessment costing in excess of US\$250 million, and there is no question that such a program would be extremely useful, but for the present the program remains unfunded.

On a more positive note, while knowledge of CCS in the Australian community is limited, there have been extensive programs to inform the wider community on CCS through the activities of state and federal governments, CO2CRC, and CSIRO. As a consequence, there is no entrenched community opposition to CCS. Indeed, Australia has had an operational storage project, the CO2CRC Otway Project, underway since March 2008, which has been able to proceed with a significant level of local support and which has received national media coverage. Therefore, while every CCS project will need to involve the community in a careful and considered manner, there are no obvious showstoppers at this time in terms of community concerns regarding the technology.

13.6.7.3 Human Capacity, Research and Development

Australia has a strongly developed skills base in the resource sector, particularly in the geosciences, materials science, and engineering, all of which are skills directly relevant to CCS.

Research and training in CCS commenced in Australia in 1998 through the Petroleum Cooperative Research Centre and its Geodisc Program and greatly expanded from 2003 onwards through the successor Cooperative Research Centre for Greenhouse Gas Technologies (CO2CRC). Through this Centre, there is an unusually broad and active program of collaborative research involving most of the major universities as well as CSIRO and Geoscience Australia. The Centre also works closely with overseas research bodies. Through CO2CRC and its collaborating universities, a large number of people have been trained in CCS. More recently a number of the bodies within CO2CRC have also developed their own specific research activities, but the Centre is still the main research body that brings CCS research together. CO2CRC is currently funded to 2015 and, with a combination of industry and government funding and in-kind contributions from research providers, has an annual budget of US\$20–25 million for its research into CO_2 capture transport and storage.

CSIRO, Australia's main research body, has a CCS program focused in particular on post-combustion capture of CO_2 with several pilot projects underway. It is also engaged in research into CO_2 storage, although most of that is through its collaboration with CO2CRC.

Geoscience Australia (the Federal Geological Survey), together with a number of the State Surveys, have a national program underway to assess storage capacity and develop infrastructure plans.

Australia has been active in the development of CCS training and capability in a number of countries, particularly in East Asia, where a number of courses have been delivered by CO2CRC, GA, and GCCSI.

At present, the Government of Australia has chosen to use direct financial assistance to take CCS forward, and the states have a similar though more modest approach. At the state level, the planning approval process has also acted as a way of ensuring that projects consider CCS as a mitigation option. However, up to now, the primary focus of the government, and to some extent industry, has been to provide funding through a range of CCS initiatives that will run until 2015 or beyond.

In late 2009, the federal government announced the formation of GCCSI with an initial annual contribution of US_{2005}\$ 65.5 million (A_{2009}\$ 100

million) from Australia for four years and the hope that other countries might contribute at some stage in the future. The GCCSI is not involved in research and is focused on global deployment of CCS and the aim of the G20 countries to have 20 large-scale CCS projects by 2020.

The Australian National Low Emissions Coal Research and Development is a recent joint government-coal industry initiative. $US_{2010}$$245 million will be made available over five years to 2015–2016 to support low emission coal technology demonstrations in Australia and to understand and address the deployment risks that early demonstration projects may face.

The National Low Emission Coal Council (now called the National CCS Council) was established in 2008 to provide guidance to the government on the overall direction of CCS development and deployment in Australia. The initial focus on coal had the effect of leaving the oil and gas industry largely out of the deliberations, despite the importance of that sector to future CCS deployment. This has now been addressed and in future initiatives will deal more broadly with CCS. The related Carbon Storage Taskforce has involved the oil and gas industry and has now produced a valuable report for a national carbon mapping and infrastructure plan, which, if implemented, will produce a major national assessment of opportunities for geological storage.

The federal government's CCS Flagships Program, should help to accelerate the deployment of large-scale integrated CCS projects in Australia through federal grants totaling $US_{2005}$$ 1.0 billion ($A_{2009}$$ 1.3 billion). Along with matching industry and state funding, it is expected that this will fund two large-scale CCS projects. Bids are currently being assessed from project proponents. Along with the Flagships Program, the Australian Government has established a companion Education Infrastructure Fund, totaling approximately $US_{2005}$$ 130 million ($A_{2009}$$ 100 million), to support research partnerships between the Flagships and research institutions, with CSIRO, and CO2CRC the designated Lead Research Organizations.

13.6.7.4 CCS Legal and Regulatory Initiatives

Australia has established an offshore regulatory regime for the geological storage of CO_2 for offshore areas under federal control. Victoria has its own onshore CCS legislation in place and several other states are in the process of defining onshore regulations for CO_2 storage. Western Australia has to date taken a project-specific approach to regulation to enable it to permit CO_2 storage under Barrow Island as part of the Gorgon LNG Project. The issue of long-term liability has proved complex in Australia, as it has with most jurisdictions. However, an agreed process is now in place to transfer offshore storage liability to the federal government at the conclusion of offshore injection and once a number of other performance criteria have been met. The onshore approach to long-term liability (under State jurisdiction) is less clear and varies from state to state. In Victoria, a regulatory regime under the R&D provisions of the EPA enabled the CO2CRC Otway Project to go ahead, but under the more recent CCS-specific provisions of that state's GHG legislation, it would be much more difficult to take such a research project forward. Therefore, one of the clear lessons from the Australian experience is to ensure that regulations take full account of the research needs of CCS. Nonetheless, overall Australia is probably more advanced than most other countries in the development of CCS legislation.

13.6.7.5 Australian CCS projects

A combination of various state and federal financial initiatives, coupled with general recognition of the importance of CCS to the Australian economy and the Australian resource and power industry, has resulted in a number of planned or proposed projects, which are summarized below and in Figure 13.11b.

The Callide Oxyfuel Project in Queensland involves oxy fuel conversion of an existing 30MW unit at Callide A (currently underway) with power generation and capture of CO_2 commencing in 2013. A second stage of the project may involve the injection and storage of captured CO_2 into a saline aquifer or depleted oil/gas fields over about three years, commencing in 2013, but as yet a suitable site has not been identified. The cost estimate for the project is approximately $US_{2010}$$218 million. The project involves CS Energy, IHI, Schlumberger, Mitsui, J-Power, and Xstrata, with extra funding from the Australian Coal Association and the Australian and Queensland governments.

The CarbonNet Project in Victoria, a CCS Flagship Project proposal, is for the development of the infrastructure for a storage and transport hub in the Latrobe Valley. It is coordinated by the state of Victoria. It aims to collect, transport, and store 3–5 $MtCO_2$/yr from Latrobe Valley industry, including coal-fired power plants (and may involve both pre- and post-combustion capture), with storage in the Gippsland Basin.

The Collie South West Hub Project in Western Australia is a CCS Flagship Project proposal coordinated by the state of Western Australia. It aims to store up to three $MtCO_2$/yr captured from industrial and power plants located southwest of Perth. At the present time, the biggest challenge the project faces is identification of a suitable storage site.

The CO2CRC Otway Project in Victoria is Australia's only operational storage demonstration project. Injection of CO_2 from a nearby gas well, initially into a depleted gas field at a depth of two km, began in April 2008 with injection of 65,000 tCO_2-rich gas to date. A major program of monitoring and verification has been implemented. A new well was drilled in early 2010 and a new phase of injection has been initiated. The A$60 million project, which is supported by 15 companies and seven government agencies, involves researchers from Australia, New Zealand, Canada, Korea, and the United States. Partners include major gas, coal, and power companies, research organizations and governments.

Additional financial support is provided by the Australian Government, the Victorian Government, and the US DOE through Lawrence Berkeley National Laboratory.

The Coolimba Project of Aviva Corporation Ltd is an early stage proposal in Western Australia for 2x200 MW coal-fired base-load power stations with the plant built ready for conversion to CO_2 capture. Sequestration sites have been sought for the storage of about 3 $MtCO_2$/yr, but the project is presently suspended.

The Gorgon Project of Chevron (operator), Shell, and Exxon is at the early construction stage. It involves a major storage project linked to the Gorgon LNG Project. The separated CO_2 will be injected under Barrow Island at a depth of about 2.3 km, with injection of 3–4 $MtCO_2$/yr. A total of 125 Mt will be injected over the life of the project. A data well has been drilled, and a major study of the subsurface is underway. All government approvals have been granted, and the final investment decision for the project to proceed has been made. A number of contracts have been awarded, and construction is underway. The storage component of the project will cost in excess of A$1 billion.

Galilee Power has an early stage proposal for a new 900 MW coal-fired power station incorporating CCS with storage of captured CO_2 in the Galilee Basin. Prefeasibility studies are underway, but activity is quite limited at the present time.

A post-combustion capture plant is operating at International Power's Hazelwood Power Station in Victoria. The solvent capture plant began operation in 2009 and is capturing and chemically sequestering CO_2 at a nominal rate of 10,000 tCO_2/yr. This project is partly funded by the Australian and the Victorian Governments.

The Latrobe Valley Post Combustion Capture Project (LVPCC) in Victoria is developing technologies for post-combustion capture from coal-fired power stations in the Latrobe Valley. The LVPCC involves International Power, Loy Yang Power, CO2CRC, and CSIRO and is partly funded by the Victorian Government. It comprises work at the Hazelwood Power Station by CO2CRC and by CSIRO at Loy Yang.

The H3 Capture Project, Hazelwood, Victoria, led by CO2CRC, is based at International Power's Hazelwood plant and exploits synergies with the Hazelwood Capture Project. A range of solvents and different process configurations are being tested using the solvent post-combustion capture plant. In addition, post-combustion techniques using adsorbent and membrane technologies are being developed, using two purpose-built rigs.

The Loy Yang Project in Victoria involved a CSIRO mobile pilot post-combustion capture facility. This has begun operation at Loy Yang Power Station and is capturing around 1000 tCO_2/yr. The facility investigated a range of solvent technology for CO_2 capture and has now concluded the research.

At the CO2CRC/HRL Mulgrave Capture Project in Victoria, CO_2 emissions were captured from HRL's research gasifier at Mulgrave in a pilot-scale pre-combustion project. The capture technologies were evaluated to identify which are the most cost-effective for use in a coal gasification power plant. Partners included CO2CRC and HRL, with funding from the Victorian Government. The research has now been concluded.

The Munmorah PCC Project in New South Wales has investigated the post-combustion capture (PCC) ammonia absorption process, and the ability to adapt it to suit Australian conditions. Tests to capture up to 3000 tCO_2 have been successfully completed. Partners involved in this project are Delta Electricity, CSIRO, and the ACA. The pilot plant has now been relocated to another site and a larger-scale demonstration project, incorporating geological storage, is under consideration.

CSIRO and Tarong Energy have installed a post-combustion capture pilot plant using an amine-based solvent at Tarong Power Station near Kingaroy, Queensland. The pilot plant will capture 1500 tCO_2/yr over a two-year research program. Construction has commenced.

Stanwell and Xstrata Coal are proposing the Wandoan Project, Queensland as a CCS Flagship Proposal. Identification of suitable storage sites in the Surat Basin of Queensland is being undertaken by the consortium.

13.6.8 Latin America

13.6.8.1 Technical Potential and Source-Sink Matching

CO_2 emissions related to fuel combustion in Latin America increased by 70% from 1990 to 2009, reaching 1212 Mt, while population grew by 32% (EIA on-line data base). Latin America includes South America, including Brazil, and Central America, including Mexico and the Caribbean. The region is a major oil producer; Mexico and Venezuela jointly produced 7.2 % of worldwide crude oil in 2009 (IEA, 2010a), and Brazil is up and coming as an oil producer and exporter. EOR is clearly seen as a possibility. Almost all countries in Latin America have CO_2 sources from cement production, refineries, and power, although much of the power in the region originates from renewables, in particular hydropower. Several of the larger countries have steel and ammonia plants and ethylene production. As companies are starting to explore EOR in the region, they are looking for high-purity CO_2 sources. In Mexico, an ammonia plant has been explored, and in Brazil, biomass production is being explored.

Except for Brazil, no comprehensive CO_2 storage atlas or assessment has been done in Latin America, although in Mexico and Argentina several reservoirs have been explored for EOR or storage. In Brazil, the CARBMAP project (Rockett et al., 2011) has done a rough assessment of sources, pipeline corridors, and reservoirs.

An additional possibility in the Latin American region is the combination of biomass and CCS (Möllersten et al., 2003). According to the IEA GHG (2008) database on CO_2 emissions, the CO_2 emissions from ethanol and biomass production are around 72 $MtCO_2$/yr, all of them in Brazil. These sources are high-purity and therefore amenable to capture, but also relatively small-scale at ca. 100,000–150,000 tCO_2 per source per year. Most of the sources are in the São Paulo region, relatively close to the ocean shore, although it is unclear at this point whether there might actually be storage potential close by. The Global Environment Facility may fund a small-scale bioethanol CCS project in Brazil.

13.6.8.2 Factors Influencing Regional CCS Costs

Distances are large and currently it is unclear whether there is storage potential and where it is. In Mexico and particularly Brazil, much of the EOR potential is likely to be offshore, negatively affecting costs.

13.6.8.3 Technical and Human Capacity

CCS does not have a long history in the Latin American region, but capacity has increased over the past five years. Countries like Mexico and Venezuela, with a significant oil industry, have some embedded capacity. In Brazil, a dedicated CCS center was established, the Brazilian Carbon Storage Research Center at the Pontifical Catholic University in Porto Alegre. Research is also done at the Sindicato da Industria Carbonifera de Santa Catarina (SIECESC). The Brazilian Carbon Storage Research Center's capabilities are clear from publications in peer-reviewed journals (e.g., Ketzer et al., 2007). The Center is partly funded by Petrobras, which is building up capacity internally for CCS and for CO_2-EOR.

13.6.8.4 CCS Legal and Policy Initiatives

There are no known legal or policy initiatives in Latin America. The Global CCS Institute commissioned a study, which examined current initiatives in Brazil (GCCSI, 2009b). This study reported that in Brazil, there is existing legislation for pipelines, environment impacts, and mining that would apply to CCS operations, but no major barriers were identified. Similar conclusions were drawn for Mexico (GCCSI, 2009c). In terms of policy incentives, the CDM may be a driver for low-cost opportunities provided the conditions in the latest UNFCCC decisions can be fulfilled.

13.6.8.5 Discussion of CCS in Latin America

CCS plays a minor role in the climate and energy debates in most Latin American countries. It is only seriously considered in Argentina, Brazil, and Mexico. In those countries, the first demonstrations are likely to be from industrial CO_2 sources rather than power, as much of the power in the region originates from renewables and there is some potential for low-cost capture opportunities. Although in private and academic sectors capabilities are being developed, legal and regulatory frameworks are still absent in all countries. It appears that either EOR or international instruments, potentially CDM, with which the region has had some success, will be the main drivers for CCS in the coming years.

13.6.9 Middle East and North Africa

13.6.9.1 Technical Potential and Source-Sink Matching

CO_2 emissions related to fuel combustion in the Middle East and North Africa (MENA) region increased by 128% from 1990 to 2007, reaching 1770 Mt, significantly outpacing population growth over the same period (+44%). Over 95% of those emissions were related to the use of oil and gas, with oil-based transport and gas-based power generation having the largest growth over the last two decades. Given the abundance of natural gas resources in the region (and its lack of coal resources), applications of CCS would be mostly limited to storage from fuel transformation, and natural gas-fueled power plants. A number of gas fields in the MENA region have relatively high CO_2 and/or H_2S content, and some of the field developments have been delayed by the issue of sour gas handling. In North Africa, the main potential for capture is in Algeria, Libya, and to a lesser degree, Tunisia. Both in Salah Gas and Gassi Touil projects in Algeria have a CO_2 content as high as 10% with nearby storage reservoirs. In Libya most of the potential is from offshore fields with a potential of use of CO_2 for EOR, while in Tunisia the largest gas field in the country (Miskar) has nearly 13% CO_2 content. In the Middle East 60% of the proven gas reserves have more than 100 ppm of H_2S and/or 2% CO_2 (IEA, 2008b). Other opportunities for capture in the areas are in fuel transformation, particularly gas-to-liquids, as well as in the growth of gas-fired power plants, and in the developing petrochemical sector.

While no detailed study of storage potential has been made in the area, the global assessment performed points to a highly favorable sedimentary environment for the MENA region. The Middle East represents the largest future potential for storage in depleted fields with the five biggest sites having a combined 180 Gt of capacity. With the caveat that deep saline aquifers are poorly understood, combined storage capacity ranges for the MENA region are estimated at (IEA, 2008a) 200–1200 Gt for oil and gas fields and 50–550 Gt for saline formations.

The region has the highest potential incremental recovery from CO_2-EOR, with estimates of additional volumes of oil ranging from 80–120 billion barrels (IEA, 2008a). Given the lack of availability of CO_2 and the incremental cost, attempts to develop this tertiary method in the region are still limited. In 2009 Saudi Arabia announced plans for a CO_2-pilot project in a waterflood of the Arab-D reservoir (Ghawar field) that could be started in 2013 with the injection of 0.8 $MtCO_2$/yr, but stressed that the country did not need EOR on a large scale at this point. In the United Arab Emirates, a pilot project (the first in the Middle East) was started by

Abu Dhabi Company for Onshore Oil Operations (ADCO) at the end of 2009 for the injection of CO_2 in the Northeast Bab's Rumaitha carbonate reservoir, while a study was launched in 2010 to use CO_2 for EOR in the Lower Zakum oil field in Abu Dhabi.

13.6.9.2 Technological Maturity

Efforts to reduce the emission of GHGs from upstream operations have been ongoing for the last two decades, including a significant reduction in gas flaring. The MENA region has the first large-scale CCS projects outside of the Organisation for Economic Co-operation and Development with the BP-Sonatrach-Statoil In-Salah Gas project (see Section 13.4.2.2.3). The region also benefits from the experience gained in both surface and subsurface processes from the oil and gas industry. Turkey had one of the earliest CO_2-EOR project in the heavy oil field of Bat Raman. In 2009 the Abu Dhabi Future Energy Company confirmed plans for a major initiative to reduce emissions from the Emirates by half using CCS. The first phase of the project would involve the capture of up to 5 $MtCO_2$/yr from three sources (a gas-fired power plant, a steel mill in Mussafah, and an aluminum smelter at Taweelah). The plan also includes the development of a specific pipeline network and the injection in Abu Dhabi National Oil Company's oilfields.

13.6.9.3 Factors Influencing Regional CCS Costs

The cost of CO_2 transport and subsurface injection is well-documented given the volume of oil and gas operations in the region. The feasibility and optimization of Water Alternating Gas processes in enhanced oil recovery still requires detailed evaluation, as the conditions of EOR operations in North America are significantly different: well spacing, reservoir heterogeneity, and thickness, along with crude gravity, all play an important role in the incremental oil recovery with CO_2. Also the development of interstate pipeline networks would allow further cost optimization. The MENA region has ample and widely distributed storage capacity, which would allow matching sources and sinks relatively easily. What remains to be determined is the potential for the region to host the emissions from nearby European sources.

13.6.9.4 Human Capacity, Research and Development

In November 2007, the Organization of Petroleum Exporting Countries (OPEC) announced pledges for a US$750 million fund to develop clean energy technologies, in particular CCS, with the participation of Saudi Arabia, Kuwait, Qatar, and the United Arab Emirates. Several initiatives have been started in the region to develop technological capabilities, including the Masdar project, and the recently created Qatar Carbonates and Carbon Storage Research Centre. Many international workshops have been convened in the region to increase awareness and assess which areas of research are most appropriate in the Middle East context. Efforts to promote technology transfer in the region have been led by the Society of Petroleum Engineers and other professional societies, along with OPEC and national organizations.

13.6.9.5 CCS Legal and Policy Initiatives

Saudi Arabia and other OPEC countries have successfully negotiated for the inclusion of CCS as a Clean Development Mechanism, allowing developed countries to offset their emissions. While awareness in the region about carbon abatement rationales and options is generally low, there is also the concern by governments to prevent a strong curbing of hydrocarbon use, which may impact the region's economic growth. Therefore, options such as fuel switching for natural gas or CCS rank amongst the highest.

13.6.10 Japan

13.6.10.1 Technical Potential and Source-Sink Matching

In 2007 Japan emitted almost 1214 $MtCO_2$. The industrial sector, led by iron and steel manufacturing, contributes to the majority of the emissions (451 Mt), followed by transportation (257 Mt), commercial sector (215 Mt), residential sector (201 Mt), and energy conversion sector (90 Mt) (Aoshima, 2009). Thermal power stations, iron and steel manufacturing plants, and cement plants are the three major stationary sources assessed for CO_2 capture (Nakanishi et al., 2009).

A storage capacity of 146.1 $GtCO_2$ has been reported in Japan (Nakanishi et al., 2009; Takahashi et al., 2009). A total of 27 potential storage areas are being investigated throughout the country, four of which correspond to regions with large emission sources: Tokyo Bay, Ise Bay, the Osaka Bay area, and northern Kyushu (Nakanishi et al., 2009). Studies identify 18 saline aquifers that can be suitable for CO_2 with storage capacity ranging between 0.01–7 Gt per saline aquifer. However, the accuracy of evaluating storage volume and effectiveness varies significantly among the identified saline formations (Ogawa et al., 2009). Existing oil and gas reservoirs and formations investigated by exploration wells and seismic surveys are estimated to have a storage capacity of approximately 36.2 Gt. Other formations, investigated by seismic surveys only, are expected to store around 109.9 Gt (Nakanishi et al., 2009; Takahashi et al., 2009). The spatial distribution of major CO_2 stationary point sources and analyzed storage basins throughout Japan shows close proximity between sources and sinks and some potential for source-sink matching (Takahashi et al., 2009).

13.6.10.2 Technological Maturity

Japan continues to develop the technological infrastructure required for CCS deployment. Eight CCS projects are completed and/or currently

active. This includes post-combustion capture, ECBM, and storage projects, at the R&D, demonstration, and industrial/commercial-scales (BRGM, 2009; Lund et al., 2008). Post-combustion capture has been implemented in Japan since 1991 to capture CO_2 emissions from Nanko power facility in Osaka. Recently, several post-combustion capture projects have been implemented in coal and gas power plants and chemical facilities. Between 2000 and 2007, the Nagaoka project involved a successful storage of 10,400 tCO_2 in a 1000 m deep saline aquifer. Also, in 2002, the first ECBM project was launched in the country with the aim of injecting CO_2 in 6–9 m thick coalbed 900 m underground in Yubari, Hokkaido (Lund et al., 2008). This rapid development of CCS projects improves Japan's experience in CCS and enhances its capability of early deployment and testing of CCS.

According to the US Energy Information Administration (US EIA), Japan has little domestic oil and natural gas reserves, which makes it the second-largest net importer of crude oil and largest net importer of liquefied natural gas in the world. In 2007 the country's total consumption of oil reached almost 5 million bbl/day (249 Mt/yr), compared to 130,000 bbl/day (6.47 Mt/yr) of production. Similarly, the total consumption of natural gas in the same year was about 100 billion m^3 (3.5 trillion cubic feet), only 1 billion m^3 (32 billion cubic feet) of which is produced domestically. Nevertheless, Japan has developed significant experience in the oil and gas industry by leading in technology and equipment development, establishing a robust refining infrastructure, and participating in exploration and production projects overseas. Today, Japan's refining capacity is the second-largest in the Asia-Pacific region, and almost 15% of the country's oil imports come from Japanese-owned concessions around the world, primarily in the Middle East (US EIA, 2010). As such, it would be reasonable to argue that Japan's experience in oil and gas exploration and production enhances the country's capability of developing CCS infrastructure both locally and internationally.

13.6.10.3 Factors Influencing Regional CCS Costs

As mentioned before, many of the currently proposed CO_2 storage sinks in Japan are onshore, and most CO_2 point sources are located either on or close to potential geologic storage formations (Nakanishi et al., 2009). Today, even though several CCS pilot projects are currently implemented, the design and layout of the potential CO_2 infrastructure and transportation network in the country has not been fully investigated (Nakanishi et al., 2009). Nevertheless, the safety aspects of CCS projects, as well as the effect of topography and various environmental factors on the cost and effectiveness of CCS implementation, have been recently addressed in a study by the Carbon Dioxide Capture and Storage Study Group within the Industrial Science and Technology Policy and Environment Bureau at the Japanese Ministry of Economy, Trade and Industry. In addition to detailing the geological requirements for safe storage of CO_2 at a large demonstration-scale, the study suggests a CO_2 transportation standard, a regulatory framework for assessing operations' safety, a methodology for environmental impact assessment of CCS-related activities, and a list of monitoring techniques to track CO_2 before and during injection for safe operation of a CCS demonstration project (Japan CCS Study Group, 2009).

According to the US EIA, around 83% of the total energy use in Japan in 2005 was met by coal, oil, or natural gas; renewable energy accounts for about 4% of the energy demand. Electricity production is estimated to increase from almost 245 GW in 2007 to around 305 GW in 2030, 40% of which will be generated from fossil fuels (compared to 59% in 2007) (US EIA, 2010). Thus, even with strong policy initiatives and major technological developments that incentivize for the implementation of energy efficiency, renewable energy, and other low carbon technologies, fossil fuels will remain a major contributor to Japan's energy fuel mix for the coming two decades. Although not the only option, CCS is expected to be a major, economically feasible tool to reduce Japan's CO_2 emissions as part of its efforts to combat climate change (Ministry of Economy, Trade and Industry of Japan, 2010).

13.6.10.4 Human Capacity, Research and Development

Japanese governmental agencies, academic institutes, and private industrial/commercial businesses are actively involved in CCS-related endeavors both locally and internationally. At the governmental level, CCS-related research initiatives have been initiated and supported by governmental agencies within the Ministry of Economy, Trade and Industry, Ministry of Science and Education, Ministry of Environment, and the Prime Minister Cabinet Office, with plans to reduce 100 $MtCO_2$ emissions through CCS by 2020 (Lund et al., 2008). Two major government initiatives are the CO_2 Storage Research Group within the Research Institute of Innovative Technology for the Earth under the Ministry for Environment, Trade and Industry (see RITE, 2011) and the New Energy and Industrial Technology Development Organization (Lund et al., 2008). The private sector is also promoting CCS initiatives either individually or in collaboration with the Japanese Government. In 2008 the Japanese CCS Company Ltd was launched by 29 power and energy firms in Japan to advise the government on the feasibility CCS implementation. Electric utilities, industrial firms, and private Japanese international companies have also funded research projects to develop advanced capture technologies and investigate ocean sequestration (Lund et al., 2008). In this regard, the CCS R&D network database of the Global CCS Institute shows that a total of 32 organizations in Japan are involved in CCS R&D, the majority of which is related to CCS technologies (GCCSI, 2011b).

In addition to the local efforts, Japan is actively engaged in international collaboration on CCS initiatives. Japan is a member of CSLF, GCCSI, and IEA CCS roadmap. In addition, Japan is collaborating with China on an EOR project that involves capturing 1–3 $MtCO_2$ from the Harbin thermal power plant in Heilungkiang Province to be injected and stored in Daqing Oilfield, China's largest oil field. The Yantani

IGCC project is another example of collaboration between both countries where Japan is primarily involved through Mitsubishi Heavy Industry. In addition to China, Japan is collaborating with Vietnam on the White Tiger CCS Project, Malaysia on Bintulu CCS Project, Australia on CS Energy Oxy-Fuel Project, and United Arab Emirates on JODCO EOR project. All aforementioned initiatives contribute significantly to building a competently educated human capital that would be expected to play a major role in advancing CCS technology (Lund et al., 2008).

13.6.10.5 CCS Legal and Policy Initiatives

Although there is currently no specific regulations, for carbon capture and storage activities in the country, Japan's national policies promote CCS as major climate change mitigation option. The *Cool Earth-Innovative Energy Technology Program* report, issued in March 2008 by the Ministry of Environment, Trade and Industry, identifies CCS as one of the major technologies that need to be focused on and developed in order to achieve substantial reductions in CO_2 emissions by 2050. The report includes CCS on the top of 21 priority-technologies to support. The program lays out a multiphase plan to concurrently accelerate technological enhancement, reduce cost, implement large-scale projects, maintain strong international collaboration, and draft domestic regulations and laws between 2020 and 2050 (Ministry of Economy, Trade and Industry, Japan, 2008).

Another important aspect affecting the deployment of CCS is the sufficiency of governmental funding. Currently, modest funding is provided by the Japanese Ministry of Economy, Trade and Industry to the Office of Environmental Affairs whose R&D budget was 5.66 billion Yen (~US$50 million) in 2006 and 4.3 billion Yen (~US$37 million) in 2007, with main focus on two areas: ocean/saline aquifer storage and clean coal technologies. Another US$10 million was allocated for international coal utilization projects by the New Energy and Industrial Technology Development Organization (Lund et al., 2008).

Studies show that the Japanese population is still not very well informed about CCS as an option to mitigate climate change: almost 68.8% of the population is not familiar with CCS, compared to less than 5% for solar or wind energy. Public media seems to have great impact on people's awareness, as 72% of the people learn about CCS from either television programs or newspapers. In that regard, four major factors are found to shape people's perception about CCS: concern about risk and leakage, understanding of effectiveness of CCS, responsibility for mitigation of CO_2, and concern about use of fossil fuel. Surveying the Japanese public opinions shows that people have a positive attitude toward the implementation of CCS, but they become less supportive when asked about CCS implementation in specific applications and locations. As such, it is unlikely that the Japanese public would voice strong opposition against CCS implementation in the future, but educating people about the CCS technologies and associated risks would play a major role in increasing public acceptability (Itaoka et. al., 2011).

13.6.11 Conclusions from the Regional Outlook

Technical potential of CCS on a global level is promising but on a regional level is differentiated. Much more work is required to realistically assess storage capacity on a worldwide, regional, and subregional basis. The information available to date indicates that there is sufficient worldwide capacity for storing at least 100 years of emissions from stationary sources in deep geological formations. On a regional basis, the distribution of deep geological formations is highly variable. In general, those regions with large fossil fuel resources, particularly oil and gas, have the largest storage potential. Some regions, including the Former Soviet Union, Northern Europe, North America, and the Middle East, have large storage capacity. Other areas, notably India, and parts of Southeast Asia, seem to have more limited geological storage capacity.

How and when CCS becomes an economically feasible option depends on the matching over time between CO_2 sources and sinks in specific regions. Besides the technical potential, the matching will depend on factors such as the electricity mix, the regulation of industry, national targets for CO_2 abatement, national and regional targets for renewables, local policies regarding nuclear power, and the existence of economic incentives. CCS comes at a cost and therefore requires appropriate incentives. Many institutional factors influence the degree to which CCS is implemented, including environmental regulations, mineral and property rights, carbon credits for CCS, international trading of carbon credits, and resolution of long-term liability issues.

13.7 Public Perception and Acceptance of CCS

The deployment of CCS technology relies on a myriad of interactions among technologies, markets, institutions, policies, regulations, and society (IPCC, 2005). Confidence about the technical feasibility of CCS has been growing, yet like any technology its deployment will be influenced by many social factors. Experiences with other technologies suggest that if public acceptance of a technology is lacking, large-scale global deployment is inhibited (Renn et al., 1995; Cormick, 2002; Kalaitzandonakes et al., 2005). Likewise, public perception and support will be critical if CCS technology is to achieve its potential as a GHG mitigation strategy (IEA, 2008a). As the number of CCS-related projects grows, and the potential for CCS technology to contribute to reducing CO_2 emissions becomes more prominent in societal debates, issues related to the public perception and social acceptance of this technology are becoming more salient. Public engagement and communication on CCS is therefore an increasingly important issue as large-scale deployment advances. This section outlines key public perception issues based on scholarly research and real world CCS projects. Additionally it

presents lessons learned from public engagement in the proposed and existing CCS projects.

13.7.1 What is Public Perception in the CCS Context?

13.7.1.1 Definition of 'Public'- What Does Public Constitute in the Context of CCS?

In the context of CCS, the term 'public' encompasses diverse subgroups or 'publics' – referring to general public, globally or within the vicinity of a project. The public also includes other segments of society such as policymakers, regulators, industry, academia, NGOs, and media, which helps the general public or communities form an opinion.

There are different dimensions of how public perception is formed and influenced –narrowly, at the project level, and more broadly, at national and global levels. At the project level, public perception and support for CCS technology will be influenced by the regulatory processes that are in place to ensure public participation in the decision-making. The direct public engagement at the project level is likely to happen through a variety of mechanisms during the different stages of a project, depending on the legal requirements or social norms in the country where the project is planned. For example, a common mechanism for public engagement includes public hearings as a part of the project approval process. These are the more concrete interactions with the public, focusing at a specific project level.

The policy debate surrounding CCS technology is the other dimension that will define broader public perception of the technology. The public is generally represented by and organized in non-governmental organizations, such as environmental NGOs, community groups and the like. How governments and other stakeholders perceive CCS, as part of their national climate change mitigation strategies, and how they frame national and international policies, will also affect the public's perception and support of the technology.

13.7.1.2 Introduction to Research Methods and Issues around Public Perception of CCS

Public perception of CCS technology has been assessed through numerous research and case studies, conducted across the world at national as well as project-specific levels. These research studies have relied on different research methods such as survey instruments, focus groups, mental model approach, factor analysis, information choice questionnaires, and discrete choice analysis to identify public perceptions of CCS at the broader societal level. Most of the studies use one or a combination of three methods: a written or digital survey method, focus or discussion groups, and experiments. In surveys, experimental surveys and experiments respondents are often given written information to read. In focus or discussion groups participants are often informed by researchers, experts or handouts, or a combination thereof (Huijts, 2003; Curry et al., 2004; 2006; Palmgren et al., 2004; Shackley et al., 2005; Sharp et al., 2006; Reiner et al., 2006; Best-Waldhober et al., 2006, Ha-Duong et al., 2009; Itaoka et al., 2004; 2006; 2009). More recently, the public has also been engaged at the specific project level (see case studies summarized in Table 13.8), although the motivations behind engaging the public living in the vicinity of the projects are slightly different than broad national-level social science-based research. The project-level public engagement aims for making better project decisions, supporting the successful design and implementation of the proposed project and, in some cases meeting the regulatory requirements.

13.7.2 Public Perception of CCS Technology

13.7.2.1 A Summary and Analysis of Research Conducted over the Past Few Years to Assess Public Perception of CCS across the World

The numbers of research studies to assess public perception of the technology around the world have grown over the past five years (for a review, see Reiner, 2008; Ashworth et al., 2007). At the broad societal level, these studies show consistency in some areas and differences in others. Both across jurisdictions and over time, all studies show that the vast majority of the public is not aware of CCS and even fewer understand the technology, its risks and benefits (Johnsson et al., 2009; Reiner et al., 2006). Differences, however, generally arise in the level of public understanding and support for CCS across countries (Reiner et al., 2006).

13.7.3 An Overview of CCS Public Perception Survey Research

Most of the studies to assess public perception of CCS have been conducted in industrialized countries. Studies to evaluate public acceptance and support of CCS in the major coal-dependent emerging economies are practically nonexistent. This can be attributed to very few to almost no CCS projects in these countries due to limited R&D, lack of government support for projects, and in those areas where projects exist, limited regulatory and institutional capacity to engage the general public.

The studies to assess public perception of CCS around the world and their findings are summarized below:

- In the Netherlands a study conducted in 2003 (Huijts, 2003) indicated that residents not living above a likely CO_2 storage site had neutral to positive attitudes about CCS but were less supportive to its development in their community or nearby, suggesting "Not In My Back Yard" (NIMBY) characteristics of public perception of CCS.
- The survey conducted by MIT to assess general public perception of CCS in the United States (Curry et al., 2004; 2007) confirms very low public awareness of CCS. The internet-based survey among samples of 1200 respondents conducted in 2003 and 2006 reveals that more

than 90% of the respondents had never heard of CCS and the results were largely consistent during both survey periods. Support for CCS is also linked to public attitudes about fossil fuel alternatives such as renewable energy, efficiency measures, and demand reduction.

- A 2004 study in the United States by Carnegie Mellon University (Palmgren et al., 2004) found that people were significantly less willing to pay for CCS than for any other major option to reduce CO_2 emissions, including new nuclear power plants.
- Studies in the United Kingdom (Shackley et al., 2005; 2007) found "slight support" for CCS in concept but also a belief that as a standalone policy "CCS might delay more far-reaching and necessary long-term changes in society's use of energy."
- A 2006 survey of 900 respondents in Australia (Miller et al., 2007) found that although most respondents believe it is very important to reduce greenhouse gas emissions at a national level, many are "neutral" toward CCS as a strategy. This study found that approximately 40% of the public believes CCS would be "a quick fix that would not solve the greenhouse gas problem." A less representative but more recent Australian study confirmed those average results (Ashworth et al., 2009).
- A 2006 study in Canada (Sharp et al., 2006) found low awareness of CCS in a survey among 1972 respondents in Canada. Although between 10% of respondents in Alberta and Saskatchewan and 15% of respondents in the rest of Canada said they had heard of CCS, very few were able to correctly identify the problem that will be addressed by CCS.
- Reiner et al. compared the awareness of CCS in the United States, United Kingdom, Sweden, and Japan (Reiner et al., 2006). The four samples in this study were mostly drawn at random from the countries' adult population and consisted of at least 742 respondents per sample. The study found low awareness of CCS in all four countries, ranging from 22% of respondents confirming they had heard or read about CCS in Japan to as little as 4% in the United States.
- A recent survey of 1076 respondents in France revealed that a vast majority of respondents were not strictly opposed of CCS but were more suspicious than supportive. The study also showed that a vast majority of respondents had not heard of CCS and only 6% of a representative sample was able to define the term (Ha Duong et al., 2009).
- A recent study in Switzerland (Wallquist et al., 2009) investigating lay people's concepts of CO_2 and CCS showed that some people were worried that CO_2 might cause cancer or even that CO_2 leaking from storage might cause DNA changes. These kinds of misconceptions are not likely to be anticipated by experts and therefore less likely to be investigated in polls or surveys or addressed in information about CCS technology.
- Other surveys in the Netherlands conducted in 2006, 2007, and 2008 (Best-Waldhober et al., 2006; 2008; Lambrichs, 2008) showed similar results. Depending on the kind of CCS technology that the three samples, a total of 918 respondents, were asked about, between 51.2–91.4% of respondents stated they were unaware of the technology.
- The survey research conducted in Japan (Itaoka et al., 2004; 2006; 2009; Tokushige et al., 2007) suggests very limited understanding of CCS technology among the respondents. The effectiveness of CCS (i.e., its effect on CO_2 emission reduction) and perception of potential benefits of CCS were the two most influential factors for public acceptance of CCS.

Some researchers have considered traditional questionnaire methodologies less suitable for examining public perceptions of CCS because with limited or no knowledge about an issue there is a risk of producing variable responses or in some instances "pseudo opinions" (Best-Waldhober et al., 2009). Malone et al. (2009) further state that, "because of the inherent difficulty of providing information in an unbiased way, surveys may be compromised at the outset if they seek to educate." Providing respondents with elaborate, understandable, recent, accurate, and balanced information on CCS technologies as well as their consequences and context is difficult and highly time- and resource-consuming. Most studies can only partially overcome these issues and are thereby unable to rule out susceptibility to bias. Therefore, the opinions found in these studies should be interpreted with care.

13.7.3.1 The Role of Information

Studies found that in some cases, when information was provided solely as part of a questionnaire, individuals were more negative toward the technology. Conversely, when information was provided with increasing depth and interactivity, individual attitudes toward CCS tended to be more positive. Some studies have tried to address this by providing respondents with information about CCS to see how informed and uninformed perceptions of CCS vary among the general public. In the United States, a survey of over 100 respondents shows that exposure to information about CCS technology increased the public level of understanding as well as support for advancing the technology (Stephens et al., 2009). Another study conducted in the Netherlands tested traditional survey methodology on a sample of 327 respondents and information choice questionnaires on 995 respondents (where information about CCS is provided to the respondents) and reported that the public is more supportive of the technology after processing relevant information (Best-Waldhober, 2009). Similar results were obtained from Japan, where a survey administered on a sample of 1006 adults in Tokyo revealed that additional information, prior to the survey, led to increased support for the technology (Itaoka, 2006; 2009).

13.7.3.2 Which Actors Are Trusted?

Research by Ashworth et al. (2006), Mors (2009), and Terwel (2009) shows that the relative trust individuals place in the information source is a key factor influencing acceptance of CCS. People put more

Table 13.6 | Strengths and weaknesses of existing public perception research.

Strengths of existing public perception research	• Successful identification of public's concerns and issues about CCS • A range of methods have been tested to assess public perception of CCS in different countries, which has not only provided insights into how public perceives CCS but also shed light on advantages and disadvantages of using different research methods • The results of public perception research has provided some guidance to policy makers and project developers • Comparison beginning to occur across countries to identify cultural similarities and differences toward CCS • Meaningful dialogue is more successful in engaging public–some activities have ventured beyond survey research
Weaknesses of existing public perception research	• Large focus on survey research in comparison with meaningful engagement and communication about CCS • Many activities directed at students, and as a subset of lay public, their views are not necessarily representative of the society • Little emphasis on evaluating perception of public toward CCS in developing countries • Lack of coordination among researchers in conducting public perception research • Limited investment and funding for CCS public communication research

Source: Ashworth et al., 2007; Reiner, 2008.

trust in environmental NGOs than in industrial organizations or the government. The previous experience with the organizations or the actors involved, concerns over accountability, and openness can also play important roles in shaping public trust (Reiner, 2008). The communication strategies by untrustworthy stakeholders may result in negative public attitudes toward CCS. Additionally, communication about CCS may result in more positive perceptions when stakeholders work together to provide information to the public rather than as separate "stand alone" organizations. The role of the CCS community, as an epistemic community, is also thought to play a role in the perception of the technology (Stephens et al., 2011).

13.7.3.3 Analysis of Existing Public Perception Research

The conclusions that can be drawn from the CCS public perception research studies depend on the kind and quality of the information as well as the method used. Methods using some kind of discussion group often have the advantage of giving insight into the perceptions lay people have of CCS technology, which might be very different from the perceptions of experts. The downside is that these kinds of methods are expensive and time-consuming, which often leads to only a few small discussion or focus groups being used, resulting in conclusions that cannot be generalized to the larger population (Shackley et al., 2005). Surveys with representative samples do not have this disadvantage. However, surveys often use a restricted set of questions leading to a restricted set of possible answers. This restriction might lead to missing certain issues that the experts or researchers had not thought of but that may be important to the public (Curry et al., 2006; Best-Waldhober, 2006; Itaoka et al., 2006; Malone et al., 2009).

Some studies have analyzed the existing CCS public perception research and communication activities, illustrated in Table 13.6 (Ashworth et al., 2007; Reiner, 2008). They conclude that little work has been done to inform the general public about CCS and the majority of activities have been surveys used to inform research, policy, and environmental NGO communities. Beyond the survey there has been very little communication activity targeted at the general public, and as a result overall public awareness of CCS is still low. The total investment in communication of CCS also remains significantly lower compared to the allocated budgets of the CCS technological research and development programs. Limited budgets have adversely impacted the scope and methodology employed for public perception research. On the positive side, the existing research provides some useful insights into similarities and differences on how the public perceives CCS across nations, globally, and locally. The studies also provide an understanding of issues of public concerns regarding CCS.

13.7.3.4 Public Perception of CCS at the Global Level

Globally, the understanding and support for CCS among the public remains low. The public opinion on CCS varies based on socioeconomic status, level of education, culture, and professional backgrounds. The results of several studies suggest that people with a higher education background have more positive attitudes toward the technology. Conversely, those of lower socioeconomic background and education levels tend to be more skeptical (Bradbury et al., 2009). Likewise, the energy industry seems to be more supportive of CCS whereas some environmental advocacy organizations and local public interest groups have come out openly against CCS. Other major environmental NGOs favor CCS along with a broad portfolio of GHG mitigation options. The lower understanding of CCS is attributed to limited engagement and lack of open and honest communication with the public about the technology. In some cases, the lack of awareness regarding CCS is also tied to the public's limited understanding of and belief in climate change (Parfomak, 2008). Some studies tried to place CCS in a broader context by investigating whether the public considers CO_2 emissions as a problem to be solved. Giving people several societal issues to rank, Curry et al. (2007) report that protecting the environment was the eleventh highest ranked priority for Americans (out of 18 issues), while Palmgren et al. (2004) respondents ranked "reducing climate change" as the lowest social priority of the 15 choices provided them. Although general awareness regarding climate change and its implications are reported to have been increasing worldwide, there are some parts of society that still do not believe or give credibility to anthropogenic climate change as a pressing global problem.

13.7.3.5 Public Perception of CCS at the Local Level

When it comes to siting a CCS project in their vicinity, the public tends to become more reluctant and often negative in their support for the technology. Research study in Japan and the Netherlands reported that the public seems to be supportive of CCS but expressed NIMBY concerns when asked if they would support a CCS project in their community (Itaoka et al., 2004; 2006; Huijts, 2003). The existing research and experience with engaging the public in the vicinity of the proposed CCS projects demonstrate that at the local level, public support or opposition to CCS is motivated by both concerns as well as benefits of the technology. For example, some communities perceive CCS projects as economic opportunities and hence support the project in their vicinity (Hund et al., 2009), while others may focus upon the unfair distribution of hazards and hence oppose a project in their vicinity (Bradbury et al., 2009; Simpson, 2009) (see case studies Table 13.8).

13.7.3.6 What Are the Public's Main Concerns Regarding CCS?

The public's concerns about CCS stem in part from the lack of understanding of the role of technology as a climate change mitigation option and its potential environmental health and socioeconomic risks.

At the specific project level, the public is concerned about potential impacts of siting a CCS project in their community. A recent study across the three regional carbon sequestration partnerships in the United States (Bradbury et al., 2009) identified a range of social concerns regarding CCS among local communities (see Table 13.7). In addition to fear of underground CO_2 storage risks, the public expressed lack of trust in government authority and the private sector as a source of information and raised concern about the fairness of CCS implementation procedures. The public was also concerned about being neglected or ignored if the project turned out to be more harmful than expected. Concerns also varied based on the potential impacts of a proposed CCS project at the individual level; thus local landowners in the vicinity of proposed projects are concerned about the effect of conducting seismic surveys on their property, the effect of potential CO_2 seepage, and other issues.

13.7.3.7 Factors Affecting Public Perception of CCS

Public opinion and support for CCS is influenced by several factors such as cultural, educational, and socioeconomic background; past experience with other energy infrastructure and development projects; perceived risks and benefits of CCS technology; and influence by media and other stakeholders such as academia, NGOs, and industry.

Table 13.7 | An overview of public concerns regarding CCS technology.

Public concerns about CCS	• Safety risks of CO_2 leak • Contamination of ground water • Upfront impacts of increased coal mining • Effect on local environment including plants and animals near site • Assumption that CO_2 is explosive or poisonous • Effect of conducting seismic survey on their property General concerns: • Availability of enough storage sites • Long-term viability and who is liable for stored CO_2 • Lack of infrastructure to support large-scale deployment • Diversion of interest and funding from alternative energy • Lack of clarity on issues such as pore space ownership • Cost-economic concerns • Risk of unknown technology
CCS benefits as cited by public	• It could provide a good bridge to the future • If successful, can avoid large quantities of CO_2 from getting into atmosphere • Allows continued use of fossil fuels which provides economic advantage for some countries or regions • Helps clean up coal-based power plants • Allows emissions to be reduced without changing lifestyle too much

Source: Ashworth et al., 2006; Bradbury et al., 2009.

13.7.3.8 Stakeholder Perception of CCS Technology

Besides understanding the general public's view of CCS, some studies have also assessed other stakeholders' perceptions of the technology. Usually those stakeholders are grouped in environmental NGOs, academia, government, and industry. However, there can be more specific groupings, such as environmental justice groups in the United States, the financing industry, or different ministries in countries that affect the overall government position. Surveys have been used to assess the views and concerns of stakeholders on CCS, but study of position papers can also lead to insights.

A global study (IEA Working Party on Fossil Fuels, 2007) evaluated stakeholder perceptions toward CCS across North America, Australia, the European Union, New Zealand, Japan, China, South Africa, and India and found relatively low levels of awareness of and support for CCS in developing countries compared to industrialized countries. The study also highlighted concerns and issues around CCS such as costs, lack of policy incentives and regulatory frameworks, and local risks of safety. It also found a growing interest in CCS among stakeholder groups in most regions. These findings are roughly consistent with the conclusions of a study specifically on stakeholder perceptions in Germany (Fischedick et al., 2008) with the exception of public acceptance: 65% of respondents in the German study flagged that as "very important," but it was not mentioned as a survey outcome in the IEA Working Party study.

A research study in Europe evaluated the perspectives of different stakeholder groups on CCS in more detail (Shackley et al., 2008) through a survey conducted among 512 respondents from most European countries.

The sample was not representative as the number of respondents was much greater from countries with an active CCS community, such as Norway, than from countries with low levels of CCS engagement, such as Hungary. The survey results showed that majority of the sample was moderately supportive of CCS and believed that it had a role to play in their own country's plans to mitigate carbon emissions. Safety risks were seen as a major concern by environmental NGOs, but much less so by other stakeholders.

An NGO survey was also done in the United States, where perceptions of national-level NGOs were inventoried through semistructured interviews supplemented by content analysis of their documents (Wong-Parodi et al., 2008). It was found that while all NGOs are committed to combating climate change, their views on CCS as a mitigation strategy vary considerably. Some NGOs, such as Greenpeace (2008), oppose CCS, arguing that it will become available too late, that costs and energy use are forbiddingly high, and that liability issues cannot be feasibly addressed. Other NGOs, particularly US environmental NGOs such as the Natural Resources Defense Council and the Environmental Defense Fund, but also the Norwegian Bellona Foundation (Stangeland et al., 2006), are generally favorable or even very supportive of CCS, although they generally warn of the risks.

In developing countries, the situation differs. A study to assess stakeholder perceptions of CCS in India (Shackley and Verma, 2008) revealed very low government support for CCS, whereas industry was fairly enthusiastic about demonstrating the technology. The study showed very limited interest and engagement by the NGO community. A multi-stakeholder survey of 700 participants in Brazil (Cunha et al., 2006) reported high support for technology from government and academia. Brazilian NGOs were less supportive of the technology, and the lay public is generally not aware of CCS. A specific case of acceptance of CCS is the support for the technology for inclusion in the Kyoto Protocol's Clean Development Mechanism. Stakeholder and government perceptions varied greatly on that matter, citing concerns over immaturity of the technology and lack of sustainable development benefits (de Coninck, 2008). For example, although Brazil is not opposing CCS in general, it opposed including CCS in the CDM.

Environmental NGOs often indicate the possibility of diverging attention and resources away from renewable energy and energy efficiency toward CCS as a major issue, as this would delay a fully sustainable energy system (Greenpeace, 2008). In the European Union study (Shackley et al., 2008) this was also evaluated, resulting in 51% of the respondents thinking there would be no such negative impacts on improving energy efficiency and reducing energy demand; 44% thought there would be some effect; very few thought such effects would be large. The study clearly indicated that NGO respondents were much more concerned about the implications for renewable energy than other stakeholders.

A relatively new area of study is how the CCS expert community itself generates and assesses information and communicates with the lay public. The CCS community is growing rapidly, exemplified by increasing attendance of conferences, expanding specific academic journals, and a long list of companies joining organizations like the Global CCS Institute. The internal communication on CCS, within the community, generally has a positive tone and is rarely critical of the technology, or of advocacy work done by CCS experts. This signals a community that is conveying a strong and coherent message on CCS to policymakers but that also, potentially, has a complacent attitude toward the technology itself, which is strengthened by the group process in the community. This signals a community that is conveying a strong and coherent message on CCS to policymakers but that also, potentially, has a complacent attitude toward the technology itself, which is strengthened by the group process in the community (Coninck, 2010; Stephens et al., 2011).

13.7.4 Implications of Public Perception for CCS

13.7.4.1 Implications of Not Acting on Public Perception of CCS

In the last few years, evidence has arisen on public perception of CCS projects in communities which provides information about what might happen if governments and project developers failed to act on public perception. The project portfolio shows mixed results. Some CCS demonstration projects were well received by the community and have been able to move forward, while others encountered local public opposition, which in several cases contributed to cancellation or stalling of the project. The case studies provide insight into what affects a community's and individual's views on CCS and on CCS projects and what the crucial factors are that may lead to the community being receptive or rejecting of a project.

A selection of the most notable and best-documented CCS demonstration projects and project plans is given in Table 13.8. It also reviews motivations behind public support or opposition.

13.7.4.2 Lessons on Public Engagement and Communication

The existing experience engaging the public indicates that at the local level, public acceptance and support for CCS is largely driven by the potential socioeconomic benefits of the project activity. In cases where the public is not supportive of a project, there is public concern about potential environmental, health, and economic impacts of deploying CCS in their vicinity. Clearly, when it comes to actually siting a project in a community, potential risks of CCS dominate over the public's concern about the potential impacts of global warming. Some studies have analyzed the existing public engagement and communication activities around CCS broadly as well as at specific project levels (Reiner, 2008; Ashworth et al., 2006; 2007; Simpson and Ashworth, 2009; Hund et al., 2009) and provide some useful recommendations for public engagement on CCS. In addition, the experience engaging with communities in the proposed and existing CCS projects (for example Table 13.8) also provide some useful lessons on public engagement, as summarized below:

Table 13.8 | A summary of some proposed CCS projects and motivation for public support or opposition.

Project	Location	Public Support	Motivations behind Public Perception
FutureGen	Illinois, USA	Yes	Industry and Government funded first-of-a-kind-in- the-world project 'cool factor', public recognition of socioeconomic benefits of the project to the community (Bielicki, 2008; Hund and Judd, 2008; Hund and Greenberg, 2010; Greenberg, 2009)
Wallula Energy Resource Center	Washington, USA	Yes	Focus on win-win attributes of the projects such as potential social and economic benefits (Hund, 2009)
Jamestown	New York, USA	No	Concerns regarding unproven geologic storage capacity, support for renewable rather then coal-fired power plant; community believes coal-fired plant will be environmentally and economically unsustainable (Simpson, 2009)
Carson	California, USA	No	Communities past experience with industries in the area and perceived environmental concerns (Stephens et al., 2009)
Barendrecht	Netherlands, EU	No	Concerns regarding added burden of another industrial facility on the environment, style of communication with public–lack of transparent and honest engagement with communities (Brunsting and Mikunda, 2010)
Vattenfall	Germany, EU	No	Concerns regarding health and environmental risks of potential CO_2 leakage, lack of large scale demonstration, diversion of funding and interest away from alternative energy, extra burden on consumers (Slavin and Jha, 2009)

- It is important to communicate with the public about CCS technology in the context of climate change mitigation and present it as a tool in a portfolio of options including renewables, energy efficiency, and demand reduction (Hund et al., 2009; Bielicki and Stephens, 2008; Simpson, 2009; Best-Waldhober, 2009; Itaoka et al., 2009).

- Honest, transparent, and clear communication is critical in establishing trust with the public. In addition, when providing information it is always better to respond to the questions and concerns expressed by communities (Simpson and Ashworth, 2009; Hund et al., 2009; Bielicki and Stephens, 2008; Simpson, 2009; Brunsting and Mikunda, 2010; and Greenberg, 2009).

- CCS is a new technology with little operational experience. Additional field tests and a demonstrated ability to mitigate risks should they arise will be necessary to improve the public's perception of risk from CCS technologies (Singleton et al., 2009). In addressing public concern about a proposed CCS project, it is important to communicate openly about potential or perceived risks and present a mitigation plan in cases where necessary to make the public aware of measures that can be taken to tackle those risks (Slovic et al., 1993).

- Engaging the public early on in the vicinity of a proposed CCS project is crucial as opinions may be slow or difficult to change once formed (Hund and Judd, 2008; Hund, 2009; de Coninck and Feenstra, 2009; Bielicki and Stephens, 2008).

- Concentric communication and engagement with the public involving thought leaders and influence groups such as local NGOs and media, in addition to general members of public, is important for successful public engagement around a proposed project (Hund and Judd, 2008; Hund, 2009; Greenberg, 2009).

- There is no one-size-fits-all approach; different publics will require different engagement and communication strategies (Bielicki and Stephens, 2008).

13.8 Summary and Conclusions

Over the past decade, there has been a remarkable increase in interest and investment in CCS. A decade ago, there was only one operating project, little corporate or government investment in R&D, and no financial incentives to promote CCS. Today there are over 234 projects of various sizes and stages of development. Many companies have significant investments in technology development, and governments around the world have committed billions of dollars for R&D, scale-up, and deployment. The coming decade will be critical in the technology development and the ultimate role this option plays in reducing GHG emissions. While the outlook is quite promising, there are a number of economic, scientific, and social challenges ahead.

CCS involves the integration of four elements: CO_2 capture, compression of, transportation to the storage location, and isolation from the atmosphere by pumping it into appropriate saline formations, oil and gas reservoirs, and coalbeds with effective seals to keep it safely and securely trapped underground. Storage in other rock types such as basalts, oil and gas shales, and subsea bed sediments may also be possible, but much less is known about their potential. Component technologies are in different stages of development, some fully mature, such as compression, and some such as storage in saline formations, in the early stages of demonstration.

Three approaches are available for capture from the power and industrial sources that produce CO_2 gas with relatively small concentration of contaminants: post-combustion capture, pre-combustion capture, and oxy-combustion capture. All have been demonstrated; some are used

routinely today for other applications, but little experience is available for integration and optimization with power production or most industrial applications. Considering full life cycle emissions, CCS technology can reduce up to about 65–85% of CO_2 emissions from fossil fuel combustion from stationary sources. CCS is applicable to the power generation and the industrial sectors (see also Chapter 12). In the future, CCS may contribute significantly to the transportation sector via hydrogen production and/or electrification of light duty vehicle and public transport, or through reducing emissions from biofuel production processes (see Chapter 17 for analyses on different pathways).

Successful experiences from five ongoing projects demonstrate that, at least on this limited scale, CCS can be safe and effective for reducing emissions. Moreover, relevant experience from nearly 40 years, currently at the rate of 45 $MtCO_2$/yr for enhanced oil recovery, also shows that CO_2 can safely be pumped and retained underground. Our best understanding of storage security can be summarized as follows:

> *Observations from **commercial storage projects**, engineered and natural analogues as well as **theoretical considerations**, models, and **laboratory and field experiments** suggest that appropriately selected and managed geological storage **reservoirs are very likely to retain nearly all the injected CO_2 for very long times, more than long enough to provide benefits for the intended purpose of CCS.***

A five- to ten-fold scale-up in the size of individual projects operating today would be needed to capture, transport, and store emissions from a large (500–1000 MW) coal-fired power plant. A thousand fold scale-up in size of today's CCS enterprise would be needed to reduce emissions by billions of tonnes per year (Gt/yr). Herein lies one of the major challenges for CCS, which raises a number of issues. Specifically, is there sufficient capacity to store these large quantities of CO_2? What will this cost? And finally, what are the institutional, economic, and technical constraints for implementing CCS on this scale? Regional factors are likely to play a major role in the extent and timing of CCS implementation. Furthermore, the scale and speed at which CO_2 transport networks will need to be built, often through densely populated areas, will pose a challenge. Although successful experiences with CO_2 transport in the past indicate that issues associated with the design and operation of such networks can be addressed, aspects such as impurities, fluctuating demand, and securing stable operational conditions (e.g., avoiding two-phase flow) need to be further addressed.

On a regional basis, storage capacity and the quality of information is highly variable. The Former Soviet Union, Northern Europe, North America, and the Middle East appear to have the largest storage capacity. Other areas, notably Japan, India, and parts of Southeast Asia appear to have more limited geological storage capacity. The IPCC 2005 Special Report concluded there is sufficient capacity to store 100 years of emissions at the high end of the technical potential (2000 Gt). Recently, more detailed capacity estimates suggest that capacity will be on the high end of the IPCC range, but there is still considerable debate about how much storage capacity actually exists. The debate is particularly significant about saline formations, which are believed to have the greatest capacity. Research, geological assessments, and most importantly commercial-scale demonstration projects, will be needed to improve confidence in and reliability of capacity estimates.

Costs of capture for first generation CCS power plants available in the early 2020s are estimated to be about \$45/tCO_2 avoided for coal and \$115/tCO_2 avoided for natural gas. Estimates vary widely depending on whether the plant is the first or n^{th}-of-a-kind, the type of fuel, capture technology, and assumptions about the baseline technology. Capital costs and parasitic energy requirements of 15–30% are the major cost drivers. Research is underway to lower costs and energy requirements. Early demonstration projects are likely to cost more. Due to high costs, CCS will not take place without strong incentives to limit CO_2 emissions. Access to capital for large-scale deployment will be a major factor limiting the widespread use of CCS, particularly if the policy regime for emission reductions and regulatory requirements for storage – especially long-term liability for stored CO_2 – remains uncertain. Estimated costs of storage range from US\$2–35/tCO_2 and experience from operating projects fall in the middle of this range of US\$6–20/tCO_2. Transportation costs are highly site specific, depending on the transport distance and size of the pipeline. Assuming a 500 MW coal plant emitting about 4 $MtCO_2$/yr and an onshore pipeline transport over a distance of 100 km, costs for transport are estimated to range from US\$1.25–3.5 tCO_2. Overall costs of CCS including capture, transportation and storage are estimated to range from US\$50–70/tCO_2 avoided for coal based electricity generation. This could increase the cost of generating electricity by an estimated 50–100%.

The environmental risks of CCS appear to be manageable, but regulations are needed to ensure due diligence over the life cycle of the project, most importantly: siting decisions, operating guidelines, and monitoring and closure of a storage facility. Many members of the public have concerns about the safety and effectiveness of CCS. More CCS projects and education are needed to establish a convincing safety record.

Social, economic, policy, and political factors may limit deployment of CCS if not adequately addressed. Critical issues include ownership of underground pore space, long-term liability and stewardship, GHG accounting approaches and verification, and regulatory oversight regimes. Significant progress is being made by governments and the private sector on all of these issues. Government support to lower barriers for early deployments is needed to encourage private sector adoption. Developing countries will need support for technology access, lowering the cost of CCS, and developing workforce and regulatory capacity for permitting, monitoring, and oversight. CCS, combined with biomass gasification, can lead to net removal of CO_2 from the atmosphere, which is likely to be needed to achieve atmospheric stabilization of CO_2 and may provide an additional incentive for CCS adoption.

Finally, public support for CCS is crucial for large-scale deployment. Today, the public remains largely unaware of the purpose and nature of CCS technology. Much work remains in this area.

Executive Summary

In the 1970s, nuclear energy was expected to quickly become the dominant generator of electrical power. Its fuel costs are remarkably low because a million times more energy is released per unit weight by fission than by combustion. But safety requires redundant cooling and control systems, massive leak-tight containment structures, very conservative seismic design, and extremely stringent quality control. As a result, the capital costs of nuclear power plants at least, in Western Europe and North America, proved to be quite high and nuclear power did not become the dominant generator of electrical power.

The routine health risks and greenhouse gas emissions from fission power are small relative to those associated with coal, but there are also high-consequence risks: nuclear weapons proliferation and the possibility of overheated fuel releasing massive quantities of fission products to the environment. The public is sensitive to these risks. The 1979 Three Mile Island and 1986 Chernobyl accidents, along with the high capital costs, ended the rapid growth of global nuclear power capacity (Figures 14.1 and 14.2). After these accidents, the industry improved its overall safety culture, particularly with regard to operator training. This chapter was completed before the large releases or radioactivity from the Fukushima Daichi nuclear power plant that began in March 2011. That event has resulted in reviews of the adequacy of nuclear power safety design and regulation worldwide and, in some countries, a reconsideration of plans for new reactors and/or reactor operating license extensions.

Today, China has 24 GW_e of nuclear capacity under construction (IAEA-PRIS, September 28, 2010) and much more planned. But, Germany has decided to phase out nuclear power; and nuclear power elsewhere in Western Europe and North America, which together account for 63% of current global capacity, is being dogged again by high capital costs and it is not yet clear that new construction will offset the losses due to the retirement of old capacity. Cost escalation is better contained in East Asia, where the International Atomic Energy Agency (IAEA) expects 44–68% of global nuclear capacity expansion by 2030 to occur in China. In Japan, however, following the Fukushima accident, the government has decided to reduce the country's dependence on nuclear power and the debate is ongoing whether to phase it out entirely. Even for its high-nuclear-growth projection which assumes a doubling of current generating capacity by 2030, the IAEA acknowledges that nuclear power's current 14% share of global electric power generation will not increase.

An important societal debate is still ongoing. Do the potential environmental benefits from low-carbon nuclear power outweigh the risks inherent in the technology? These risks occur in reactor operation and possibly in disposal facilities,

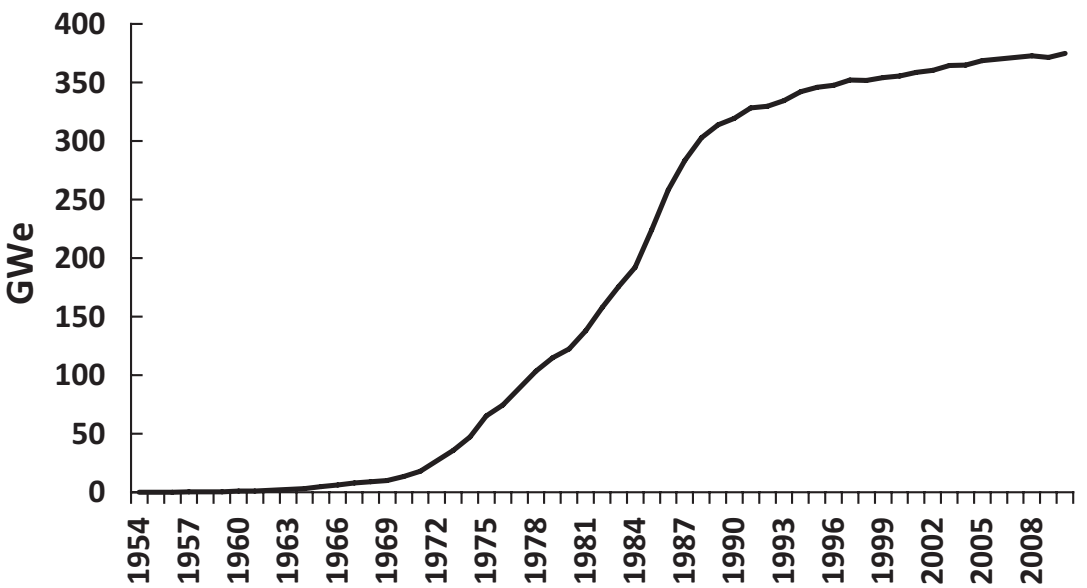

Figure 14.1 | Growth of global nuclear power capacity (GW_e). Source: data from IAEA-Pris, 9 January 2010.

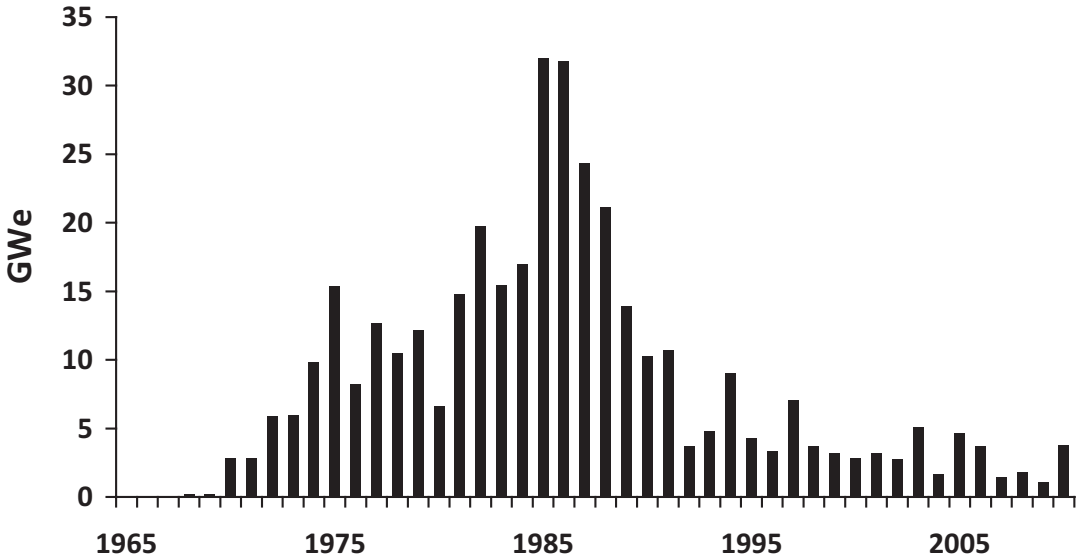

Figure 14.2 | Global nuclear capacity installed by year (GW_e). Source: data from IAEA-Pris, 9 January 2010.

but, in the view of the authors of this chapter, the most important risk from nuclear power is that its technology or materials may be used to make nuclear weapons. Of the 30 nations that have nuclear power today, seven are nuclear weapon states,[1] and most of the non-weapon states have had their non-weapon status stabilized either by being part of the European Union, the North Atlantic Treaty Organization (NATO) or otherwise being under the security umbrella of the United States, or by having been part of the Soviet Union or the Warsaw Pact in the past. The non-weapon states with the weakest security ties to the United States and Soviet Union – Argentina, Brazil, South Africa and Sweden – for a time used their nuclear power programs as covers for nuclear weapon programs. The majority of the countries that have expressed an interest in acquiring their first nuclear power plants (see Introduction, Table 14.2) are similarly not tied to constraining alliances such as NATO and the former Warsaw Pact, and some may have mixed motives for their interest in acquiring nuclear technology. That nuclear weapons may spread with nuclear power technology is therefore a danger that must be taken seriously.

The dominant type of nuclear power reactor in operation today, the light-water reactor (LWR), is relatively proliferation resistant when operated on a "once-through" fuel cycle. It is fueled with low-enriched uranium (LEU), which cannot be used to make nuclear weapons without further enrichment. Its spent fuel contains about 1% plutonium but it is mixed with highly radioactive fission products that make it inaccessible except by "reprocessing" with remotely controlled apparatus behind thick radiation shielding. Given the availability of low-cost uranium and the possibility to dispose spent fuel as waste there is no compelling economic or waste-management reason today to separate out this plutonium.

Much of the leadership of the global nuclear energy establishment, including in France, India, Japan, and Russia, however, continue to promote the uranium conservation and waste-reduction benefits of recovering plutonium from the spent fuel and recycling it. These arguments provided cover for India's nuclear weapon program, which used plutonium produced using a research reactor supplied under the international "Atoms for Peace" program to make its first nuclear explosion in 1974, and also for the weapons dimensions of at least six other nuclear programs.[2] Even when done for

1 In historical order: the United States, Russia, the United Kingdom, France, China, India and Pakistan. Israel and North Korea have nuclear weapons but do not have nuclear power plants.

2 Argentina, Brazil, South Korea, Pakistan, Sweden, and Taiwan. Fortunately, all but Pakistan have abandoned their nuclear weapons programs.

peaceful purposes, plutonium recycling is destabilizing because it dramatically reduces the time required for a country to implement a decision to acquire nuclear weapons.

The other route to nuclear weapons involves the enrichment of uranium to a level above 20% uranium-235 (typically to more than 90%). Historically, acquiring this capability required a massive investment in a gaseous diffusion plant, with thousands of stages of compression of an ever-smaller stream of corrosive uranium hexafluoride gas through porous barriers. Today, however, the dominant enrichment technology is the gas centrifuge, which, as Brazil, India, Iran, and Pakistan have demonstrated, can be deployed in affordable plants that can begin operating on an even smaller scale than that required to fuel a single gigawatt-scale LWR. Unfortunately, such plants can easily be used or reconfigured to produce weapon-grade uranium, and a plant sized to fuel a 1-gigawatt electric (GW_e) LWR could produce enough material for 25 nuclear weapons per year. Today, members of the nonproliferation community are devoting much of their attention to preventing the spread of small national centrifuge enrichment plants.

The final issue that contributes to the uncertainty of the future of nuclear energy is the persistent opposition from a significant portion of the public. As memories of the accidents at Three Mile Island and Chernobyl faded and concerns about the consequences of climate change increased, the trend was toward public opinion that was more favorable. The Fukushima accident has revived concerns about reactor safety, however. Public concern about radioactive waste and opposition to the siting of central spent-fuel storage sites have also helped keep reprocessing plants alive as alternative destinations for spent fuel, despite their poor economics and the proliferation dangers they pose. Of the countries that are most advanced in siting repositories, Finland and Sweden do not reprocess and France does. The radiological hazards from properly designed deep underground waste repositories are small in comparison with those of a Chernobyl-scale release to the atmosphere from a nuclear power plant accident. Perhaps it is due to their recognition of this fact that the communities that have agreed to host radioactive waste repositories already host nuclear power plants.

In the 1970s, nuclear power proponents expected that by 2010 nuclear power would produce perhaps 80–90% of all electrical energy globally (US AEC, 1974). Today, the official high-growth projection of the Organisation for Economic Co-operation and Development Nuclear Energy Agency estimates that nuclear power plants will generate about 20% of all electrical energy in 2050 (NEA, 2008a). Thus, nuclear power could make a significant contribution to the global electricity supply. At the other extreme, it could be phased out, especially if another accident or terrorist incident causes a Chernobyl-scale release of radioactivity. If the spread of nuclear energy cannot be decoupled to a much larger extent from the spread of nuclear weapons, for example, by ending reprocessing and shifting from national to multinational enrichment, it should be considered a last resort energy option.

14.1 Introduction

Fission energy is released when the nucleus of a very heavy atom such as uranium-235 or plutonium-239 splits into two. Fission is induced by the absorption of a neutron and releases typically two or three neutrons. If there is a sufficient concentration and mass of fissile material, i.e., a "critical mass," a sustained fission chain reaction can occur.

Most current-generation fission reactors are "slow-neutron" reactors.[3] The fast neutrons emitted by fission are slowed by multiple collisions with the nuclei of a "moderating" material before they cause additional fissions (Figure 14.3). Because the probability that fissile nuclei will capture neutrons increases greatly at low neutron velocities, this makes it possible to sustain a chain reaction in a mixture in which the fissile atoms are quite dilute. Indeed, the first reactors were fueled by natural uranium in which uranium-235 constituted only one out of 140 uranium atoms but captured about half of the slow neutrons. The remaining atoms in natural uranium are virtually all non-fissile uranium-238, which captures most of the slow neutrons not absorbed by uranium-235 and is thereby converted into chain-reacting plutonium-239.

Fission power is climate friendly. The emissions of greenhouse gases per kilowatt-hour (kWh) from fission power on a life-cycle basis are on the order of a few percent of those from fossil-fueled power plants.[4] A nuclear capacity of 500–700 GW_e, i.e., 1.3–1.8 times current global nuclear capacity, could forestall the annual release of 10^9 tonnes of carbon to the atmosphere if used to replace coal-fired power plants that do not sequester their carbon dioxide emissions.[5] This would be about one-eighth of the global amount of carbon released into the atmosphere from fossil fuel use and cement production in 2005 (IPCC-PSB, 2007: 139) and 5–12% of the releases projected for 2030 in the full range of IPCC scenarios (IPCC-SRES, 2000: Figure 5–2). The other routine occupational and environmental impacts of nuclear power plants per kWh are relatively low compared with those of fossil power (see Chapter 4). But the potential for catastrophic releases of radioactivity makes the reputation of the global nuclear industry vulnerable to unsafe practices in any country. It is therefore critical to maintain high safety and security standards in design, construction, and operation everywhere.

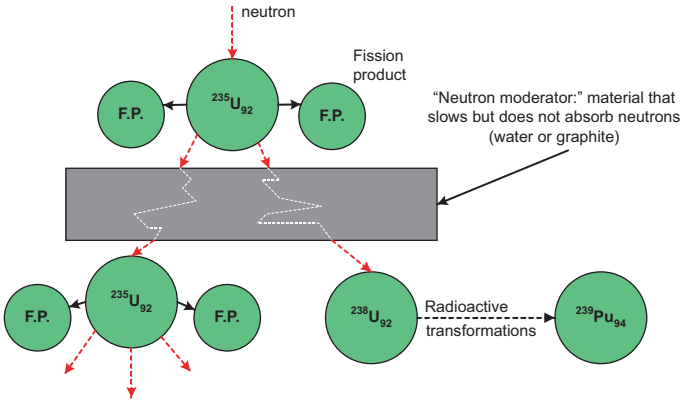

Figure 14.3 | A fission chain reaction in a slow-neutron reactor. Each fission splits a nucleus of a fissile atom (shown here as U-235) into two unequal medium-weight nuclei (fission products, F.P.) and also produces typically two or three neutrons that can go on and cause further fissions. In almost all of today's power reactors, these neutrons are slowed by collisions with the nuclei in "moderating" material (typically with hydrogen nuclei in water) which increases the probability that they will cause fissions. In a reactor operating in steady state, one fission causes on average one fission. The extra neutrons are mostly absorbed by U-238, converting it into U-239, which decays by electron (and antineutrino) emission into neptunium-239 (which has 93 protons) and then into plutonium-239 (94 protons). Plutonium-239 is itself a fissile isotope and contributes increasingly to the chain reaction in the reactor core as the U-235 is depleted and the plutonium concentration builds up.

Although relatively little nuclear capacity has been added in recent years (Figure 14.2), the average capacity factors of nuclear power plants have increased steadily to about 80%.[6] Between 1988 and 2001, they therefore maintained their share of generated electricity at about 17%, before dropping to about 14% by 2009 (IAEA, 2010d: Tables 3 and 4).[7] For nuclear energy to maintain its share of the global electrical power market there will have to be a dramatic increase in nuclear capacity construction – especially as most existing nuclear capacity will have to be replaced during the period 2010–2050.[8]

Given the uncertain capital costs of nuclear power plants, the risks associated with uncertain demand growth projections in North America and Europe, and the possibility of catastrophic accidents, private capital is unlikely to be available to fund nuclear power plant construction without government guarantees. Such support is available, however, in the form

3 "Slow" here is used as a relative term. Ultimately, neutrons are slowed down so that they have the kinetic energy associated with the atoms in the material through which they are passing. At this velocity, they are often called "thermal" neutrons. The velocity associated with the temperature of the water in a light-water reactor (about 300˚C) is about 4 km/s, more than ten times the speed of sound in the atmosphere.

4 Emissions from coal-fired power plants are about 1000 g CO_2/kWh. Emissions estimates for nuclear power plants range from 1.4 to 200 gCO_2/kWh (Sovacool, 2008a). Eliminating incomplete estimates and estimates associated with extremely low grades of uranium ore, and reducing two inexplicably high estimates for the emissions associated with decommissioning, we obtain a range of 38±27 g CO_2/kWh. The uranium ore being mined today typically has concentrations of 0.1% uranium and above (van Leeuwen, 2008, Figure D-3).

5 Assuming that 25.8 kg of carbon are released to the atmosphere per 10^9 J of energy from bituminous coal (World Energy Assessment, 2000, box D.1), an efficiency range for new coal power plants of 35–50% and an average nuclear-power plant capacity factor of 90% (478.5–683.6 GWe). See also Pacala and Socolow (2004).

6 There are substantial variations in these capacity factors, even among those states with the largest nuclear programs. For the period 2007–2009, the average capacity factors for the United States and France were 91 and 95%, respectively, and in Japan and Russia 63% and 81%, respectively (IAEA, PRIS, 11 Nov. 2010).

7 The average capacity factor ("unit capability factor" in the IAEA's terminology) is the ratio of the average output of a power plant as a percentage of its full generating capacity. The "up-rating" of nuclear power plants, i.e. operating them at higher power than their original design capacity, has also contributed to a lesser degree to increasing the number of kilowatt hours being generated by nuclear power during the period when few new plants were being built.

8 Assuming operating lifetimes of 40–60 years (see Figure 14.2).

of direct government funding, loan guarantees, or guaranteed payback of investments through government-regulated markets for electric power.

In China, the construction of nuclear power plants by state-owned companies is centrally approved in the five-year plans of China's National Development and Reform Commission, and investors receive tax incentives and low-interest loans. In France, two large government-owned companies – AREVA, which sells reactors and fuel-cycle services, and Électricité de France, the national utility – are partnering to finance and build reactors in other countries. In Russia, Rosatom, the government-owned company that builds and operates reactors and supplies fuel-cycle services, is using government funding and its own income to invest in a major expansion of both domestic capacity and sales overseas. In India, the national government is financing the construction of nuclear power reactors. In the United States, the US Congress passed a major package of incentives and loan guarantees in 2005 to restart reactor orders after a hiatus of three decades. Some state regulators in the United States also are allowing utilities to charge their customers for the costs of construction before their reactors start generating power.

All this government support will certainly result in the construction of some nuclear power reactors. Whether the new construction will be significant on a global scale remains to be seen. The IAEA believes that, with high growth rates for electric power consumption and favorable public policies, both electric power demand and nuclear power production could approximately double by 2030, with nuclear power slightly increasing its current 14% share of the global market for electric power to 16% by 2030. The IAEA's low-growth scenario shows global nuclear power capacity increasing by 47% by 2030 but its market share staying constant (IAEA, 2010d).

Much of the continuing political support for nuclear power stems from the large government nuclear research and development (R&D) establishments in the nuclear weapon states. The first power reactors in the former Soviet Union, the United Kingdom, and France were derivatives of their natural-uranium-fueled, graphite-moderated, plutonium production reactors.[9] Canada developed a natural-uranium-fueled heavy-water-moderated reactor and exported it to other countries interested in independence from foreign suppliers of enrichment services, most notably in India. Today's most successful power reactor, the low-enriched uranium-fueled light-water reactor (LWR), stems from the compact water-cooled reactors developed for submarine propulsion.

Most of the initial R&D relevant to nuclear power technology was therefore paid for by government military nuclear budgets. Later, separate

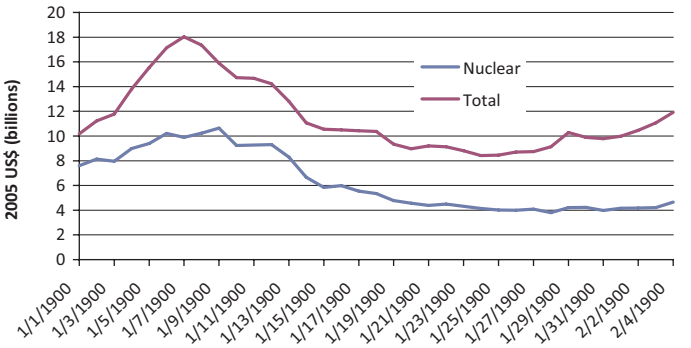

Figure 14.4 | Government energy RD&D expenditures in the OECD countries, 1974–2006. Nuclear includes both fission and fusion. Source: based on IEA, 2008.

civilian nuclear energy R&D programs developed but they continued to have privileged access to national treasuries relative to other energy R&D programs. Over the past three decades they have received more than 50% of government expenditures on energy research, development and demonstration (RD&D) projects (Figure 14.4). This bias toward nuclear energy spread to the national R&D establishments of some non-weapon states, most notably that of Japan.

Perhaps the most important question with regard to fission power is whether it can grow and spread without spreading nuclear weapons. Various efforts have been undertaken in the past to contain the spread of national spent-fuel reprocessing and uranium enrichment plants that remain the keys to producing nuclear weapon materials. There is reluctance in have-not countries, however, to forgo the option of acquiring a national enrichment plant. And, even though reprocessing and plutonium recycling are uneconomic and have few environmental benefits when used with current nuclear power reactors, many local communities have opposed plans to expand spent-fuel storage facilities at reactor sites or to host central interim storage facilities. This opposition has sustained reprocessing in Japan as an alternative destination for spent fuel, and has helped foster a revival of interest in reprocessing in the United States and South Korea.

14.1.1 Global and Regional Nuclear Capacity

Today, 29 countries plus Taiwan have operating nuclear power plants: 18 in Europe (including Armenia, Russia, and Ukraine), five in Asia (plus Taiwan), five in the Americas, and one in Africa (South Africa) (see Figure 14.5).

At the end of 2009, global nuclear generating capacity was 372 GW_e, of which 46% was in Europe (including Eastern Europe, Armenia, Ukraine and Russia), 30% in North America, and 21% in the Far East. The rest of the world – Africa, Latin America, the Middle East and South Asia – accounted for only 3% of this capacity (Table 14.1), but contributed a large part of the controversy over the proliferation implications.

9 Graphite and heavy water are used in reactors fueled with natural uranium to "moderate" (slow down) the typically two or three neutrons emitted by fissions to speeds where a large fraction of them will be absorbed by the U-235 and continue the chain reaction. The probability that the graphite or heavy water will itself absorb the neutrons is relatively low. The probability of neutron absorption is higher in the ordinary water used in light-water cooled reactors, which is why LWRs require enriched uranium fuel.

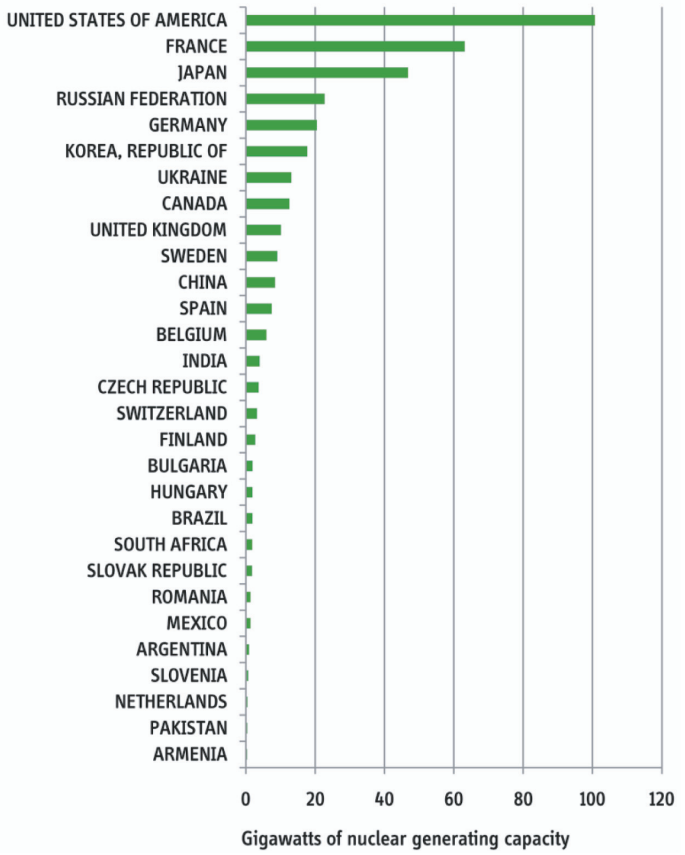

Figure 14.5 | Capacities of nuclear power reactors in operation by country, end of 2009. Source: data from IAEA-PRIS, January 9, 2010.

14.1.2 Projections for Expansion

The IAEA makes annual projections of global nuclear growth. Between 1985 and 1995, even the low projections were higher than what was actually built by 2000 and 2005 (IAEA, 2007a, figures 29, 30). There were few new orders for nuclear power plants and many orders were either cancelled or delayed because of falling electric power consumption growth rates and licensing and construction delays. As a result, projections of growth declined through 2000, and the low projections in 2000 even showed future declines in global nuclear generating capacity as the number of old plants being retired exceeded new builds.

Table 14.1 | Global distribution of nuclear power generating capacity, end of 2009.

Region	Nuclear generating capacity (GW_e)
North America	113.3
Western Europe	122.7
Pacific OECD Far East	46.8
Eastern and Central Europe	11.2
Former Soviet Union	36.4

Other Pacific Asia	22.7
Middle East and North Africa	0.0
Latin America	4.1
Sub-Saharan Africa	1.8
World Total	371.9

Source: IAEA, 2010d.

New orders resumed in 2005, however, and most power reactor licenses in the United States are being extended to allow operation for up to 60 years. The projections, therefore, began increasing again. The IAEA's 2010 projection was for a net increase in global nuclear generating capacity of 174–431 GW_e by 2030 (IAEA, 2010d). The high end of the range corresponds to more than a doubling of the 2009 global nuclear capacity and assumes an average net annual addition of new capacity of 25 GW_e/yr between 2020 and 2030. This corresponds to a growth rate that was only achieved in the past during the late 1980s (Figure 14.2).[10]

Much of the projected increase would be in the Far East (119–189 GW_e) and Eastern Europe (including Russia) (36–63 GW_e), reflecting in particular the ambitious plans of China and Russia (see the country studies in Section 14.3). North America is also projected for an increase (15–53 GW_e). In the low projection, nuclear capacity in Western Europe declines by 37 GW_e, while in the high projection, it increases by 35 GW_e. The other world regions – Latin America, Africa, the Middle East, South Asia, Southeast Asia, and the Pacific – together are projected to add 38–79 GW_e.

The IAEA's low and high growth projections for nuclear power are associated respectively with 2.1 and 3.1% average annual growth rates in global electric power production between 2009 and 2030 (IAEA, 2010d). For comparison, between 1996 and 2006, global electricity consumption increased at an average annual rate of 3.3% (US EIA, 2008b). Given the likelihood of an increase in electricity prices associated with a shift away from fossil-fuel-based generating capacity, global electricity consumption growth rates could decline below the range assumed by the IAEA. On the other hand, if a significant fraction of automobile transport shifts to electric cars or plug-in hybrids, that could help offset the price effect.[11]

Reflecting the revived interest in nuclear power, as of 2010, 61 countries had requested advice from the IAEA about acquiring their first nuclear

10 According to the press release accompanying the 2009 IAEA projection, "The low projection … assumes that … there are few changes in the laws and regulations affecting nuclear power… The high projection assumes … that recent rates of economic growth and electricity demand, especially in the Far East, continue. It also assumes that national policies to reduce greenhouse gas emissions are strengthened, which makes electricity generation from low-carbon technologies, like nuclear power and renewables, more attractive."

11 The current global population of automobiles is about 700 million (Transportation Energy Databook, 2009, Table 3.1). If they travel 15,000 km each on average, that would total about 10^{13} automobile-km/yr. Assuming that 0.2 kWh would be required per km (Electric Auto Association Europe, 2008) about 2×10^{12} kWh/yr would be required, equivalent to the output of about 250 GWe of generating capacity operating at an average capacity of 90%.

power plants (IAEA, 2010e). Excluding Iran, whose first nuclear power plant is virtually complete, and including Israel, which is the only country that is on a similar list developed by the Organisation for Economic Co-operation and Development (OECD) Nuclear Energy Agency but not on the IAEA list (NEA, 2008a, Table 2.1), the 61 countries are listed in Table 14.2.[12] In 2009, one of them, the United Arab Emirates (UAE), contracted with South Korea to build four 1.4-GW_e LWRs (Reuters, December 27, 2009).

12 A 2008 report by the OECD's NEA lists 25 countries, five of which have "planned or approved projects" and 20 of which have "proposed or intended" projects. "Planned or approved projects": Bangladesh, Belarus, Indonesia, Iran, Turkey and Vietnam. "Proposed or intended projects": Bahrain, Bangladesh, Egypt, Georgia, Ghana, Israel, Kazakhstan, Kuwait, Libya, Malaysia, Namibia, Nigeria, Oman, Philippines, Qatar, Saudi Arabia, Thailand, Uganda, UAE, and Yemen. More detailed information on how serious the interest is in many of these countries can be found in the Survey of Emerging Nuclear Energy States by the Centre for International Governance Innovation (CIGI, 2010).

The widespread interest in nuclear power reflects a broadly shared perception of the need to shift away from fossil fuels because of concerns about climate change. In some countries, nuclear power also is seen as a way to reduce the dependence on imported fuels. There is a concern, however, that a small fraction of countries are also interested in moving toward a nuclear weapon option. Currently, there is special concern that the nuclear weapon option inherent in Iran's uranium enrichment program may stimulate efforts by some of its neighbors to pursue their own nuclear weapon options. In the UAE–US Agreement for Peaceful Nuclear Cooperation, the UAE agreed to forgo the acquisition of uranium enrichment or spent-fuel reprocessing technologies (UAE–US, 2009) but other countries in the region have been unwilling to give up these rights.

Table 14.2 lists the 2007 gross domestic product (GDP) for the 61 countries and the generating capacity in GW_e that would have been required, at a 60% capacity factor, to produce the electric energy that they generated in 2006, 2007, or 2008. In terms of GDP, some countries, such as Mongolia (2009 GDP, US$5 billion) are so poor that it is difficult to understand how they could pay back the $US_{2005}$$4 billion cost of a standard 1-GW_e nuclear power plant (World Bank, 2009). The World Bank and Asian Development Bank do not provide loans for the purchase of nuclear power reactors (Schneider et al., 2009: 55). Until recently, South Africa (2009 GDP, $US_{2005}$$252 billion) had plans to add 20 GW_e of nuclear capacity by 2025. In December 2008, however, the South African government announced the cancellation of its request for tenders for the first 4 GW_e of capacity because "it is not affordable at this present juncture" (*WNN*, December 5, 2008). It seems unlikely that a country with an annual GDP of less than US$50 billion could afford a US$4 billion nuclear power plant. This situation could be eased if nuclear power plant exporters were willing to provide low-cost loans.

A second issue is that the capacity of many countries' grids may not be large enough to accommodate a standard 1-GW_e nuclear power plant. The IAEA recommends that a single nuclear power reactor not constitute more than 5–10% of the generating capacity on a grid (IAEA, 2007b: 39; 2010f, para. 59).

Of the 61 countries interested in acquiring a first nuclear power plant, listed in Table 14.2, only 24 pass both a US$50 billion annual GDP and a 5-GW_e grid capacity screening requirement (indicated with crosses, ×). Even though the threshold size for a grid required to support a nuclear power reactor has been reduced to 5 GW_e, to allow for the possibility of a doubling of the grid capacity before the first nuclear power plant comes online, the grid requirement appears to be the most stringent. It is mitigated, however, in regions where there is a strong supranational grid. There is an existing grid connecting Malaysia, Singapore, and Thailand, for example, and a proposed West Africa grid that would include Ghana and Nigeria. The grid constraint could also be eased by the use of nuclear power plants with lower generating capacities.

Beyond 2030. The OECD's Nuclear Energy Agency (NEA) has made high, low and phase-out projections of global nuclear capacity beyond 2030

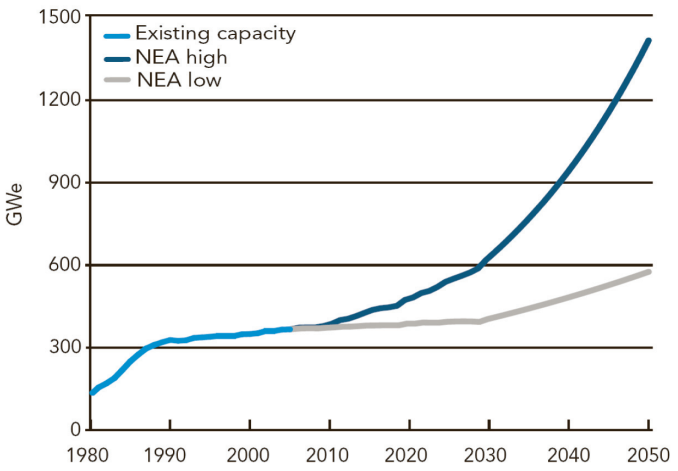

Figure 14.6 | Two Nuclear Energy Agency growth scenarios for nuclear power to 2050. Phase-out scenarios were also considered. Source: NEA, 2008a, Figure 3.11.

(Figure 14.6, phase-out scenarios not shown). They are rather arbitrary, but the high projection reflects a judgment as to the maximum credible rate at which nuclear power could be expanded worldwide. In the high scenario, it is assumed that, after the industry tools up over the next two decades, it will be able to bring online an average of more than 40 GW_e/yr of nuclear capacity during 2030–2050, slightly more than twice the rate of buildup between 1972 and 1987. Even so, the NEA high scenario has nuclear power generating only 22% of global electric energy in 2050 – up from 14% in 2009 (NEA, 2008a: 105).[13] In 2010, the IAEA produced almost identical projections for 2050 (IAEA, 2010d).

14.1.3 Fuel cycles

Nuclear fuel is derived from natural uranium. For use in the dominant reactor type, the LWR,[14] the chain-reacting uranium-235 is enriched from its natural level of 0.7% to between 4% and 5%. Uranium in this enrichment range is called low-enriched uranium (LEU).[15] The remainder of the uranium is almost entirely non-chain-reacting uranium-238.

The fuel resides in the reactor core for a few years until most of the uranium-235 has been fissioned. About 2% of the uranium-238 is converted by neutron absorption into plutonium. About half of this plutonium is also fissioned, so that, at the time of discharge, plutonium constitutes about 1% of the heavy elements (uranium plus reactor-produced transuranic elements) in the fuel (Figure 14.7).

13 At the country level, China and India have more ambitious plans than the capacity assumed in the NEA high scenario, which assumes approximately 120 GWe in China and 90 GWe in India in 2050 (see country studies below).

14 The core of an LWR is cooled by ordinary "light" water. The hydrogen nuclei in the water also slow down or "moderate" the neutrons in the chain reaction.

15 The IAEA defines uranium enriched to less than 20% in uranium-235 as LEU (IAEA, 2001). Uranium enriched to 20% or higher is called highly enriched uranium (HEU) and is considered weapon useable.

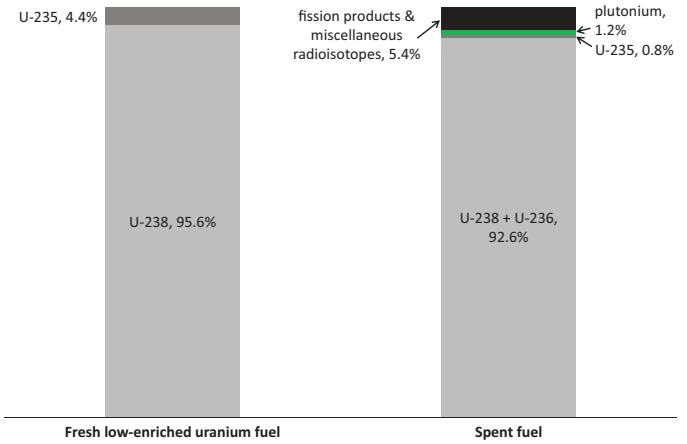

Figure 14.7 | Example of the composition of fresh and spent LWR fuel. Fresh fuel used in standard LWRs is "low-enriched" in uranium-235 (in this case 4.4% U-235) when it is put into the reactor core. Three to five years later, when the fuel is "spent," most of the U-235 has been fissioned, and some has been converted to U-236 by neutron absorption without fission. About 2% of the non-chain-reacting U-238 has been converted to plutonium and heavier "transuranic" isotopes, but more than half of the plutonium has been fissioned. Adapted from: NEA, 1989, Table 9, assuming 53 MW-days/kgU energy release.

The fission products in "spent" fuel are highly radioactive and generate so much heat that the fuel must be water cooled in deep pools for several years. After this period, the fuel can be placed in air-cooled, radiation-shielded dry casks for either transport or storage (Alvarez et al., 2003). After about a century, the radiation level from a spent fuel assembly will drop to a level below that considered "self-protecting" by the IAEA.[16]

14.1.3.1 Uranium enrichment

There are two technologies in commercial use for enriching uranium: diffusion and centrifugation of uranium hexafluoride (UF_6) gas. A third technology, based on the selective ionization of UF_6 molecules containing uranium-235 with finely tuned lasers, may soon be commercialized.

Gaseous diffusion. Gaseous diffusion was the first uranium enrichment technology to be used on a large scale. It was originally used in the United States, Russia, the United Kingdom, France, and China to produce highly enriched uranium (HEU) for weapons. Because of the compression work involved, gaseous diffusion enrichment is very energy intensive and, because of the thousands of stages involved, economies of scale resulted in enormous plants. A 10-million separative work unit (SWU)[17] gaseous diffusion plant that can supply enrichment services for 65 GW_e of LWR capacity requires about 3 GW_e of electrical power to operate at full capacity (Zhang and von Hippel, 2000, endnote 8). Because of its energy inefficiency, gaseous diffusion is used today only in one plant each by the United States and France, and these are being replaced.

Gas centrifuge. Gas centrifuge enrichment technology is more than ten times more energy efficient than gaseous diffusion, and was first deployed in the early 1960s in the Soviet Union and in the 1970s in Western Europe. UF_6 gas is spun at high speed in a vertical cylinder. Because the molecules containing uranium-238 atoms are slightly heavier, they concentrate near the wall. The fraction of the gas nearest the cylinder's axis is thereby slightly enriched in uranium-235 and can be skimmed off.

In a gas centrifuge system, the separation factor of a single stage is 1.3 to 1.7 (Glaser, 2008, Table 2).[18] For a separation factor of 1.5, only 15 stages are required to produce low-enriched uranium, and 40 stages to produce weapon-grade uranium. With a smaller number of stages, it is possible to build small plants, and more countries have been able to acquire them – in some cases for weapons purposes (Table 14.3).

Laser enrichment. Laser enrichment technology has been a candidate to compete with centrifuge enrichment since the 1980s, but was unsuccessful due to unresolved technical difficulties. The difficulties may now have been overcome, however, and, in 2008, a joint subsidiary of GE and Hitachi, later joined by the Canadian uranium producer, Cameco, was formed to commercialize in the United States a laser-enrichment technique developed by the Silex Company of Australia (GE-Hitachi, 2008).

If all the planned capacity shown in Table 14.3 is built, the global enrichment capacity in around 2017 will be about 70 million SWU/yr, enough to support at least 500 GW_e of LWR capacity.

14.1.3.2 Spent-fuel reprocessing

In France, India, Japan, and the United Kingdom, most spent fuel is shipped to "reprocessing plants" where it is dissolved using equipment operated remotely behind thick radiation shielding, and the uranium and plutonium are separated from the fission products. In France, the recovered plutonium is mixed back with uranium (about 7–8% plutonium) to make "mixed oxide" (MOX) fuel for LWRs (Figure 14.8). Since the plutonium from about 7 tonnes of spent LEU fuel is required to make about 1 tonne of MOX fuel (NEA, 1989), plutonium recycling can reduce EU fuel requirements by approximately 15%. This is currently being done in France. Japan has begun to do the same but its program has been delayed by mistakes and public opposition for about a decade (CNIC, November/December 2008). Russia and China reprocess only a small fraction of their spent fuel. Some of the uranium recovered by

16 The IAEA's self-protection standard is more than 1 Gray (100 rad) per hour at a distance of 1 meter (IAEA, 1999: Infcirc-225, Rev. 4, p.11, footnote).

17 SWU is a measure of the output of a uranium enrichment plant. Production of 1 kg of uranium containing 5% U-235 from natural uranium containing 0.72% U-235 with 0.3% U-235 remaining in the depleted uranium requires 7.2 SWUs.

18 The definition of the separation factor is $(e^p(1-e^t))/((1-e^p)e^t)$, where e^p and e^t are respectively the fractional amounts of uranium-235 of the product and depleted "tails" from a single stage of enrichment. For low enrichment, the separation factor can be approximated as e^p/e^t.

Table 14.3 | Centrifuge and laser-enrichment plants, operating, under construction and planned (including planned expansions). All plants, other than the proposed GLE laser-enrichment plant in the United States, are gas centrifuge plants.

Country	Plant (year for projected growth) (reference)	Capacity (10^6 SWU/yr)

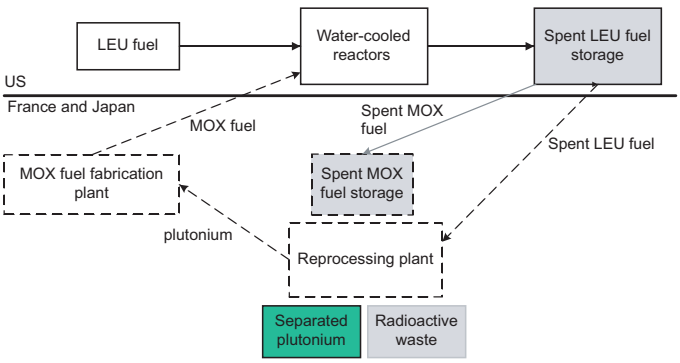

Figure 14.8 | Current spent-fuel disposal strategies. The "once-through" fuel cycle as currently practiced in the United States and many other countries is shown above the horizontal line; LEU fuel is irradiated in a LWR and then stored. The reprocessing and recycling system that is in operation in France and is planned in Japan is shown below the horizontal line. It currently involves the separation of the plutonium for recycling once in MOX fuel. The spent MOX fuel is then stored. Because of the high cost of reprocessing, it is much more expensive to produce MOX fuel than LEU fuel, and most countries have decided that it is not worthwhile. MOX fuel reduces the reactivity safety margins of LWRs somewhat. Except for LWRs specially designed for MOX fuel, the fraction of the core that is made up of MOX fuel is therefore limited to about one third.

reprocessing is also recycled (IAEA, 2007e). If it were all recycled, it could reduce the demand for natural uranium by almost an additional 10%. Similar reductions in uranium demand could also be achieved by reducing the depleted uranium assay for enrichment from the typical value of 0.3% to lower values.

A study for the French Prime Minister in 2000 estimated that reprocessing and plutonium recycling increase the cost of nuclear power by about 0.2 US¢/kWh (Charpin et al., 2000, converting 5 French francs = US_{2005}1). A study for the Japan Atomic Energy Commission in 2004 found the cost increase due to reprocessing in Japan to be about three times higher, at ¥0.6/kWh (about US_{2005}¢0.6/kWh) (CNIC, 2004b).

14.1.4 Current Reactor Technology

The dominant power reactor technology today is the LWR, which accounts for 89% of global operating nuclear power capacity (IAEA-PRIS, January

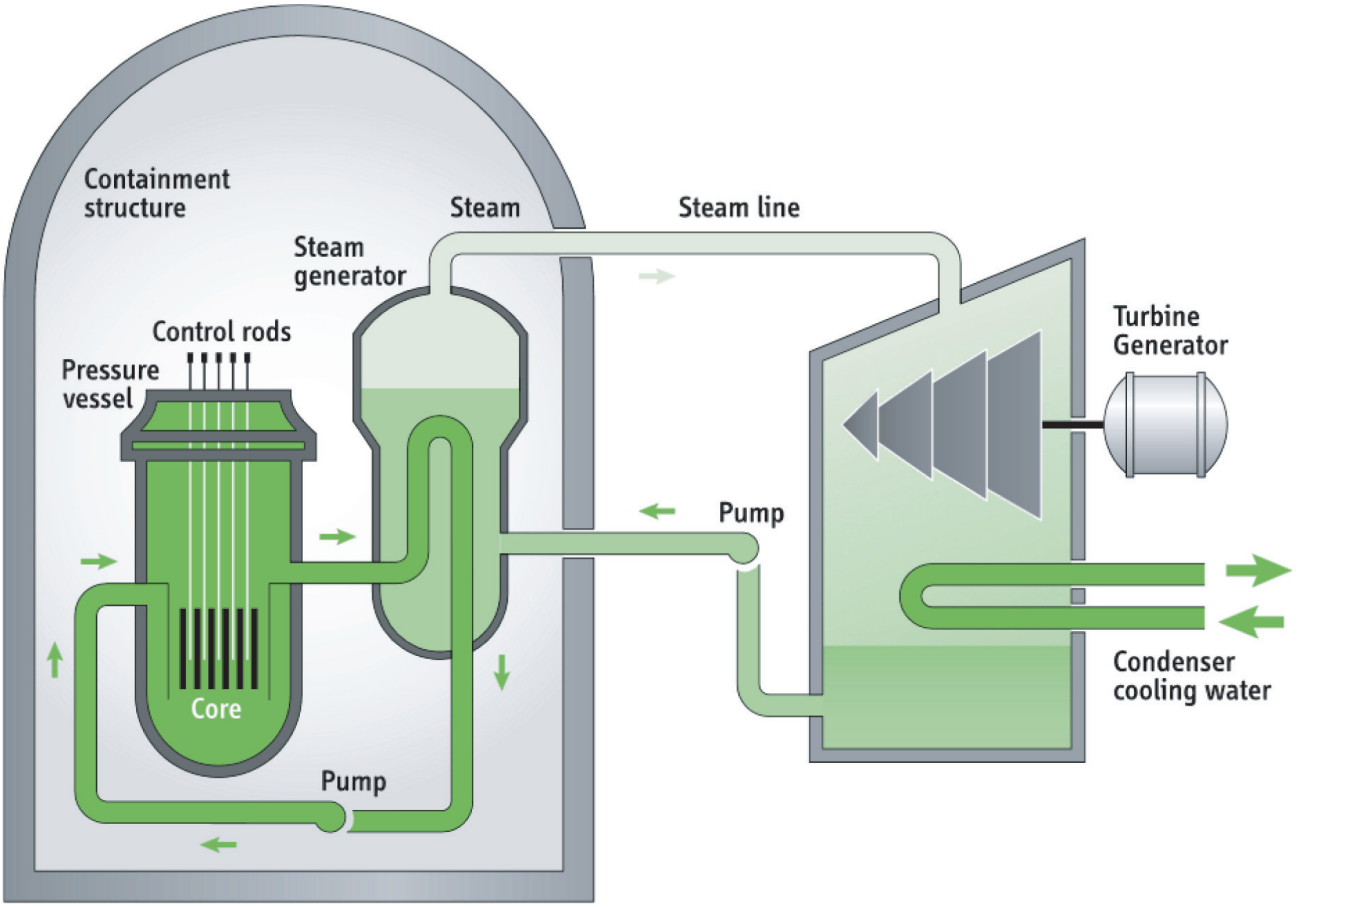

Figure 14.9 | Pressurized light-water reactor. Source: adapted from US Nuclear Regulatory Commission, 2010b.

9, 2009).[19] The fuel is in the form of cylindrical uranium oxide pellets about 1 cm in diameter stacked inside long, thin, sealed zirconium alloy tubes. This fuel is immersed in pressurized water that both slows down ("moderates") the neutrons in the chain reaction as they travel from rod to rod (Figure 14.3) and removes the fission heat from the fuel.

There are two basic types of LWR. In a pressurized water reactor (PWR), the superheated water is not allowed to boil but rather transfers its heat to secondary water that boils in a "steam generator," and the steam then drives a turbo-generator (Figure 14.9). In a boiling water reactor (BWR), the water boils in the reactor and the high-pressure steam goes directly to the turbine.

14.2 The Costs of Nuclear Power

Capital cost. The cost of nuclear power is determined primarily by the capital cost of the plant. For LWRs ordered today, this capital cost is both uncertain and in flux. Based on recent orders worldwide, the median capital costs are around $US_{2005}\$4000/kW_e$, and projected total generating costs are in the region of US$0.08/kWh (MIT, 2009). The capital costs, however, can vary by ±US$2000/$kW_e$.

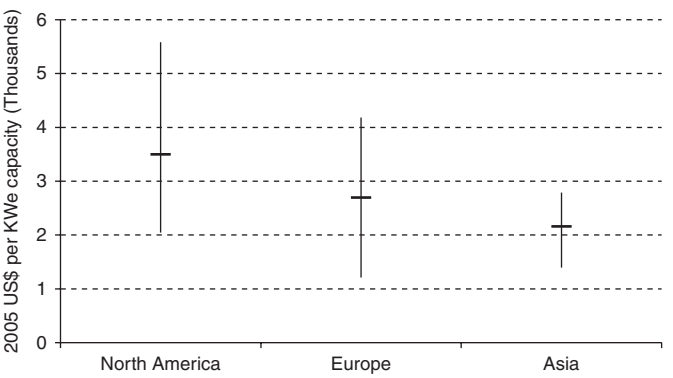

Figure 14.10 | Ranges of 2007–2008 "overnight" construction costs (excluding interest during construction) for plants in North America, Europe (including Russia), and Asia. Source: IAEA, 2009a.

19 Some 6% of global nuclear-power generating capacity is heavy-water-moderated reactors; 5% is graphite-moderated reactors (both water and gas cooled), and two liquid-sodium-cooled fast-neutron breeder reactors constitute 0.2%.

Figure 14.10 shows the results of a compilation of "overnight" costs (most of them are estimated) of the construction of 1 kW_e of nuclear generating capacity for plants in North America, Europe, and Asia in 2007–2008. "Overnight" costs exclude the interest during construction. Over a 4–10 year construction period, a 10% annual interest rate would increase the capital cost by 28–75%.

The large range of costs can be attributed to a number of factors, including:

- Whether costs such as site costs and transmission connections are included.
- Biases in the estimates, depending upon the institutional interests of the estimator (e.g., a vendor estimating low in order to obtain a contract to build a reactor, or a utility estimating high because it wishes to obtain a larger loan guarantee).
- Whether the estimate is for the first or second reactor at a particular site (follow-on reactors at the same site should be less costly to build).
- Assumptions about escalating material costs relative to general inflation.

There is a high level of uncertainty about estimates of nuclear power plant construction costs in North America since no new construction has been launched since 1978. Many projects have been announced but cancellations, postponements and cost increases are announced monthly. In Europe, the high end of the cost estimates are based primarily on the only two units that are under construction by AREVA in Finland and France (see Section 14.3.7). The low end reflects costs quoted for Russian-built units. The IAEA lists 15 nuclear power reactors as under construction by Rosatom in Russia and in Eastern Europe. Ten of these units have, however, been nominally under construction since the 1980s (Schneider et al., 2009). About half of the 52 power reactors listed by the IAEA as under construction today are in East Asia (25 units in China, South Korea, Japan, and Taiwan). Today, nuclear power plant construction costs are the lowest in these countries.

The fact that the estimated capital costs of nuclear power plants are higher in North America and Western Europe, where the nuclear power plant industry is being restarted with new designs, suggests that costs should come down as more plants are built. This is not certain, however. Figure 14.11 shows that during the late 1970s and 1980s, when France and the United States brought most of their current nuclear power plants online, the capital costs of LWR construction in the two countries (measured in constant French francs and US$, respectively) actually increased. There are several reasons why cost savings were not realized from industrial learning:

- Much of the construction of nuclear power plants is on-site, and locally hired workers tend not to benefit from experiences at other sites.
- The lack of standardization. In the United States, designs were customized, while in France, they were standardized across the country but new models were introduced as the program developed.
- Quality standards in the nuclear industry are necessarily very high, and mistakes often require defective work to be torn out and done again.

Table 14.4 | Civilian spent-fuel reprocessing plants.

Country	Reprocessing plant (Reference)	Level of activity[a] (tonnes of spent fuel per year)
China	Yumenzhen (LWR) (Nuclear Fuel, 7 April 2008)	50 → 100 (design)
France	La Hague, UP1 + UP2 (LWR) (AREVA-EDF, 2008)	1050 (domestic use)[b]
India	Tarapur and Kalpakkam (natural-U-fueled HWRs)[c]	100 + 100 (Mian et al., 2006)
Japan	Rokkasho (LWR)	Not operating, 800 (design)
Russia	Ozersk, RT-1 (LWRs, BN-600, isotope production, naval & research reactor fuel)	50[d]
UK	B-205 (Magnox)[e] and Thorp (LWR), Sellafield	B-205 to be shut down; future of Thorp uncertain.

a For data on design throughput, see IAEA, 2008a, Annex I.

b The reprocessing of foreign fuel once constituted about 50% of the reprocessing activity at La Hague, but Germany and Japan, the largest foreign customers, as well as Switzerland and Belgium, decided not to renew their contracts. Thus almost all the spent fuel now reprocessed at La Hague is domestic fuel (Schneider and Marignac, 2008).

c HWR = heavy-water moderated reactor. In heavy water, ordinary hydrogen is replaced by heavy hydrogen (deuterium) in which the atomic nucleus contains a neutron as well as a proton.

d Anatoli Diakov, personal communication, 13 October 2009.

e Magnox reactors are natural-uranium-fueled, graphite-moderated, gas-cooled reactors. Their phase-out is to be completed in 2012.

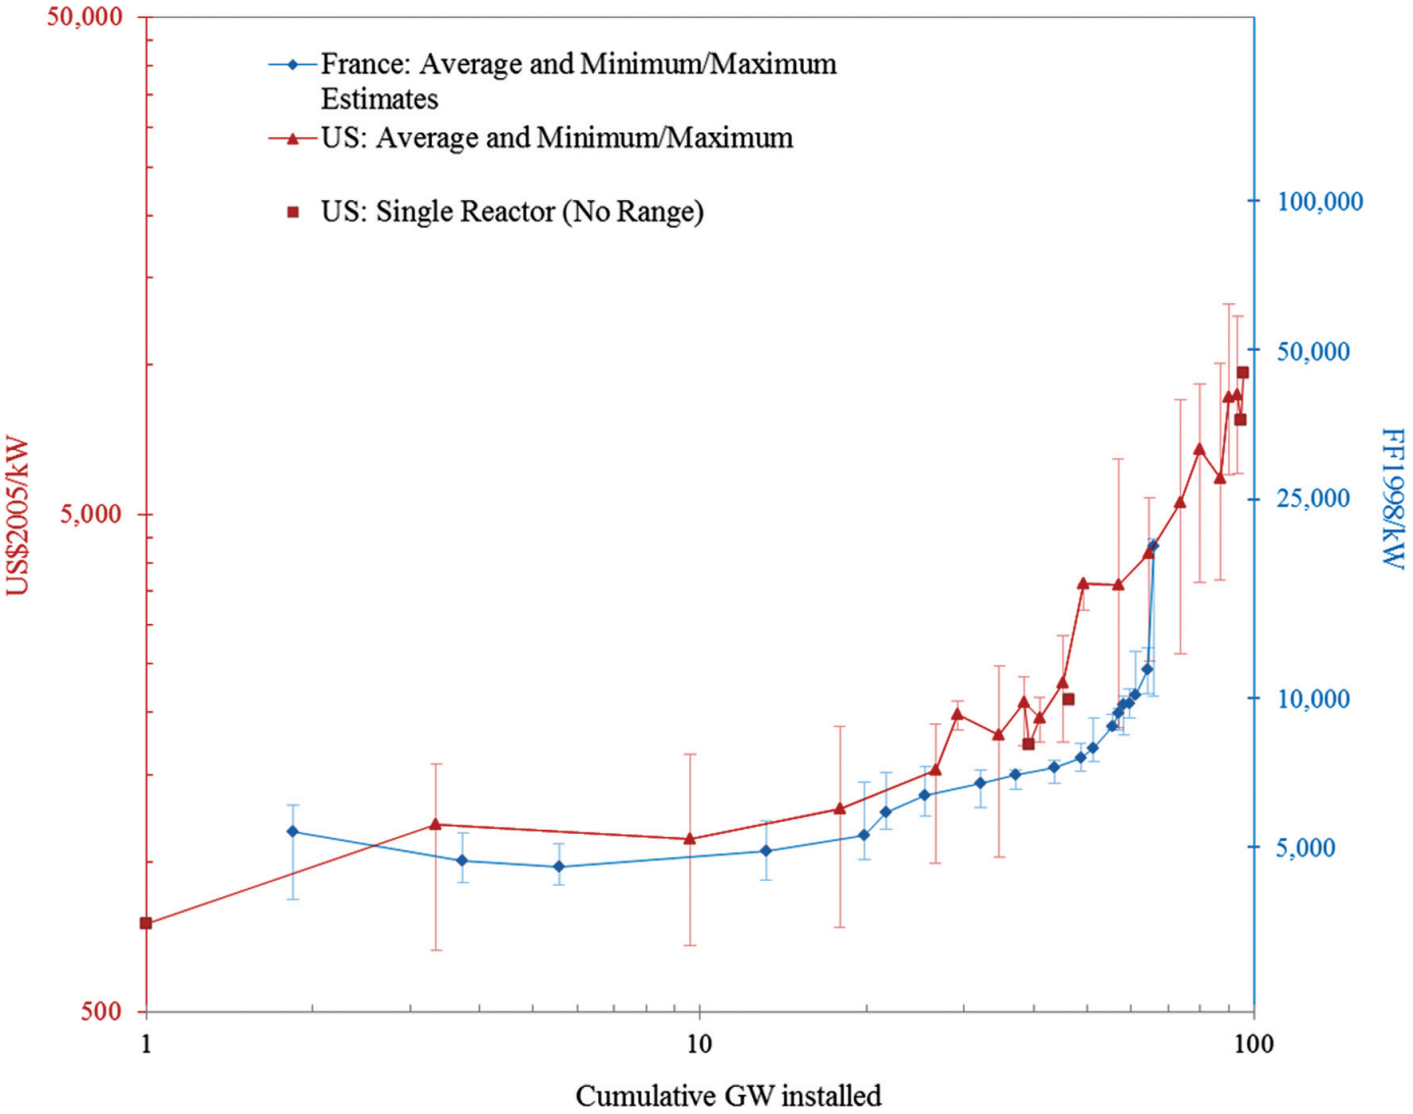

Figure 14.11 | French and US nuclear reactor construction costs (including interest during construction), by completion year, average for all reactors completed in a given year and minimum/maximum (in US_{2005} per kW installed capacity). In the United States, after the 1979 accident at Three Mile Island, there were prolonged delays in licensing plants under construction. The original French cost data (in French Francs 1998) are also shown for comparison. Data sources: US: Koomey and Hultman, 2007; all other data: Grubler, 2010.

- Regulatory requirements become more stringent as the understanding of potential design problems improves.
- Delays in completion result in extra interest charges.

In France, the increase in nuclear power plant construction costs was roughly the same as that of construction costs in general. In the United States, this was true until the 1979 accident at Three Mile Island, after which there were prolonged delays in licensing plants under construction. In France, the duration of construction also increased because of a shift to higher-power reactors with larger components and changes in component designs (Hultman et al., 2007; Grubler, 2010).

Other costs. The costs of decommissioning nuclear reactors are higher than those for other infrastructure because of the neutron-induced radioactivity of the primary pressure vessel and its internal components. The World Nuclear Association cites, without sources, decommissioning costs of US$190–520/$kW_e$ for water-cooled reactors (WNA, 2007, converted to $US_{2005}$$), while the IAEA reports that the costs for decommissioning the 0.4 GW_e LWRs built by the former Soviet Union ranged from $US_{2005}$$600–3800/kW_e (IAEA, 2002).[20] Operating and maintenance costs are about $US_{2005}$$0.02/kWh (Harding, 2007). For a "once-through" fuel cycle, fuel

20 The large cost range reflects in part the different approaches to decommissioning in different countries. Finland, which had the least costly project, disposed of the waste on site. Germany had the most costly project. Costs in the East European countries fell between these extremes.

costs are only about US$0.007/kWh[21] and interim spent-fuel storage costs are about US$0.00035/kWh.[22] Spent-fuel reprocessing costs in Japan are estimated at ¥0.63/kWh (US_{2005}0.006/kWh; JAEC, 2004).

Because of their high capital costs and relatively low operating costs, nuclear power plants are ordinarily operated in a "baseload" fashion, i.e., at full power whenever they are not down for refueling, inspection, maintenance, and/or repair.[23]

14.2.1 Government Subsidies[24]

Subsidies for nuclear power include government-funded research, development and demonstration projects; limitations on liability for catastrophic accidents; low-cost and guaranteed loans; and guarantees of private investments.

Research, development and demonstration. Between 1974 and 2007, the nuclear weapon states and Japan made huge national investments in fission-energy RD&D. In addition to investments in the development of enrichment and reactors for the production of nuclear weapon materials, and the development of LWRs for naval propulsion,[25] Japan, the United States, France, the United Kingdom, and Germany spent an estimated US_{2005}156 billion on civilian fission-energy R&D (IEA R&D Statistics, 2009). This corresponds to about US$700/$kW_e$ of nuclear capacity in these countries at the end of 2009 (IAEA, 2010d).

Loan and export guarantees. Some governments – notably, France, Japan, Russia, and the United States – are supporting their nuclear power industries with loan and export guarantees. These subsidies are critical because the repayment of the capital cost of nuclear power plants largely determines the cost of the power, and loan guarantees allow the purchasers of reactors to obtain the lowest possible interest rates. Loan guarantees also make it possible to finance a larger fraction of the cost of a plant with debt. This is an advantage because, even on low-risk projects, investors require about twice the rate of return on their capital as banks charge in interest on loans (IAEA, 2008b; US NAS, 1996: 427–428).

Guarantees are especially important for nuclear power plants, which are considered risky investments. In 2003, the US Congressional Budget Office estimated, based on historical data, that the risk of default on guaranteed loans for nuclear power plants "to be very high – well above 50%" (US CBO, 2003). The US Energy Policy Act of 2005 (Title XVII) provides government loan guarantees up to 80% of the project costs. Congress authorized up to US$18.5 billion for this purpose in the Consolidated Appropriations Act of 2008 and, in its budget proposal for fiscal year 2011, the Obama Administration recommended increasing the limit to US$54.5 billion (US DOE, 2010b: 259). One US utility has estimated that a loan guarantee would reduce the costs of generating electricity from its proposed nuclear power plant by 40% (Schneider el al., 2009: 79).

Limitations on liability for catastrophic accidents. In many countries, nuclear power plants are government owned and the governments would decide after the fact on how much restitution to make for the consequences in the event of a catastrophic accident. In the United States, the government began encouraging private investment in nuclear power in 1954 but found the private market unwilling to invest without its liability being limited. Liability limitation was granted in the Price–Anderson Act of 1957, which has been modified and extended four times, most recently in the 2005 Energy Policy Act. In the current version, plant owners are required to obtain the maximum amount of liability insurance available from private insurers (US$300 million in 2004). Beyond, that, if an accident occurs, each owner is required to contribute up to US$96 million (to be adjusted for inflation) to a pool of about US$10 billion per incident to help cover damages. Beyond that, the government would be responsible (Hore-Lacy et al., 2008). Estimates of the cost savings to utilities from such limitations on liability are highly uncertain (Heyes and Liston-Heyes, 1998; Heyes, 2002).

14.3 Country Studies

This section provides brief case studies of the current nuclear expansion programs of China, India, Japan, South Korea, Russia, the United States, and Western Europe.

14.3.1 China[26]

China's engagement with nuclear power began in 1970. The technology has been drawn from France, Canada, and Russia, with local

21 Assuming a cost of US$150/kg of natural uranium, US$150/SWU, US$11/kg to convert natural uranium to UF_6 or back, and US$300/kg of uranium for fuel fabrication (von Hippel, 2008b, 2005 US$).

22 Assuming a capital cost for interim dry-cask storage of US$150/kg of spent fuel (Alvarez et al., 2003).

23 Nuclear power reactors constitute such a large fraction of France's generating capacity that they operate in load-following mode.

24 Energy subsidies are discussed more generally in Chapter 6.

25 The United States spent about US$130 billion on the production of plutonium and HEU between 1948 and 1966 and US$51 billion on naval nuclear propulsion between 1948 and 1996 (Schwartz, 1998: 65, 143).

26 Professor Yu Suyuan (Tsinghua University, China) and Dr. Ming Ding (Delft University, the Netherlands), lead authors. The sources for this section include the China National Development and Reform Commission, *State Mid–Long Term Development Plan for Nuclear Power Plants (2005–2020),* October 2007; and *China Nuclear Power*, Vol. 1, Nos. 1–4, 2008. See also *Nuclear Power in China* (WNA, 2010b) and "China's nuclear industry at a turning point" (Kubota, 2009). We would like to thank Dr Yun Zhou, currently with Harvard University's Managing the Atom Project, for sharing with us a draft of her working paper, *China's Nuclear Energy Policy: Expansion and Security Implications*.

development based largely on French designs. The latest technology has been acquired from the United States (the AP1000 reactor) and France (the European Pressurized Reactor (EPR)). As of the end of 2009, China had 9 GW_e of operating nuclear capacity under two companies: China National Nuclear Corporation (CNNC) and China Guangdong Nuclear Power Holding Company (CGNPC). CNNC is state owned, has a major R&D capability and provides architect-engineer services to CGNPC. Because of the huge planned expansion of China's nuclear generating capacity, additional power companies are co-investing in nuclear power plants but are not building or operating the plants themselves.

Prior to 2000, China was in an exploratory mode with regard to nuclear technology. Over a period of about 15 years, it built an indigenous 0.3-GW_e PWR, ordered two GW_e-scale reactors each from Canada (heavy-water reactors), France, and Russia (PWRs) and built two PWRs in a China–France joint venture. Recently, however, the Chinese government has committed itself to a large-scale PWR construction program that emphasizes initially an indigenized version of the French PWR, the CPR1000. Domestic production of pressure vessels for the Westinghouse AP1000 reactor has begun and it is proposed to develop an indigenized 1.4 GW_e version, the CAP1400 (Kubota, 2009).

In March 2008, China's newly formed State Energy Bureau set a target for 2020 of 5% of electricity from nuclear power, requiring at least 50 GW_e to be in operation by then. In June 2008, the China Electrical Council projected 60 GW_e of nuclear capacity by 2020. The total capacity of the nuclear power units under construction as of the end of 2010 was 25 GW_e (IAEA-PRIS, October 12, 2010).[27]

In May 2007, China's National Development and Reform Commission announced that its target for nuclear generating capacity for 2030 was 120–160 GW_e, which corresponds to an average rate of construction of 5–7 GW_e/yr. Sites have been nominated for a potential total nuclear generating capacity of about 155 GW_e. Various tax incentives have been provided for the construction of nuclear power plants.[28]

This projected growth of China's nuclear capacity cannot be dismissed. However, while China has realized extraordinary growth rates in other areas of infrastructure, the rapid expansion of the nuclear industry faces multiple challenges, in particular the lack of trained personnel. The universities are not producing sufficient nuclear engineers, so engineers with other backgrounds have been recruited and given one year of training to familiarize them with nuclear technology. Construction company staff with experience building coal-fired power plants are also being trained to build nuclear power plants, starting with the non-nuclear buildings and turbo-generators. The capabilities of China's nuclear regulatory agency, the National Nuclear Safety Administration, will also have to be strengthened. Finally, China's nuclear operators will have to develop a safety culture, including information sharing among plants with regard to safety-related incidents. Li Ganjie, director of China's National Nuclear Safety Administration, has warned that, "if we are not fully aware of the sector's over-rapid expansion, it will threaten construction quality and operation safety of nuclear power plants" (*New York Times*, December 16, 2009). He has also indicated that China's nuclear industry faces challenges on all fronts (Kubota, 2009):

- shortages of trained personnel;
- an inadequate foundation in R&D;
- lack of manufacturing and installation capabilities;
- inadequate management;
- weak safety oversight; and
- insufficient dialogue with the concerned public.

China's ambition to generate nuclear energy on a large scale has attracted the country's largest heavy engineering enterprises to develop the capacity to manufacture nuclear power plant equipment. Much of the equipment used in nuclear power plants, including steam generators, main pumps, and high-pressure piping, can be manufactured in China. The China First Heavy Industries Corporation has also developed the capability to produce pressure vessels for GW_e-class pressurized water reactors.

Uranium supply. China's known uranium resource at a recovery cost of less than US$130/kg ($US_{2005}$122/kg) is 70,000 tonnes, but estimates of undiscovered resources in favorable areas exceed 1 million tonnes (NEA, 2008c: 155, Table 2). Domestic production of 840 tonnes/yr provides about half of China's current requirements, and the remainder is reportedly imported from Kazakhstan, Russia, and Namibia. In 2006, China signed a deal with Australia, the world's leading uranium mining country, to buy up to 20,000 tonne/yr, enough to supply about 100 GW_e of LWR capacity (BBC, April 3, 2006).

Fuel cycle – front end. China's original enrichment plants used gaseous-diffusion technology but these have been replaced with gas centrifuge plants imported from Russia under agreements made in the mid-1990s between the Tenex subsidiary of Rosatom and the China Nuclear Energy Industry Corporation. The agreements have resulted in the construction of 1.5 million SWU/yr enrichment capacity at two sites in China, based on Russian sixth-generation centrifuges, and work to expand this capacity by an additional 0.5 million SWU/yr is underway.

27 In 2008, China began construction of 6 GWe of capacity; in 2009, 9 GWe; and as of October, 6 GWe in 2010. China's most recently completed nuclear power plants, Tianwan 1 and 2, took eight and seven years to build, respectively.

28 These tax incentives for the construction of nuclear power plants include: 1) a rebate of 75% on the value-added tax during the first five years of operation, decreasing to 70% in the subsequent five years and 55% for the third five-year period; 2) a waiver of tariffs on imports of nuclear energy equipment and materials that cannot be produced domestically; 3) a rebate on taxes on land associated with nuclear power plants; and 4) a 15% income tax rate with a reduced tax base and possible tax waiver (Dr Yun Zhou, personal communication, April 22, 2009).

This is enough for about 17 GW_e of LWR capacity. Reportedly, additional capacity expansion is planned (Kubota, 2009). China also buys enrichment services abroad. It has contracted URENCO, an international enrichment company, to supply 30% of the enrichment for the two 0.944-GW_e LWRs at Daya Bay. Tenex, Russia's nuclear materials exporting company, has agreed to supply 6 million SWU in LEU to China between 2010 and 2021.

Spent fuel and reprocessing. In 1987, China announced at an IAEA conference that it was pursuing a "closed" fuel cycle, i.e., one in which plutonium would be recycled from spent to fresh fuel. Accordingly, the CNNC has drafted a state regulation requiring the reprocessing of power reactor spent fuel. Construction of a centralized spent-fuel storage facility for a pilot reprocessing plant at the Lanzhou Nuclear Fuel Complex near Yumenzhen, in Gansu province, in western China, began in 1994. The initial storage capacity is 550 tonnes, which could be doubled. The pilot PUREX reprocessing plant was opened in 2006 with a capacity of 50 tonnes/yr, which also could be doubled.

In November 2007, AREVA and CNNC signed an agreement to assess the feasibility of building commercial-scale reprocessing and MOX fuel fabrication plants in China, at an estimated cost of €20 billion (US_{2005}25 billion). In mid-2008, the CNNC stated that an 800 tonnes/yr reprocessing plant would start operations in 2025, probably in Gansu province. High-level reprocessing wastes would be vitrified, encapsulated and put into a geological repository 500 m below the surface. Site selection for a repository is focused on six candidate locations and is to be completed by 2020. An underground research laboratory would then operate for 20 years and actual disposal would begin in 2050.

14.3.2 India[29]

India's nuclear power program dates back to the late 1940s. Thanks to decades of sustained government support, the Department of Atomic Energy (DAE) has developed expertise and facilities that cover the entire nuclear fuel cycle, from uranium mining to the reprocessing of spent nuclear fuel (Sundaram el al., 1998).

Most of India's current power reactor capacity is based on 0.22 GW_e heavy-water reactors (HWRs), modified versions of the CANDU reactors that India imported from Canada before its 1974 nuclear test resulted in a cutoff of its nuclear imports. Two Russian 1-GWe LWRs are under construction at Koodankulam at the southern tip of India, and there are plans to build two to four more such reactors at the same site over the next decade. A 0.5-GW_e prototype fast breeder reactor, to be fueled with MOX (plutonium–uranium) fuel, is under construction at Kalpakkam on the southeast coast.

The DAE's program is still based on the three-stage strategy first announced in 1954 by Homi Bhabha, the founder of India's nuclear program (Bhabha and Prasad, 1958):

1. Heavy-water-moderated reactors are fueled with natural uranium, and the spent fuel is reprocessed to recover the produced plutonium.

2. The separated plutonium is to be used to provide startup cores for fast-neutron plutonium-breeder reactors. These breeder reactors would produce more plutonium than they consumed, and the excess would be used to provide startup fuel for additional breeder reactors.

3. After a large enough fleet of breeder reactors has been established, thorium is to be substituted for uranium in the fast-breeder reactor blankets to produce fissile uranium-233. The bred uranium-233 is to be used to fuel the fast-neutron reactors, which would operate with a lower breeding ratio – but still above a self-sustaining level – using India's abundant thorium resources as their ultimate fuel.

DAE planners have a history of making optimistic projections for the growth of nuclear power in India. In 1962, Bhabha predicted that India would have 20–25 GW_e of installed heavy-water and breeder-reactor capacity by 1987 (Hart, 1983: 61). This was subsequently replaced by the goal of 43.5 GW_e of nuclear capacity by 2000 (Sethna, 1972). At the end of 2009, however, India's nuclear capacity amounted to just 4.5 GW_e, about 3% of the country's total electric power generating capacity (IAEA-PRIS, January 11, 2010).

Prior to the 2008 lifting of the Nuclear Suppliers Group (NSG) ban on uranium and nuclear technology trade with India, the DAE projected a nuclear generating capacity of 20 GW_e by the year 2020 and 275 GW_e by the year 2052 (Grover and Chandra, 2006). Since the NSG waiver, there have been even higher predictions of 40 GW_e by 2020 and 470 GW_e by 2050 (*Financial Express*, October 14, 2008; India, Ministry of Power, 2008). The US Energy Information Administration (US EIA) reference case projection is for India's nuclear power capacity to grow to 20 GW_e by 2030 (US EIA, 2008c).

Uranium constraint. India has known resources of about 60,000 tonnes of low-cost uranium (NEA, 2008c: 207), sufficient for a 40-year-lifetime supply for only about 10 GW_e of HWR capacity. India's relatively small resource base of uranium has been the primary justification for the DAE's plans to focus on breeder reactors designed to have a very high breeding ratio for plutonium.[30] This justification has not

29 Dr. M.V. Ramana of Princeton University, lead author.

30 The breeding ratio is increased by eliminating material that could slow down the neutrons. For this reason, all of India's fast breeder reactors after 2020 are to be fueled with metal fuel rather than the higher-melting-point oxide fuel that has been used in demonstration reactors in other countries (Grover and Chandra, 2006).

yet changed despite the recent lifting of the NSG ban on natural and enriched uranium exports to India.

The plutonium supply constraint. The rate at which India can build up its breeder capacity is limited by the rate at which it can produce excess plutonium for the initial cores. The DAE assumes a starting capacity of 6 GW_e of high-breeding-ratio, metal-fueled breeder reactors in 2022. This would require about 22 tonnes of fissile plutonium for startup fuel. Because of the limited rate of plutonium production by India's heavy-water reactors, the DAE's stock of fissile plutonium is unlikely to exceed this amount by 2022.[31] Of this inventory, the DAE plans, however, to use at least 15 tonnes for startup fuel (including the first two fuel reloads) for the four oxide-fuel-based breeder reactors with a low breeding ratio that are to be an intermediate step toward the more advanced metal-fueled breeder reactors. The remaining plutonium will therefore be sufficient only to start about 1 GW_e of metal-fueled breeder reactor capacity by 2022.

The DAE's projected growth rates after 2022 are also unachievable. Even with a fuel residence time of two years inside the reactor and an optimistic out-of-reactor time of only two years to cool the spent fuel, reprocess it, and fabricate the extracted plutonium into new fuel, it would take four years for a given batch of plutonium loaded into a breeder reactor to become available for recycling with some extra bred plutonium that could be used as startup fuel for new breeder reactors. A careful calculation finds that the resulting plutonium growth rate is only 17–40% of the DAE's estimates, depending on whether realistic or optimistic assumptions are used for various parameters (Ramana and Suchitra, 2009). Unless India's nuclear establishment shifts its focus away from breeder reactors, nuclear power is unlikely to contribute significantly to electricity generation in India for the next several decades.

Cost of breeder electricity. Even if the capital costs of breeder and heavy water reactors were the same, electricity from the breeders would be more expensive because of their high fuel-cycle costs. The cost of electric power generated from India's first commercial-scale breeder reactor will be at least 80% higher than from heavy water reactors, mostly because of the high costs associated with reprocessing and fabricating plutonium-containing fuel (Suchitra and Ramana, 2011). Breeders are competitive with heavy water reactors fueled with natural uranium and operating on a once-through fuel cycle only for uranium at prices well above US$1000/kg. In recent decades, the average price of uranium has been around US$50/kg.

14.3.3 Japan[32]

Japan has the world's third largest nuclear generating capacity. It is one of the few non-weapon states with an enrichment program and the only one that reprocesses spent fuel.

Nuclear generation capacity and projections. As of the end of 2009, Japan had 53 operational commercial LWRs with a generating capacity of 47 GW_e. Two LWRs (2.7 GW_e) are under construction[33] and 10 (13.6 GW_e) were to be commissioned by 2020. Some of Japan's older reactors are being decommissioned, while others are proposed to have their licenses extended.[34] Prior to the 2011 Tōhoku earthquake and tsunami, a total of 66 LWRs (65.1 GW_e) were expected to be operating in 2020 according to the plans of the electric utilities. These plans now seem likely to be scrapped, at least for the near term. Indeed, Prime Minister Kan, before stepping down, proposed phasing out nuclear power entirely.

Uranium enrichment capacity. Japan Nuclear Fuel Limited (JNFL), the nuclear fuel cycle subsidiary of Japan's nuclear utilities, started operating the country's first commercial enrichment plant with a capacity of 150,000 SWU/yr in 1992. Its capacity was increased every year by one module with a capacity of 150,000 SWU/yr until it reached a nominal capacity of 1.05 million SWU/yr in January 2009. All seven modules have been permanently shut down due to technical troubles, however. Cumulatively, only about 1 million SWUs have been produced.[35]

JNFL launched the development of a more advanced type of replacement centrifuge in 2000. Prototypes began testing with UF_6 gas in 2007. JNFL plans to introduce the new centrifuges into commercial operation starting in 2010 and hopes to achieve an enrichment capacity of 1.5 million SWU/yr by around 2020 (JNFL, 2007).

Spent-fuel management. The local governments hosting Japan's power reactors are generally opposed to the expansion of on-site storage. Japan's policy is therefore to reprocess its spent fuel. In the late

31 The fissile isotopes of plutonium that chain-react with slow neutrons are plutonium-239 and plutonium-241. The spent fuel of India's pressurized heavy-water reactors contains about 2.6 kg of fissile plutonium per tonne. The amount of plutonium that India can separate is limited by the capacity of its reprocessing plants. It is estimated that India will have separated about 10 tonnes of fissile plutonium by 2018. That is the earliest that India could bring online significantly more reprocessing capacity. Assuming that its reprocessing capacity increases tenfold to 2000 tonne/yr thereafter, and operates at 80% capacity, it is estimated that India could separate out anaother 13 tonnes of fissile plutonium during 2019–2021 (Ramana and Suchitra, 2009).

32 Dr Tatsujiro Suzuki, Tokyo University (now vice chair of Japan's Atomic Energy Commission) and Professor Tadahiro Katsuta, Meiji University, Tokyo, lead authors.

33 Two 1.37-GWe advanced boiling water reactors, Shimane-3 and Ohma, are scheduled to go into operation in 2011 and 2012, respectively.

34 On February 17, 2009, Japan Atomic Power published its plan to extend the operation of Tsuruga-1, a 0.357-GWe boiling water reactor, commissioned in 1966, for another 20 years.

35 Some 1599 tonnes of uranium have been enriched. Assuming 4.4% enrichment with 0.3% uranium-235 in depleted uranium, this would correspond to 1.2 million SWU.

1970s, Japan contracted to ship 5500 tonnes of spent fuel to France and the United Kingdom for reprocessing (Albright et al., 1997, Tables 6.4 and 6.5). Japan subsequently decided to build a domestic reprocessing plant at Rokkasho, at the northern tip of the main island, with a design capacity of 800 tonne/yr of uranium throughput. Commercial operation of the plant was to begin in 2003 but, due to various technical problems, has repeatedly been postponed, most recently until late 2012 (*Japan Times*, 2010).

As a result of the many years of delays in starting up the Rokkasho reprocessing plant, Japan has a developing shortage of spent-fuel storage pool capacity. As of September 2007, 12,140 tonnes of spent nuclear fuel were being stored at nuclear power plant sites (JAEC, 2008). Utilities were installing new racks for denser storage in the pools and transferring spent fuel from one pool to another within the same site. A 3000-tonne capacity storage pool at the Rokkasho reprocessing plant started accepting spent nuclear fuel in 2000, but was almost full (2817 tonnes of spent fuel) as of the end of 2008 (JAEC, 2008). The first away-from-reactor interim storage facility at Mutsu City in Aomori prefecture near the reprocessing plant is under construction and is planned to start operation in 2012. Ultimately, it is to have 5000 tonnes of spent-fuel storage capacity. Japan will need about five interim storage facilities of this scale by 2050, even if the reprocessing plant operates as planned (Katsuta and Suzuki, 2006; Japan-METI, 2008).

The reprocessing of spent fuel that Japan sent to France has been completed. Its reprocessing contract with the United Kingdom, which was to have been completed in 2003, has been delayed by problems at the UK reprocessing plant (Forwood, 2008). As a result of its foreign reprocessing program and domestic pilot program, as of the end of 2008, Japan had about 47 tonnes of separated plutonium, most of it in France and the United Kingdom (IAEA, 2009c, Japan).[36] Japan's second commercial reprocessing plant, originally due to begin operating in 2010, is now not scheduled to become operational before 2040.

MOX fuel program. As a result of various scandals and public opposition, Japan's plan to partially fuel 16–18 LWR power plants with MOX (plutonium–uranium) fuels made from Japanese plutonium in Europe by 2010 has been delayed (CNIC, 2008). The first MOX fuel was finally loaded into a Japanese LWR (Genkai 3) in October 2009 (*WNN*, November 5, 2009).

JNFL plans to produce MOX fuel for Japan's LWRs from plutonium separated in Japan. A commercial MOX fuel fabrication plant is to be built next to the Rokkasho reprocessing plant with a maximum capacity matched to that of the reprocessing plant, about 10 tonnes of plutonium mixed with 120 tonnes of uranium to make 130 tonne/yr of MOX fuel. Construction was to have started in October 2007, but the plant is still in the pre-construction licensing phase. According to JNFL, commercial operation will start in 2015 (JNFL, 2010).

Breeder reactor R&D. Japan's first experimental breeder was the Joyo (140 megawatt thermal (MW_t), no electricity generation), which has operated about 27% of the time since it achieved first criticality in 1977. Japan's prototype 280 megawatt-electric (MW_e) fast breeder reactor, Monju, suffered a sodium leak and fire in 1995 after its first three months of operation. After repairs and many delays, it finally restarted 15 years later, in May 2010, only to be shut down indefinitely again due to a refueling accident in August 2010. In 2006, the Nuclear Energy Subcommittee of the Ministry of Economy, Trade and Industry's advisory committee published a long-term program under which a follow-on demonstration breeder reactor would be built by 2025. Commercialization of breeder reactors, the original justification for Japan's reprocessing program, has slipped by 80 years from 1970 to 2050 (Japan-METI, 2006; Suzuki, 2010).

High-level radioactive waste disposal. In May 2000, Japan passed a "Law Concerning the Final Disposal of Specific Radioactive Waste" that outlines legal responsibilities, cost sharing, and site selection processes. A voluntary site selection process started in December 2002. Thus far, only one application (Toyo Town) has been received and officially accepted, but it was subsequently withdrawn due to local public opposition.

Budget. Japan accounts for almost half of the total nuclear energy R&D carried out in the OECD countries. In 2007, Japan devoted ¥261 billion (US_{2005}2 billion) to nuclear energy R&D, about 65% of its budget for energy R&D (IEA, R&D Statistics).

14.3.4 South Korea[37]

The Republic of Korea (ROK) has the world's fifth largest nuclear generating capacity; 20 units with a capacity of 17.7 GW_e, with eight units (9.6 GW_e) under construction as of the end of 2009 and four more (5.6 GW_e) planned for completion by 2021. Except for four heavy-water reactors, all of these are PWRs, located at four sites. The new reactors are all of Korean design with all the major components, including pressure vessels, produced in Korea. South Korea has been actively trying to export its reactors and, at the end of 2009, obtained a US$20 billion contract from the United Arab Emirates for four 1.4-GW_e reactors to be completed by 2020, and another US$20 billion contract to jointly operate them for 60 years (Reuters, December 27, 2009).

South Korea has the world's largest nuclear power program without a national enrichment or reprocessing facility. This reflects the desires of its close ally, the United States, and also the 1992 Joint Declaration with North Korea on the Denuclearization of the Korean Peninsula, under which the two countries agreed not to acquire enrichment or reprocessing facilities. North Korea violated this agreement and there is

36 Since 2007, Japan's government has reported to the IAEA only the quantity of "fissile" isotopes (plutonium-239 and plutonium-241) held abroad. Based on a comparison of the declarations of 2005 and 2006 with 2007, these numbers must be multiplied by approximately 1.5 to obtain the tonnage of total plutonium.

37 This section is mostly based on von Hippel (2010).

resentment within South Korea's nuclear establishment that the United States acquiesced to Japan acquiring these technologies and not South Korea. Following North Korea's nuclear test in May 2009, there were calls from South Korea's opposition party for "nuclear sovereignty," i.e. that South Korea should have the same rights as Japan.

As in Japan, the spent-fuel pools at South Korea's older reactors are filling up and local governments are resisting the construction of more on-site storage. As a solution to the problem, South Korea's Korea Atomic Energy Research Institute (KAERI) proposes a form of reprocessing, "pyroprocessing,"[38] the electro-refining of the fuel in molten salt and the use of liquid-sodium-cooled fast-neutron reactors to fission the recovered plutonium and minor transuranic elements. This vision is supported by one of the ROK's R&D ministries, the Ministry of Education, Science and Technology, but not the Ministry of Knowledge and Economy, which is worried about the cost. The G.W. Bush Administration was also interested in pyroprocessing and supported joint R&D between the US Department of Energy's (US DOE) nuclear laboratories and KAERI.

South Korea, like most other countries with nuclear power programs, is having difficulty siting radioactive waste repositories. It succeeded in siting an underground low- and intermediate-level radioactive waste repository at one of its reactor sites in exchange for US$300 million plus US$600 per waste drum for up to 800,000 waste drums for the local government and a commitment by the government-owned utility, Korea Hydro and Nuclear Power, to move its headquarters and staff from Seoul to a small city near the site (Park Seong-won et al., 2010). This is still a small cost, however, compared with Japan's ¥1 trillion (US$10 billion) programmed payments to Aomori prefecture for accepting the Rokkasho reprocessing plant (Takubo, 2008), and the ¥11 trillion (US_{2005}94 billion) estimated cost of building, operating and decommissioning the Rokkasho reprocessing plant (CNIC, 2004a).

14.3.5 Russia[39]

Russia has the world's fourth largest nuclear generating capacity, 22.7 GW_e, provided by 16 PWRs, 11 graphite-moderated, water-cooled RBMK-1000 (Chernobyl-type) reactors and the BN-600 sodium-cooled fast breeder prototype reactor.[40] The expansion of this capacity and foreign sales of Russian-designed reactors and fuel-cycle services have become a key economic goal of the Russian government. In April 2007, then President Vladimir Putin consolidated Russia's civilian nuclear activities into one giant state-owned company, Atomenergoprom, under another state-owned company, Rosatom, which also operates Russia's military nuclear programs (*Moscow Times*, May 2, 2007).[41]

Seven 1-GW_e PWRs and a 0.8-GW_e demonstration breeder reactor are currently under construction (IAEA-PRIS, October 8, 2010).[42] According to the Russian government's 2008 long-term plan (Russia Federal Target Program, 2008), starting in 2009, construction was to be initiated each year on two new 1.2-GW_e PWRs. By the end of 2015, 11 new nuclear power units were to be put into operation, and the construction of a further 10 initiated (see Figure 14.12). In late 2009, the schedule slipped, and only eight of the PWRs are expected to be completed by the end of 2015 (WNA, 2010a).[43] Beyond 2015, Rosatom is supposed to find its own funding.[44]

Outside Russia, Rosatom has under construction two VVER-1000 PWRs[45] at the Koodankulam nuclear power plant in India and one at the Bushehr plant in Iran (Rosatom, September 26, 2008). Russia has agreements, but not in most cases binding contracts, to construct: in India, eight more VVER-1200s (four at Koodankulam and four in West Bengal); in China, two more units at the Tianwan nuclear power plant, where two VVER-1000s are already operating, and two BN-800 breeder reactors; in Bulgaria, two VVER-1000 units; in Turkey, four VVER-1000 units; in Armenia, one VVER-1000 unit; and in Ukraine, two VVER-1200 units.[46]

Uranium supply. Russia's confirmed uranium reserves could support about 100 GW_e of LWR capacity for 45 years.[47] All uranium mining activity has been consolidated within Rosatom under Atomredmetzoloto JSC

38 In pyroprocessing, spent fuel is dissolved in molten salt and the transuranics are separated electrochemically.

39 Professor Anatoli Diakov, Moscow Institute of Physics and Technology, lead author. This section provides an update of a more detailed chapter in the *Global Fissile Material Report* 2007 (IPFM, 2007). www.fissilematerials.org.

40 The numerical suffixes indicate the approximate gross electric power generating capacity in MW_e. The net capacity is typically about 10% lower (see IAEA-PRIS).

41 See Rosatom's English-language website: www.rosatom.ru/en.

42 One graphite-moderated reactor, Kursk-5, has also been listed as under construction since 1985. Barge-mounted reactors are discussed separately below.

43 The reactors under construction at the end of 2010: two VVER-1200 light-water reactors at Rostov nuclear power plant (NPP), two VVER-1200 units at Leningrad-2 NPP, two VVER-1200 units at Novovoronezh-2 NPP, one VVER-1000 unit at Kalinin NPP, and one BN-800 unit at Beloyarskaya NPP (IAEA-PRIS). Rosatom's website also lists two VVER-1200 units under construction at the Baltiyskaya NPP (www.rosenergoatom.ru/rus/development).

44 After 2015, Rosatom plans to build two VVER-1200 units/yr, costing a combined US$4.6 billion (2005 US$). According to Figure 14.12, in 2015, Atomenergoprom would have a capacity of 33 GWe. Assuming that these reactors operate at an 80% capacity factor, they would generate 0.23 trillion kWh/yr. Atomenergoprom therefore would have to be raising capital investments of US$0.02/kWh generated.

45 VVER: Vodo-Vodyanoi energetichesky reactor, the Russian version of the pressurized water reactor.

46 See www.nuclear.ru/rus/press/nuclearenergy/2117970/ (in Russian).

47 Operating at a 90% capacity factor, a 1-GWe VVER would require 140–200 tonne/yr of natural uranium, assuming 0.1–0.3% uranium-235 in the depleted uranium. In 45 years, 100 GWe of VVER capacity would, therefore, require 630,000–900,000 tonnes of natural uranium. Russia is reported to have 545,600 tonnes of uranium

(ARMZ). ARMZ plans a major expansion of its uranium mining, including joint ventures in Kazakhstan. If these plans are realized, in 2025, ARMZ will be mining enough uranium to support about 100 GW_e of LWR capacity. ARMZ is also planning joint ventures with companies in Canada, Armenia, Mongolia, and the Republic of South Africa (Atomenergoprom, 2008).

Reprocessing. Russia has a small reprocessing plant (Mayak) near Chelyabinsk in the Urals, where it reprocesses the spent fuel of the last six of its first-generation VVER-400 reactors along with its naval and research-reactor spent fuel. Russia has declared to the IAEA that, as of the end of 2008, about 45 tonnes of civilian separated plutonium were stored at its reprocessing plants (IAEA, 2009c, Russia).[48] Rosatom is funding R&D related to the possibility of building a pilot reprocessing plant on the site of the never-completed RT-2 reprocessing plant at the Krasnoyarsk Mining and Chemical Combine in Zheleznogorsk (Russia Federal Target Program, 2006).[49]

Breeder reactors. As shown in Figure 14.12, Russia's nuclear establishment, like India's, is still planning on the near-term, large-scale commercialization of plutonium breeder reactors. One 0.8-GW_e BN-800 liquid-sodium-cooled reactor, on which construction began in 1985, is now scheduled to be put into operation in 2014 (AtomInfo, 2009). China is considering ordering two units (WNA, 2010a). A 1.8-GW_e BN-1800 is being designed to be deployed in the 2020s. In January 2010, the Russian government approved a 10-year, 110 billion ruble (US$3.6 billion) federal target program for the development of fast-neutron reactors and their fuel cycle (Rosatom, 2010).

MOX (plutonium–uranium) fuel for Russia's first plutonium breeder reactors could be fabricated using Russia's separated civilian plutonium. In addition, Russia has committed to dispose of 34 tonnes of excess weapon-grade plutonium in parallel to US use of an equal amount of excess weapon-grade plutonium in MOX LWR fuel. Russia plans to dispose of its excess weapon-grade plutonium in breeder-reactor fuel. Until Russia builds a MOX fuel fabrication pilot plant, however, the BN-800 will be fueled with HEU enriched to slightly above 20%, as the BN-600 has been since 1980 (Nigmatulin and Kozyrev, 2008).

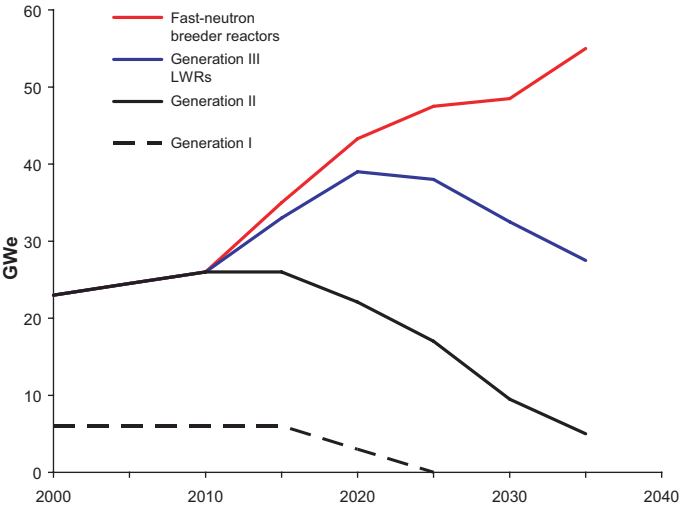

Figure 14.12 | Plans for Russian nuclear power expansion as of 2007. Source: Adapted from Saraev, 2007.

14.3.6 United States

The United States has the world's largest nuclear-generating capacity: 104 power reactors with a net generating capacity of 100.6 GW_e as of the end of 2009 (IAEA-PRIS). The construction of all of these reactors began before 1978, more than three decades ago (US EIA, 2008d). As of the end of 2009, US utilities had applied for 18 combined construction and operating licenses for 28 reactors with a total capacity of 37 GW_e (US NRC, 2010a), but only 12 of these applications were active,[50] and only five had signed engineering, procurement and construction contracts with reactor vendors (for nine reactors) (WNA, 2010c). The IAEA still listed only one reactor under construction in the United States; the Tennessee Valley Authority's Watts Bar II, a reactor on which construction began in 1973 and was suspended in 1988 when it was about 80% complete because of a reduction in the growth rate of US electric power demand (Reuters, August 1, 2007).

Renewed US interest in nuclear power reflects in part concerns about the future cost of natural gas, following a temporary tripling in real wellhead prices between 1998 to 2008 (US EIA, 2010)[51] and a move away from coal-fired power plants in anticipation of policies aimed at reducing greenhouse gas emissions. It also reflects government incentives. In the

in "reasonably assured resources" plus "inferred" extensions of explored deposits recoverable at up to US$130/kgU, plus 276,000 tonnes in "prognosticated" resources (estimated resources in partially explored geologies) and 714,000 tonnes in "speculative" resources (undiscovered resources based on statistical inferences from geological types) (NEA, 2008c). The price of uranium in 2009 was about US$100/kgU.

48 It is possible that this includes some of the separated plutonium stored at the Seversk and Zheleznogorsk reprocessing plants. These plants produced weapon-grade plutonium for Russia's weapons program but, according to the 1997 Russia–US "Agreement … Concerning Cooperation Regarding Plutonium Production Reactors," any plutonium separated at these plants after January 1, 1997 will not be used for weapons purposes (Annex III, Subsidiary Arrangement B, Article II).

49 According to Task 30 of the 2006 Federal Target Program, sources other than the federal budget (presumably Rosatom) are to supply 1.617 billion rubles (US$65 million at US$24.6/ruble) through 2015 for R&D in support of a pilot reprocessing plant at the Krasnoyarsk Mining and Chemical Combine.

50 The applications for Callaway Unit 2, Grand Gulf Unit 3, River Bend Unit 3, Victoria County Station Units 1 and 2 are shown as suspended, and that for Nine Mile Point Unit 3 has been inactive since 2008. The review of the application for Turkey Points Units 6 and 7 has not yet begun (see application review schedule for each project at US NRC, 2010a).

51 Prices dropped by a half between 2008 and 2009, however, as gas from hydrofracturing shale began to enter the market in large quantities (US EIA, 2010).

Energy Policy Act of 2005, the US government created major incentives to investors to commit quickly to build new nuclear power plants. These included (Title XVII) government loan guarantees equal to up to 80% of project costs. Congress authorized up to US$18.5 billion for this purpose in the Consolidated Appropriations Act of 2008. In June 2008, the US DOE solicited requests for the loan guarantees. The response was applications for US$122 billion in guarantees to cover 65% of the cost of 21 reactors with a total generating capacity of 28.8 GW_e (US DOE, 2008a). In its budget proposal for fiscal year 2011, the Obama Administration proposed to increase the funding available for nuclear loan guarantees to US$54.5 billion (US DOE, 2010b: 259). The four companies that were on the shortlist for the first tranche of loan guarantees were also among the five companies that signed engineering, procurement and construction contracts for new nuclear power plants (Bloomberg, December 17, 2009). (The fifth was responding to state-level incentives; see below). In January 2010, one utility received a loan guarantee for US$8.3 billion ($US_{2005}$$7.6 billion) that reportedly would cover up to 70% of the project costs for two 1.1-GW_e reactors, amounting to at least US$5.4 billion/$GW_e$ ($US_{2005}$$4.9 billion/GW_e). Additional loan guarantees might be provided by the Japanese government because the reactors will be built by Westinghouse, which is now a subsidiary of Toshiba (*New York Times*, February 17, 2010).

The Energy Policy Act also allows for up to US$2 billion to compensate companies building the first six nuclear power reactors for regulatory delays in the startup process. Finally, Title XIII provides for a production tax credit of US$0.018/kWh, up to a total of US$6 billion, for power produced by 6 GW_e of advanced nuclear power capacity during the first eight years of operation.[52]

State-level policy is also important. Out of the 50 states, 36 regulate the investments of utilities in the generation and transmission of electric power.[53] Under these regulations, if a state regulatory authority authorizes investment in the construction of a power plant, the investor is allowed to charge customers for the cost of building and operating that power plant, plus a guaranteed rate of return.

In Florida, the Public Service Commission has gone further and permits investors to start charging the customers even before a nuclear power plant is under construction. If, for some reason, the plant is never completed, the owners of the reactors still will be entitled to recoup "prudent" costs from their customers.[54] The only utility that has signed engineering, procurement and construction contracts for new nuclear power plants without the expectation of a loan guarantee is Progress Energy, a Florida utility that is the beneficiary of such a ruling. Georgia has a similar policy (*WNN*, 18 March 2009). Plans for a plant in Missouri were shelved after the utility proposing it was unable to obtain the repeal of a state law banning charges for construction work in progress (*Fuel Cycle Week*, April 24, 2009).

In late 2009, the US EIA projected that only 8.4 GW_e of new nuclear electric generating capacity will actually come online in the United States by 2035 (US EIA, 2009). After 2030, US nuclear power plants will reach 60 years at an average rate of about 5 GW_e/yr. US power reactors will have to be licensed to operate for more than 60 years – a possibility that is already being discussed – or the rate of reactor construction will have to increase greatly if US nuclear capacity is not to decline (US EIA, 2008a).

14.3.7 Western Europe

At the end of 2009, nuclear capacity in Western Europe totaled 122 GW_e, with two new 1.6-GW_e units under construction in Finland and France by the French company AREVA Nuclear Power (IAEA-PRIS).

In seven of the nine WEU countries with operating nuclear reactors, the youngest reactor was built in the 1980s (or earlier, in the case of the Netherlands). The United Kingdom completed one reactor in the 1990s. France completed an average of one power reactor per year during the 1990s, but none since then.[55] Due to retirements, Western Europe's nuclear generating capacity has declined by about 4 GW_e since 2000 (IAEA, 2007a; 2010d). Unless the reactor licenses are extended or the rate of construction picks up, Western Europe's nuclear capacity will continue to decline during the next few decades.

France accounts for a little more than half of Western Europe's nuclear capacity (63.3 GW_e) and for one of the two new units under construction (IAEA, 2010d, Table 1). The equivalent of about 76% of France's electricity is generated by nuclear power (IAEA, 2010a). France is a major net exporter of electric power (Schneider et al., 2009: 101). France's national utility, Électricité de France, is also considering investing in nuclear power plants in China, the United Kingdom and the United States, and possibly also in Italy and South Africa (*WNN*, December 4, 2008). Both of the new 1.6-GW_e EPR reactors being built by AREVA are suffering from serious delays and cost overruns, however. As of the end of 2008, the EPR under construction at Flamanville,

52 The US Congressional Budget Office puts the limit at US$7.5 billion (US CBO, 2008).

53 Some 14 states deregulated electric power production (Connecticut, Delaware, Illinois, Maryland, Maine, Massachusetts, Michigan, New Jersey, New Hampshire, New York, Ohio, Pennsylvania, Rhode Island, Texas). Eight have re-regulated (Arkansas, Arizona, California, Montana, Nevada, New Mexico, Oregon, Virginia). The remaining 28 states never deregulated (US EIA, 2008e).

54 In late 2008, the Florida Public Services Commission authorized two utilities to charge their customers US$0.6 billion during 2009 for pre-construction expenses they expected to incur for four nuclear power reactors that they hoped to build (Florida Public Service Commission, 2007/8). One of the utilities, Florida Public and Light, estimated that the cost for completing the building of two Westinghouse AP1000s would be US$5780–8071/$kW_e$ (*Nucleonics Week*, February 21, 2008).

55 The last reactor came on line in Belgium in 1985, Finland in 1980, France in 1999, Germany in 1989, the Netherlands in 1973, Spain in 1988, Sweden in 1985, Switzerland in 1984, and the United Kingdom in 1995 (IAEA-PRIS).

France, was expected to cost €4 billion (US_{2005}5.8 billion) or US$3600/$kW_e$ (*WNN*, December 4, 2008). In early 2009, the Finland's Olkiluoto EPR was 18 months behind schedule and expected to cost close to €5 billion (US_{2005}7.2 billion) (*Nucleonics Week*, March 5, 2009). AREVA NP's client in Finland, TVO, was suing for compensation of €2.4 billion (US_{2005}3.5 billion) for power replacement and other losses due to the delay. AREVA, for its part, accused TVO of having slowed down the licensing procedure more than necessary and filed an arbitration case with the International Chamber of Commerce for about €1 billion in compensation (*Nucleonics Week*, March 19, 2009).

In both cases, a large part of the problem seems to be inadequately trained workers and poor quality control leading to the rejection of completed work by safety inspectors (*New York Times*, 29 May 2009). To some extent, these problems reflect a loss of expertise in the nuclear industry that might be overcome if the number of orders increases to the point where crews can move from one project to another at a nearby location in the same country. At the moment, this condition is met only in China and South Korea.

Of the remaining eight West European countries with operating nuclear power plants, two have laws mandating a phase-out: Belgium (with 54% of electric power generated by nuclear plants in 2008) and Germany (28%) (IAEA, 2010a). Spain's current government favors a nuclear energy phase-out (WNA, 2010g). The Netherlands is currently considering the construction of new nuclear power plants (WNA, 2010f). Despite its experience with AREVA, Finland is considering buying a second new nuclear power reactor from another vendor (*WNN*, February 5, 2009). Sweden had a phase-out law but, in 2010, decided to allow replacement of its current units as they are retired (WNA, 2010e).

The United Kingdom has the third largest nuclear capacity in Western Europe (10 GW_e).[56] The last of its first-generation "Magnox" graphite-moderated, gas-cooled nuclear power plants are to be shut down in 2012 (UK NDA, 2010). Its advanced gas reactors (AGRs) have a design life of 35 years, which would have them all shut down by 2024.[57] In early 2008, the UK government, which has an ambitious plan to reduce carbon dioxide emissions, came out in support of the building of new nuclear power plants, but declared that it would not subsidize their construction (*Times*, January 11, 2008). In September 2008, France's government-owned utility, Électricité de France, bought the UK nuclear utility, British Energy, for US$23 billion with the intention of building four new 1.6-GW_e EPR LWRs on the AGR sites (*International Herald Tribune*, September 24, 2008). Other companies are also considering building new nuclear reactors in the United Kingdom (WNA, 2010d).

56 Germany has the second largest capacity, with 20 GWe.

57 They may have to be shut down even earlier (*New Scientist,* March 25, 2004).

14.4 Advanced Reactor Technology

The major reactor vendors have developed and are licensing and selling advanced (generation III+) LWRs (see, e.g., US NRC, 2010a). With the renewed interest in nuclear power, however, there has also been renewed interest in exploring alternatives to the LWR. This section first briefly discusses advanced LWRs, and then considers two types of alternative reactors – fast-neutron and slow-neutron[58] – and finally, small and transportable reactors, which may be of interest to countries or regions with small power grids.

14.4.1 Generation III+ Light-water Reactors

After the 1979 accident at Three Mile Island, there were few reactor orders. The reactor vendors that survived used this period of slow business to develop and license evolutionary designs of LWRs intended to be both safer and less costly per unit output. The resulting so-called Generation III+ LWR designs and their instrumentation have been simplified and standardized, and some contain "passive" safety systems that operate automatically even if electrical power to the control system and pumps is lost. In the Westinghouse-Toshiba AP1000, for example, valves are designed to open automatically when the level of water in the reactor falls below a certain level. Emergency cooling water then is driven into the reactor, initially with steam and nitrogen pressure. After the reactor vessel is depressurized, water flows in from elevated tanks without pumping and, after evaporating, is condensed at the top of the containment building and returns to the tanks to flow into the reactor again (Westinghouse, 2009). These systems are calculated to reduce considerably the probability of a core meltdown accident.

Despite their inherent reliability, the pressures generated by gravity-driven passive systems are modest in comparison with those produced by pumps. Their performance is therefore less certain in a situation where hot fuel can generate steam backpressure. Also, by giving credit to the passive systems for reducing the probability of a core meltdown, the US Nuclear Regulatory Commission (US NRC), whose regulations are usually treated as world standards, has reduced the reliability requirements on the active backup systems by not requiring them to be safety grade, and has allowed less robust containments. As a result, the net effect on overall safety of installing the passive systems is uncertain (Lyman, 2008).

58 In slow-neutron reactors, fission neutrons are "moderated" or slowed down by collisions with the nuclei of light elements. In contrast, neutrons lose relatively little energy to the recoil of the heavier nuclei of the liquid metals used to cool fast-neutron-reactor fuel. A primary advantage of slow-neutron reactors is that they can sustain a chain reaction in low-enriched or even, in some cases, in natural uranium. A primary advantage of fast-neutron reactors is that, when fueled with plutonium, they can be designed to breed more plutonium than they consume.

14.4.2 Fast-neutron Reactors for Breeding and Burning

Although there is no reason to expect the dominance of LWRs to end in the foreseeable future, the major government nuclear-energy R&D establishments continue to develop potential successors. The OECD's Generation IV (Gen IV) International Forum coordinates research on six reactor types (Gen IV, 2008) and the IAEA-based International Project on Innovative Nuclear Reactors and Fuel Cycles focuses on methodologies and generic technical challenges (IAEA, 2010b).

The most attention – but relatively little funding – is going to the liquid-sodium-cooled "fast-neutron" reactor, the reactor type in which the nuclear R&D establishments invested their greatest efforts in the 1960s and 1970s (Figure 14.13). Fast-neutron reactors fueled with plutonium can be designed to produce more plutonium from uranium-238 than they consume. This makes uranium-238, which constitutes 99.3% of natural uranium, the ultimate fuel of fast-neutron breeder reactors.

Plutonium breeder reactors were pursued when it appeared that resources of high-grade uranium ore were very limited and global nuclear power capacity was expected to increase by 2010 to several thousand GW_e (IPFM, 2010). But nuclear capacity plateaued and high-grade uranium ore proved to be much more abundant than previously believed. Enough low-cost uranium has been found to sustain 500 GW_e of capacity for 50 years (NEA, 2008c)[59] and much more probably remains to be discovered (see discussion below). The contribution of the cost of uranium to the cost of power at the cutoff grade in these estimates (uranium recoverable at a cost of US$130/kg or less) would only be about 0.3¢/kWh.

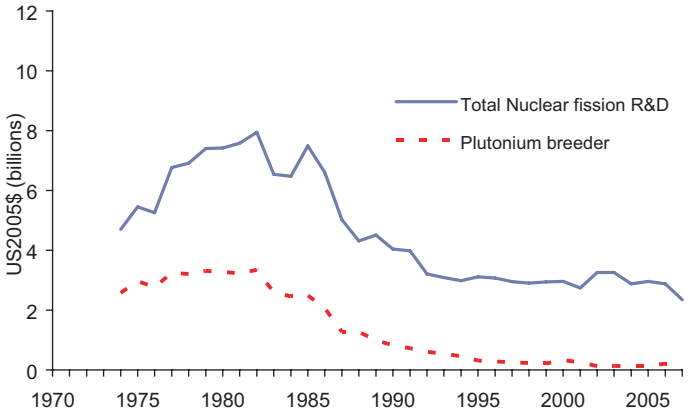

Figure 14.13 | Total fission and breeder research, development and demonstration (RD&D) funding in the OECD countries with substantial breeder programs, 1974–2007 (Belgium, France, Germany, Italy, Japan, Netherlands, UK, and United States). The breeder share is understated because France, which had the world's largest breeder program in the 1980s and 1990s, did not report most of its breeder RD&D activities as such. Source: data from IEA, R&D Statistics, 2009.

59 Between 160 and 200 tonnes of natural uranium are required annually to fuel a 1-GWe LWR operating at a capacity factor of 90%, assuming 0.2–0.3% uranium-235 remaining in the depleted uranium from enrichment. With a global LWR capacity of 500 GWe, 10 million tonnes of uranium would last 100–125 years.

Fast-neutron reactors cannot be cooled by water, because (as occurs in the collisions of billiard balls) neutrons are drastically slowed down by a relatively small number of collisions with the light nuclei of the hydrogen atoms in the water. Liquid metal therefore is used because (as with the collision of a golf ball with a boulder) the heavy nuclei of the atoms take away little energy in a collision. As already noted, most development has focused on reactors cooled by molten sodium. Because sodium burns on contact with air or water, however, sodium-cooled reactors have proved to be much more costly and difficult to operate than water-cooled reactors, and only a few experimental and "demonstration" reactors have been built with government support. Japan's 0.28-GW_e Monju fast breeder demonstration reactor, which began operating in 1995, shut down a few months later as a result of a sodium fire, and only restarted briefly 15 years later in May 2010. The largest demonstration liquid-sodium-cooled reactor built to date, France's 1.2-GW_e Superphénix, spent so much time in repair that it had an average capacity factor of only 7% over its operating life (1985 to 1996). Russia's BN-600 is the exception. Despite 15 sodium fires in 23 years, it has been kept online with an average capacity factor of about 74% (Oshkanov et al., 2004).[60]

There are various ideas for reducing the cost of fast-neutron reactors, including the use of alternative coolants such as molten lead. Helium is also being considered, but has the safety disadvantage that it has little heat capacity if there is a loss of pumping power.

Breeder reactors and uranium resources. Superphénix cost about three times as much as an LWR of the same capacity.[61] If the capital cost of a commercialized fast-neutron reactor were higher than that of an LWR by only US$1000/$kW_e$, it would require the cost of uranium to rise to about US$1200/kg for the uranium savings from a breeder reactor to offset its extra capital cost (Bunn et al., 2005, Figure 3; MIT, 2003; IPFM, 2010). This is about 10 times the cost of uranium in early 2009.

Most uranium exploration has focused on deposits with recovery costs of less than US$80/kg and finds are reported only when the recovery costs would be less than US$130/kg (NEA, 2008c). These resources range from 0.03–20% uranium (IAEA, 2009b). The concentration at which the amount of electric energy extractable from the uranium in 1 tonne of ore with a once-through fuel cycle would equal the amount of energy extracted from 1 tonne of coal is approximately 0.005–0.02%.[62]

60 The BN-600 is actually fueled by HEU because its core would not be stable with plutonium fuel. It is therefore not a breeder reactor.

61 The capital cost of the 1.2-GWe Superphénix was FF 34.4 billion (about US$8 billion in 2005 US$) according to France's public accounting tribunal, the Cour des Comptes (*Nucleonics Week*, October 17, 1996).

62 At 0.005% uranium, 1 tonne of ore would contain 50 g of natural uranium. That would produce 6.25 g of 4.4% enriched uranium (assuming 0.2% uranium-235 is left in the depleted uranium). For a burnup of 53 MWt-days/kg, the amount of fission energy released from the 6.25 g of LEU would be 28×10^9 J, about the amount of energy released from the combustion of 1 tonne of coal. Van Leeuwen has the breakeven level at 0.02%, in large part because he uses 50% gross thermal efficiency of the coal plant versus 32% for an LWR and a uranium recovery factor of 50% (Van Leeuwen, 2008).

Despite consumption and inflation, known uranium resources with recovery costs less than US$40/kg continue to increase from year to year (NEA, 2008c, Table 1). Resources also are likely to go up rapidly at higher recovery costs (Deffeyes and MacGregor, 1980). Figure 14.14 compares the known conventional resources of uranium reported by the OECD's Nuclear Energy Agency (NEA, 2008c) with crustal abundance models and the estimated cost of recovering uranium from seawater (Schneider and Sailor, 2008):

- The cost of recovery used to translate estimated crustal abundance to cost in Schneider and Sailor's "conservative" and "optimistic" crustal models is assumed to be simply proportional to the amount of rock that must be mined, crushed, and leached to recover 1 kg of uranium. Thus, for ore with half the concentration of uranium, it would cost twice as much to recover 1 kg of uranium.

- The Kim & Edwards cost curve assumes that the recovery cost per kilogram increases somewhat more rapidly than inversely with declining ore concentration. Thus, for example, the cost of recovering a kg of uranium from an ore grade with one-tenth the concentration would be 19 times as high.

- The ocean contains about 4.5 billion tonnes of uranium but at a very low concentration of 3.3 parts per billion by weight. The estimate shown in Figure 14.14 that uranium would be recoverable from seawater at a cost of US$200/kg was developed by the US Department of Energy Generation IV Fuel Cycle Cross Cut Group (see also Tamada et al., 2006).

All the curves in Figure 14.14 are constrained to agree on uranium resources at a uranium recovery cost of about US$40/kg.

If the crustal model approach is correct, 20–60 million tonnes of uranium should be recoverable at a cost of less than US$130/kg. Some 25 million tonnes of uranium would be required to sustain a once-through LWR economy until the year 2100 if global nuclear capacity increased linearly from 2020 to approximately 4000 GW_e. An LWR capacity of 4000 GW_e would require about 6.4 million tonnes of uranium per decade.[63] Thus breeder reactors would be unlikely to be competitive until well beyond the end of the century, even if global nuclear capacity climbs into the thousands of GW_e. A recent MIT study has come to a similar conclusion (MIT, 2010).

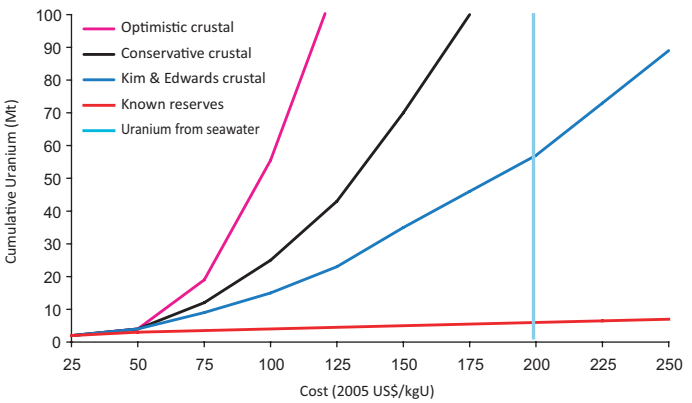

Figure 14.14 | Uranium resource availability. Known conventional reserves as reported in the NEA–IAEA "Red Book" [NEA, 2008c] compared with three geological estimates of crustal abundance as a function of recovery cost and an estimated cost of US$200/kg for recovery of uranium from seawater. adapted from: Schneider and Sailor, 2008.

It would be much more useful to determine whether the crustal model is approximately correct and to refine the technology and cost estimates for recovering uranium from seawater than to embark on the promotion of a hugely expensive proliferative technology involving the separation and recycling of plutonium because of probably unfounded fears of uranium shortages.

Fast-neutron "burner" reactors and the spent-fuel problem. In 2006, the US DOE proposed to design and build fast-neutron reactors as "burner" rather than breeder reactors (US DOE, 2006). This was because of the presence of long-lived transuranic isotopes (plutonium, neptunium, americium, and curium) in spent nuclear fuel and public concerns about uncertainties about the performance of geological repositories over a time scale of hundreds of thousands of years. Unlike LWRs, fast-neutron reactors can fission all the long-lived transuranic isotopes in spent LWR fuel relatively efficiently.

This was not a new proposal. In 1992, the US DOE had asked the US National Academy of Sciences (US NAS) to study proposals to reduce the longevity of the radioactive waste problem through separation and transmutation of long-lived radioisotopes. The resulting study (US NAS, 1996) was quite skeptical. It concluded that:

- "Although a significant fraction (90–99%) of many of the most troublesome isotopes could be transmuted (to shorter-lived or stable isotopes) this reduction of key isotopes is not complete enough to eliminate all the process streams containing HLW (high-level radioactive waste)… Transmutation thus, would have little effect on the need for the first repository…"

- "It would take about two centuries of operating time to reduce the inventory of the residual (transuranics) to about 1% of the inventory of the reference LWR once-through fuel cycle…"

- "Estimates of changes in dose (from nuclear power and radioactive waste) are small… Taken alone, none of the dose reductions seem large enough to warrant the expense and additional operational risk of transmutation…."

- "The excess cost of (a separation and transmutation) disposal system over the once-through disposal of the 62,000 (tons heavy metal

63 Assuming 160 tonnes of natural uranium per GWe-yr, i.e., a depleted uranium assay of 0.2%.

in) LWR spent fuel (the approximate legislated limit on what could be stored in Yucca Mountain before a second US repository came into operation) is uncertain but is likely to be no less than US$50 billion and easily could be over US$100 billion ($US_{2005}$$120 billion ($US_{2005}$$0.3–0.6+¢/kWh), not including the extra cost of the fast-neutron reactors or other transmutation systems)."

- "The committee concluded that the once-through fuel cycle should not be abandoned… (T)his has the advantage of preserving the option to retrieve energy resources from the wastes for an extended period of time. This can be achieved by adopting a strategy that will not eliminate access to the nuclear fuel component for a reasonable period of time, say about 100 years, or by preserving easy access to the repository for a prescribed period of time, or by extending the operating period of the repository… A reason for supporting continued use of the once-through fuel cycle is that it is more economical under current conditions."

- "Widespread implementation of (separation and transmutation) systems could raise concerns of international proliferation risks…"

The last comment relates to the fact that, as currently envisioned, fast-neutron reactors only achieve the benefits of uranium savings and more complete fissioning of transuranics with a "closed" fuel cycle (one in which spent fuel is processed and the plutonium and other transuranic elements are recycled repeatedly in new fuel). Since the transuranic elements could be used to make nuclear weapons, this creates a proliferation risk. We discuss this issue below.

In 2007, the US Office of Management and Budget requested that the National Academies of Sciences review US DOE's nuclear energy R&D program. The response was even more unequivocal; "domestic waste management, security and fuel supply needs are not adequate to justify early deployment of commercial-scale reprocessing and fast reactor facilities" (US NAS, 2007: S-8).

14.4.3 Thermal (slow)-neutron Reactors

On its list of reactor types of interest, the Generation IV collaboration has three types of thermal-neutron reactors: supercritical water-cooled reactors, very high-temperature gas-cooled reactors, and molten-salt reactors. The supercritical reactor would allow LWRs to take advantage of the increased efficiency of the conversion of heat into electricity at higher coolant temperatures. Some fossil fuel plants already operate at supercritical temperatures.

Very high-temperature gas-cooled reactor designs, with coolant temperatures up to 950°C, are being examined in the United States, primarily as a way to produce hydrogen by heat-driven instead of electricity-driven chemical reactions. The "Nuclear Hydrogen" project was launched in the Energy Policy Act of 2005. The US DOE and the US Nuclear Regulatory Commission have defined a joint research program to provide the analytical tools to license such a reactor (US DOE, 2008d). Otherwise, R&D in this area has been confined primarily to the development of thermochemical processes (US DOE, 2008c). Charles Forsberg, a nuclear engineer at the Massachusetts Institute of Technology, has suggested that a more important use of high-temperature gas-cooled reactors that could produce heat with a temperature of 700°C would be to replace fossil fuels in providing process heat for oil refineries and for extracting liquid fuels from oil shales and tar sands (*Oil and Gas Journal*, August 11, 2008).

Finally, the molten-salt reactor would have its fuel dissolved in molten salt. The heat would be extracted by pumping the salt through a heat exchanger and the fission products could be removed and new fuel added by chemically processing a side stream. The problem with this design, however, is the complexity of operating a reactor with an integrated small reprocessing plant (Gen IV, 2008).

14.4.4 Low-power and Transportable Reactors

The IAEA recommends that a single nuclear power reactor should not constitute more than 5–10% of the generating capacity on a grid (IAEA, 2007b). As discussed previously (Table 14.2), gigawatt-scale reactors therefore require large grids. Smaller reactors could provide an alternative for countries and regions with small grids and expensive power. Proponents also claim that economies of scale in factory production could make them less costly than today's reactors, which involve costly field construction. A few relatively low-power LWR designs are available (WNA, 2008).

The low-power (~0.2 GW_e) graphite-moderated high-temperature gas (helium)-cooled reactor has been under development since the 1970s and continues to be the most plausible, relatively safe alternative to the LWR in the near term. It is being actively investigated in China, Japan, Russia, South Africa and the United States.

Some small reactor designs emphasize long core life. The tradeoff is that the initial core would be more costly per unit output (IAEA, 2005a, Table 5; IAEA, 2007c; US NRC, 2009).

One transportable nuclear power plant is under construction, a barge carrying twin 0.035-GW_e reactors based on a design used in some of Russia's nuclear-powered icebreakers. These reactors would be refueled after four years of operation. The first floating power plant is being constructed in St Petersburg with completion projected for 2011 (Bellona, May 18, 2009; IAEA, 2005a, Annex 6.5; Greencross, 2004). In 2006, Rosatom was planning to complete seven floating nuclear power plants by 2015 (Rosatom, 2006a, b). It is believed that, because of Russia's interest in exporting these reactors, they will be fueled with LEU rather than the weapon-usable highly enriched uranium used in Russia's submarines and nuclear-powered icebreakers (Sokov, 2006).

14.4.5 Safer Reactor Designs

Operational safety has been improved and, as discussed above, the new Generation III+ light-water reactor designs have passive safety features that might make emergency cooling independent of the availability of power for days. Nevertheless, the probability of terrorists attempting to cause Chernobyl-scale releases of radioactivity appears to be greater today than it was in the 1980s. This is a major reason why attention should be devoted to less vulnerable designs as well as to improved physical security.

In the case of the high-temperature gas-cooled reactor, attempts to give it inherent safety have been made by putting the uranium into small particles, encapsulated in layers of pyrolytic carbon and silicon carbide, in order to contain the fission gases. The chain reaction would shut down because of negative temperature feedback effects on the reactivity and the reactor would eventually reach thermal equilibrium by radiating away to the cooler wall of the containment the heat generated by the declining radioactivity of the fission products in the fuel. If the reactor power is low enough (less than 0.3 GW_e), the peak temperature could be kept below the failure temperature of the particles (Labar, 2002). Oxidation of the graphite moderator by penetrating air could provide an additional source of heat, but one analysis has found that, even with a break in the largest coolant pipe, the rate of air inflow would be limited to a level where graphite oxidation would not drive the core temperature significantly higher (Ball et al., 2006).

A recent report on the operational history of Germany's 46 MW_t gas-cooled AVR (Arbeitsgemeinschaft Versuchsreaktor) pebble-bed reactor, which operated between 1967–1988, has called into question the adequacy of its safety design. It was revealed that the reactor had suffered a serious leakage of fission products into the helium coolant. One possible reason was "inadmissible high core temperatures … more than 200 K higher than calculated." Another was that cesium-137 (30-year half-life), the most dangerous radioisotope released by the Chernobyl accident, appears to have diffused through intact particle coatings. It was therefore concluded that the reactor would require a leak-proof containment similar to that required for modern LWRs, which would erase a major cost saving. Additional safety issues were noted for designs such as the AVR, in which water ingress into the graphite was possible. "Thus a safe and reliable AVR operation at high coolant temperatures (does) not conform with reality" (Moormann, 2008, abstract).

With questions about the safety of what has been claimed by General Atomics for decades to be an "inherently-safe" reactor design (General Atomics, 2010), it would be useful to launch a new R&D program to consider the possibilities for a truly inherently safe, reliable, and economic design.

14.5 Once-through versus Plutonium Recycling

Today, five weapon states (China, France, India, Russia, and the United Kingdom) plus Japan reprocess at least some of their spent fuel. The Netherlands has contracted with France to have the spent fuel from its single reactor reprocessed (van der Zwann, 2008). Of the reprocessing states, France, India, and Japan currently plan to reprocess most of their spent fuel. The United Kingdom is expected to end reprocessing when it has fulfilled its existing contracts (*Nuclear Fuel*, June 18, 2007, July 28, 2008a). Russia reprocesses only the spent fuel from its first-generation VVER-440 LWRs and its BN-600 demonstration fast-breeder reactor, with a combined capacity of 3 GW_e (IAEA-PRIS). It also receives and mostly stores spent fuel from Bulgaria and Ukraine. China has built a pilot reprocessing plant.

Of the remaining 21 countries with nuclear energy programs, 11 have not reprocessed their spent fuel[64] and 10 that shipped their spent fuel to France, Russia, or the United Kingdom for reprocessing in the past, have not renewed their contracts.[65] All 21 have decided on interim storage. As a result, measured in terms of fission energy released, worldwide, about one-third of spent fuel is reprocessed today (Table 14.5). The percentages shown for some countries in the first column reflect various limitations on the fraction of the spent fuel reprocessed.

There are two primary reasons why almost all customer countries have stopped shipping their spent fuel abroad for reprocessing:

1. reprocessing and plutonium recycling are much more costly than spent-fuel storage, and

2. countries providing reprocessing services are requiring (or, in the case of Russia, keeping the option to require) their foreign customers to take back the high-level waste from reprocessing.

Thus, foreign reprocessing simply converts, at considerable cost, a politically difficult spent-fuel disposal problem into a politically difficult spent MOX fuel and high-level waste disposal problem. It is politically attractive only for an interim period because it buys a decade or so of respite.

Only Russia has routinely kept its customers' separated plutonium. Among France's and the United Kingdom's former reprocessing customers, Belgium, Germany, Japan, and Switzerland have been recycling their separated plutonium in MOX (plutonium–uranium) fuel in the LWRs that produced it. France is doing the same. India and Russia plan to use their separated plutonium for startup cores for plutonium breeder reactors. France has kept Spain's separated plutonium[66] and presumably will do the same for Italy. It has included that offer in proposed reprocessing contracts to other countries such as South Korea (*Nuclear Fuel*, 13 July 2009).

64 Ignoring US reprocessing prior to 1973.

65 In 2008, Italy contracted with France to have reprocessed 235 tonnes of irradiated fuel from reactors that were shut down after the 1986 Chernobyl accident.

66 The reprocessed fuel was from the Vandellós-1 reactor, a graphite-moderated, gas-cooled reactor that operated from 1972 to 1990 (WISE, 1999).

Table 14.5 | Civilian spent-fuel reprocessing by country

Countries that reprocess spent fuel (GW_e)		Customer countries that have quit or are planning to quit reprocessing (GW_e)		Countries that have not reprocessed (GW_e)	
Bulgaria (in Russia)	1.9	Armenia (in Russia)	0.4	Argentina	0.9
China (30%)	10.0	Belgium (in France)	5.9	Brazil	1.9
France (80%)	63.3	Czech Republic (in Russia)	3.7	Canada	12.6
India (~50%)	4.2	Finland (in Russia)	2.7	Mexico	1.3
Japan (90% planned)	46.8	Germany (in France/UK)	20.5	Pakistan	0.4
Netherlands (in France)	0.5	Hungary (in Russia)	1.9	Romania	1.3
Russia (15%)	22.7	Slovak Republic (in Russia)	1.8	Slovenia	0.7
UK (ending?)	10.1	Spain (in France/UK)	7.5	South Africa	1.8
Ukraine (in Russia, ~50%)	13.1	Sweden (in France/UK)	9.3	South Korea	18.7
		Switzerland (in France/UK)	3.2	Taiwan, China	4.9
				US (since 1972)	100.6
Total	172.6	Total	56.9	Total	145.2

The United Kingdom is not recycling its own separated plutonium and as yet has no disposal plans. By the time its domestic spent-fuel reprocessing contracts are fulfilled, the UK stockpile of separated plutonium will amount to about 100 tonnes – enough for more than 10,000 nuclear explosives. The UK Nuclear Decommissioning Authority is now examining disposal options (UK NDA, 2009). The storage of separated plutonium and reprocessing waste is significantly more expensive than storage of unreprocessed spent fuel. In addition, after several years in storage, americium-241, a decay product of plutonium-241 (14-year half-life), builds up in plutonium and has to be separated before fuel fabrication.[67]

Where plutonium is being recycled in LWR MOX, it is only being recycled once. Irradiation results in a net reduction of the plutonium in the MOX fuel by about one-third, but also results in a shift of the isotopic mix in the plutonium toward the even isotopes (plutonium-238, plutonium-240 and plutonium-242) that are less easily fissioned in slow-neutron reactors (NEA, 1989, Table 12B). With repeated recycling in "non-fertile" fuel with LWRs, i.e., without uranium-238 in which neutron capture produces more plutonium, it would be possible eventually to completely fission plutonium and the other transuranics except for reprocessing and fabrication losses. It would require shielded fuel fabrication, however, and long intervals (20 years) are recommended between cycles to allow radioactive decay to offset the steady buildup of neutron-emitting curium and californium isotopes. Achieving a significant reduction in the global inventory of transuranic elements would therefore take centuries (Shwageraus et al., 2005).

In its Global Nuclear Energy Partnership (GNEP) initiative, the G.W. Bush Administration proposed that "fuel-cycle countries" would supply fresh fuel and take back and reprocess spent fuel from countries with reactors but no enrichment or reprocessing facilities. The "fuel-cycle countries" would recycle the separated transuranic elements domestically in fast-neutron reactors and dispose of the reprocessing waste in domestic geological repositories. Although about US$100 billion has so far been spent worldwide in efforts to commercialize fast-neutron reactors, no country has yet succeeded. Nor has any country yet been willing to volunteer to take other countries' radioactive waste. The US Congress became skeptical about GNEP; the Obama Administration cancelled the proposal to build a reprocessing plant; and the US reprocessing program has returned to a focus on R&D, and in particular on the feasibility of developing more economic and proliferation-resistant methods of recycling plutonium and other transuranic elements. An evaluation of the resistance of the alternative recycling technologies proposed thus far against national proliferation has been discouraging, however (Bari et al., 2009). Attention has therefore been turning to "breed and burn" concepts in which plutonium is bred and burned in place without separation from fission products (Finck, 2010).

14.5.1 Radioactive Waste[68]

Geological disposal is very widely accepted in the nuclear community as technically feasible and adequately safe (NEA, 2008b). Absolute proof that there will be no significant releases over 100,000 years or more as a result of natural processes or human intrusion is impossible, however. In the United States, Congress mandated in the 1987 amendments to the Nuclear Waste Policy Act that a site characterization program for a geological repository for spent power-reactor fuel be carried out only at Yucca Mountain, Nevada, and, if justified by the results of that program, a repository should be built and licensed by 1998. More than US$10 billion have been spent on the project and an application for a license was

67 Current MOX fuel fabrication plants cannot process LWR plutonium after the americium has built up for more than 3–5 years.

68 Charles McCombie, executive director, Association for Regional and International Underground Storage, adviser.

submitted in 2008 (US DOE, 2008b). In this sense, this repository was the most advanced in the world. It may never be completed, however, because of fierce political and legal opposition from the state of Nevada, now supported by President Obama, who has proposed to cancel the repository project and has established a "Blue Ribbon Commission" to study alternatives (US DOE, 2010a).

Other countries have encountered similar opposition from potential host communities for geological repositories. This is resulting in the abandonment of centralized "decide–announce–defend" siting approach in favor of a more consultative approach with possible host communities (Isaacs, 2006).

Finland and Sweden have adopted the consultative approach and, until its recent site selection, Sweden actually had two communities with nuclear power plants competing to host its repository (*WNN*, 3 June 2009). In Finland, the construction of an underground test facility that is expected to become a spent-fuel repository is underway next to a nuclear power plant, following acceptance by the local community and formal approvals granted by the regulator and the parliament (McCombie and Chapman, 2008). More recently, local governments in Spain have competed to provide the site for a national radioactive waste repository. Here again, the finalists are communities that already host nuclear power plants (Deutsche Welle, 2010).

In the design envisioned for the Finnish and Swedish repositories, the spent fuel is to be encapsulated in a 5-cm thick copper cask and then embedded in bentonite clay, which swells when it is wet. Recently a technical challenge has emerged to the assumed durability of the cask (Hultquist et al., 2009). Whether this will derail progress toward the repositories remains to be seen.

The fact that communities that already have nuclear facilities appear to be more willing to host radioactive waste repositories suggests that they may have a different assessment of both the risks and benefits than do communities without nuclear facilities. This certainly makes sense on an objective basis since, as the Chernobyl accident showed, the potential scale of radioactive contamination of the surface from an operating nuclear facility dwarfs any potential surface contamination from an underground facility. Also, if no off-site destination can be found for a nuclear power plant's spent fuel, putting the spent fuel underground nearby would reduce the long-term risk to the local community.

Given the already large number of relatively small national nuclear energy programs, there is interest in regional radioactive waste repositories in Europe and East Asia, although no country has yet expressed interest in hosting one. In the past, Russia has taken spent fuel back from Eastern Europe and Ukraine. There is still interest in Russia's nuclear establishment in doing so. Disposing of foreign spent fuel is seen as potentially profitable and the plutonium in the spent fuel is seen as a future energy resource. Much of Russia's public disagrees, however, and, for now, the leadership of Rosatom is not pushing to import foreign spent fuel other than Russian-origin fuel from power reactors exported by the Soviet Union or Russia.

In Europe, the European Commission has encouraged projects aimed at developing shared repositories for its smaller member states (ERDO, 2010). There should be economies of scale in the construction of repositories. A theoretical exploration, based on an identification of fixed and variable costs in the cost models developed by the Swedish, Finnish, and Swiss repository projects, finds savings of 5–10% from building one repository instead of two, each with half the capacity. It estimates 60% savings if 14 European countries with small nuclear energy programs share a single repository, but notes that 60% of those savings would result from the countries sharing repository R&D costs (Chapman et al., 2008).

Economies of scale may not be realized in the real world, however. The estimated cost of the large US geological repository proposed for Yucca Mountain was as high as or higher per tonne of spent fuel than the costs of the smaller disposal projects being developed in Europe. In 2008, the estimated cost of the US repository, not including transportation costs, was US$76.8 billion [$US_{2005}$72 billion] for the equivalent of 122,100 tonnes of spent fuel,[69] or about US_{2005}590/kg (US DOE, 2008b). For comparison, the estimated costs for disposing of 9500 tonnes of spent fuel in Sweden was about US_{2005}650/kg;[70] for 5600 tonnes in Switzerland, about US_{2005}500/kg;[71] and for 5800 tonnes in Finland, about US_{2005}365/kg.[72]

Since implementing geological repositories is politically difficult and not technically urgent, and interim dry-cask storage is inexpensive and relatively safe, it is not surprising that interim storage at nuclear power plants has become the de facto spent-fuel management strategy in the United States, Germany and a number of other countries. It also avoids the risks of dispersal of radioactive waste while it is in liquid form at the reprocessing plant.[73]

Interim storage is not immune to controversy, however, because of concerns that interim may become permanent. Indeed, with a few

69 This total would include 109,300 tonnes of spent civilian fuel. The remainder would be "defense nuclear wastes," including solidified high-level waste from US plutonium production for weapons and naval-reactor spent fuel.

70 46.5 billion Swedish krona (SEK), assuming SEK7.5 (2003) per 2005 US$ (SKB, 2003).

71 Assuming that 2065 packages of spent fuel and 720 packages of vitrified high-level waste are equivalent to 5570 tonnes of spent fuel, and that 4.4 billion Swiss francs (2001 SFR) equal US$2.8 billion (2005 US$) (Chapman et al., 2008, Appendix).

72 Assuming that 2899 spent-fuel containers hold 5800 tonnes of spent fuel and that €2.54 billion (2005 €) equal US$2.12 billion (2005 US$) (Chapman et al., 2008, Appendix).

73 Both France and the UK have accumulated years of production of high-level liquid waste at their reprocessing plants because of technical problems with the vitrification (glassification) process. This waste contains on the order of 100 times the amount of cesium-137 (30 year half-life) that was released in the Chernobyl accident.

exceptions, local governments in Japan and South Korea have vetoed the construction of additional on-site interim storage. This is one of the reasons for the persistence of reprocessing in Japan (Katsuta and Suzuki, 2006) and the interest in reprocessing in South Korea (von Hippel, 2010).

The cost of dry-cask interim spent-fuel storage is relatively low (US_{2005}100–200/kg, or 0.02–0.05¢/kWh) and keeps open all future options, including deep underground disposal and reprocessing/recycling. It is relatively safe because the fuel is typically about 20 years or more old and the heat generated by the radioactivity has declined to less than 2 kW_t/tonne (Alvarez et al., 2003: Figure 5).[74] Ten tonnes in a typical 100-tonne cask therefore generate less heat than an ordinary automobile engine and only passive air-cooling is required. The temperature of the fuel in the cask remains well below the fuel operating temperature in a reactor and its zirconium-alloy fuel rod cladding is expected to remain intact indefinitely. In Germany, Switzerland and Japan, the casks are stored inside thick-walled buildings. In the United States, they are stored outside (Figure 14.15). It is possible to puncture such casks with a missile tipped with a shaped charge but, based on an experiment with simulated fuel, it was concluded that, for a single puncture, only a few parts per million of the cesium-137 in the cask would be released. Even a fractional release 100 times larger would still be negligible on the scale of the Chernobyl accident, where the equivalent of the amount of cesium-137 in approximately three casks of spent fuel was released (Alvarez et al., 2003).

14.6 Risks from Large-scale Releases of Radioactivity to the Atmosphere

The most serious release of radioactivity to the environment from a nuclear power plant accident occurred at Chernobyl, on the border between Belarus and Ukraine, in late April and early May 1986. It was caused by an accidental supercriticality that produced a power spike that ruptured the cooling tubes, followed by a steam explosion as the water contacted the hot graphite in the core, and finally a graphite fire after the core was opened to the air.

The physical consequences of the Chernobyl accident included the following:[75]

- The deaths of 28 emergency workers from radiation illness within weeks.
- Exposure to high radiation fields of 600,000 civilian and military "liquidators" who were involved in the emergency decontamination of the reactor, the reactor site and nearby roads, and in the construction of the temporary "sarcophagus" over the reactor.[76]

Figure 14.15 | Dry cask storage of older spent fuel at a US nuclear power plant. Each year, a 1000-MW_e light-water reactor discharges spent fuel that originally contained about 20 tonne of uranium. Each cask typically holds about half that amount and costs US_{2005}1–2 million. Reprocessing spent fuel costs about ten times as much. Source: Connecticut Yankee, 2008.

74 Spent fuel can be placed in dry-cask storage as soon as three years after discharge, when the decay heat is about 6 kW_t/tonne.

75 Unless otherwise stated, the source of information in this section is UNSCEAR, 2000, vol. II, Annex J.

76 The dose limit was 0.25 sieverts (Sv). The average recorded doses were 0.17 Sv in 1986, 0.13 Sv in 1987, 0.03 Sv in 1988 and 0.015 Sv in 1989 (***ibid.,*** p. 470).

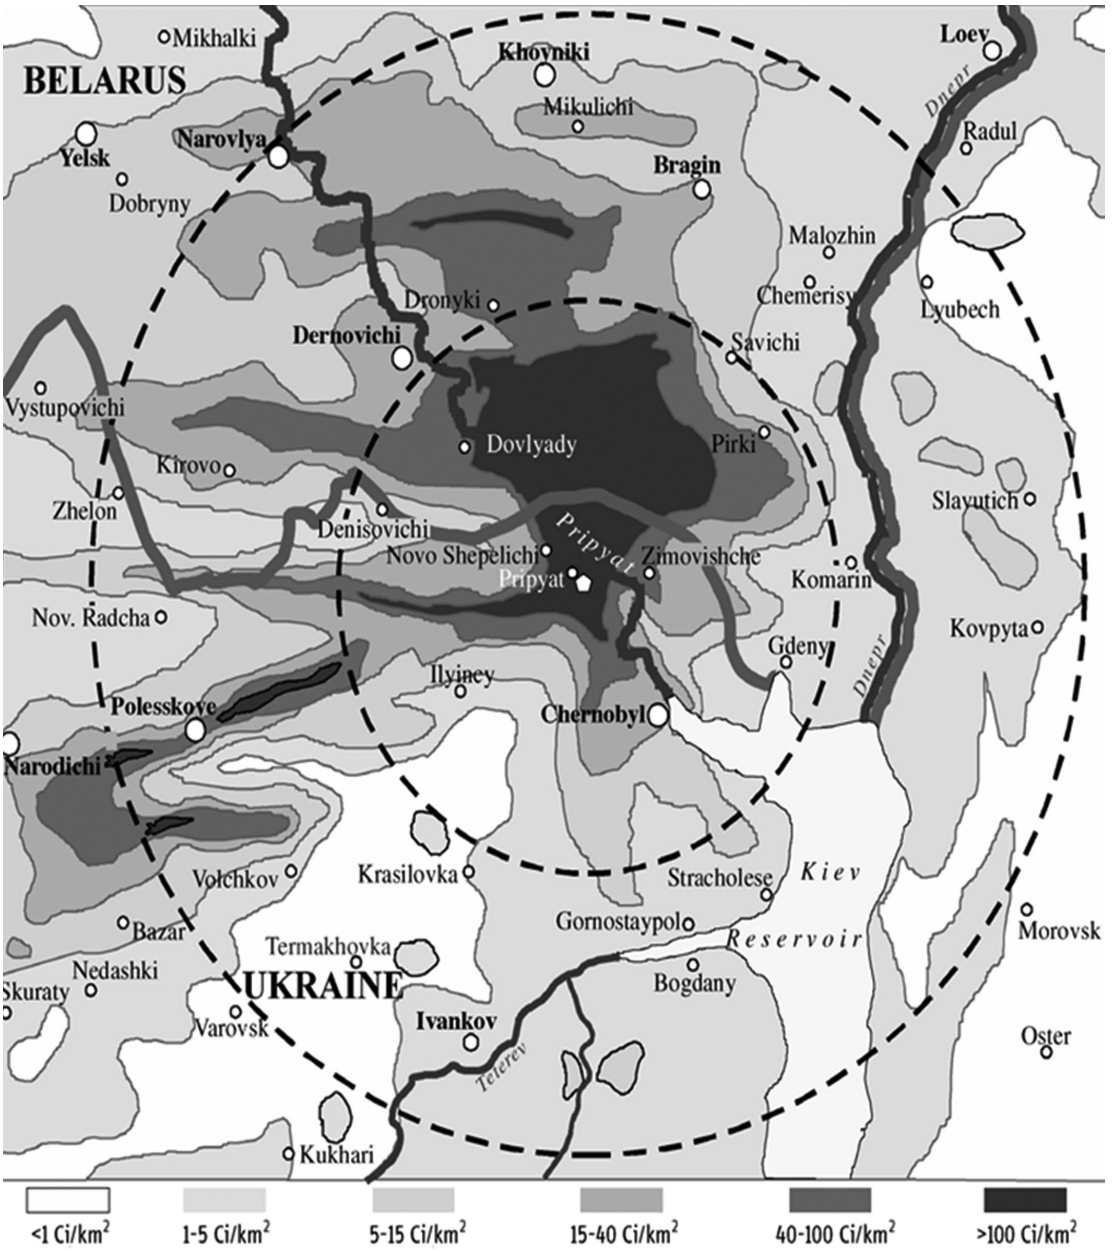

Figure 14.16 | Cesium-137 contamination levels around the Chernobyl reactor measured during the decade after the accident. Source: UNSCEAR, 2000, vol. II, Annex J, Figure VII. About 3000 km^2 contaminated to greater than 1.48 MBq/m^2 (40 Curies (Ci) cesium-137 per km^2) are still officially evacuated. Areas with contamination levels between 0.56 and 1.48 MBq/m^2 (15 and 40 Ci/km^2) were designated as areas of strict radiation control, requiring decontamination and control of intake of locally grown food. As a result, the annual accident-related effective dose in these areas has been kept below a level of about 5 mSv/yr – approximately twice the global average natural background rate (UNSCEAR, 2000, vol. 1, Table 1; Annex, para. 108). A population subject to such a dose rate indefinitely would incur an extra cancer risk of about 3.5%, about half of which would be fatal (US NAS, 2006: 4, 8).

- Radioactive contamination of an area of about 3000 km^2 by cesium-137, the 30-year half-life gamma emitter, to levels that resulted in the long-term evacuation of residents (Figure 14.16).[77]
- A still-growing epidemic of thyroid cancer among people in the region who received large doses from ingested and inhaled radioactive iodine (see Figure 14.17).
- Other radiogenic cancers are suspected but undetectable in a much larger background of cancers due to other causes.[78] One recent theoretical estimate, based on dose estimates and dose–risk coefficients derived from Hiroshima and Nagasaki survivors, is typical: 4000 extra cancer deaths among the 600,000 Chernobyl liquidators, 5000 among the 6 million people living in "contaminated areas" (above 37 kBq/m^2 of cesium-137), and about 7000 in the population

77 The area within a 30-km radius of the reactor was evacuated, as well as some heavily contaminated villages outside this zone.

78 Almost 30% of deaths in developed countries are from cancer (American Cancer Society, 2007).

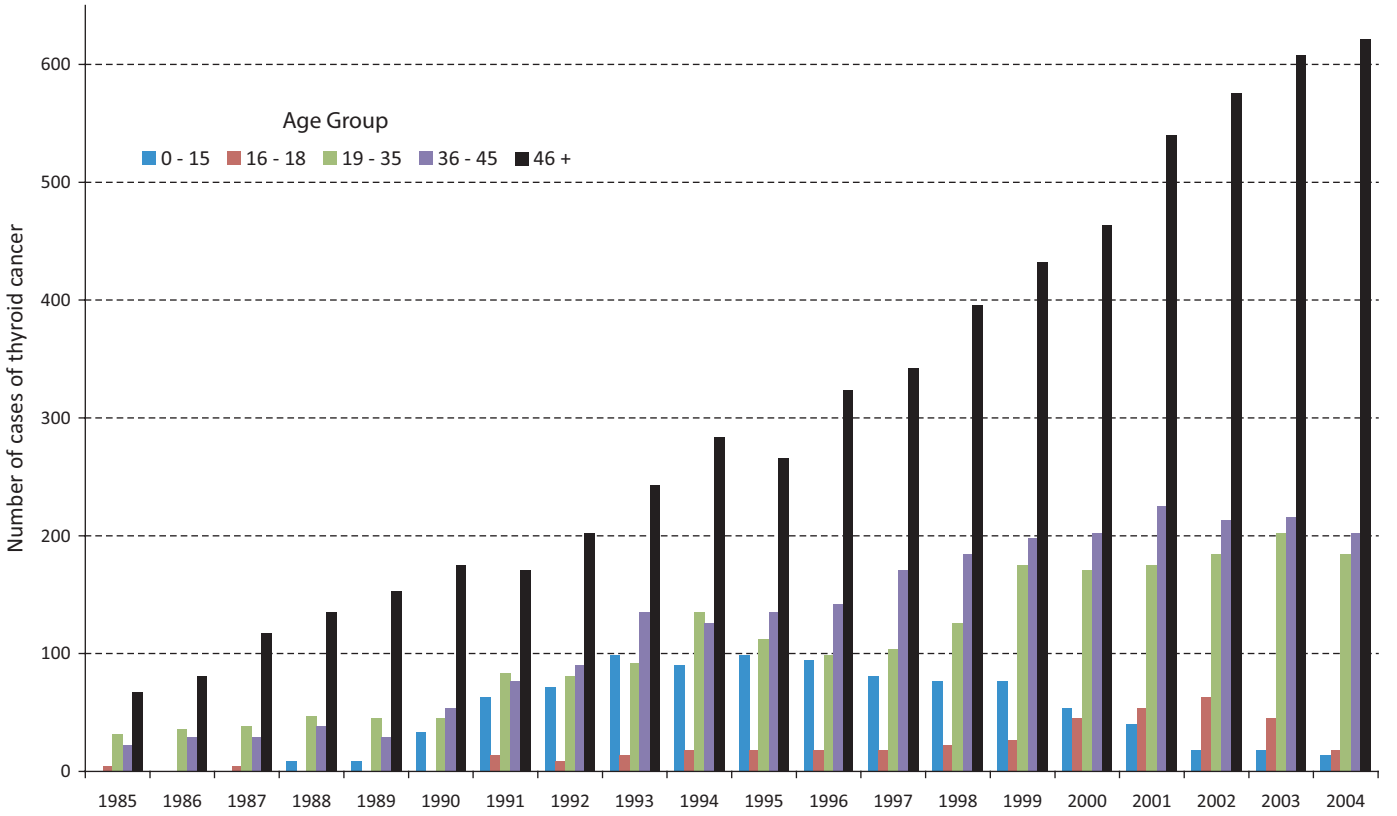

Figure 14.17 | Epidemic of thyroid cancer in Belarus following the 1986 Chernobyl accident. Annual number of cases of thyroid cancer grouped by age at the time of diagnosis. Note that the incidence of thyroid cancer in the youngest group (0–15 years) returned to low levels in 2002 when all the exposed population had graduated into older groups. In the younger groups the death rate due to thyroid cancer has been low. This does not appear to be true, however, for the increasing number of cases among those aged 46 and over. In 2004, this group would have been over 27 at the time of the Chernobyl accident. Source: Bespalchuk et al., 2007.

of 500 million of the rest of Europe who were subjected to lower doses. The total number of extra cancer deaths over the expected lifetime of the exposed population was estimated at 6000–38,000 (95% confidence level) (Cardis et al., 2006).[79]

Averaged over the approximately 10,000 GW_e-yrs of nuclear reactor capacity accumulated as of the end of 2008, an estimated 16,000 deaths from the Chernobyl accident amount to less than two cancer deaths per GW_e-yr. This is a rather modest level compared with the occupational and air-pollution deaths associated with coal-fired power plants. Perhaps the greatest harm from the Chernobyl release, however, has been the social and psychological trauma to the approximately 200,000 people who were permanently evacuated from their homes, and the millions of people now living in dread of the long-term consequences of their radiation exposure (UNSCAER, 2000, Appendix J, II.B&V.D).

Estimates of the economic cost of the Chernobyl accident range from US$6.7 billion (Sovacool, 2008b) to US$235 and US$148 billion by the governments of Belarus and Ukraine, respectively (years unspecified). In Belarus, the costs of dealing with Chernobyl amounted to 20% of the national budget in 1992, falling to 5% in 2001. These costs were paid for in part by a special tax of 18% on all wages paid by non-agricultural firms in 1994 (UNDP, 2002, sections 5.04ff). Estimates of the potential costs due to the evacuation of the population and the loss of assets due to contamination by hypothetical spent-fuel pool fires at a range of US sites also run to hundreds of billions of dollars (Beyea et al., 2004).[80]

The Chernobyl accident occurred in a reactor type that is now being phased out. The Three Mile Island accident in 1979, where the reactor core partially melted but there was not a major release of radioactivity from the containment occurred in a pressurized water reactor and the three core meltdowns at the Fukushima Daiichi nuclear power plant, which released on the order of one tenth as much radioactivity to the atmosphere as the Chernobyl accident, were in boiling water reactors (von Hippel, 2011). In the Chernobyl and Three Mile Island accidents, the operators' lack of understanding of what was happening was a key factor. Since that time, operator training has been greatly improved with the use of simulators. A wide range of other steps have been taken to

79 An estimated figure of 4000 cancer deaths from the IAEA's 2005 Chernobyl Forum is often quoted in rebuttal to higher estimates, but the Chernobyl Forum estimate was limited only to the projected cancer deaths from doses in the most contaminated areas of Belarus, Russia, and Ukraine (IAEA, 2005c, Table 5.13).

80 The range of releases of cesium-137 considered was 130–1300 PBq (3.5–35 megacuries, MCi), 1.5–15 times the estimated release from Chernobyl.

improve safety culture, learn lessons from safety incidents, share best practices, and review safety-related aspects of the design and operation of individual plants. There were about 1500 GW_e-yrs of nuclear power before the Chernobyl accident, and about 8500 after than until the March 2011 Fukushima Daichi accident.[81] That accident raised concerns about the possible release of radioactivity from the spent fuel pools. The dangers of loss of water from spent fuel pools and possible remedial actions had been the subject of debate in the United States (Alvarez, 2003; US NAS, 2006b).

In 2002, at the Davis-Besse nuclear power plant (Ohio, United States), it was discovered that leaking boric acid had eaten almost through a reactor pressure vessel head before it was discovered, despite the presence of iron oxide in the air and dried boric acid deposits on the outside of the vessel. The incident was a potent reminder that nuclear safety requires constant vigilance (US GAO, 2004).

Major efforts will also be necessary to ensure that countries building nuclear power plants for the first time, or those rapidly expanding their reactor fleet, as in China and India, put effective safety measures in place. These measures include instilling a strong safety culture and granting independent regulators the power, resources, and expertise they need to do their jobs.

Given the steps that have been taken in recent decades to improve safety, the probability of a catastrophic release occurring purely by accident may be lower than the probability of such a release occurring as a result of malevolent action. Yet there is far less focused attention today to reactor security than to reactor safety. The possibility of terrorism puts an even greater premium on trying to design reactors that are more inherently safe than they were in the past.

In many cases, design for safety and design for security are complementary. Ensuring that redundant control systems cannot all be disabled by one fire or one explosive charge, for example, is important for both safety and security. Protecting against terrorism, however, also requires effective physical protection measures, designed to ensure that major nuclear facilities are adequately protected against attack by small groups on the ground or from the air.

14.7 Nuclear Weapon Proliferation

Nuclear weapon acquisition was the first priority of the United States and most other early national nuclear programs. Civilian nuclear energy programs contributed to some later nuclear weapon programs as a vehicle for acquisition of technology and building infrastructure and expertise for parallel nuclear weapon programs. Indeed, all of the countries outside the two former Cold War blocs[82] that have acquired nuclear power have done so in the context of nuclear weapon programs. Fortunately, most of these countries abandoned the weapon dimensions of their nuclear programs.[83]

Will it be possible to extend nuclear power to tens more countries without spreading the bomb along with it? This will depend on both technological and institutional choices.

14.7.1 The Nonproliferation Regime

Today, an extensive regime to limit the spread of nuclear weapons is in place, with the Treaty on the Non-Proliferation of Nuclear Weapons (NPT) as its cornerstone. Only three countries have not joined the NPT – India, Israel and Pakistan – and only North Korea has withdrawn. While this regime has been highly successful, it is now under substantial stress.

A wide range of proposals to strengthen the nonproliferation regime and reduce the potential proliferation impact of nuclear power have been put forward. International support for these measures will require the nuclear-weapon states – especially Russia and the United States – to live up to their end of the NPT bargain and drastically reduce the numbers, roles, and readiness of their nuclear weapons (see, e.g., WMD Commission, 2006; ICNND, 2009; Perkovich et al., 2005).

Under the NPT, all non-nuclear-weapon states commit not to acquire nuclear explosives and to accept IAEA inspections of all their nuclear activities to assure that they are peaceful. The traditional safeguards agreement negotiated to fulfill this NPT requirement focuses primarily on accountancy and containment and surveillance to provide "timely detection" of the diversion of "significant quantities" of uranium and plutonium (IAEA, 1972). The IAEA adopted the recommendation of its Standing Advisory Group on Safeguards Implementation (SAGSI) that a "significant quantity" of nuclear material – the amount required to make a first nuclear weapon, taking into account likely losses in processing – should be taken as 8 kg of plutonium or uranium-233, or 25 kg of uranium-235 contained in HEU (IAEA, 2001: 23). For practical reasons, however, the IAEA set its timeliness objective for detection of the diversion of a significant quantity of material at one month – longer than recommended by SAGSI.[84]

More fundamentally, at a large reprocessing plant such as Japan's Rokkasho, which is designed to separate 8 tonnes of plutonium (1000

81 This does not mean that there had not been worrisome incidents at many nuclear power plants (Kastchiev et al., 2007).

82 The regions included in the Cold War blocs were North America/Western Europe/Japan, and the former Soviet Union/Eastern Europe, and China. Countries with nuclear power programs outside these blocs include Argentina, Brazil, India, Pakistan, South Africa, South Korea, and Taiwan.

83 Including Argentina, Brazil, South Africa, South Korea, and Taiwan.

84 SAGSI estimated the times required to convert various types of nuclear material into nuclear-weapon components as one week for plutonium or HEU metal (IAEA, 2001: 22).

significant quantities) per year, measurement uncertainties make it impossible to verify that one significant quantity has not been diverted – especially in the case of small diversions occurring over an extended period. Critics therefore argue that safeguards at large bulk-processing facilities are ineffective (Sokolski, 2008). IAEA experts respond by arguing that a wide range of containment and surveillance measures implemented throughout the plants provide substantial (though unquantifiable) additional confidence that no material has been diverted.

The IAEA inspections in Iraq after the 1991 Persian Gulf War dramatically demonstrated that the focus of IAEA safeguards at the time were too narrow. Iraq had mounted a program to produce highly enriched uranium for nuclear weapons, largely at undeclared facilities that were therefore not under safeguards. In response to this wakeup call, member states of the IAEA agreed to take a series of steps to extend the reach of safeguards. Some of these required the negotiation of an "Additional Protocol" to complement the traditional safeguards agreement.

The Additional Protocol (IAEA, 1998) requires states to provide the IAEA with more information and access to a broader range of sites, in particular relevant facilities with technology and equipment that could contribute significantly to a capacity to produce plutonium or HEU. The IAEA has been integrating this information with open-source data (including commercial satellite photographs) intelligence provided by member states, and information from its own inspection activities, into an overall picture of the nuclear activities of each state. This so-called "state-level approach" makes it possible for the Agency to raise questions and focus resources on questionable activities (Cooley, 2003).[85]

Export controls are another critical element of the nonproliferation regime. The NPT requires that states only export nuclear materials or technologies for producing them to non-weapon states if they will be under safeguards. The Zangger Committee was established under the NPT to define what specific items should be controlled to fulfill this requirement. After India's nuclear detonation in 1974, the major suppliers established a separate NSG under which each participant makes a political commitment to follow much more restrictive export guidelines.

There is an ongoing struggle, however, between those states that are attempting to slow the spread of sensitive technologies and those trying to acquire them. After the 1991 Persian Gulf War, it was discovered that Iraq had succeeded in illicitly importing a wide range of controlled items for its nuclear weapons program from companies in many countries (Fitzpatrick, 2007). This provoked many countries to strengthen their nuclear export control systems. In 1992, the NSG supplemented its rules with restrictions on exports of "dual-use technologies" and called for states to adopt "catch-all" provisions covering any technology that an exporter suspected was going to an entity involved in proliferation activities.

Nevertheless, in 2003, it was revealed that a global black-market nuclear technology network led by Pakistan's A. Q. Khan had been marketing centrifuge technology and even nuclear-weapon designs, and had been operating in some 20 countries for more than 20 years. These revelations made it clear that far more needs to be done to control the spread of the most sensitive nuclear technologies (Fitzpatrick, 2007).

14.7.2 Controlling Enrichment and Reprocessing Technologies

The most important potential proliferation impact of the civilian nuclear energy system is through the spread of what the 1946 Acheson–Lilienthal Report called the "dangerous" nuclear technologies for uranium enrichment and the chemical "reprocessing" of spent fuel to recover plutonium (Acheson–Lilienthal, 1946). Concern about the spread of these technologies declined during the late 1950s and 1960s, when the United States and former Soviet Union promoted competitive "Atoms for Peace" programs. But India's use of US-supplied reprocessing technology to separate plutonium for its 1974 "peaceful" nuclear explosion convinced the US government to stop promoting reprocessing both at home and abroad, and to organize the Nuclear Suppliers Group as a forum in which it could be agreed that sales of reprocessing and enrichment technology would no longer be used as "sweeteners" in the international competition for sales of nuclear power plants.

Today, there is a similarly catalytic international crisis over Iran's insistence on its "inalienable right," under Article IV.1 of the NPT, to build a national uranium-enrichment plant.[86] The nominal purpose of the plant is to produce LEU for Iran's future nuclear power plants, although Iran has acknowledged that its centrifuge program began in 1985, a time when it had no plans for nuclear power plants and was locked in a war with Iraq, which was using chemical weapons and was suspected of seeking nuclear weapons. The plant could potentially be converted to the production of HEU for nuclear weapons or provide a civilian cover for a parallel clandestine enrichment program.

85 An inadvertent testimonial to the effectiveness of these new approaches was provided by Hassan Rohani, then Iran's nuclear negotiator and secretary of Iran's Security Council, in a speech to the Supreme Council of the Cultural Revolution in 2005. Rohani complained that, as a result of the IAEA finding a dissertation and a journal article that mentioned certain covert nuclear activities, "the IAEA was fully informed about most of the cases we thought were unknown to them" (Rohani, 2005).

86 Article IV.1 of the NPT reads: "Nothing in this Treaty shall be interpreted as affecting the inalienable right of all the Parties to the Treaty to develop, research, production and use of nuclear energy for peaceful purposes without discrimination and in conformity with articles I and II of this Treaty." The debate over Iran's program has concerned whether its intentions are peaceful. The IAEA has found that Iran repeatedly failed to comply with its safeguards obligations and the UN Security Council has legally obligated Iran to suspend all its enrichment activities and make its nuclear program fully transparent to the IAEA. However, Iran has refused to comply.

The Acheson–Lilienthal report proposed that enrichment and reprocessing be allowed only at plants owned by an international "Atomic Development Authority." Attenuated versions of this idea were discussed during the 1970s and early 1980s, including the idea of multinationally controlled reactor parks in which spent fuel could be reprocessed and the recovered plutonium recycled into on-site reactors (see, for example, Chayes and Lewis, 1977; SIPRI, 1980). In 2003, former IAEA Director-General Mohammed ElBaradei proposed another look at multinational control (ElBaradei, 2003) and subsequently initiated a high-level study of multilateral approaches to the fuel cycle (IAEA, 2005b).

In 2004, President G.W. Bush proposed that reprocessing and enrichment plants not be built outside of countries already operating full-scale plants, i.e., the nuclear-weapon states, Western Europe and Japan. A number of leading non-weapon states firmly rejected such a two-class solution,[87] however, and the Bush Administration proposed to include states with pilot-scale facilities.[88] Currently, efforts are underway to give countries such as Iran greater confidence in foreign sources of enrichment services as an alternative to building their own enrichment plants. This includes an IAEA-controlled bank of LEU as a last resort.[89] Over the longer term, ElBaradei has argued, "the ultimate goal … should be to bring the entire fuel cycle, including waste disposal, under multinational control, so that no one country has the exclusive capability to produce the material for nuclear weapons" (ElBaradei, 2008).

Enrichment. The fundamental issue with enrichment is that the same technology that can be used to produce LEU for civilian fuel can produce material for nuclear weapons. Indeed, most of the enrichment work required to produce 90% enriched HEU for weapons has already been done in enriching material to 4% for reactor fuel.[90] Gas-centrifuge cascades, now the dominant technology for producing LEU, can be used or relatively quickly reconfigured to produce weapon-grade uranium (Glaser, 2008).

With regard to the spread of enrichment technology, there are two contradictory trends:

- URENCO, an international enrichment group, is expanding its enrichment plants in Germany, the Netherlands, and the UK, and is building large new enrichment plants in France and the United States while Russia is doing the same in China.
- Small national enrichment plants are being built in Brazil and Iran and are being proposed in Argentina and South Africa (Nuclear Fuel, August 25, 2008).

Japan is an intermediate case. It has for a long time had a medium-sized enrichment plant that has not been economically competitive and whose centrifuges have mostly failed, but plans to rebuild its enrichment capacity on the same scale (JNFL, 2007).

The small national enrichment plants in Brazil and Iran have different histories. Brazil's program grew out of its navy's ambition to build nuclear-powered submarines. The primary public rationale for Iran's enrichment plant has been to provide it with fuel security for its nuclear power plants.

Iran currently has only one nuclear power plant, whose fuel is being supplied by Russia. Iran has announced, however, an ambitious program for bringing 20 GW_e of nuclear capacity online by 2025 (NEA, 2008c). Given its bad relationship with the United States, and its earlier history of being refused enrichment services by the European Gaseous Diffusion Uranium Enrichment Consortium (EURODIF),[91] Iran states that it is unwilling to depend upon other countries for enrichment services. Its limited resources of natural uranium, however, would require its proposed large nuclear program to depend upon imported uranium.[92] It would therefore have to stockpile imported natural uranium to protect itself against uranium supply disruptions. If so, why not stockpile imported LEU to protect itself from disruptions of uranium enrichment services as well (von Hippel, 2008b)?

Argentina's interest in enrichment goes back to the military nuclear program that it abandoned in tandem with Brazil in 1990. South Africa's interest in enrichment similarly goes back to its nuclear-weapon program, which it ended in 1991. Canada's largest uranium company, Cameco, was interested in adding value to its exports by acquiring

87 Including Argentina, Brazil, Canada, and South Africa.

88 Including Argentina and Brazil, according to a statement by Richard Stratford, Director of the US Department of State's Office of Nuclear Energy Affairs at the Carnegie Endowment International Nonproliferation Conference in June 2004.

89 American billionaire Warren Buffett offered US$50 million through the US-based Nuclear Threat Initiative toward establishing an IAEA fuel bank, and the US government, European Union, United Arab Emirates, and Norway have pledged contributions. The United States and Russia are also establishing supplementary reserves of LEU on their territories (in the US case, to be produced by blending down excess HEU), upon which countries in good standing with regard to their nonproliferation commitments will be able to draw (US NAS-RAS, 2008).

90 One way to understand this is to note that, by the time 4% enrichment has been achieved, the uranium-235 has been separated from over 80% of the uranium-238 in natural uranium. A separative work unit (SWU or, more precisely, a kg-SWU) is a measure of the amount of work done in isotope separation. To extract 1 kg of uranium-235 from natural uranium, which contains about 0.7% uranium-235, and concentrate it to 90% enriched "weapon-grade" uranium, leaving 0.3% uranium-235 in the depleted uranium, would require about 200 SWUs. About two-thirds of that separative work would be required to concentrate the same quantity of uranium-235 to 4.5% enrichment.

91 Iran still owns 10% of EURODIF via a 40% interest in Sofidif (Société franco–iranienne pour l'enrichissement de l'uranium par diffusion gazeuse), which holds 25% of EURODIF SA. The company has not paid out dividends to Iran since various restrictions were imposed on Iran following its non-compliance with the UN Security Council order of 31 July 2006.

92 Iran also does not currently have the technology to fabricate fuel for light-water reactors.

an enrichment plant. In 2008, however, after URENCO refused to sell it a gas-centrifuge enrichment plant, Cameco bought a 24% share of a laser-enrichment company whose plant is to be built in the United States (GE-Hitachi, 2008).[93]

Multilateral arrangements. As noted above, the controversy over Iran's uranium enrichment program has revived the idea of non-national – this time multinational – ownership of fuel-cycle facilities. In 2004, IAEA Director-General ElBaradei created an expert group to study the multinational option. In its report, the expert group noted that four multinationally owned enrichment plants already exist – the EURODIF plant in France and the three URENCO plants in Germany, the Netherlands, and the United Kingdom (IAEA, 2005b).

In the case of EURODIF, France built and operated a large gas-diffusion enrichment plant in which other countries (Italy, Spain, Belgium, and Iran) invested, in exchange for rights to a share of the enrichment work. Iran loaned the consortium US$1 billion for the construction of the plant and prepaid US$0.18 billion for future enrichment services. After Iran's 1979 revolution, it temporarily lost interest in nuclear power and requested its money back. After a protracted process, it did get back its US$1 billion plus interest in 1991. When it requested delivery of the enrichment services for which it also had paid, however, France's position was that the contract had expired. Iran views this refusal as proof of the unreliability of outside nuclear supplies and uses the EURODIF episode to argue that it requires its own enrichment plant (Meier, 2006).

Recently, Russia, in an arrangement very similar to EURODIF, created an International Uranium Enrichment Center (IUEC) at Angarsk as a commercial open joint stock company. The IUEC will buy enrichment services from the Angarsk enrichment plant and, perhaps in the future, a share in the plant itself. Holders of IUEC stock will have a guaranteed supply of enriched uranium and/or a share in the profits. Russia will continue to manage the enrichment plant and have sole access to its technology.

Thus far, Kazakhstan has committed to buy 10% of the IUEC (*Nuclear Fuel*, September 24, 2007).[94] Ukraine (*Nuclear Fuel*, November 30, 2009) and Armenia (*Nuclear Fuel*, April 20, 2009) also are expected to become partners. Russia offered Iran a share as an alternative to Iran building its own enrichment plant, but the offer was declined.

This arrangement has been at least partially successful as a nonproliferation initiative, however, in that it has apparently convinced the partner countries that they do not need to have their own national enrichment plants. But it appears that the operation of the plant will be no more transparent to the investors than to non-owner customers. In a non-weapon state such as Iran, therefore, this form of multinational ownership would not provide an additional level of nonproliferation assurance beyond that provided by IAEA inspections.

URENCO provides another model for multinational arrangements. Each of the original partner countries (Germany, the Netherlands, and the United Kingdom) had its own technology R&D team and enrichment plant. Obviously, the joint management and sharing of technology within URENCO provides greater transparency among the partners. In the past, however, the consortium has not maintained effective control of the technology. URENCO subcontractors were the source of the technology that A. Q. Khan used to build Pakistan's enrichment complex and to export centrifuge enrichment technology to Iran, Libya, North Korea, and perhaps other countries. Iraq similarly acquired centrifuge technology through German companies that were supplying URENCO with centrifuge components (Kehoe, 2002).

More recently, URENCO has expanded its business through a joint subsidiary, Enrichment Technology Company (ETC), to provide centrifuges and design services for enrichment plants in France and the United States. France's nuclear services provider, AREVA, has purchased a 50% share of ETC, but without access to the technology. The centrifuges are being built in ETC facilities in Germany and the Netherlands, and are assembled into cascades by ETC employees in France and the United States (ETC, 2008). Russia has similarly built enrichment plants in China (*Nuclear Fuel*, December 19, 2005). The centrifuges are described as "black boxes" as far as the host country is concerned, though regulators in the countries where these plants operate inevitably have to understand some aspects of the technology to be able to confirm its safety. Since France, the United States and China are all weapon states, however, URENCO and Russia have not yet faced the full challenge of protecting their technologies in a non-weapon state.

Canada's uranium company Cameco has been refused a black-box enrichment plant by URENCO and it appears that the United States will not allow export of a laser-enrichment plant to Canada because of doubts about the feasibility of operating this technology in black-box mode (*Nuclear Fuel*, August 25, 2008). URENCO has rejected a proposal to resolve the international crisis over Iran's enrichment program by putting it under multinational control and replacing Iran's centrifuges with black-boxed URENCO centrifuges (*Nuclear Fuel*, July 30, 2007). Such an arrangement would not likely be of interest to Iran either.

Former IAEA Director-General ElBaradei has proposed that all future enrichment and reprocessing facilities should be under some form of multinational or international control. The nonproliferation advantages and disadvantages of such approaches have been discussed (US NAS-RAS, 2008; Thomson and Forden, 2006). If a plant were owned by several countries, or by an international institution, with the plant location

93 The three largest suppliers of uranium are Kazakhstan, Canada, and Australia. Kazakhstan has become a partner in Russia's Angarsk enrichment facility. Australia has supported enrichment R&D but is not currently actively pursuing the idea of building its own enrichment plant.

94 In a separate arrangement, Kazakhstan and Russia have agreed to make equal investments in a new 5-million SWU enrichment plant adjoining the existing Angarsk facility (*Nuclear Fuel*, 28 July 2008b).

designated as extra-territorial – as are embassies and the laboratory of the European Organization for Nuclear Research (CERN) in Switzerland – this would pose a somewhat higher political barrier to the host state seizing the plant to use it for weapons purposes, as this would require expropriating the property of other states or a multinational organization. If the full-time operating staff of such a plant included multinational personnel, this would provide greater transparency into plant operations than IAEA inspections do, and relationships among the foreign and host-state personnel might provide greater insight into whether some of the host state experts were disappearing to work on a covert facility. On the other hand, any multinational approach would have to pay extremely careful attention to technology protection. Access to sensitive technologies should be limited to staff from countries that already possess such technology, with appropriate clearance and screening.

Reprocessing plants. With regard to reprocessing, the simplest alternative would be to forgo the practice. As practiced today, reprocessing and plutonium recycling are not economic and do not significantly simplify spent-fuel disposal (von Hippel, 2007, 2008a; Schneider and Marignac, 2008; Forwood, 2008). Reprocessing costs about ten times as much as interim storage of spent fuel in dry casks, and recycling plutonium in LWRs once, as is the current practice, does not significantly reduce its long-term radiological hazard. Most countries are abandoning reprocessing (see Table 14.5).

An exception is Japan, where it is politically unacceptable to allow spent fuel to accumulate at nuclear power plants and prefectures have been reluctant to host centralized spent-fuel storage facilities.[95] A reprocessing plant, with large tax payments to the local town and prefecture, turned out to be more attractive and is being used to provide a centralized interim destination for Japan's spent fuel and also for high-level waste being returned from the reprocessing of Japanese spent fuel in France and the United Kingdom (Katsuta and Suzuki, 2006). Japan's nuclear establishment also argues that eventually, if fast-neutron plutonium breeder reactors are introduced, plutonium recycling could make Japan independent of uranium imports.

Japan's reprocessing plant, when operating at its design capacity of 800 tonne/yr of spent fuel, will separate about 8000 kg/yr of plutonium. The first-generation Nagasaki bomb contained 6 kg of weapon-grade plutonium metal (almost pure plutonium-239), which would be roughly equivalent, in terms of critical masses, to 8 kg of power reactor-grade plutonium (Kang and von Hippel, 2005, Table 1).

A shift to more "proliferation-resistant" reprocessing technologies was proposed by the G.W. Bush Administration in 2003 (US DOE, 2003). An evaluation of the added proliferation resistance of the proposed technologies found, however, that it was not significant (see, e.g., Collins, 2005; Hill, 2005; Kang and von Hippel, 2005). Ultimately, the Administration proposed to deploy a reprocessing plant very little different from those in France and Japan. It insisted that pure plutonium would not be separated, i.e., that it would be mixed with uranium. Since it is not difficult to separate plutonium from uranium, however, this would be of only modest significance.

14.7.3 Risk of Nuclear-explosive Terrorism

In addition to the problem of proliferation of nuclear weapons to more nations, there is also the risk that terrorists could acquire and detonate a nuclear explosive (Bunn, 2010). Repeated studies by the US and other governments have concluded that, if a well-organized and well financed terrorist group acquired plutonium or HEU, it might well be able to make at least a crude nuclear explosive. Attempts by groups such as al-Qaeda and the Japanese cult Aum Shinrikyo to acquire nuclear weapons or the materials needed to make them, and to recruit nuclear experts, have demonstrated that the danger is more than theoretical. A number of cases of theft and smuggling of at least small quantities of plutonium and HEU have already occurred (Zaitseva, 2007).

Neither HEU nor separated plutonium are present when current-generation nuclear power plants operate on a once-through fuel cycle. The fresh fuel is made from LEU, which cannot support an explosive nuclear chain reaction without further enrichment – a challenge that is beyond plausible terrorist capabilities in the near term – and it would be very difficult for terrorists to steal the intensely radioactive spent-fuel assemblies and separate out plutonium for use in a nuclear weapon. For decades, however, there have been concerns that fuel cycles involving plutonium separation and recycling might significantly increase the risk of nuclear theft and terrorism (Willrich and Taylor, 1974; Mark et al., 1987).

Weapon-usability of power-reactor plutonium. The Acheson–Lilienthal report contained a misunderstanding concerning the weapon-usability of power-reactor plutonium. It stated that both "U-235 and plutonium can be de-natured" for weapon use (Acheson–Lilienthal, 1946: 30). That is correct for uranium-235. When diluted with uranium-238 to less than 6% concentration, uranium-235 cannot sustain an explosive chain reaction. Indeed, when the percentage is less than 20%, the fast critical mass is considered too large for fabrication of a practical nuclear weapon (IAEA, 2001, Table II). This is the basis for the belief that LEU, defined as containing less than 20% uranium-235, is not directly weapon-usable.

The authors of the Acheson–Lilienthal report apparently believed that the isotope plutonium-240 could be used to denature plutonium for weapons. Plutonium-240 fissions spontaneously and therefore generates neutrons continually at a low rate. In the Nagasaki weapon implosion design, these neutrons could start the fission chain reaction before the optimal time for maximum yield. In the Manhattan Project, great efforts therefore were

95 At the end of 2008, however, Chubu Electric Power Company proposed to build a dry-cask storage facility with a capacity of 700 tonnes of spent fuel, in connection with a proposal to build a new 1.4 GWe reactor to replace two old reactors with a comparable generating capacity (CNIC, 2009).

made to keep the percentage of plutonium-240 below a few percent. LWR plutonium contains about 25% plutonium-240 (NEA, 1989, Table 9). In the Nagasaki design, this could have reduced the yield from 20,000 tonnes of chemical explosive equivalent to as low as 1000 tonnes (Oppenheimer, 1945; Mark, 1993). Such an explosion would still be devastating, however. The radius of total destruction, which was 1.6 km at Hiroshima, would still be 0.7 km for a one-kilotonne (1 kt) explosion.[96] For more advanced designs, such as those in the arsenals of the NPT weapon states, there might be no significant reduction in yield (US DOE, 1997: 38–39).

Today, therefore, any mix of plutonium isotopes containing less than 80% plutonium-238 is considered weapon usable (IAEA, 2001, Table II).[97] Since the amount of plutonium-238 in the world is only 1–3% as large as the total amount of plutonium (NEA, 1989: Table 9), it would be impractical to attempt to use it to denature a significant fraction of the world's plutonium.

14.8 Institutional Requirements[98]

Because of the safety, security, and proliferation risks it poses, the use of nuclear energy requires worldwide vigilance. Each nation operating nuclear facilities is responsible for their safety and security. But all states have an interest in making sure that other states fulfill these responsibilities, creating a need for international institutions. For nuclear power to grow enough to make a significant contribution to mitigating global climate change, stronger institutions at both the national and international levels will be required.

In the decades since the Chernobyl accident, many countries have strengthened their safety practices and regulations substantially, but there is clearly more to be done. The Fukushima accident has provoked a global discussion concerning what national and international institutions and approaches need to be changed. Even in the United States, which has some of the world's most stringent nuclear safety regulations and more reactor-years of operating experience than any other country, both internal and external critics continue to argue that the Nuclear Regulatory Commission too often subordinates enforcement to the industry's cost concerns (US NRC, 2002; UCS, 2007). Countries building nuclear power plants for the first time will need to build up adequate groups of trained personnel, put in place effective nuclear regulatory structures, and forge nuclear safety cultures (IAEA, 2007b; Acton and Bowen, 2008). Countries such as India and China, which are rapidly expanding their civilian nuclear infrastructures, will have to take care that the expansion does not outpace the growth of capabilities to provide expert personnel to build, operate and regulate these facilities.

The development of regulatory requirements for securing nuclear facilities against sabotage and the theft of fissile and radioactive material is at a much earlier stage. Some countries still have no regulations specifying what insider and outsider threats should be defended against, and some do not require armed guards even to protect weapon-usable nuclear material from theft. Substantial steps are needed worldwide to reduce vulnerability (Bunn, 2010).

National institutions also play a critical role in nonproliferation. Foreign ministries, export controls and intelligence agencies all have key roles. And IAEA safeguards cannot function without each state having an effective state system of accounting and control.

14.8.1 International Institutions

International institutions promoting safety, security, and nonproliferation include not only the IAEA but also industry organizations such as the World Association of Nuclear Operators (WANO), the Western European Nuclear Regulators Association and professional associations such as the Institute for Nuclear Materials Management.

Safety. The IAEA's International Nuclear Safety Group (INSAG) has produced a diagram (Figure 14.18) showing the international organizations, networks, and activities to promote nuclear power plant safety that have grown up in the two decades since the Chernobyl accident.[99] Ultimately,

Figure 14.18 | The global nuclear safety regime. Source: IAEA-INSAG, 2006, Fig. 1.

96 The radius of blast destruction is proportional to the one-third power of the yield (Glasstone and Dolan, 1977, equation 3.61.1).

97 Plutonium-238 is relatively short-lived (88-year half-life) and generates a great deal of decay heat (0.56 kW_t/kg). It therefore would be difficult to fabricate into a nuclear explosive. It has been exempted from safeguards because it is used as a heat source for applications such as space probes to the outer planets, but the exemption has been drawn as narrowly as possible.

98 Professor Matthew Bunn, Kennedy School of Government, Harvard University, USA, Lead Author.

however, decisions on nuclear safety measures are still left to each state. The Convention on Nuclear Safety, for example, does not set specific safety standards and reporting on safety problems is entirely voluntary.[100]

The IAEA plays a critical role by publishing standards, guides and recommendations, and organizing discussions of critical issues and best practices. It manages an incident reporting system with the OECD Nuclear Energy Agency that collects and assesses information on operating experience and safety-related incidents. It also organizes in-depth, three-week safety reviews of facilities by an international team of safety experts. In those cases where a follow-up mission has been performed, the IAEA has found that sites either have implemented or are implementing some 95% of the teams' recommendations (IAEA, 2007d).

IAEA safety peer reviews occur, however, only when a member state asks to be reviewed, and only a minority of the world's power reactors have ever undergone such a review.[101] In 2008, a "Commission of Eminent Persons" appointed by Director-General ElBaradei recommended that states "enter into binding agreements to adhere to effective global safety standards and to be subject to international nuclear safety peer reviews" (IAEA-CEP, 2008).

WANO, an industry group established after the Chernobyl accident, is another key international nuclear safety institution.[102] WANO is divided into four regional groups with headquarters in Atlanta, Moscow, Tokyo, and Paris. A reactor's affiliations with one or more of these headquarters is determined by a combination of its location and reactor type. All operators of nuclear power reactors worldwide are participants in WANO and accept international peer reviews as a condition of membership. WANO also manages a system for reporting incidents and operating experiences, and helps organize exchanges of best practices. The reactor vendors also play a key role helping countries to put effective regulations and operating practices into place. Also both the G8 countries and the European Union have pursued extensive nuclear safety assistance programs, especially in former Soviet-bloc countries. Finally, there are also several international groupings of nuclear regulators (IAEA, 2007d).

Despite all of these efforts, INSAG has reported important weaknesses in international information sharing and actions. For example, the fact that WANO maintains confidentiality can delay national regulators becoming aware of the incidents being reported (IAEA-INSAG 2006) and some types of incidents continue to recur. In 2006, Luc Mampaey, then WANO managing director, complained that some utilities were not reporting at all (*Nucleonics Week*, September 27, 2007).

Security. Most countries shroud their security practices in secrecy, and international institutions for promoting nuclear security are therefore substantially weaker than those for nuclear safety. The Conventions on the Physical Protection of Nuclear Material and Facilities, and on the Suppression of Acts of Nuclear Terrorism do not set specific standards for how secure nuclear materials or facilities should be, and include no mechanisms for verifying that states are complying with their commitments. The IAEA has published physical protection recommendations, but they too are vague. They call for having a fence with intrusion detectors around significant stocks of plutonium or HEU, for example, but say nothing about standards of effectiveness.

UN Security Council Resolution 1540 legally obligates all UN member states to provide "appropriate effective" security and accounting for any nuclear weapons or related materials they may have. A common interpretation of what key elements are required for a nuclear security and accounting system to be considered "appropriate" and "effective" therefore could provide the basis for a legally binding global nuclear security standard (Bunn, 2008).

Since the mid-1990s, bilateral and multilateral assistance programs have played a critical role in improving nuclear security. The United States in particular has invested billions of dollars in programs designed to help former Soviet-bloc countries install and operate improved security and accounting systems at sites with significant quantities of plutonium and HEU. It has also mounted a global program outside Russia to convert research reactors to use LEU rather than HEU (Bunn, 2010). Less attention has been devoted, however, to protecting nuclear power plants, fuel cycle facilities and nuclear shipments against terrorist actions. In 2008, the World Institute of Nuclear Security (WINS) was established, modeled in part on WANO. It is designed to provide a confidential forum for nuclear security managers around the world to exchange best practices and discuss issues they have confronted in the hope of improving nuclear security practices worldwide (Howsley, 2008).[103]

In April 2010, leaders from 47 countries gathered in Washington D.C. for the first nuclear security summit and endorsed the objective of securing all vulnerable nuclear material worldwide within four years. They agreed on a broad communique and modestly more specific work plan, and some countries made important national commitments, such as Ukraine's commitment to eliminate all the HEU on its soil by 2012. A second nuclear security summit was scheduled in Seoul for March 2012. This summit process has elevated nuclear security to the top levels of government.

99 For a useful overview of international activities related to nuclear safety, see IAEA (2007d).

100 For a critique and a suggestion of a more robust approach, see (Barkenbus and Forsberg, 1995).

101 The first-ever IAEA Operation Safety Review Team review in Russia was held in 2005 at the Volgodonsk plant. The plant prepared for months and received a very positive review (M. Lipar, Head, Operational Safety Section, IAEA, personal communication, April 2008).

102 The US Institute of Nuclear Power Operations was formed to play a similar function at the national level after the 1979 Three Mile Island accident near Harrisburg, Pennsylvania.

103 WINS' first director is Roger Howsley, previously head of security, safeguards and international affairs at British Nuclear Fuel Services Limited: www.wins.org.

Nonproliferation. The 1968 NPT is the foundation for all international efforts to stem the spread of nuclear weapons and has been highly successful. The nonproliferation regime is now under stress, however. Iran's refusal to comply with the UN Security Council's demand that it suspend its enrichment program, combined with North Korea having become the first state ever to withdraw from the NPT and manufacture nuclear weapons, have raised concerns about the ability of the international community to enforce compliance. In addition, the treaty's legitimacy has been undercut by the perception that the NPT nuclear-weapon states have not lived up to their obligation under Article VI of the NPT "to pursue negotiations in good faith on … nuclear disarmament."[104] Many non-weapon states also see efforts by the United States and some other states to prevent the spread of national enrichment and reprocessing plants as undermining the treaty's Article IV guarantee of the "inalienable right of all the Parties to the Treaty to develop, research, production and use of nuclear energy for peaceful purposes and without discrimination…"

Of the institutions established to implement the nonproliferation regime, the IAEA is the most important. IAEA safeguards play a critical role in verifying the peaceful use of nuclear energy around the world. The IAEA faces important constraints in access to sites, information, resources and technology, however, as well as challenges in balancing its efforts to maintain essential positive relationships with states with an appropriate investigatory attitude.

The Additional Protocol to the NPT is a major advance with regard to access to sites and information, but many issues remain. First, more than a decade after its adoption, there are a number of non-weapon states with significant nuclear activities or ambitions that have not acceded to the Additional Protocol.[105] Also, despite its expansion beyond the traditional focus on nuclear materials, the Additional Protocol focuses primarily on the IAEA's rights to inspect sites with technologies related to the production of nuclear materials. As a result, when the IAEA wanted to investigate a site in Iran where implosion experiments related to nuclear-weapon design allegedly had taken place, there were no undisputed legal grounds for doing so.[106] Pierre Goldschmidt, former IAEA Deputy Director-General for safeguards, has suggested that the UN Security Council pass a resolution that would require any state found to be in violation of its safeguards agreements to provide access beyond that required by the Additional Protocol and to allow IAEA inspectors to interview, in private, key scientists and other participants in nuclear programs (Goldschmidt, 2008). The UN Security Council has, in fact, demanded that Iran provide such a level of transparency.[107]

With respect to resources, the IAEA's regular budget for implementing nuclear safeguards worldwide in 2007 is only US$100 million, or about 0.004¢/ kWh generated by the world's nuclear power plants (IAEA, 2010d). In the context of renewed hiring in the nuclear industry, the Agency also has increasing difficulty recruiting and even retaining nuclear experts. This is especially serious, given that, in 2008, roughly half of all senior IAEA inspectors and managers were within five years of the agency's mandatory retirement age (IAEA-CEP, 2008). The IAEA also does not have the resources to do its own R&D to develop new safeguards technologies. It depends on support programs from member states.[108]

The IAEA also plays a major promotional role by helping states acquire and apply nuclear technology for research, medical and agricultural purposes. Overall, by informal agreement among the member states, the IAEA budget for promoting and assisting with nuclear energy and other applications of nuclear technology is kept at about the same size as the budget for safeguards.[109]

Despite a call from former IAEA Director-General ElBaradei for negotiation of a universal nuclear export control regime, no progress has been made in that direction. The Nuclear Suppliers Group has tried to fill this space but faces ongoing challenges to its legitimacy because it is a self-selected group. Also, the decision to exempt India from the NSG requirement of membership in the NPT has strengthened the impression that economically powerful countries do not have to comply with the rules. The NSG has traditionally operated by consensus but, as more and more states have joined, consensus on strengthening its rules has become more and more difficult to achieve. Most NSG participants, for example, strongly support making the Additional Protocol a condition for nuclear exports from NSG states, but Brazil (which has not accepted the Protocol) has resisted.

104 The entire article, whose interpretation has been clarified by a legal opinion (International Court of Justice, 1996) and subsequent commitments by the weapon states at the 1995 and 2000 NPT Review Conferences (UN, NPT, 2000), reads as follows: "Each of the Parties to the Treaty undertakes to pursue negotiations in good faith on effective measures relating to cessation of the nuclear arms race at an early date and to nuclear disarmament, and on a Treaty on general and complete disarmament under strict and effective control."

105 Including Algeria, Argentina, Brazil, Egypt, Iran (signed but not ratified), Iraq (signed but not ratified), Mexico (signed but not ratified), Syria, United Arab Emirates (signed but not ratified), Venezuela and Vietnam (signed but not ratified) (IAEA, 2010c).

106 The IAEA asked Iran to voluntarily accept a visit to that site, which Iran eventually did.

107 In its Resolution 1803 of 3 March 2008, the UN Security Council ordered Iran to "take the steps required by the IAEA Board of Governors in its resolution GOV/2006/14, which are essential to build confidence in the exclusively peaceful purpose of its nuclear programme and to resolve outstanding questions." IAEA Board of Governors resolution GOV/2006/14 calls on Iran to "implement transparency measures, as requested by the Director General, including in GOV/2005/67, which extend beyond the formal requirements of the Safeguards Agreement and Additional Protocol, and include such access to individuals, documentation relating to procurement, dual use equipment, certain military-owned workshops and research and development as the Agency may request in support of its ongoing investigations."

108 In recent years, however, the IAEA has established an expanded effort to identify new technological approaches to address some of its key safeguards needs, and to work with member states to develop and deploy them (Khlebnikov et al., 2007).

109 In 2007, the total IAEA budget was US$268 million. Excluding central management and information services, it was US$199 million, of which US$103 million went to safeguards, US$71 million to nuclear energy and development and US$22 million to nuclear safety and security. An additional US$37 million of extra-budgetary funds were contributed by interested countries – mostly for the safeguards, safety and security programs (IAEA, 2008c).

14.9 Public Acceptance[110]

Historically, fission power has inspired more public opposition than any other energy source, except possibly hydropower in India and a few other countries. According to a survey of public opinion in 18 countries done for the IAEA in 2005, on average 62% of the respondents did not want existing nuclear power plants to be shut down, although almost the same percentage opposed building new ones (Figure 14.19). In Western Europe and the United States, a majority of the population has consistently opposed the construction of new nuclear reactors since the early 1980s (Rosa and Dunlap, 1994; Bolsen and Cook, 2008; EC, 2007). As memories of the accidents at Three Mile Island (1979) and Chernobyl (1986) faded and concerns about the consequences of global warming increased, however, the trend prior to the 11 March 2011 accident at Japan's Fukushima Daiichi nuclear power plant was toward more pro-nuclear public opinion, and government policies were moving even more rapidly in that direction. Public opposition also diminishes when new nuclear power plants are built at existing sites, as is often the case. In China, where many new sites are being established, public opposition was relatively limited, at least prior to the Fukushima Daiichi accident (WISE, 2007).

Individuals oppose nuclear power for different reasons. Some feel that the technology is too expensive, while others are concerned about the fact that nuclear energy technologies can be used to produce nuclear weapons. The main source of opposition, however, is the public concern

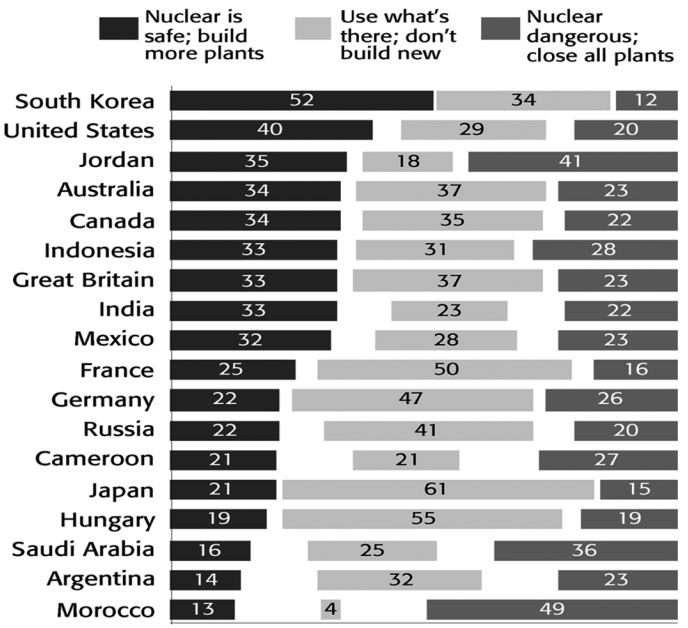

Figure 14.19 | Attitudes to nuclear power by country. The white spaces represent "don't know," "none of the above," "other" or "no answer." Source: Globscan, 2005.

about the production of radioactive waste and the potential for high-impact accidents.

This public perception of risk has been something of a puzzle to many technical experts, since they do not view the risk to the public from nuclear power plants as especially high.[111] Technical experts often assess risk probabilistically through injuries and deaths per GW_e-yr of nuclear energy generated. On this scale, nuclear power does not seem particularly dangerous.

Public perceptions are the result of various psychological, social, and cultural processes, however, that can heighten or attenuate risk signals (Kasperson et al., 1988). Typically, attenuation occurs with everyday hazards such as indoor radon, smoking, and driving. In the case of nuclear power, in contrast, the risks are often amplified. Indeed, some scholars studying public perceptions have argued that nuclear energy is "subject to severe stigmatization" (Gregory et al., 1995).

Faced with public antipathy, the nuclear industry and some governments have tried to persuade the public to see risk the way experts see it, such as through campaigns pointing out that the annual risk from living near a nuclear power plant is equivalent to the risk of riding an extra three miles in an automobile (Slovic, 1996). But such comparisons do not address the aspects of the risk that people believe to be important, and often produce more anger than enlightenment.

The assumption that public opposition results from ignorance may not be correct (US OTA, 1984). One analysis of the debate over the risks from the Diablo Canyon nuclear plant in California found that,

> "proponents and opponents were equally knowledgeable about nuclear power factual information, but those who supported nuclear energy expressed more trust in the credibility of information received from government and industry officials and were more trusting that the officials would protect the public" (Levi and Holder, 1988).

Indeed, many studies reveal a widespread belief that the institutions that manage nuclear power are untrustworthy as sources of information (Wynne, 1992). A 2001 survey by the European Commission found that only 12% of Europeans trusted the nuclear industry (EC, 2008). Both trust and distrust tend to reinforce and perpetuate themselves (Slovic, 1993). Today, however, concerns about nuclear power are confronted by another major concern: the consequences of global climate change. The nuclear industry, some independent scientists, and some governments are increasingly reframing the debate as one about whether public fears

110 Dr. M. V. Ramana, Princeton University, USA, lead author.

111 Enrico Fermi, who designed the first chain reacting "pile," apparently anticipated the public's concerns, however, well before the US nuclear power program was launched. He is reported to have commented (as paraphrased by Alvin Weinberg) that it "is not certain that the public will accept an energy source that produces vast amounts of radioactivity as well as fissile material that might be diverted by terrorists" (Weinberg, 1994).

about nuclear power have to be subordinated to the need to limit climate change. In a 2005 survey, this argument resulted in a 10% increase in public support for building new nuclear power plants (Globescan, 2005).

In the United Kingdom, the debate has been particularly intense because of the national commitment to reduce carbon dioxide emissions, the declining supplies of North Sea gas, and the retirement of the country's first-generation Magnox reactors. The government, the nuclear industry, major scientific leaders and professional societies have all been promoting a "new build" of nuclear capacity. One study used a survey and focus groups, to evaluate the impact on public attitudes of a reframing of the issue of nuclear power around the need to reduce carbon emissions, and found "reluctant acceptance" (Bickerstaff et al., 2008). The study found, however, that radioactive waste was regarded with even greater dread than climate change, and there was great mistrust of the competence of the nuclear power establishment and the government to manage nuclear power safely. The respondents were also concerned about the possibility of terrorist attacks on nuclear facilities. If it were feasible to make a more rapid shift to renewable sources of energy, that would attract greater support. In the United States, a national poll in 2008 found that 42% of the population supported an increased commitment to nuclear power, compared with 93% for solar, 90% for wind, 52% for natural gas, 33% for coal, and 22% for oil (Greenberg, 2009).

14.10 Policy Recommendations

Throughout its history, the debate on nuclear power has focused on two questions: is it necessary, and to what extent can the dangers that it poses be reduced?

The first question can only be answered in the larger context of an examination of the alternatives, the rates at which they can be deployed, and their costs, both economic and external. This is the subject of several chapters in this volume, especially Chapter 17 (Global and Regional Scenarios). If public attitudes are to be respected, however, nuclear power should be introduced or expanded in a country only after a comparative assessment, with public review and participation, of alternative means of matching energy supply and demand.

With regard to the second question, the greatest dangers that need to be minimized are Chernobyl-scale releases of radioactivity into the environment and the possibility that nuclear power facilitates the proliferation of nuclear weapons and nuclear terrorism. There are a number of initiatives that could help to reduce but not eliminate both of these risks.

14.10.1 Reducing the Risk of Catastrophic Releases of Radioactivity

The light-water reactors (LWRs) that dominate nuclear power today, and will continue to do so for the foreseeable future, were originally developed for naval propulsion. The primary design consideration was therefore that they be compact. When they were adapted for use as power reactors, that constraint was loosened and redundant emergency cooling systems and a containment building were added. These additions helped, but as the recent Fukushima Daiichi accident showed, a core meltdown accident with a large release of radioactivity to the human environment is still possible. Indeed, the successful containment of the 1979 Three Mile Island melt-down was to some extent a matter of luck. Some US containment buildings would not have been able to withstand the pressure increase from the hydrogen burn that occurred during the Three Mile Island accident, while others would be over-pressured by the carbon dioxide that would be released if a molten core began to eat its way through the concrete floor of the containment (Beyea and von Hippel, 1982).

The owners of LWRs have made significant improvements in operator training since the Three Mile Island accident and the "Generation III" LWRs that are being introduced today have significant improvements in safety design. The pressure to increase safety has not been so effective in the regulatory area, however. In 2002, after the US NRC acceded to the operator's insistent demands and allowed the Davis-Besse nuclear reactor to continue to operate in what was later established to be an extremely dangerous condition, the US NRC Inspector General commented that "NRC appears to have informally established an unreasonably high burden of requiring absolute proof of a safety problem, versus lack of reasonable assurance of maintaining public health and safety…" (US NRC, 2002).

And what of the alternatives to the conventional LWR that are currently being examined in the Generation IV (Gen IV) reactor R&D effort? Although safety is a desideratum, relative safety does not appear to be a criterion for selecting among the different types of reactors under consideration. Rather, safety studies are being pursued with the objective of making each existing design type as safe and licensable as practicable (Gen IV, 2008: 54). In any case, Gen IV industry representatives have repeatedly stated that, whatever the design type, commercial operation is still decades away.

An effort should therefore be mounted, with a higher priority than the Gen IV efforts, to design a reactor for safety, including associated spent-fuel storage, and then to see how the design could be optimized economically, rather than the other way around.

Given license extensions to 60 years and perhaps beyond,[112] many of the existing plants are likely to be operating for a very long time. In the aftermath of the Fukushima Daiichi accident, national regulations and international standards should be tightened, to ensure that nuclear facilities are prepared for the full spectrum of foreseeable earthquakes, floods, blackouts, and other disasters – and for terrorist attacks of the

112 In its 2009 projections for US nuclear capacity, the US Energy Information Administration assumed that the licenses of US nuclear power plants will be extended to 80 years (US EIA, 2009).

scale and sophistication of the September 2001 aircraft hijackings. Reactor operators should be required to protect against spent fuel burning if a spent fuel pool loses water and fuel that is sufficiently cool should be moved into safer dry casks. They also should be required to retrofit reactor containments with robust filtered vents that could greatly reduce the amount of radioactivity released in a severe accident (Beyea and von Hippel, 1982; Schlueter and Schmitz, 1990). Operators and nearby agencies such as police and fire departments must have effective emergency plans in place and regularly exercise them, so they all know what to do in the event of a crisis. The role and capabilities of the IAEA and WANO also should be significantly strengthened, including expanded and more transparent peer reviews.

14.10.2 Increasing Proliferation Resistance

There are three obvious steps by which the proliferation resistance of civilian nuclear energy could be increased:

1. phase out reprocessing as quickly as possible,

2. place enrichment plants under multinational ownership and management, and restrict them to politically stable regions, and

3. establish regional spent-fuel storage and repositories.

1. Phase out reprocessing as quickly as possible. In the fuel cycle of an LWR fueled with LEU, weapon-usable material becomes directly accessible only as a result of spent-fuel reprocessing, i.e., the separation of plutonium (possibly mixed with other transuranic elements) from the intensely gamma-emitting fission products that, 10 or more years after discharge, are dominated by cesium-137, with a half-life of 30 years. As discussed above, there is general agreement that, for the foreseeable future, fuel cycles involving reprocessing and plutonium recycling will not be economically competitive with "once-through" fuel cycles in which the spent fuel is stored. Proliferation resistance is therefore aligned with economics in this case, and there would only be economic benefits from phasing out reprocessing. In some countries, such as Japan and South Korea, political obstacles would have to be overcome to the extended interim storage of spent fuel on nuclear power plant sites or at a central site.

2. Place enrichment plants under multinational ownership and management and restrict them to politically stable regions. Multinational ownership and management, if well designed, could make it more difficult for a host government to convert an enrichment plant to the production of HEU for weapons or to divert expertise and components to the construction of a clandestine national enrichment plant. Multinational ownership does not necessarily mean ownership by multiple governments. It could include ownership by companies that are owned by or answerable to multiple governments. An arrangement intermediate between that of URENCO, which involves technology sharing, and that of EURODIF and Angarsk, in which non-host countries are passive investors, might be optimal. This could include multinational teams of operators in the enrichment plant control room. Indeed, the black-box model that has been adopted by URENCO in France and the United States, and by Russia in China, might be near the correct balance. In this arrangement, management of the plant can be shared, making operations, but not the technology, more transparent among the partners.

In order to make this approach politically feasible, it will probably be necessary to convert existing national facilities in the weapon states into multinational facilities. This could be done without significantly disrupting existing commercial arrangements, for example, if companies from other countries bought shares of ownership in existing facilities, and ultimately began participating in the staffing of those facilities. It will also be desirable to agree that new facilities not be built until a minimal level of contracted demand exists to make it economically viable (at least the equivalent of 10 GW_e of LWR capacity, corresponding to an enrichment capacity greater than 1 million SWU/yr).

It would be desirable that such facilities be built in politically stable regions. If, as in the case of Iran, neighboring countries feel that their security would be threatened by a proposed enrichment plant, that perception should be regarded as a major argument against the facility.

Finally, it would be important to have arrangements to reduce the danger that new enrichment plants will be used to justify the host countries mastering enrichment technology. Today, URENCO's ETC and Russia's Rosatom make the most cost-effective gas centrifuges.

3. Establish regional or international spent-fuel storage facilities and repositories. In the not too distant future, perhaps 50 countries, many with only a few nuclear power reactors, will be accumulating spent fuel. This may create the danger that countries will begin to "reprocess" their spent fuel as a "solution" to their spent-fuel problem as is being urged in South Korea today. Also, after about a century, the radiation field around spent fuel declines to a level where it is no longer considered self-protecting and "quick-and-dirty" reprocessing would become easier.

Interim spent-fuel storage facilities and geological repositories should be established in countries willing to host them for a price lower than the cost of reprocessing and national disposal of the associated reprocessing wastes. This puts quite a high ceiling on the price and, given the minimal risks involved from a well-designed spent-fuel storage facilities and repositories, could make hosting them economically attractive. The designs of the spent fuel storage facilities and repositories should be subject to international standards and oversight in order to ensure that the import of spent fuel does not create environmental hazards in countries with less well developed regulatory infrastructures. The repositories should also be designed to be retrievable for a period of a century or so in order to keep options open for alternative disposal strategies.

14.11 Fusion Power[113]

Nuclear fusion may be an alternative to a longer-term commitment to fission energy. In nuclear fusion, energy is produced by fusing together the nuclei of deuterium and tritium, the two heavy isotopes of hydrogen, to form helium and a neutron.[114] Effectively unlimited quantities of the primary fuels, deuterium and lithium (from which tritium is produced), are easily available. (The quantity of uranium is also effectively unlimited, when used in fast breeder reactors.) Due to the low fuel inventory and the high heat capacity of a fusion reactor, an explosive runaway reaction or a meltdown of a fusion energy system are not possible. Radioactive waste products from fusion decay with half-lives of decades. The proliferation risk from fusion is greatly reduced since the introduction of "fertile" materials from which fissile materials such as plutonium could be produced could be made easily detectable in a pure fusion system under safeguards. In a "breakout" scenario, fissile material would not become available until after significant operation of the fusion power plant, and could be prevented by international action.

Current fusion energy research is focused on the confinement of hot ionized gas, called a plasma, in a toroidal (doughnut-shaped) magnetic field. Substantial progress has been made in developing a quantitative understanding of the physical processes that determine the behavior of fusion plasmas. Laboratory experiments have now produced about 10 MW_t of heat from fusion for about one second. The international thermonuclear experimental reactor (ITER) project, under construction in France by a consortium that includes China, Europe, India, Japan, Russia, South Korea, and the United States, is expected to produce 300–500 MW_t of heat from fusion for hundreds of seconds. It is designed to be able to produce about 100 MW_t averaged over a period of weeks.

An alternative route to fusion power production is to heat a small pellet of fuel to high temperature so rapidly that it burns and produces significant fusion energy before it disassembles. The disassembly time is set by the mechanical inertia of the fuel, so this approach is called "inertial fusion energy." It is being pursued today predominantly for its value in providing understanding of the physics of nuclear weapons, but it presents an alternative approach to commercial fusion energy as well. The National Ignition Facility (NIF) has recently begun operation at the Lawrence Livermore National Laboratory in California.

ITER and NIF are fusion research facilities at the scale of fusion power plants. They are first-of-a-kind facilities, and have proven to be expensive, more so than originally planned. Critics of fusion tend to focus on specific technological issues such as the production of tritium fuel or the development of neutron-resistant materials (Moyer, 2010), for which solutions are under development (Hazeltine et al., 2010). There is an appropriate overall concern, however, that fusion power plants will be large and complex high-tech facilities, and as a result their economic practicality cannot be assured despite favorable projections (Maisonnier et al., 2005; Najmabadi et al., 2006). Very considerable R&D is required to move from scientific feasibility to technological feasibility to practical demonstration (FESAC, 2003; US BPO, 2009). In parallel with ITER, supporting research is planned in each of the national fusion R&D programs to facilitate progress toward higher power and continuous operation, and to qualify advanced materials and components to withstand the heat, particle and neutron fluxes from fusion plasmas. Some national programs anticipate demonstration fusion power plants in the 2035–2040 timeframe, with commercialization starting in mid-century.

While fusion will not provide a solution to reducing carbon emissions in the near term, energy needs will continue to grow in the second half of the 21st century, and carbon emissions will need to continue to decline. Fusion energy, if it is indeed developed by mid-century, could in principle obviate the need for reprocessing and fission breeder reactors, which carry with them significant safety and severe proliferation risks.

14.11.1 Resources

The current focus is on producing fusion energy from the two heavy isotopes of hydrogen, deuterium (D) and tritium (T).[115] Tritium is not available in significant quantities in nature, because it has a half-life of only 12.3 years. However the D–T reaction produces a neutron:

$$D + T \rightarrow {}^{4}He + n + 17.6\ MeV$$

This neutron, multiplied moderately through (n, 2n) reactions with beryllium or lead can be used to produce tritium through the reaction:

$$n + {}^{6}Li \rightarrow T + {}^{4}He + 4.8\ MeV$$

Thus the basic fuels for D–T fusion energy are deuterium and lithium-6. Deuterium is present in water at 154 atoms per million hydrogen atoms, and lithium-6 comprises about 7.5% of natural lithium. Other materials used in the construction of fusion systems are not considered to limit the expansion of fusion power.

113 Robert Goldston, Princeton University, USA, lead author.

114 The nucleus of deuterium contains a proton and a neutron and that of tritium a proton and two neutrons, as distinct from an ordinary hydrogen atom, whose nucleus contains no neutrons.

115 The power density achievable for a given plasma pressure is about 35 times higher for the D–T reaction than for any other potential fusion fuel system. This ratio is appropriate for comparison with the D–D reaction, assuming that all T and ^{3}He produced in the D–D reaction is subsequently burned as well.

Three gigawatt-years (GW-yr) of thermal energy from fusion, including the 4.8 MeV produced in generating the needed tritium, requires the burning of 90 kg of deuterium and 265 kg of lithium-6. Therefore, the natural resources required for a year's operation of a 1 GW_e fusion power plant would be the deuterium in 5000 tonnes of natural water and the lithium-6 in 4 tonnes of natural lithium. Deuterium is already being separated from water on an industrial scale to produce the moderator for heavy-water reactors. Assuming US_{2005}300–600/kg for heavy water (Miller, 2001; Ramana, 2007) and ignoring the relatively minor cost of recovering deuterium from heavy water by electrolysis, the cost would be US$3000/kg of deuterium or US$0.003/kWh of electric energy generated from fusion, assuming an efficiency of one-third in the conversion of thermal to electrical energy. At the year-2000 price of about US$20/kg ($US_{2005}$23/kg), world resources of lithium are estimated at more than 12 million tonnes (USGS, 2007; Fasel and Tran, 2005). This corresponds to a cost of about US$300/kg of lithium-6, which, at that price, would contribute only about 0.001¢/kWh to the price of fusion-generated electricity. Increasing lithium-6 enrichment to the levels proposed for fusion reactors (up to ~80%) would cost approximately US_{2005}3000/kg of lithium-6, or 0.01¢/kWh (Rhinehammer and Wittenberg, 1978).

Lithium reserves of 12 million tonnes would allow the full-power operation of 2000 1- GW_e power plants for 1500 years. It should be economically possible to extract an additional 200 billion tonnes of lithium from seawater for this purpose.[116] The reserves of deuterium in seawater are effectively unlimited.

14.11.2 Technologies

14.11.2.1 Magnetic confinement fusion

The primary approach to developing fusion energy is to use strong magnetic fields to confine a very hot, circa 100 million °C, ionized deuterium–tritium gas, or plasma. Ions and electrons spiral along magnetic fields and magnetic field lines can be contained within a closed volume, specifically, a torus. The hot plasma can therefore be suspended in a vacuum while it is at fusion temperature. The main toroidal magnetic field (i.e., going around the torus the long way) is provided by toroidal field (TF) coils (see Figure 14.20). Shielding these coils from the fusion neutrons are the first-wall components that face the hot plasma and lithium-bearing blankets in which the neutrons are absorbed and the tritium fuel is produced. Some of the heat energy from the plasma flows in the form of energetic ions, directed by magnetic field lines into localized "divertor" regions at the top and/or bottom of the vacuum chamber.

The overall D-shaped cross-section of the plasma is produced by the interplay between the magnetic field produced by a strong electrical current that flows within the plasma around the torus (in the tokamak configuration shown in Figure 14.20) and the magnetic fields produced by currents flowing in poloidal field coils. (These coils produce magnetic fields with no component in the toroidal direction; their fields face only the short way around the torus.) The toroidal current is initiated by a pulsed central solenoidal magnet that creates a toroidally directed electric field and is sustained by external means such as radio-frequency waves. D–T fuel is injected through ports in the form of frozen pellets. Coolant is supplied and tritium is removed through pipes connected to the blankets.

14.11.2.2 Inertial confinement fusion

An inertial fusion energy system would consist of four major components:

- A large laser, ion beam, or other means to provide megajoules (1 megajoule = 1 MW-s) of energy to a millimeter-sized target in about 10 ns, in order to compress and heat the fusion target to high temperature before it disassembles.
- A factory to produce precision cryogenic D–T targets at low cost, at a rate of 5–15 per second.
- A system to inject a new target accurately and rapidly into the target chamber 70–200 ms after each explosion.
- A target chamber capable of withstanding repetitive explosions (and being cleared rapidly thereafter), converting the fusion power to heat, and with a lithium blanket to capture the neutrons and produce replacement tritium.

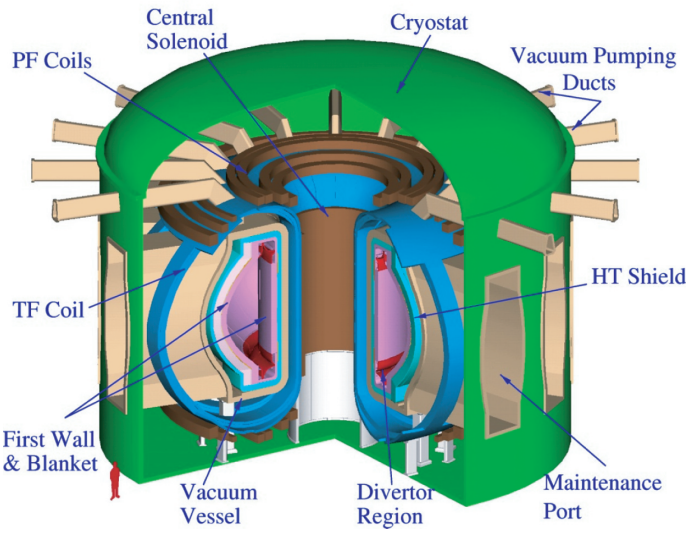

Figure 14.20 | Schematic of the ARIES Advanced Tokamak fusion power core. Source: Najmabadi et al., 2006.

116 Seawater contains 0.18 ppm lithium by weight; the concentration of uranium by weight is 56 times lower, while the requirement for power production in LWRs is 50 times higher.

14.11.3 Comparison of Fusion and Fission Power

14.11.3.1 Safety

A magnetic fusion reactor cannot undergo the equivalent of a prompt criticality accident, such as occurred at Chernobyl. The time constant for a thermal excursion is set at about 5 s by the ratio of the heat content of the fuel to the heating rate of the plasma by the 3.5 MeV helium nuclei from fusion. This time constant is much longer than the approximately10 ms characteristic time constant of a prompt-critical thermal neutron fission reactor. Were the plasma density and fusion rate to rise on this a 5-second scale, the limits to the pressure of the plasma, set by the underlying plasma physics, would rapidly extinguish the reaction. Most likely, before this occurred the increased heat flux to the plasma-facing components would erode their surfaces with a resulting influx of impurities into the plasma that would also quench the reaction. The most energetic physically possible excursion could damage internal components, but could not massively breach the vessel containing the fuel, as happened at Chernobyl.

Like fission reactors, fusion reactors could have loss-of-coolant or loss-of-coolant-flow accidents. Even after the fusion reaction stopped, the decay heat released by radioactive isotopes created by transmutation of the materials of internal components would continue to heat the reactor's structure. The structure of a fusion reactor is more massive than that of a fission reactor core, however, and with appropriate choice of reactor materials, the radioactive decay heat source would be reduced to the point where, even with no active cooling, the heat could be conducted and radiated away from the hottest components as fast as it was generated without a risk of breaching the vessel containing the fuel (Petti et al., 2006).

Fusion systems have significant radioactive inventories because of the large flux of energetic fusion neutrons through the reactor structure facing the plasma, which transmutes non-radioactive atoms into radioactive species. There is also a significant inventory of tritium within the vacuum vessel. While the physical mechanisms that could massively breach the vessel of a fission system do not exist in a fusion system, it is still important to determine the biological hazard potential of all components of the reactor, and to examine how much radioactivity in the structure could be mobilized and released into the atmosphere if the largest credible leak in the vessel were sustained. Figure 14.21 compares the amount of air that would be required to dilute the amount of tritium in a fusion reactor to permissible concentrations with that required to dilute the amount of radioactive iodine in a fission reactor.

In one study of a hypothetical reactor, designed with a silicon carbide structure to reduce the inventory of long-lived activation products, it was found that the hazard was dominated by tritium absorbed into the surface of the plasma chamber, activation products in the molten lead coolant, and activation products in structural tungsten.[117] If the full

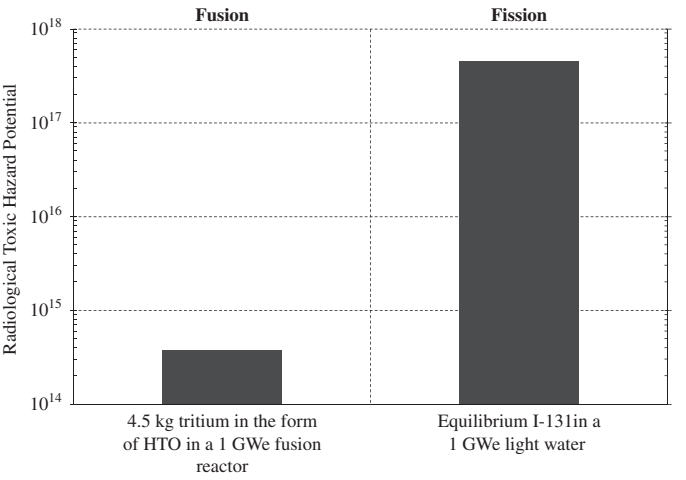

Figure 14.21 | Comparison of biological hazards from potential releases of tritium and iodine-131 from nuclear fusion and fission reactors, respectively, measured in terms of the volume of air required to reduce their concentrations to maximum allowed levels. Source: Kikuchi and Inoue, 2002.

"mobilizable inventory" were released during average weather conditions, doses of more than 1 sievert (Sv) could result at the site boundary 1 km away, and 10 Sv for worst-case meteorology. A dose of a few sieverts within a period of a few weeks could be lethal. Such a release would require a massive breach of the containment vessel, however, which the authors of the study found physically not credible. They found that, for the worst credible leak, the reactor structure and containment building would reduce the releases to a level where the site boundary dose would be below the 0.01 Sv threshold at which evacuation would be required (Petti et al., 2006).

In summary, nuclear fusion has the safety advantages over fission that the primary fission accident initiators of a prompt criticality event (Chernobyl) or meltdown (Three Mile Island, Fukushima-Daichi) are absent. Furthermore, the biological hazard potential of the mobilizable inventory is far below that of a fission reactor. The consequences of an accident are thus reduced to levels dramatically below those of worst-case fission accidents by the choices of structural materials and coolants. Calculations of reductions in releases due to the performance of the reactor containment and other measures below the level required for an evacuation plan would nonetheless likely be controversial and require rigorous regulatory review.

14.11.3.2 Proliferation

The proliferation risk from fusion energy systems is much smaller than that from fission systems because no chain-reacting fissile material

117 The most important neutron-activation products in lead are polonium-210 (138-day half-life) and mercury-203 (47 days). The most important activation products in tungsten are: rhenium-184 (38 days), rhenium-184m (165 days), rhenium-186 (4 days), and rhenium-188 (17 hours); and tungsten-181 (121 days), tungsten-185 (75 days), and tantalum-182 (114 days) and tungsten-187 (24 hours) (Petti et al., 2006).

or fertile material that could be converted to fissile materials by neutron absorption need to be present in a fusion power plant at any time (Glaser and Goldston, 2011b). Thus, while an inspection regime would be required, it would only need to detect the presence or absence of heavy fissile or fertile isotopes.[118] Fairly simple detection schemes could very sensitively detect small quantities of fertile materials or fission products in a fusion system whose neutrons are being used to breed fissile material.

One could be concerned about a "breakout" scenario for fusion, in which a nation expelled IAEA inspectors or unplugged remote monitoring devices and then reconfigured a fusion power system to breed fissile material. There is a very important qualitative difference between fission and pure fusion in the breakout scenario, however. In the fission case, such as occurred in North Korea, the reactor owner already has in hand spent and cooled fuel containing plutonium at the moment that the inspectors are expelled. There is nothing that can be done, short of military invasion, to prevent the separation of this plutonium for use in nuclear weapons. Bombing a fission reactor and its spent fuel storage facilities risks spreading radioactivity, or, if highly controlled, leaves the plutonium available to be mined from the rubble. Neither bombing nor invasion was considered practical in the case of North Korea, nor would they likely be considered practical in many other cases.[119]

By contrast, in the case of a fusion power plant, at the time of "breakout," no fissile material is yet in hand, so the challenge becomes the prevention of the operation of a reconfigured version of the power plant, capable of fissile material production. A fusion power plant could be rendered inoperable quickly and easily by a conventional cruise-missile strike on any of a number of support facilities: cryogenic systems, power conversion systems, or even cooling systems, without risk of a significant release of radioactivity.[120]

A fusion power plant consumes – and so must replace – about 130 kg of tritium per full-power year. Access to grams of tritium to "boost" the yield of nuclear weapons would be harder to prevent if many fusion power systems were in operation around the world. Tritium is not now controlled under the Non-Proliferation Treaty, whose focus is on preventing the diversion of fissile materials for use in weapons. Consideration should be given to strengthening international controls over tritium (Kalinowski and Colschen, 1995).

One might also be concerned that the science associated with inertial confinement fusion would be proliferated along with inertial fusion energy systems, and that key tests relevant to nuclear weapons could be undertaken on these facilities, as they will be at the NIF in California. Classified radiation-hydrodynamics codes are used to predict the performance of nuclear weapons. Their equivalents in the non-classified world could be calibrated against inertial fusion experiments, and could become widely available. A second concern is that if plutonium or other nuclear materials were used in the target of an inertial fusion R&D facility, critical information could be gained about relevant equations of state. The design of first-generation fission weapons, however, does not require experimentally validated advanced design codes, nor information on the equation of state of materials under such extreme conditions. In principle, these could help in the design of advanced weapons, but further review is required (Goldston and Glaser, 2011a).

Some researchers have considered "hybridizing" fusion and fission; these ideas have recently been reviewed and evaluated (Freidberg and Finck, 2010). In principle, the neutrons from fusion can be used for three purposes related to fission power:

- multiplying the 20-MeV energy output from each fusion reaction by using fusion neutrons to induce fission reactions (200 MeV each) in a sub-critical fission blanket surrounding the fusion system;
- breeding fuel for fission systems by transmuting uranium-238 or thorium-232 to plutonium-239 or uranium-233, respectively; and/or
- using the energetic neutrons from fusion to "burn" plutonium-239 and other transuranics recovered from the reprocessed spent fuel of fission power plants.

The advantages are that the fusion system could operate at lower gain and possibly lower neutron wall loading, and the fission system could operate sub-critically, reducing some of the accident potential compared with fast-neutron breeders. It also appears, however, that fusion-fission reactors would combine the majority of the scientific and technological development issues of the fusion systems with the majority of the proliferation risks of fission systems with reprocessing.

It should be noted that even if fusion comes into large-scale use after mid-century, plutonium and other transuranics will remain from LWRs and will constitute a potential proliferation risk. In case 3, where fusion-fission hybrids are used to burn transuranics, possibly more efficiently than "burner" fast reactors, one would have to balance the diversion

118 Uranium-238 and thorium-232 are both termed fertile isotopes because the addition of a neutron followed by radioactive decay produces artificial chain-reacting or fissile isotopes: plutonium-239 and uranium-233, respectively.

119 Attacks on reactors have happened. Iran and Israel both bombed Iraq's Osiraq reactor, in 1980 and 1981 respectively, while it was under construction, because they thought that Iraq would try to use it or its fuel to make nuclear weapons. Similarly, Iraq repeatedly bombed Iran's Bushehr reactor while it was under construction during the period 1984–88. The Unites States was on the verge of bombing North Korea's power reactor at Yongbyon in 1994 because it was being used to make plutonium, but was deterred in part because of concern about the international reaction to the first attack against an operating reactor and the associated radiation release.

120 See, for example, the layout of the ITER complex, www.iter.org/gallery/com_image_download.

risks from reprocessing this material multiple times as it is consumed, versus those of placing it in monitored underground repositories.

14.11.3.3 Radioactive waste

Fusion radioactive waste, unlike that from fission, does not originate from the burning of the fuel, but rather from neutron irradiation and consequent activation of the structural and blanket materials that face the reacting fuel. In typical designs, the first 20 cm or so of the chamber wall would need to be replaced approximately every four years. Neutron activation products can have half-lives of millennia, just like long-lived transuranic elements and fission products.[121] Power plant studies indicate, however, that structural materials can be selected that reduce the radiological hazard from the fusion reactor waste to as low as one-hundred thousandth that of fission-reactor waste (Fetter, 1987) or even one-millionth, as shown in a more recent Japanese study (Kikuchi and Inoue, 2002; see Figure 14.22). The concentration of the radioactivity would be low enough so that the material could be classified as Class C low-level radioactive waste and shallow burial (less than 30 m deep) would be permitted by US regulatory standards (Henderson et al., 2000; US Federal Code of Regulations, Part 61.7(5)).[122] It has also been proposed that the waste from fusion systems could be stored on site, and/or that a significant fraction could be recycled. Nevertheless, despite the potential for greatly reduced waste production, fusion power could still face significant public concerns about the disposal of its wastes.

14.11.3.4 Cost

At this point in the R&D process, it is difficult to project the costs of constructing and operating a fusion power plant. Based on simple consideration of the mass of the major technical components of a 1- GW_e fusion system relative to that of a fission system, and the complex materials required for some components, it appears unlikely that, without accounting for externalities, electricity produced by fusion systems would be less expensive than that from light-water reactors. Studies of magnetic fusion-power systems have been undertaken in the United States (Najmabadi et al., 2006) and in Europe (Maisonnier et al., 2005). Assuming success with the R&D issues discussed below, they conclude that the cost of electricity from a 1- GW_e magnetic fusion power plant would be in the range of US_{2005}\$0.05–0.13/kWh, for a tenth-of-a-kind power plant. The cost of electricity is estimated to be reduced by 20% for 1.5- GW_e plants, due to economies of scale. These estimates should, however, be treated with extreme caution, due to the distance of extrapolation.

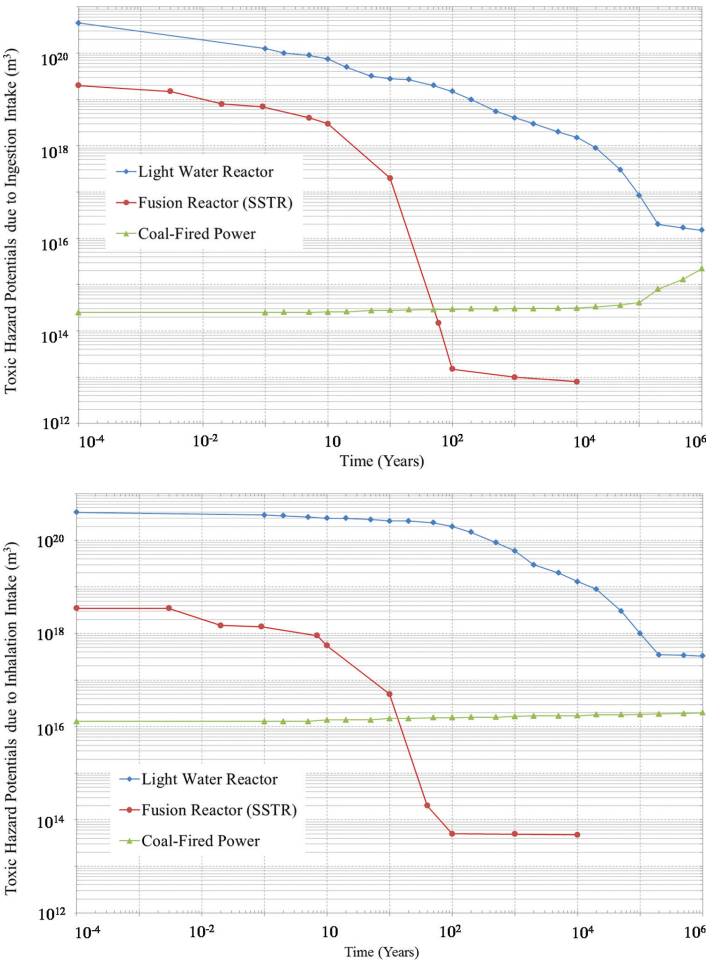

Figure 14.22 | Comparison of radioactivity hazard potential from lifetime operation of fission and fusion reactors. Based on the tritium inventory and the calculated lifetime production of radioactive transmutation products by the Japanese-designed Steady State Tokamak Reactor fusion reactor compared with that of the spent fuel discharged over the lifetime of a light-water reactor, and the uranium and decay products in the ash from a coal-fired power plant accumulated over its operating lifetime. Source: Kikuchi and Inoue, 2002.

Integrated cost projections have not been undertaken recently for inertial fusion energy, but the extrapolation distance to a cost estimate for inertial fusion energy is even greater with respect to the repetition rate of the driver beams, the lifetime required for high-power final optics for systems involving laser-driven pellet implosion, and the required cost reduction for target fabrication.

14.11.4 R&D Status

14.11.4.1 Magnetic confinement fusion

The basic concept behind magnetic fusion is that strong magnetic fields are used to contain a plasma, so that it can be heated to high temperature and can burn in a sustained manner. The two central scientific challenges are:

1. thermally insulating the plasma sufficiently well so that the fusion process itself can provide most of the needed plasma heating,

121 Important long-lived activation products in fusion-reactor studies are: carbon-14 (half-life: 5700 years), aluminum-26 (710,000 years), and three activation products of molybdenum, molybdenum-93 (3500 years), niobium-94 (24,000 years), and technicium-99 (213,000 years) (Henderson et al., 2000).

122 US Code of Federal Regulations, Part 61.55 gives the limits in Ci/m^3 for a small number of relevant nuclides for waste to qualify as Class C waste: carbon-14 (8); nickel-59 (220), and niobium-94 (0.2).

allowing a high power gain (energy output divided by energy input) to be sustained; and

2. containing a high enough pressure plasma that it can provide sufficient fusion power density to justify the cost of the magnetic "bottle."

Very substantial scientific progress has been made in addressing both of these challenges. The basic mechanisms that allow heat to escape across magnetic fields have been identified and modeled computationally.

While issues remain for scientific confirmation, the overall experimental picture is consistent with the presence of fine-scale turbulence driven largely by the gradient in the temperature between the center of the hot plasma and its cooler edge. This results in an overall energy confinement time (energy stored in the plasma divided by power required to heat it) that scales consistently across the many experimental devices that have been operated around the world (Figure 14.23). Scaling from these experiments gives a projection that the international ITER project will have a gain of 10, meaning that 10 times more fusion power will be produced than the heat input from microwaves or other inputs from outside of the plasma required to sustain it at fusion temperature. Since 20% of the heat from fusion stays within the plasma in the form of energetic helium nuclei, this means that two-thirds of the power heating the plasma will come from the fusion reactions themselves. Demonstrating this self-sustaining plasma heating is the primary scientific goal of ITER. A magnetic fusion power plant will require a gain of about 25.

Substantial progress has also been made in identifying the limits to the plasma pressure that can be contained in a magnetically confined fusion plasma. Indeed, these pressure limits, as determined by limits of the ratio of plasma kinetic pressure to the pressure of the magnetic field, are now accurately predicted on the basis of theory. Since the fusion rate is approximately proportional to the square of the plasma pressure, this sets the power production capability of fusion systems. ITER is predicted to be able to produce at least 500 MW_t of fusion power. Fusion power production multiplied by the pulse length gives the energy released per pulse from fusion systems. In the 1970s, the toroidal magnetic confinement configuration called the "tokamak" achieved fusion power production of 1/10 of 1 W for one-hundredth of a second. ITER, also configured as a tokamak, is planned to operate for at least 300–500 s at a gain of at least 10, with a goal of effectively steady-state operation at gain of 5. Because ITER will produce significant power levels from fusion for significant periods of time, many of the technologies for ITER are similar to those that would be used in a fusion power plant. Thus the mission of ITER is to "demonstrate the scientific and technological feasibility of fusion energy for peaceful purposes."

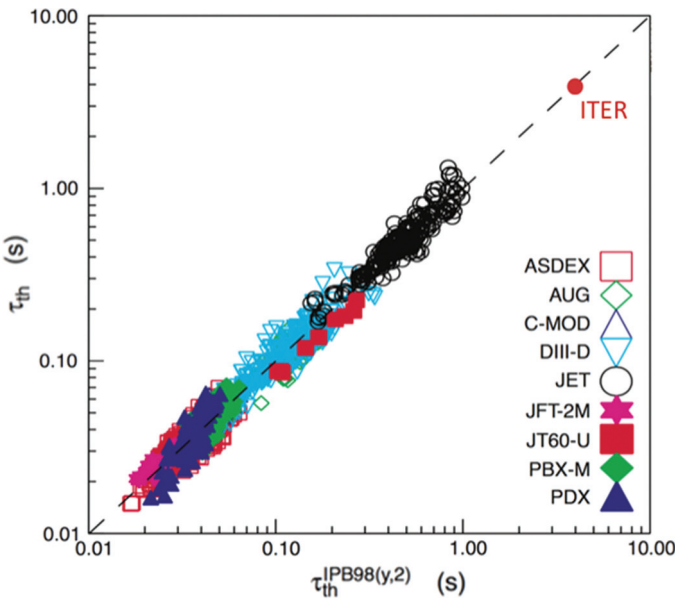

Figure 14.23 | Experimental confinement time of thermal energy vs. regression fit [IPB98(y,2)] to experimental results from nine tokamak experiments world-wide. Source: Shimada, 2000

14.11.4.2 Inertial confinement fusion

The concept underlying inertial fusion is that a small pellet of D–T fuel is compressed to very high density, but mostly at low temperature. A few percent of the fuel is heated to fusion temperature, however, and, as it burns, it "ignites" a fraction of the remaining fuel, which burns as well, igniting more fuel and ultimately providing adequate gain for net power production. The key recent scientific advances have been in the development of fully three-dimensional codes that can predict the evolution of the fundamentally unstable compression process, as well as the unstable burn process. These calculations define the requirements on the manufacturing precision required for the spherical fusion targets, and on the timing and uniformity of the laser or other beams used to compress and heat the targets. Furthermore, new ideas are being developed on means to heat the "hot spot" that initiates the burn, for example using special very short-pulse lasers (called "fast ignition") or carefully timed shocks. These may allow higher gain or lower laser driver energy for fusion energy systems.

A second issue, particular to inertial fusion driven by lasers, is laser–plasma interaction. The very high power laser light can interact with the plasma it produces in the vicinity of the target, with the result that the laser beam is steered away from the target, and/or energetic electrons are produced that heat the target and impede implosion. This is an active topic of research at the National Ignition Facility.

In inertial fusion, gain is defined as fusion yield divided by the laser light energy input. It is reduced by the relatively low efficiency (~20%) of conversion of laser light to X-rays which actually impinge on the pellet and implode it, in the geometry used at the NIF. To set a clear goal, a US NAS (1997) report defined ignition at the NIF as gain of unity. The total fusion energy released per pulse at the NIF will, at gain of unity, be 1–2 MW-s, 100,000 less than anticipated in ITER. The pulse repetition rate at high gain will be of the order of a few per day, as compared with ~50/day in ITER.

While magnetic fusion needs a gain of about 25 for a practical power plant, the low overall efficiency of the pulsed system in laser-driven inertial fusion requires a gain of about 150. The NIF will perform pellet shots at a rate of a few per day, as compared with a fusion power system that would need to perform shots at a rate of order 5–15 per second. Since the technologies used at the NIF are quite different from those to be used in a fusion power plant, it is viewed as demonstrating the scientific feasibility of inertial fusion, but not its technological feasibility.

14.11.5 R&D Needs

14.11.5.1 Magnetic confinement fusion

The key R&D needs for magnetic fusion (FESAC, 2007) are in support of:

1. higher power gain than ITER (25 versus 10) at higher total power output (~2500 MW_t versus 500 MW_t) in fully continuous operation;
2. efficient techniques to handle the power and ion flux from such a plasma; and
3. efficient techniques to handle the neutron flux from such a plasma while producing the needed tritium fuel.

Major new experimental facilities in China, South Korea, Japan, and Europe are now under construction or are beginning operation to investigate advanced operating modes and plasma configurations to address the first issue. These are superconducting tokamaks and "stellarators," comparable to the size of current experiments, but capable of very long pulse operation. To avoid irradiation problems, these experiments are designed to use hydrogen and deuterium "fuel" for physics studies, not DT for power production. Stellarators are more complex to construct than tokamaks, having a cross-section that rotates and distorts around the torus. They have the advantage, however, that they do not require external energy inputs to sustain internal plasma current and so can operate more efficiently in steady state than tokamaks. Results from these experiments are anticipated in parallel with ITER operations, and ITER itself will explore higher-performance operating modes once its basic goals are achieved.

Figure 14.24 | Laser beam lines at the National Ignition Facility at Livermore National Laboratory, California. Source: FESAC, 2003.

In the Unites States, experiments with D–D fuel are also being considered that could cost-effectively address the issue of how best to handle the power and ion flux from the plasma (OFES, 2009).

The European Union and Japan are working together on the design and engineering validation of a facility to address the issue of qualifying materials to handle the high fluence (time-integrated neutron flux) of very high-energy neutrons from fusion plasmas. This would be based on an intense deuterium ion beam penetrating a liquid lithium target to produce energetic neutrons. Material tests are to be done with displacements per atom and volumetric helium production expected for fusion power plant plasma-facing structures. Promising experimental results have already been achieved with nano-composited ferritic alloys, tested using ion beams to simulate energetic neutrons.

ITER will provide a test bed for tritium breeding modules at relatively low neutron fluence. Integrated testing in a pilot plant or demonstration power reactor would be needed before commercialization could be undertaken.

14.11.5.2 Inertial confinement fusion

The key R&D needs for inertial fusion are:

1. higher gain than the NIF's base mode of operation (150 versus 1);
2. cost-effective, repetitively pulsed driver systems (about 5–15 per second, versus a few per day for the NIF), perhaps using beams of heavy ions that can be produced with smaller energy conversion losses than laser light;
3. cost-effective, very-high-throughput, precision D–T target manufacture;
4. techniques to place targets in the fusion chamber with high accuracy and speed; and
5. target chambers and final beam focusing systems that can handle repeated 400 MJ explosions (the equivalent of 100 kg of TNT) while providing the required precisely controlled environment quickly after each explosion.

The National Ignition Facility itself will likely investigate higher-gain operation, as will a fast ignition experiment, called FIREX, in Japan. The Omega-EP experiment at the University of Rochester in the United States will also study fast ignition. Small efforts are underway in the United States, Japan and Europe to investigate other technological issues, such as the development of ion beams as a more efficient alternative to lasers (allowing lower pellet gain). But the main purpose of the large inertial fusion studies in the United States and France (Laser Mega Joule facility) has been to support nuclear-weapon science.

14.11.6 Possible Deployment Scenarios

Progress toward fusion energy depends on funding as well as scientific and technological success. In the United States, the Magnetic Fusion Engineering Act of 1980 projected a demonstration power plant by 2000, and authorized funding for magnetic fusion of US_{2005}34 billion. The actual level of funding appropriated was about one-third of this.

A study was undertaken (FESAC, 2003) to determine the program that would be required to bring on line a fusion demonstration power plant within 35 years. The scientific and technological issues listed above were considered in detail, and it was estimated that the United States could be one of several leaders worldwide in the development of fusion if an investment of about US_{2005}27 billion were made over the 35-year period. This would include aggressive R&D in both magnetic and inertial fusion, until a down-selection before construction of major new DT facilities.

If a number of successful demonstration fusion power plants were brought online around the world in the time frame of 2035–2040, one could imagine the commercial construction of fusion power plants beginning in 2050. Whether this is practicable will depend on whether the significant R&D issues discussed above can be resolved. Fission power, during its period of growth in 1975–1990, increased its share of electricity production at a rate of 1.2%/yr. If we posit fusion energy growth at 0.9%/yr of total electricity production, it could achieve about a 30% share of world electricity production by 2100. Assuming world electricity consumption of 12 TW_e in 2100, this would correspond to the construction of an average of 50 1.5- GW_e power plants per year, worldwide.

14.11.7 Policy Recommendations

Fusion is clearly attractive from the points of view of waste, safety and proliferation, particularly when compared with fission based on reprocessing and breeding. At the same time, it should be recognized that success with the technical development of fusion energy is not assured, and that the cost of fusion energy is difficult to project. Each of the major candidates for baseload electric power in the next decades – coal with carbon sequestration, major expansion of fission, and renewables with large-scale energy storage and transportation – faces serious challenges, however. Thus the availability of fusion energy could be important for stabilizing CO_2 levels in the atmosphere as energy demand continues to grow in the latter half of the 21st century (Goldston, 2011).

Further opportunities for international collaboration/coordination should be pursued. As the goal is to determine whether commercialization of fusion can be achieved by mid-century, however, it will be prudent to continue to pursue the development of fusion energy science and technology in the world's domestic fusion programs, in parallel with international participation in the ITER project and other projects, perhaps a neutron irradiation facility.

Taking at face value the development plan articulated in the United States, and perhaps multiplying by four to obtain a global figure, an investment in the range of US$100 billion over the next 30 years would be required to bring fusion online on the timescale discussed above. This corresponds to a worldwide investment rate of US$3.3 billion/yr, comparable to the investment rate in fusion R&D in the 1970s. Thus, once ITER construction is well under way, the world level of investment in fusion research will need to approach US$3 billion/yr to sustain healthy domestic research efforts as well as construct ITER. If the yearly level of investment were to remain at about that level after completion of ITER, this could provide the needed resources for the R&D and demonstration projects needed to support the beginning of the commercialization of fusion by mid-century. Because of the large size of the energy market, investments of this scale in energy R&D can be justified on a purely economic basis (Goldston, 2006).

In the opinion of the present authors, diverting current fusion research towards fission–fusion hybrids could be counter-productive. The destruction of wastes from fission might be an application of fusion energy, but the primary attraction of fusion is its high level of safety, low level of waste, and, especially, its low proliferation risk when compared with fission. A fusion-fission hybrid likely would not have those advantages.

Executive Summary

A sustainable future depends on more efficient use of the Earth's abundant energy resources in order to meet the rapidly increasing demand for energy services as well as to provide broader access to everyone. In 2005 the overall efficiency of the energy system from primary energy to useful energy was only about 34%. Owing to diverse geographic inequities in both sources and people, supply cannot always meet the demand where needed. Energy pathways from source through conversion, transmission, storage, and distribution to end-users are complicated and presently consist of numerous discrete pathways that differ widely for each energy source and carrier. These include solid fuels, liquid fuels, gaseous fuels (including hydrogen), electricity and heat. Aging equipment, congested networks, and extreme demands complicate this picture in many countries of the Organisation for Economic Co-operation and Development (OECD). Development of new infrastructure in both non-OECD and OECD countries will lock-in future dependence on conventional or non-conventional energy sources. This chapter aims to assist decision-makers by providing up-to-date knowledge on the full range of energy pathways, their management, and operation. Energy systems to achieve a sustainable future should be made much more flexible in order to deal with societal needs and the probable deployment of technologies not yet commercially available (such as smart appliances, electric vehicles, fuel cells, and carbon capture and storage). Technology and policy solutions are available for supporting more energy for sustainable development, but in order to meet the transition necessary to avoid unacceptable events such as social unrest and/or climate change driven temperature rise, they should be put in place rapidly, and done in concert with each other.

Major energy supply pathways[1] today include oil, natural gas, and coal fossil fuel sources, nuclear energy, and renewable energy converted to energy carriers mostly as liquids, electricity and/or heat, and then used in households, for transport, and by industry. In future, larger contributions can be expected from purpose-grown energy crops and waste streams, wind, geothermal, small hydro and solar energy, as well as natural gas and, at least in some places, nuclear power. Electricity, and perhaps hydrogen, are expected to play increasing roles in the overall energy system, and perhaps with a trend away from centralized energy systems to decentralized and distributed generation. Increased use of electricity is key to greater energy access and more energy for sustainable development across the world, and to increasing energy efficiency throughout the energy supply-chain. Electricity is distinguished by its capacity to transform a broad array of raw energy resources efficiently and precisely into useful energy services (such as building thermal comfort and street lighting, motor-drives for industrial applications and mobility, heating and cooling), irrespective of scale. Local, state and national governments will continue to place a high priority on supplying heating, cooling, transport and particularly electricity to their citizens.

The goal for the energy system should be to make the transition from analogue to modern digital technologies having optimized interconnected networks using up-to-date information and communications technology and linking energy carrier, transmission and distribution sub-systems. In planning, constructing and operating such an energy system, redundancy, robustness and flexibility are critical. Integrated energy storage is an area where technology lags and needs intense development if systems with optimum overall efficiency gains are to be attained.

In most cases, the private sector will lead in developing and deploying the most effective energy system approaches, but will need to work closely with a stable governance policy framework. Success will depend on rapid creation and implementation of robust global-scale public-private partnerships that will, in turn, depend on unprecedented levels of integration and cooperation between the partners. This must be accompanied by increased investment in, and development of cleaner energy-sector technologies together with their wide deployment and efficient management and operation.

1 Quantities of energy carriers required vary according to the energy end use efficiency level achieved, see Chapters 8–10 and 17.

15.1 Overview

Chapter 15 reviews recent literature on the movement and conversion of energy from its source to end-use. The various conversion steps involve "energy carriers[2]," which may include a secondary (converted) form of energy, such as electricity, heat, or hydrogen, or a primary energy source itself, such as natural gas, wind, or biomass (Figure 15.1). For all the known sources of energy displayed in the lower left part of the Figure, from crude oil to nuclear, as one moves across the horizontal line, the intersections denote conversions of the energy source to a form in which energy is moved to a point of use. The size of the dot at the intersection denotes which conversions are currently major uses of sources for an energy carrier. Moving from left to right, the first two lines represent solid fuels (coal, peat or woody biomass); the next two vertical lines represent liquid fuels (gasoline, diesel, jet fuel, biofuels); the following two lines represent gaseous fuels (natural gas, biomethane, propane or hydrogen); and the two lines, farthest to the right, represent electricity and heat forms of energy carriers. Energy end-uses are shown at the top.

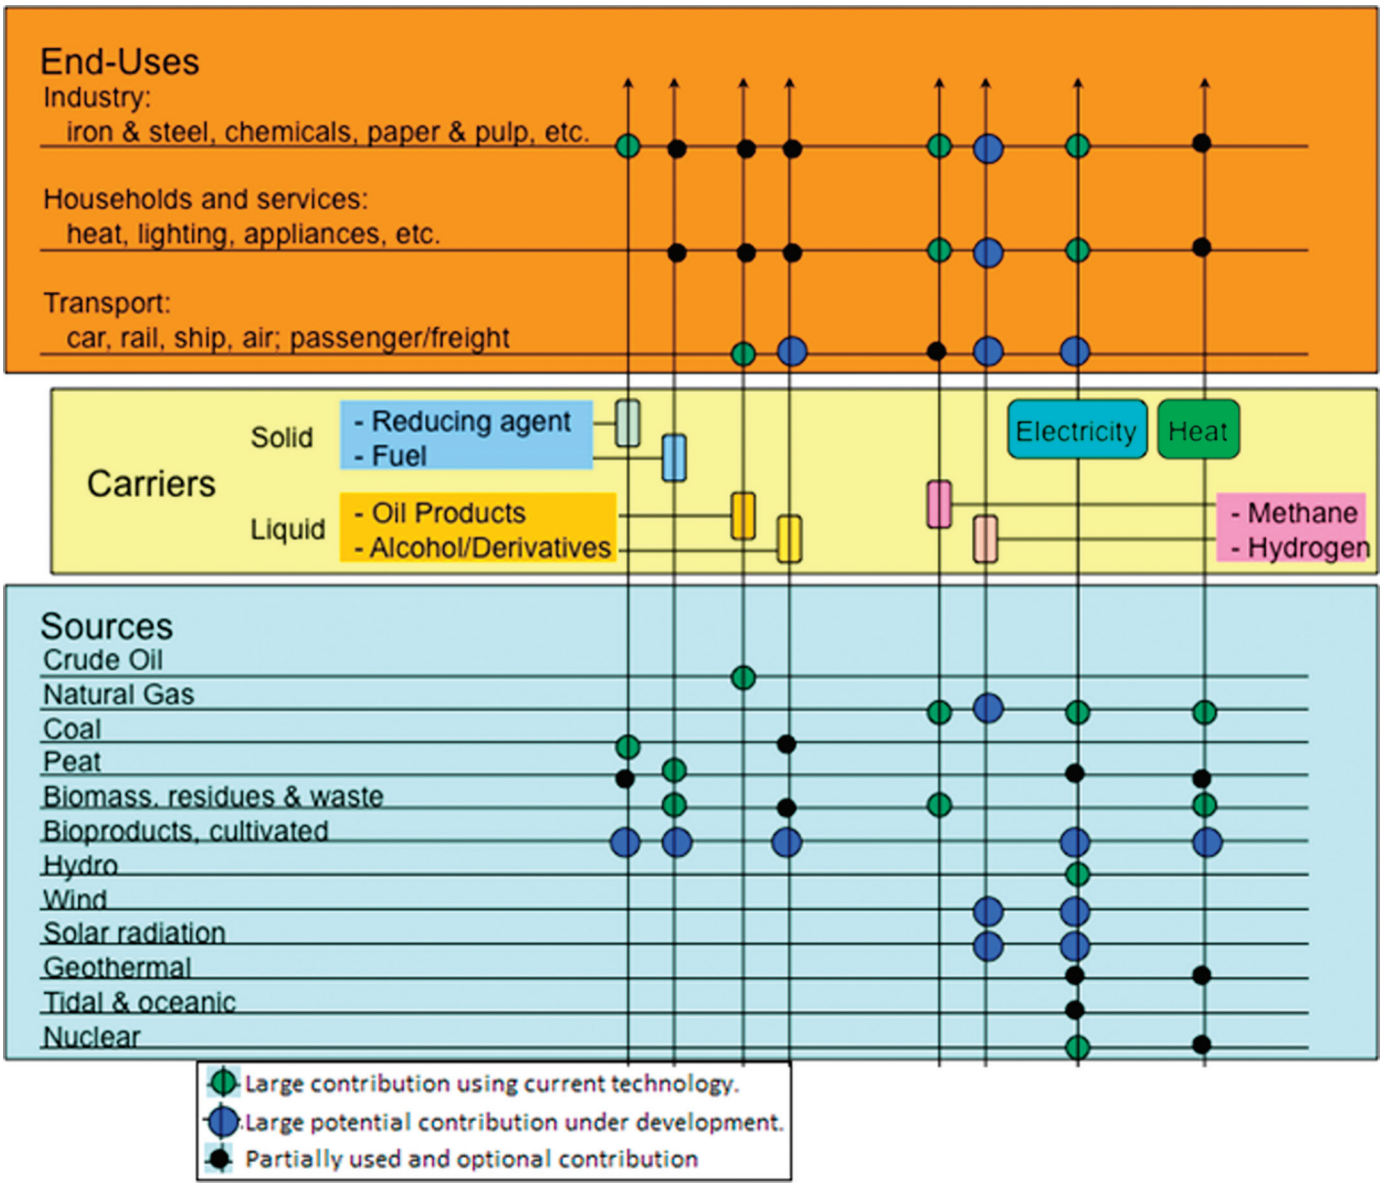

Figure 15.1 | Relationships from energy sources through conversion to energy carriers and end-uses, showing intersections where current technologies make large contributions, where the intersection is partially used and/or optional and where underdevelopment and a large future contribution to conversion and distribution is expected.

2 An energy carrier is a substance or phenomenon that has the ability to produce mechanical work or heat, or to operate chemical or physical processes (from ISO 13600).

The largest dots indicate the major uses of energy carriers for generalized areas of end-use, e.g., vehicles, homes, industry.

Primary and secondary energy can be converted to provide energy services in the forms of heating, cooling, lighting, entertainment, motor engines, and mobility (transport). This Chapter assesses the interrelationships between energy sources, conversion technologies, and energy carriers (referred to as "secondary energy" in Chapter 1), in terms of both their distribution and delivery to end-users today, and as innovative possibilities for the future. It presents potential pathways to a sustainable future. Energy sectors differ between regions, between major economies, and between developing and developed countries. The chapter describes varying approaches toward the transitions necessary for the creation of sustainable development, while noting how and why supportive energy policies that work successfully in one region may fail in another.

The focus is on energy carriers and the distribution systems for these carriers, including, but not limited to, electricity, solid fuels, liquid fuels, gaseous fuels, and heat. The chapter examines technologies and their potential development for these conversion and distribution steps. It gives more space to electricity because of the advanced state of electricity production and distribution networks, their ubiquity in modern economies, and the future potential for electricity to power heat pumps and electric vehicles, thereby displacing some current fossil fuel demand in the heat and transport sectors. Other energy carrier and distribution systems can learn a great deal from the electricity supply and distribution network.

Research, development, and demonstration (RD&D) in this area of energy supply and operation is assessed in terms of expenditures, both current and likely future costs, along with an examination of where funds may have to come from and where investments will need to be made (see Chapter 24 for a comprehensive discussion of RD&D). Critical questions include whether future competition will or should be between energy sources alone, between end-uses, between sources and end-uses, between integrated systems, or some combination of these. In this Chapter, current policies are assessed for effectiveness, and then related to more effective action in the future (see also Chapters 7–16 as well as Chapter 22).

15.2 Background

Throughout history, mankind's ability to live in harmony with the natural environment and its resources has depended on the availability of energy. Only through broader and more efficient access to the world's diverse energy resources, made possible by continuous advances in science and technology, can a sustainable global energy future be achieved. The overall efficiency of the energy supply chain (extraction, conversion, delivery, and use) has reached only about 34% (Figure 1.5). Major opportunities for improving efficiency exist at every link in this chain.

For millennia, human societies have obtained useful energy for heating and cooking by the combustion of "traditional" solid fuels, such as wood, animal dung, whale blubber, and other forms of biomass. In addition, manual labor and animal power depended on chemical stores of energy in the form of food and animal feed. Coal became prominent during the mid-19th century replacing much human and animal power as the northern hemisphere industrialized. The liquid-fuel era began in the late 1800s as the first oil fields were developed. It was not until after the middle of the 20th century that oil began to dominate the global primary energy mix. Natural gas was also consumed to a limited degree over this period, but real growth in demand only occurred in the past two to three decades as gaseous fuels began to replace liquid fuels. This on-going trend from solid to liquid to gaseous fuels continues to be driven by cost and convenience.

Between 1850 and the early 1900s, as human and animal power was replaced, primary global energy demand grew from around 17 EJ/yr (0.4 Gtoe/yr) sourced from traditional biomass and coal, to around 42 EJ/yr, as oil and gas now made up around 25% of the mix. Throughout the 20th century, the world's population grew, people in developed countries became more mobile, and more countries became industrialized. As a result, primary energy demand continued to increase, growing by over 10 times that original figure (see Chapter 1, Figure 1–3). By 2008, it was about 500 EJ/yr.

There are major differences between nations in energy use when considered on a per capita basis. Residents of the least developed countries, such as Eritrea, Haiti, and Senegal, use around 12 GJ/person each year on average, whereas people living in the wealthiest regions of the world (such as the Middle East and the United States) use 30–40 times more per person. The global average annual energy use is currently around 70 GJ/capita (average rate of 2.3 kW). China is 25% below average, but rising. Overall, each year, the billion wealthiest people on the planet use more than 25 times more primary energy than the poorest two billion who still rely on traditional biomass fuels to provide their very limited energy services.

Energy use per unit of gross domestic product (GDP) is another indicator of regional differences, as are greenhouse-gas emissions per unit of GDP. Countries in the Organization for Economic Cooperation and Development (OECD) generally have lower greenhouse gas emission intensities (around 0.5–0.7 $kgCO_2$-eq/GDP US$PPP[3]) than transition and developing countries, which can have intensities up to three times higher due to the higher use of fossil fuels and less efficient energy conversion equipment including boilers, vehicles, and power plants (IPCC, 2007).

The critical requirement for transforming energy into refined carriers (electricity or heat) from the locations where it is converted into useful work and services is a system to transfer the energy (so that it is readily available where and when it is needed). Any leakage or loss during the

3 PPP = purchasing power parity.

transmission and distribution process will result in increased cost and emissions per unit of energy for final use. Electricity, oil and natural gas transmission networks cover hundreds and even thousands of kilometers, linking energy conversion centers and energy users. These networks have been developed to meet the needs of large facilities, such as central electrical generation plants or large manufacturing plants, often located at some remote distance from demand. For electricity systems, transmission and distribution networks account for 54% of the global capital assets (IEA, 2008a).

Energy systems have four overall requirements: they should meet demand fluctuations, they should adapt to supply fluctuations, they should operate efficiently, and they must abide by regulations. Energy transfer may often, but not always, involve storing the energy in some form that can be utilized at a later time. This infrastructure demands storage, transmission, and distribution elements, all of which are connected with an energy carrier. Both energy carriers and storage systems contain energy that can be converted to useful energy for use at another time or in a different physical location.

Storage decouples energy supply and energy demand, thereby giving greater system flexibility, essential for both technical and economic reasons. Energy may be stored in chemical, mechanical, kinetic, electromagnetic, or thermal forms. Fossil fuels, such as coal and natural gas, already contain stores of energy, whereas electricity, gasoline, ethanol, and hydrogen contain energy derived from some other source. Some forms of energy are easily stored in their existing states: solid fuels require little in the form of containment, whereas liquid fuels require a sealed container. No technology advances are needed, as current methods are sufficient. However, gaseous fuels are not so easily stored for all intended applications, and so new storage technologies should better manage their inherent low density. Devices exist for converting electricity into energy forms that can be more easily stored using advances in technology (including pumped hydro, compressed-air, compressed natural gas, batteries, flywheels, super-capacitors, and superconducting magnetic systems). Such storage is useful for enabling more cost-effective and efficient, and therefore expanded, use of electricity, particularly in small autonomous systems and in systems with high penetration levels of variable renewable energy (such as wind and solar photovoltaics). Heat is generally stored simply by heating a thermal mass (e.g., bricks, stones, concrete, and water) to an elevated temperature and then extracting the heat for later use. Technology developments could lead to much better use of heat energy. The status and potential of storage technologies will be described later in this Chapter, along with the corresponding energy carrier.

The concept of an energy pathway from the energy source to its end-use, with storage, transmission, and distribution in between, sounds simple. However, in actual applications, it may not be this simple three-step bridge, but may comprise storage-transmission-distribution-storage, or some other combination. Moreover, in the latter example, the two storage steps may be substantially different. It is therefore essential to take an overall integrated system approach – or energy pathway – to a life-cycle-based, benefit-cost analysis of energy-supply operations. The other key element that requires robust development is the infrastructure for each of the energy carriers or combinations thereof.

In the case of electricity, it is widely recognized that aging infrastructure needs to be modernized, but that alone is insufficient. A "grid of the future" or "smart grid" could be developed to accommodate energy sources in a more optimal way. In the case of hydrogen, for example, it is not a modification of the infrastructure that is needed, but rather an entirely new infrastructure specifically tailored for a hydrogen carrier and storage system.

Aging equipment, congested networks, and extreme peak-load demands contribute to system losses and low reliability, especially for electricity systems in developing countries that often require substantial upgrades. Existing infrastructure also needs to be modernized to improve security, to add information and controls, and to reduce emissions. Future infrastructure and control systems will become more complex in order to be able to handle higher and more variable loads; to recognize and dispatch energy at distribution and end-use sites; and to integrate variable and decentralized sources with higher load flows, frequency oscillations, and quality (e.g., electric voltage or gas pressure) without reducing system performance. In general, energy supply systems need to have more flexibility to accommodate higher penetrations of variable renewable energy. These problems are exacerbated by different degrees of decentralization and differing strengths of distribution systems, so that one solution cannot be applicable to all.

Superconducting cables, sensors, and rapid response controls that could help reduce electricity costs and line losses are already available or close to commercial development. System management can also be improved by incorporating devices that will help efficiency, for example, by rapidly routing flows on the grid, and introducing advanced pricing methods (such as time-based pricing, including, but not limited to, time-of-use (TOU) pricing, critical peak pricing, real-time pricing, and peak load reduction credits). The aim is to avoid peaks, as well as to take advantage of less expensive, off-peak electricity. Energy security challenges from technical failures, theft, physical threats, and geopolitical actions will become more important. Although co-utilization by various end-uses (e.g., plug-in hybrid vehicles) is introduced in this report, it will be developed in Chapter 16, with particular discussion of the concept and its related economic, social and environmental consequences.

In planning, constructing, and operating energy systems, we should not simply focus on a cost optimized system, but also include a sufficient level of risk preparedness, which may be implemented in terms of redundancy, robustness, or flexibility. These aspects are important because energy is essential for human society, which is now both complex and interdependent, with connections between states and regions forged by a highly globalized market economy. A single incident in an energy system can have enormous negative effects, as we have seen in

recent years in several large power-transmission network failures. Those blackouts vividly illustrated how deeply dependent the system is on reliable networks, rather than on traditional one-way routes from suppliers to end-users.

Also, cultural differences, as well as physical differences, mean that local/regional/national energy systems, although they may converge on a common set of best-available technologies, are likely to evolve in different ways that are locally suitable and affordable. This means that they may eventually vary considerably from each other, at least within the time horizon of this assessment.

15.3 Sources

15.3.1 Overview

In terms of final consumer energy use (including heat, electricity, direct combustion of oil, coal, gas and biomass, and other renewable energy products), industry uses about 27%, transportation 28%, residential and commercial buildings 36%, and feedstock 9% (see also Chapter 1). Electricity generation accounts for over a third of the world's primary energy demand, with an average conversion efficiency of just over 40% (ranging from up to 90% for large hydro to less than 15% for some older coal-fired power stations).

Of primary energy use, 40% results in useful heat (IEA, 2008a). Where feasible, using "waste" heat from thermal and geothermal power stations, industrial process heat, district-heating schemes, etc. makes combined heat and power (CHP) systems much more efficient. Almost half of all electricity generated is used in buildings (households, commercial services, and the public sector) and about one-third by industry.

15.3.2 Oil and Gas

Known reserves of oil and natural gas (including unconventional sources) will meet global demand for many decades at current rates of use (WEC, 2010; Moniz et al., 2010). The uses of oil and gas are partly interchangeable (for boiler fuels, light vehicle fuels, power generation), and this compatibility largely explains their correlation in global price fluctuations. The International Energy Agency's *World Energy Outlook 2008* analyzed ultimately recoverable reserves in detail and concluded that remaining proven oil reserves are equal to over 40 years of production at current rates of consumption, while proven gas reserves are equal to over 60 years (IEA, 2008a; see also Chapter 7).

Besides conventional fossil-fuel reserves, unconventional sources of liquid fuels are available from oil shale, oil sands, coal-to-liquids, gas-to-liquids, heavy oils, and biofuels. Unconventional gaseous fuels include coal-bed methane, shale gas, methane hydrates, and clathrates. These are very large in quantity (see Chapter 7) but challenging to extract and refine, and the environmental impacts are many. Therefore, unconventional liquid and gaseous fuels may cost more.

15.3.3 Coal and Peat

From 2003 to 2008, coal was the fastest growing fossil fuel (EIA, 2009) in spite of its relatively high greenhouse gas and local air pollution emissions. Coal is the world's most abundant fossil fuel, and continues to be a vital resource in many countries (see Chapters 12 and 13 for detail). In 2009, it accounted for around 29% of total world energy use (about 153 EJ), primarily in the electricity and industrial sectors. Global proven recoverable reserves of coal are at least 20,000 EJ and an estimated additional possible resource of more than 400,000 EJ for all types. Coal resources have also been discovered on the Antarctic continent and in newly explored parts of Australia, but it is difficult to estimate the exact amounts. For details about the distribution of coal resources, see Chapter 7. In general, the northern hemisphere has more coal than the southern, especially concentrated in temperate and sub-boreal regions. Together, coal resources represent stores of over 12,100 GtC. Consumption in 2009 introduced approximately 14.7 $GtCO_2$/yr into the atmosphere.

Peat (partially decayed plant matter together with minerals) has been used as a heating fuel for thousands of years, particularly in northern Europe. In Finland, it still provides 7% of electricity and 19% of district heating (IPCC, 2007), but globally it is a small resource.

15.3.4 Renewable Energy[4]

Renewable energy, by definition, is essentially time-limitless energy stemming from various energy forms. At present, enough renewable energy flows are captured and converted to provide around 18% of global electricity (mainly from hydroelectric power) and around 4–5% of the global heat market (from solar thermal, geothermal, and modern bioenergy). In addition, traditional biomass for cooking and heating, which is mainly used in rural areas, accounts for around 10% of global primary energy use (IEA, 2008a). Liquid biofuels provide around 1.5% of the world's transport fuels. Detailed analyses of the potentials for each renewable energy resource category are given in Chapter 11 (and in IPCC, 2011) – but major uncertainties must be acknowledged, particularly for biomass and ocean energy.

Most energy scenarios assume rapid growth in renewable energy for the next few decades. For example, the IEA, in its "Blue-MAP" scenario (IEA, 2008a) suggests that to achieve 450 ppm CO_2-eq stabilization of atmospheric greenhouse gases, in tandem with nuclear power and thermal power generation plus carbon capture and storage (CCS), electricity generation from hydro, wind, solar and geothermal would need to rise to around 35% of global total power generation by 2030 and to almost

4 See also Chapter 11.

half of total generation by 2050. In GEA pathways, which achieve limiting climate change to less than 2°C compared with preindustrial times, the share of renewable energy of total primary energy ranges from 28–74% in 2050 (Table 17.12). This is supported by recent analysis in the IPCC renewable energy special report (IPCC, 2011). Increased heat demand could be met in part by solar (mainly for water heating and passive-solar building designs), geothermal (from direct heating and ground source heat pumps), and modern biomass (including from crop and forest residues, landfill gas, biogas, and CHP). Assessing the future potential for transport fuels based on renewable energy generated electricity, hydrogen and biofuels is very difficult for light-duty vehicles: the rate of introduction of electric cars, plug-in hybrids, fuel-cell vehicles, high-speed electric trains, behavioral changes, etc., are uncertain, as are the likely improvements to efficiencies of conventional vehicle engines and drive trains.

Increased renewable energy growth is just one component required if the necessary transition of the energy system to combat climate change is to be achieved (together with energy efficiency, nuclear, and CCS, see Chapter 17). Continued extraction and use of fossil fuels without CCS would be unsustainable due to the resulting carbon emissions. The IEA has analyzed the transition needed to achieve a 50% reduction of greenhouse-gas emissions from current levels by 2050 (roughly equivalent to a 2°C temperature rise limit) and has identified this huge challenge (IEA, 2007; see also Chapter 3).

15.3.5 Nuclear Power[5]

In the long term, the potential of nuclear power depends on available uranium resources. Reserve and resource estimates of uranium vary with the assumptions for its use (see Table 7.22, Chapter 7). Used in typical light-water reactors (LWRs), identified reserves and resources of 5.5 Mt of uranium, at prices up to US$130/kg, correspond to about 3200 EJ of primary energy and are sufficient for about 100 years at the 2006 level of consumption (Chapter 7). The total conventional proven (identified) and probable (yet undiscovered) uranium resources are about 16 Mt (9300 EJ). Unconventional uranium resources are contained in phosphate minerals (7–22 Mt), which are recoverable for between US$60–100/kg (NEA and IAEA, 2004, IPCC, 2007, see also Chapter 3). Together the total conventional resources and uranium in phosphate minerals could amount to 38 Mt (22,000 EJ, using current LWR technology) and would last for about 700 years at the 2006 consumption level. Furthermore, huge total amounts of uranium are contained in seawater, albeit in low concentrations, resulting in a resource base about a hundred times larger.

When used in current reactor designs with a "once-through" fuel cycle, only a small percentage of the energy content is utilized from the fissile isotope ^{235}U (0.7% in natural uranium). Around 60% of the present mining of uranium takes place in three countries: Canada 23%, Australia 21%, and Kazakhstan 16% (NEA and IAEA, 2010).

During recent years, the price of natural uranium has been rather volatile, and in mid-2007 the price peaked at US$297/kg ($US_{2005}$$280/kg). Since then, the price has declined to a level of US$110/kg ($US_{2005}$$104/kg), which is roughly at the level of the long-term average price, as expressed in constant $US_{2007}$$.

Nuclear fuels could also be made from thorium. There are identified and probable resources of about 6 Mt (NEA and IAEA, 2010); India, in particular, has large reserves. Thorium-based reactors appear capable of at least doubling the effective resource base, but the technology is yet to be developed in order to determine its commercial feasibility (IAEA, 2005). The thorium (or ^{232}U) fuel cycle is more proliferation-resistant than the uranium (^{235}U) cycle because fissionable ^{233}U is produced instead of plutonium, and emits high-energy photons, making the material difficult to handle.

15.4 Solid Fuel Applications (including Coal, Biomass, Uranium, and Thorium)

15.4.1 Overview

15.4.1.1 Coal

Total recoverable reserves of coal around the world are estimated at over 20,000 EJ thermal energy (Table 7.18, Chapter 7) – thus reflecting a reserves-to-production ratio of 137 (EIA, 2009). Historical estimates of recoverable coal reserves, although relatively stable, have declined gradually from 1145 Gt in 1991 to 1083 Gt in 2000 to 929 Gt in 2006 (see Chapter 7).

15.4.1.2 Biomass

Biomass is the major source of food and fiber for both people and animals. It is also used for heating, generating electricity, liquid fuels (Section 15.5), structural materials, and chemicals. Sources include forest and agricultural residues, livestock wastes, energy plantations and dedicated crops, and the organic part of waste streams such as municipal solid waste, biogas, and landfill gas. Uses of biomass for heating purposes range from the more traditional, such as cooking (with fuel wood, dung, and crop residues), to more modern applications, such as conversion into industrial process heat and district heating plants (Figure 15.2, Biomass currently provides about 50 EJ/yr of primary energy; see also Chapters 1 and 11).

Energy carriers for biomass include solid fuels such as chips, pellets, briquettes, and logs, as well as liquid biofuels and gases (see Figure 15.1).

5 See also Chapter 14.

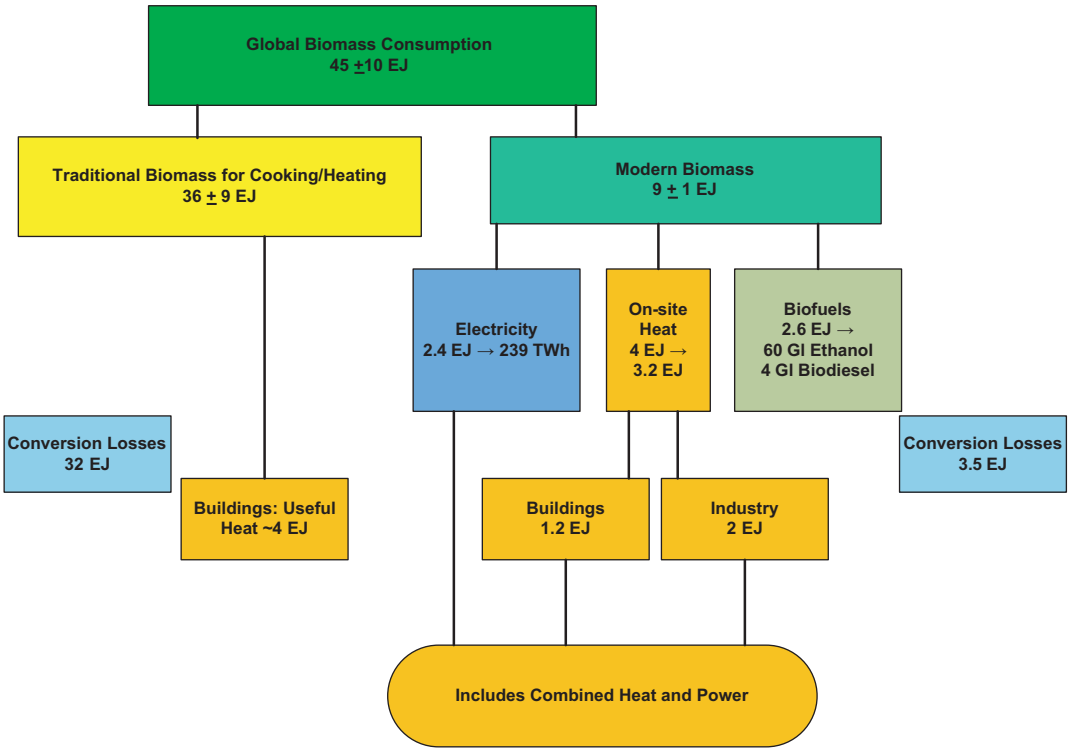

Figure 15.2 | Breakdown of global biomass consumption by type. Source: IEA, 2008a.

Before conversion, biomass feedstocks usually have a lower specific-energy than fossil fuels, and much lower specific-energy than nuclear fuel. Thus, the cost of accumulation, storage, transport, and handling raises the cost-per-unit of energy. In cases where the material is already accumulated for other reasons, such as residues from wood or sugarcane processing, these costs can be drastically reduced when the bioenergy is used on site.

15.4.1.3 Uranium[6]

Nuclear reactors reflect three basic fuel cycles. Conventional thermal reactors operate in a "once-through" mode, where spent fuel is sent directly to disposal. Thermal reactors can operate in a "closed" fuel cycle, where waste products are separated from unused and recycled fissionable material. Fast reactors use reprocessed fuel in a closed cycle, which dramatically increases the nuclear fuel supply. Each of these nuclear fuel cycles has its advantages and disadvantages in addressing the four core issues related to the use of nuclear energy (cost, safety, waste, and nuclear-weapons proliferation). The development choice depends on the priorities placed on each of these issues, and how soon the deployment decision must be made. Even the most advanced closed-cycle reactor designs could be ready for large-scale commercial deployment by 2030 if the necessary development investment is promptly committed (see also Chapter 24).

With fast reactors in a closed fuel cycle, reprocessing of spent fuel and extraction of the un-utilized uranium and plutonium, reserves of natural uranium may be extended to several thousand years at current consumption levels. In the recycle option, fast-neutron spectrum reactors utilize depleted uranium, and only plutonium is assumed to be recycled, so that the uranium resource efficiency is increased by a factor of 30 (Pauluis and Van den Durpel, 2001). As a result, the estimated availability of the total conventional uranium resources corresponds to about 240,000 EJ of primary energy. If advanced breeder reactors are introduced in the future to efficiently utilize recycled or depleted uranium and all actinides, the resource utilization efficiency will be further improved by an additional factor of up to eight (NEA, 2006; NEA and IAEA, 2008), depending on the detailed design of these reactors.

15.4.1.4 Thorium

Further technical development is underway, predominantly in India (WNN, 2009). A government committee in Norway studying the opportunities for using thorium as an energy source concluded that current knowledge of thorium-based electricity generation and related geology is not sufficient to assess the potential value for Norway of a thorium-based system for long-term electricity supply. However, the committee recommended that the thorium option be kept open since it may offer the potential to complement the use of uranium, and so strengthen the long-term sustainability of nuclear energy. It is also worth bearing in mind that the thorium

6 See also Chapter 14.

cycle leaves only half the amount of long-lived radioactive waste per unit of energy compared with mainstream LWRs (WNN, 2009).

15.4.2 Conversion

Coal is unevenly distributed and abundant, and can be converted to liquids, gases, heat, and electricity, although more intense use demands viable CCS technologies if greenhouse-gas emissions are to be limited. Bioenergy can be used in similar conversion technologies to those used for coal, as outlined below. Although the conversion efficiencies are lower for bioenergy, atmospheric CO_2 concentrations can be reduced, assuming all the biomass used is regrown. Moreover, the process of biomass pyrolysis can produce bio-char as a co-product – and this can be incorporated in the soil as a long-term carbon sink (Lehmann et al., 2006), thereby removing carbon from the atmosphere.

Most coal-fired, electricity-generating plants are a conventional subcritical, pulverized-fuel design, with typical conversion efficiencies of about 35% for the more modern units, although lower for biomass. Supercritical steam plants are in commercial use in many developed countries and are being installed in greater numbers in developing countries such as China. Current supercritical technologies employ steam temperatures of up to 600ºC and pressures of 280 bar, delivering fuel to electricity at cycle efficiencies of about 42%. Conversion efficiencies of almost 50% are possible in the best supercritical plants, but these are more costly. Improved efficiencies have reduced the amount of waste heat and CO_2 that would otherwise have been emitted per unit of electricity generation (see also Chapters 12 and 13).

Technologies have changed little since those reported in the IPCC's 4th Assessment Report (IPCC, 2007). Supercritical plants are now built to an international standard. An Australian Commonwealth Scientific and Industrial Research Organization (CSIRO) project is underway to investigate the production of ultra-clean coal that reduces ash below 0.25%, and sulfur to low levels. With combined-cycle direct-fired turbines, it can reduce greenhouse-gas emissions by 24% per kWh, compared with conventional coal-fired power stations. Gasifying coal before conversion to heat reduces the emissions of sulfur, nitrogen oxides, and mercury, resulting in a much cleaner fuel, while reducing the cost of capturing CO_2 emissions from the flue gas. Continued development of conventional combustion integrated gasification combined cycle (IGCC) systems is expected to further reduce emissions (IPCC, 2007).

Coal-to-liquid (CTL) is well-understood and regaining interest, but will increase greenhouse-gas emissions significantly without CCS. Liquefaction can be performed by direct solvent extraction, and hydrogenation results in liquid production at up to 67% conversion efficiency. Indirect gasification can also produce liquids by employing the Fischer-Tropsch (FT) process, producing synthetic diesel fuel (80%) plus naphtha (20%) at 37–50% thermal efficiency. Lower-quality coals reduce thermal efficiency, whereas co-production with electricity and heat increases it, thereby reducing costs by around 10% (IPCC, 2007; see also Chapters 12 and 13).

The Fischer-Tropsch process is performed in three main types of reactors: fluidized-bed, slurry-phase bed, and fixed-bed. Many companies are competing to further develop fixed bed and slurry reactors. The conversion efficiency of the fixed bed and the slurry bed is almost the same. The main advantages of slurry-bed reactors are lower operating and reactor construction costs. Fixed-bed reactors are easily scaled up, which means it is easier to realize large capacity. Wax/catalyst separation is easier and costs less than for fluidized- and slurry-bed reactors, which also have high capital costs and difficult process controls (Dry, 2002).

The first coal-to-methanol technology was commercialized by BASF in 1923. A major improvement was achieved in the 1960s by producing a sulfur-free synthesis gas that enabled the British ICI company to use the more active Cu/ZnO catalyst. This resulted in a significant reduction of the compression and heat exchange duty in the recycle loop. The lower reaction temperature also improved the selectivity by virtually suppressing the co-production of light hydrocarbons. Besides reducing the consumption of synthesis gas by a few percent, it also saved 5–10% cooling duty by avoiding the heat released by the side reactions (Lange, 2001). Nowadays, there are several kinds of methanol-composing technologies, and the technology is very mature. In the modern methanol-synthesizing production technology, the low-pressure methanol synthesis process is more widely used than the high- or mid-pressure processes because of the energy saving. ICI and the German Lurgi Company provide this technology for 70% of production facilities (Lou et al., 2006).

Dimethyl ether (DME), a hydrocarbon fuel that can be used to displace liquid petroleum gas (LPG) in vehicles, cooking stoves etc., can be synthesized from coal or biomass by methanol dehydration or direct synthesis. Methanol dehydration is called the "two-step DME process," while direct synthesis is the "one-step process." The two-step process offers some advantages, such as low temperature, high conversion ratio, and high selectivity, but the costs are too high and the process also has serious environmental problems, so it has been gradually phased out.

The one-step DME process uses two kinds of reactors: a gas-phase fixed bed and a slurry-phase bed. The slurry reactor offers a number of advantages: for example, although the DME synthesis reaction is highly exothermic and makes removing the heat of reaction difficult, in a slurry reactor, the heat of reaction is quickly absorbed by a solvent with a large heat capacity and high heat conductivity, and the temperature within the reaction vessel is easily controlled. In addition, there are fewer restrictions on the shape and strength of the catalyst in the slurry bed than in the fixed bed. Generally, the slurry bed could use coal-based syngas, which has a high DME productivity ratio, high selectivity, low energy use, and industrial scalability, with obvious economic and social benefits (Adachi et al., 2000; Lou and Wang, 2006).

Solid biomass is similar to coal in that it can be readily converted into liquids, gases, heat, or electricity. Many conversion technologies are mature for producing bioenergy carriers, while others are under development. The use of biomass products such as sugarcane bagasse, bark, or sawdust used for CHP in industrial, residential, and commercial uses is widespread globally and expanding. Co-firing of biomass with existing fossil-fuel conversion technologies, particularly coal, to produce heat or electricity is a rapidly evolving field. Conversion to liquid biofuels has many routes with various conversion efficiencies, typically around 30–40% (Sims et al., 2010).

The energy converted from uranium or thorium is essentially all used to generate electricity, but with considerable residual heat (see Chapter 14), and thus the energy converted is usually only about 35% using current technology.

15.4.3 Transmission and Distribution

Solid fuels can be costly to transport by road, rail, or ship but less so if the energy density is high. Movement over long distances is usually not cost effective for biomass due to its aforementioned low energy density. It is thus usually utilized near its place of production and harvest (e.g., wood process residues, sugarcane bagasse, cereal straw, energy crops). Wood pellets are an exception as they have a higher energy density (16–18 GJ/t) and about 50 PJ/yr (0.05 EJ) are traded internationally (Zwart, 2010).

Coal, with its higher energy density (20–30 GJ/t) saw about 23 EJ of primary (thermal) energy transported between countries in 2006 (EIA, 2011), representing about 17% of world coal production. There is active movement of uranium ore and enriched uranium (much to Europe), since more than half is currently mined in Australia, Kazakhstan, and Canada (see Section 15.3.5) and of those only Canada now utilizes uranium energy. This is cost-effective owing to the very high energy density of uranium (80 TJ/kg in LWR fuel), one kg being equivalent, on average, to 3000 tonnes of coal.

An innovative technology is being developed to transport coal through a water-filled pipeline over long distances. This "coal log pipeline[7]," technology has low water requirements and costs comparable to existing railways. The coal-to-water-mass ratio is three to one (Marrero, 2006).

Biomass is normally used locally, but transport for sale elsewhere of commercial firewood, wood chips, pellets, and liquid biofuels by truck, train, or boat is commonplace. The energy density is generally too low to pay for long-distance transportation, meaning conversion usually takes place near the source, although millions of tonnes of wood pellets are being shipped annually from the west coast of Canada to Europe. Bioenergy gases can be upgraded and transported in trucks or in natural gas pipelines as blends.

7 Coal is pressed into logs and then floated through the pipeline.

15.4.4 Storage

Storage of energy along any of the paths in Figure 15.1 is optional and may be desirable (but is not shown in the figure). Coal is often transported long distances and stockpiled at various points between the source and the user. Thus, coal piles come in many shapes and sizes, from the huge multiline longitudinal piles frequently found at ports, to ring blending beds at large power plants, to simple conical or irregular piles common at industrial plants. Although many of the same issues that apply to most other bulk materials are encountered when storing coal, the risk of spontaneous combustion makes it a special case. The US National Fire Protection Association (NFPA), in its publications NFPA 850 and 120, identifies the hazards associated with storing and handling of coal and the recommendations against these hazards. The NFPA recommends that storage structures be made of non-combustible materials, and designed to minimize the surface area on which dust can settle. This includes the installation of cladding to reach underneath the building's structural elements. However, because of coal's propensity to heat spontaneously, ignition sources are almost impossible to eliminate, and any enclosed area where loose dust accumulates is at great risk. Furthermore, even a small conflagration can result in a catastrophic secondary explosion if the small event releases a much larger dust cloud (Geometrica, 2006).

If the biomass is seasonally produced, storage is essential if the feedstock is to be supplied to a bioenergy, biogas or biofuel conversion plant all year round. Using a mix of feedstocks in a plant could reduce the storage requirements. Wet feedstocks can be stored as silage but some energy content loss will occur naturally over time, as is also the case for stored dry feedstocks such as straw or woodchips but at a lower rate. Biomass storage can also lead to possible spontaneous combustion, for example bagasse. Liquid biofuels can deteriorate in energy properties over time since they have a biological base, and their cold properties can be problematic for winter and aviation use. Biomass is usually used relatively soon after harvest, but when needed, storage is not an issue for solid or liquid biomass resources. Current trends indicate that investments in technical processes for biomass conversion technologies can pay dividends in reduced costs of utilization (IPCC, 2007). Developing a bioenergy plant can be challenging, particularly in gaining resource consent and securing long-term biomass supplies (IEA, 2007). Current concerns relating to providing sustainable biomass supplies, with minimal impacts from land-use change, related greenhouse-gas emissions, or water supplies, are being debated by several organizations, including the Global Bioenergy Partnership (GBEP, 2011).

15.4.5 Policy and Investment Considerations

15.4.5.1 Raw Materials

As international coal prices spiked in 2008, US coal prices tripled (Nelder, 2008). As Asian production and consumption of coal fell, local suppliers there suffered. The loss of China's coal exports indirectly translated

to higher demand for North American coal, driving its price upwards. Reduced output from foreign producers, along with record prices, has meant that more of US coal has been sent to buyers in Europe and in Asia than was the case in 2007.

Biomass resource costs delivered to the processing plant vary with source and location. Processing residues produced and used on site can be around US$1–2/GJ, or even negative, where for the "waste" biomass disposal costs have been avoided by using the resource. Collection and transport of residues from forests and crops are around US$4–6/GJ depending on transport distance, whereas biomass produced from dedicated energy crops can be double this or higher. Transporting biomass materials between locations can spread diseases, pests, and weeds, so some border controls may be advisable. However, such contamination risks can be avoided if sufficient heat for sterilization is generated when the biomass is processed into pellets, bio-oil, liquid fuels, etc. before it is transported. Policies to support biofuel production and use also need to take account of the fact that significant subsidies already exist for the fossil fuel industries (IEA, 2008a), and that sustainable land use practices, including carbon emissions from changes in land use, need careful assessment (Fritsche et al., 2010).

15.4.5.2 Final Product

Production costs of CTL appear competitive when crude oil is around US$35–45/bbl, assuming a coal price of US$1/GJ. Converting lignite at US$0.50/GJ close to the mine could compete with production costs of about US$30/bbl. The CTL process is less sensitive to feedstock prices than the gas-to-liquid (GTL) process, but the capital costs are much higher. An 80,000 bbl/day CTL installation would cost about US$5 billion and would need at least 2–4 Gt of coal reserves available to be viable (IPCC, 2007).

Biomass resources converted to liquids or gases often require government subsidies to make them cost-competitive. Exceptions to this are sugarcane-bagasse-ethanol, produced in Brazil, landfill gas from MSW, and biogas from sewage treatment systems using anaerobic digestion.

15.4.5.3 Policy Considerations

There are significant opportunities for technology to improve the efficiency and environmental performance of coal use. The key is to refine rather than burn coal. Coal refining depends on the conversion of coal under reducing conditions into a synthesis gas composed primarily of methane and carbon monoxide (see Section 15.8.2). This concentrated synthesis gas is purified of contaminants, and can be used either as a clean fuel for relatively high efficiency combustion turbine/combined-cycle power generation, or as feedstock for synthetic petroleum, diesel, aviation fuel, and chemical production, as well as for hydrogen. These coal refineries would most efficiently operate as flexible, around-the-clock facilities. Their synthesizing gas production would be selectively routed either to electricity generation or liquid fuel/chemical production, as market demands dictate. The necessary technology is well developed and has been demonstrated to be economically competitive under a variety of conditions worldwide.

The future investments needed by the whole coal industry are rather difficult to predict. However, it is possible to estimate them for some application technologies, especially for the main equipment components. This is also true of heat and power from bioenergy. The general flow of CTL technologies is described in Figure 15.3 (see also extensive discussion in Chapter 12).

Static system investment is calculated by adding up all the separate equipment costs. Each budgetary investment is estimated by plant cost indices and an exponential coefficient method. The overnight cost C, of a component having size S, is related to the cost Co, of a single unit of a reference component of similar size.

$$C = \sum C_i = \sum [n \times Co_i \times (S_i \,/\, So_i)^f] \quad (1)$$

where n = domestic factors and f = scale factor.

Table 15.1 gives the investment costs for the main equipment used in CTL technologies as one example. Parameters used for estimating overnight capital costs (including installation, balance-of-plant, general facilities, engineering, overhead and contingencies) are in US_{2002}\$[8].

Nuclear power has been a technologically dependable choice for filling the gap between reducing dependence on fossil fuels and the deployment of renewable energy. Recent developments in Japan have caused this belief to be reassessed. About 85% of the world's nuclear power generation today is by reactors derived from designs originally developed for naval use. Today, so-called "third-generation" reactor designs include greater design standardization, longer (60 years) operating life, reduced core melt potential, and higher fuel burn-up efficiency for less fuel use and waste. However, expansion will depend on resolving to public satisfaction several currently perceived limiting issues, including cost, waste, accident safety and proliferation.

Over the coming decades, two additional issues must be resolved if nuclear power is to fulfill its service capability. These are the quality and availability of waste repository space, and uranium resource availability. "Fourth-generation" nuclear reactor systems are intended to shape this more robust global future for nuclear energy. For example, the Generation IV International Forum, an international government and industry task force, selected six such advanced systems.

8 To convert US_{2002}\$ into US_{2005}\$, multiply US_{2002}\$ value by 1.085.

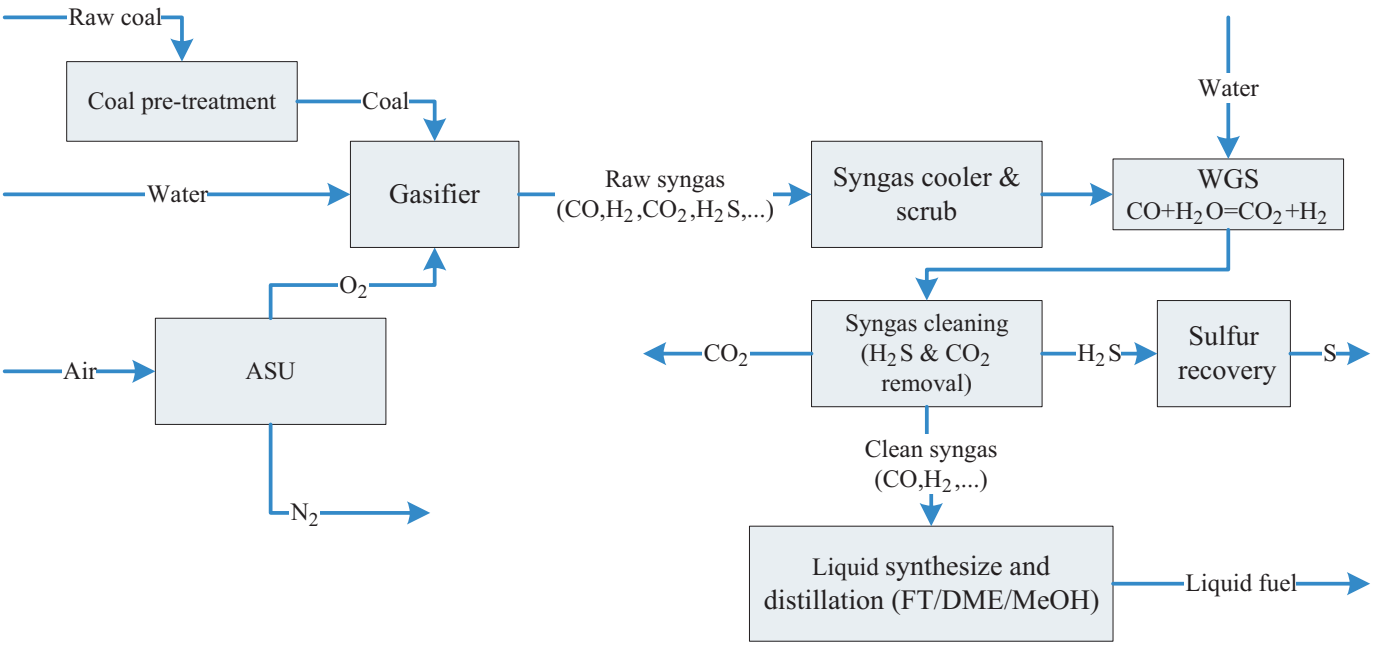

Figure 15.3 | The general flow of coal-to-liquid technologies.

Table 15.1 | Investment (US_{2002}) of main equipment used in CTL technologies.

Equipment or process	Scaling parameter	So	Unit of So	Co (M$)	f
Coal storage, prep, handling	Raw Coal feed	27.4	kg/s	29.10	0.67
Gasifier + syngas cooler & scrub	MAF[9] coal input (LHV)	697	MW	144.30	0.67
Air separation unit (O_2 at 1.05 bar)	Pure O_2 produced	21.28	kg/s	40.40	0.5
O_2 compression (from 1.05 bar)	Compression power	10.0	MW	6.30	0.67
N_2 compressor (GT NO_x control)	Compression power	10.0	MW	4.7	0.67
WGS reactors, heat exchangers	MAF coal input (LHV)	1377	MW	39.80	0.67
Selexol H_2S removal & stripping	Sulfur input	81	t/d	33.6	0.67
Selexol CO_2 absorption, stripping	Pure CO_2 captured	2064.4	mol/s	32.80	0.67
Sulfur recovery (Claus, SCOT)	Sulfur input	29.3	mol/s	22.90	0.67
Fischer Tropsch reactor	FT liquid produced	100	MW	73.5	1
DME recycling synthesize and distillation	Amount of feed gas (H/C=1)	8680	mol/s	87.37	0.65
MeOH recycling synthesize and distillation	Amount of feed gas (H/C=2)	10810	mol/s	81.77	0.65

These are: gas-cooled fast reactors, lead-cooled fast reactors, sodium-cooled fast reactors, molten salt reactors, supercritical water-cooled reactors, and very high-temperature gas reactors. Beyond these nuclear fission systems lies the relatively unlimited, but also unproven, potential of nuclear fusion-based energy. For a more comprehensive discussion, see Chapter 14.

9 Moisture and ash free coal.

15.5 Liquid Fuel Applications (including Petroleum and Biofuels)

15.5.1 Overview

Most of the world's liquid fuels today are refined from conventional crude oil (petroleum) and used mainly in the transport sector, but liquid energy carriers made from unconventional deposits (heavy oil, oil sands, oil shale, coal-to-liquids, processing of various biomass feedstocks)

are increasingly being made available in the marketplace where their promise is to reduce the very high dependence on conventional petroleum. Resulting GHG emissions ($kgCO_2$-eq/km traveled) are higher for some alternatives and claims of reduced GHGs from using biofuels are being carefully scrutinized since land use changes are often involved. The utilization of liquid fuels is shown schematically in Figure 15.1.

15.5.1.1 Petroleum

Of the world's total final energy demand, 44% comes from petroleum (Chapter 1). Most of the production comes from the Middle East (30%) and Russia (13%), while almost 50% of consumption is in the United States and Europe (BP, 2010). This results in a significant movement of oil from source to consumers, at a rate of over 50 Mbbl/day. Conventional oil resources are estimated at two trillion barrels, or enough to supply the world for over 60 years at present rates of consumption. However, consumption rates are expected to increase over time. About three times as much oil resources are estimated from unconventional reserves, but these are likely to cost more to extract, even with new technology.

15.5.1.2 Liquid Biofuels

Raw biomass materials can be broadly classified into wet or dry resources as well as liquids or solids. Solid dry sources are best used for thermo-chemical processes, and wet liquids and gases for biochemical conversion. A number of conversion processes are commercially available to produce both bioethanol and biodiesel (triglyceride esters) as vehicle fuels. Other processes still under development include hydrothermal gasification, enzymatic hydrolysis of lignocellulosic feedstocks, biodiesel hydrogenation and the production and use of algal oils.

15.5.2 Conversion

Petroleum is converted in a refinery to consumer products such as gasoline, lubricating oil, or asphalt. Global refinery capacity utilization in 2008 was between 70 and 90% (BP, 2010). Because of demand centers, almost 28% of refinery throughputs are in Europe, whereas the United States accounts for almost 20%. Both these percentages are decreasing, but Asia Pacific countries account for 28% of throughput and this figure is rising. Most recent refinery additions have been in Asia, particularly in China, to meet this increasing demand for petroleum products.

Solid or liquid biomass feedstocks can be converted using numerous technologies to provide more convenient energy carriers in the form of liquid fuels, such as methanol, ethanol, biodiesel, and bio-oil. Biomass feedstocks with a high moisture-content are usually preferred for anaerobic digestion, pyrolysis, or biofuel production, although there is continuing interest in producing advanced biofuels from lignocellulosic feedstocks (Sims et al., 2010). The energy inputs, related carbon savings, and water demands needed for biofuel vary with the process. High-energy input/output ratios (for example, corn ethanol processing when using coal-fired power and heat) can lead to limited GHG mitigation benefits. Stringent planning regulations, feedstock supply security and sustainable production can constrain biofuel plant developments (IEA, 2007).

15.5.3 Transmission and Distribution

Petroleum is moved, either as liquid crude oil or as refined products, predominantly by pipeline, or, in the case of intercontinental transmission, in oil tankers. The petroleum that moves from the Middle East is mostly by ship and from the former Soviet Union is mostly by pipeline. Current oil markets and trade are shown in Figure 15.4.

Liquid biofuels ranging from raw vegetable oils to highly refined liquid transport fuel blends can be transported in similar fashion, usually by road tanker or ship. Pipelines are also being planned for bioethanol. In Brazil for example, the company Uniduto Logistica has begun construction of a 600 km, US$800 million pipeline from São Paolo to the port of Santos, being the first phase of a major network. In the United States, Magellan Midstream Partners and the biofuel producer Poet are together undertaking a feasibility study of a 2700 km pipeline from northwest Iowa to the New York harbor (IEA, 2008a). At a cost of US$3.5 billion, it would collect ethanol produced in Iowa, South Dakota, Minnesota, Illinois, Indiana, and Ohio. Technical challenges include the corrosive nature of ethanol, its affinity for absorbing moisture, and how it might react with other products and substances within the pipeline. A dedicated ethanol line is therefore preferable, but at a relatively high cost per volume carried if the pipeline is not used to its full capacity.

15.5.4 Storage

Storage of vegetable oils and biofuels over time is problematic due to the biological origin of these materials, as well as their being hazardous and flammable. In general, the standard storage and handling procedures used for petroleum diesel can be used for biodiesel. Ideally, a clean, dark environment free of moisture is required, using storage tanks made from aluminum, steel, polyethylene, or polypropylene. Biodiesel corrodes copper, brass, lead, tin, and zinc, and therefore these metals should be avoided in all components.

For ethanol, some components and equipment used for storing and dispensing of conventional gasoline, as well as for internal combustion engines, do not have adequate compatibility with ethanol or gasoline-ethanol blends above E10. Hence, a range of national and state regulations exists (Wisconsin Department of Commerce, 2005).

Metals such as zinc, brass, or aluminum, commonly found in conventional fuel storage and dispensing systems, are incompatible with ethanol. In addition, components made from natural rubber, polyurethane,

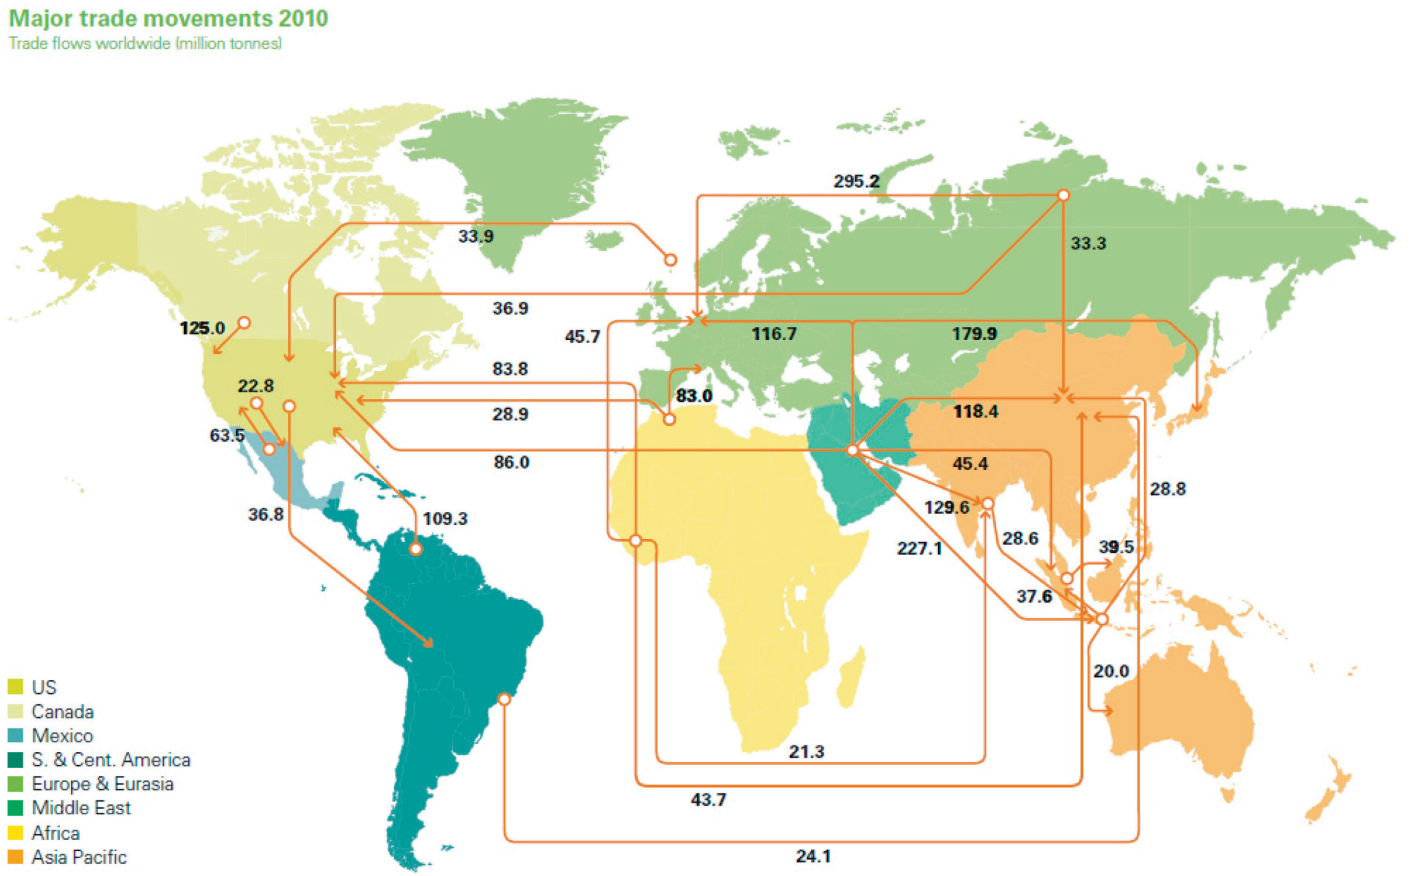

Figure 15.4 | Current oil markets and trade. Source: BP, 2011, data based on Cedigaz and GIIGNL.

cork, certain adhesives, elastomers, and polymers used in flex piping, bushings, gaskets, meters, and filters may also degrade. If water is present, it can cause premature failure of components such as probes, line leak detectors, submersible pumps, fuel dispensers, piping, hoses, and nozzles. Being miscible with ethanol, it can result in phase separation of the blend. Storage in single-walled tanks can leak and condense, so lined- or double-walled underground storage tanks at service stations are usually necessary.

Emissions of liquid effluents or leachates from biofuel plants could affect watercourses, groundwater, and soils, and so need treatment before disposal to land or water. Policy drivers for biofuels are increasing and now exist in around 80 countries and states (REN21, 2011).

15.6 Gaseous Fuel Applications (Including Natural Gas and Biogas)

15.6.1 Overview

Natural gas is the cleanest burning of all fossil fuels, but known reserves are somewhat limited. However, recent successes in extracting gas from deep shale deposits using horizontal drilling techniques, especially in North America, are releasing more resources worldwide. Estimates of future natural gas availability vary widely from hundreds to thousands of years. Such estimates depend on assumptions about the future rate of use, and the development of technology to drill for gas in more difficult geographical conditions. The utilization of gaseous fuels is shown schematically in Figure 15.1. Methane can also be extracted from coal, peat, and oil shale as well as from organic materials, such as landfill gas or biogas. If these sources can be successfully exploited, the world's methane supply will be extended another 500 or more years (see Chapter 7).

In 2007, the world's proven reserves of natural gas were nearly 177 trillion cubic meters (Tm^3), of which 45 Tm^3, or 25%, were in Russia (Chapter 7). Following the depletion of cheap local gas, natural gas markets will require larger investments to transport gas from more remote areas. A growing number of market participants, each with different institutional frameworks, leads to higher uncertainties and risks.

Exploration for gas is currently at a significantly lower degree of completeness than for oil, with the exception of certain regions, such as North America. Thus, significant portions of the world's conventional gas resources are yet to be discovered. Future gas exploration is anticipated in the Arctic domains, in fold-belt provinces, and in deep sedimentary basins. Results from recent hydrocarbon exploration,

combined with new technological progress, suggest a high potential for future discoveries. Even though exploration in geological fold belts has contributed to past success, it has been focused on shallow-water locations that are the easiest to identify. Deepwater exploration has not been undertaken on any sizeable scale, leaving potential for future major discoveries.

The Arctic basins present a very high potential for gaseous hydrocarbons, since the offshore area is underexplored. On-shore resources, even though more developed, also present significant potential. The remaining exploration potential could, in a favorable scenario, be of the same order as the resources already discovered.

15.6.2 Conversion

As production from the most developed gas fields enters the depletion stage, accelerating depletion rates and falling rig efficiency rates indicate that the gas resource base could be reaching maturity, though annual world production continues to increase (see Figure 7.11, Chapter 7). In the past, natural gas recovered while extracting petroleum could not be profitably transported for sale and was simply flared at the oil field. This wasteful practice is now illegal in many countries. Oil and gas companies now recognize that revenue from the gas can often be achieved by conversion to liquefied natural gas (LNG), compressed natural gas (CNG), or other energy carriers easier to transport.

Producing biomethane from landfill gas collection and from anaerobic digestion of farm and food-processing wastes and dedicated green crops involve mature technologies, with the gas usually being used for heat and power at the local and community scale. After cleanup and compression, the gas can be used to power vehicles, if the engines are designed or converted as if running on CNG. DME produced from coal or biomass can be used in similar fashion to displace liquefied petroleum gas.

Synthesis gas can be produced from biomass (as well as from coal) via gasification, but cleaning the gas and removing tars remains a challenge in some gasifier designs at both small (100 kW) and medium (20 MW) scales. Hydrogen can also be produced from biomass or fossil fuels as well as through water electrolysis. Direct conversion through reduction of water at high temperatures is also possible but a more costly option. Storage of small hydrogen molecules remains an issue, but their use through direct combustion or in fuel cells is reasonably well understood.

15.6.3 Transmission and Distribution

The major difficulty in transmitting natural gas and biomethane is their low density. Natural gas pipelines are presently impractical for transmission across oceans. The development of new technologies for gas processing and transport, especially over greater distances (Figure 15.5), to a certain extent remove "regional borders." Biomethane can be produced at high enough quality so that it can be injected into natural gas pipelines. The volume of the world's LNG trade, including intercontinental and spot markets, has been growing at 6–7% annually, faster than the growth of pipeline gas exports at 2–2.6% annually. This growth is expected to continue due to technological advances in gas liquefaction and LNG transport and utilization. This means that national and regional markets are no longer isolated from each other.

Capital intensity of LNG production has halved in the past decade, with high-capacity tankers now costing 50–60% less than 10 years ago. Additionally, demand for LNG has been enhanced by the importers' drive to diversify supplies and the overall liberalization of the natural gas market. The pool of LNG exporters is currently limited to Indonesia, Algeria, Malaysia, Qatar, Trinidad and Tobago, Nigeria, and Australia, with Russia joining Atlantic and Pacific markets.

With 15 nations accounting for 84% of the world's gas production, access to natural gas has become a significant factor in international economics and politics, and control over international gas pipelines is a major strategic factor. Natural gas is transmitted through various high-pressure pipelines, forming national and international gas-transmission networks connected to medium- and lower-pressure pipelines, operated by distribution companies that eventually reach end-users. Gas distribution systems are the piping networks that deliver the gas to buildings and businesses, downstream of a city's gate stations. The main problem in distribution systems is ensuring adequate maintenance and monitoring of the safety of these piping networks.

LNG ship carriers transport natural gas across oceans, while tank trucks can carry LNG or CNG over shorter distances. They may transport natural gas directly to end-users, or to distribution points such as pipelines.

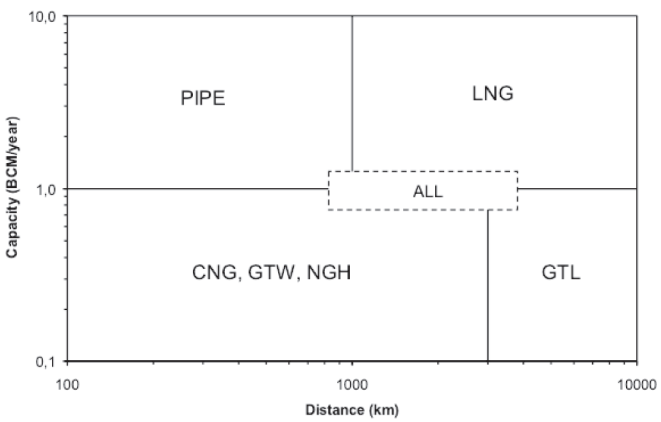

Figure 15.5 | Capacity versus distance for forms of natural gas transport. Pipe is gas pipeline, LNG: liquefied natural gas, CNG: compressed natural gas, GTW: gas to wire (electricity conversion in place), NGH: natural gas hydrate, and GTL: gas-to-liquids. Source: Gudmundsson and Mork, 2001.

Additional facilities incur additional costs – for liquefaction or compression at the production point, and then gasification or decompression at the end-use facility or for a pipeline.

The limited number of countries with a meaningful gas-pipeline export capacity includes Canada (92 Gm^3 in 2009), Russia (176 Gm^3), Norway (96 Gm^3), the Netherlands (50 Gm^3), Algeria (31 Gm^3), and the United Kingdom (12 Gm^3) (BP, 2010; see Figure 15.6).

Any future system development requires the continued creation of a gas infrastructure. This includes:

- ensuring that the growth of LNG production, transportation, and utilization facilities is faster than consumption, thus raising the LNG share of global gas consumption;
- building intercontinental gas pipelines that, by 2020, should include the Europe-Russia-Central Asia-North Africa network, Russia-Central Asia-China-Asia-Pacific network, a network covering much of Latin America, and the Australia part of an Oceania-Southeast Asia network;
- shaping a single system of well-structured technological management standards for gas-transport facilities to promptly reroute gas, including routine and emergency reserves, into regions in need, thus rendering the entire gas transport system more stable and reliable.

During the gas liquefaction process, impurities are removed, and heavy hydrocarbons separated. The material is cooled down until the gas liquefies and is then stored. The construction of a liquefaction plant is a critical factor in the LNG chain, taking the largest portion of overall costs. The power required for operation of a liquefaction plant can be up to 900 MW, as large as a thermal power station. Therefore, the costs of running the liquefaction plant represent a substantial part of the overall costs of the LNG chain, and depend on the energy efficiency of the plant. For example, the use of large axial compressors can reduce energy use by 15% compared with centrifugal compressors.

Significant cost reductions can also be obtained through economies of scale and more advanced technologies to generate electricity. In older plants, the power to drive the compressors is produced with steam turbines (with a thermodynamic efficiency at lower heating value (LHV) of about 30–35%), while more modern units use combined-cycle gas

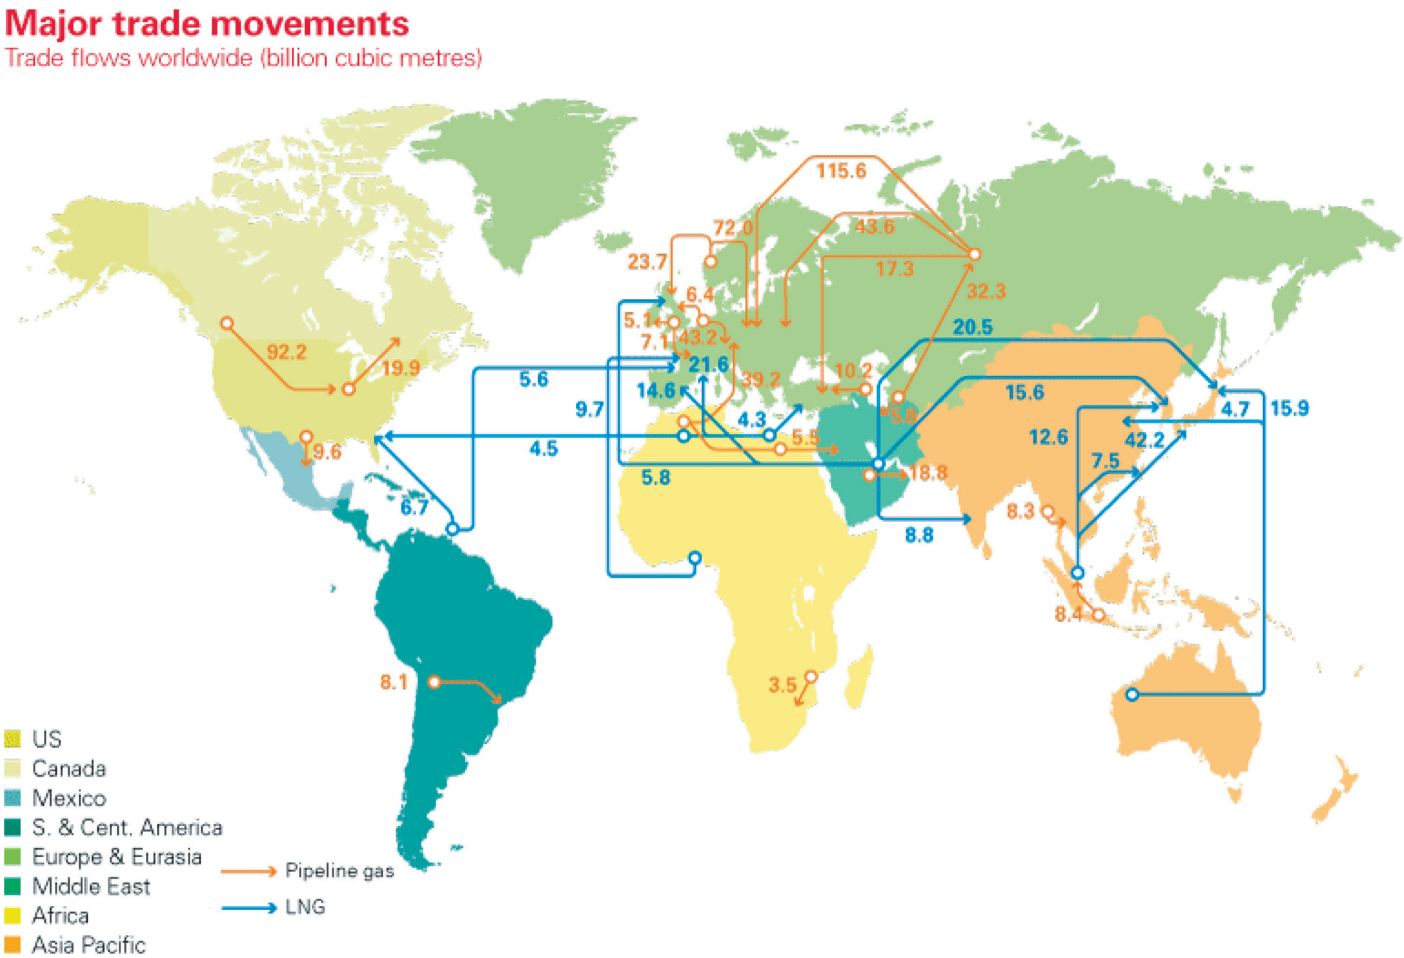

Figure 15.6 | Current gas markets with transport by pipeline or as LNG. Source: BP, 2010, data based on Cedigaz and GIIGNL.

turbines (CCGT). Natural gas fuels the turbine, and the heat generated produces steam, which in turn drives a steam turbine. The overall conversion efficiency of CCGT can be around 50–60%.

While no floating liquefaction plants have yet been constructed, the concept and design is currently being developed. Such floating plants could exploit remote or stranded gas fields that are not economical for fixed platforms. Shorter construction times and the fact that they can be reused for other sites allow the costs of such plants to be spread over several projects. Floating liquefaction plants can also minimize environmental impacts on coasts. The main challenge they present is the carrying out of liquefaction, storage, and loading on a mobile platform, under changing weather and sea conditions.

Due to public opposition to LNG terminal construction and safety issues associated with the operation, two new concepts for a coastal reception terminal have been developed. A structure resting on the seabed is constructed at depths ranging from 15–25 m, in a similar fashion to building offshore concrete production platforms. A floating storage and regasification unit (FSRU) is modeled on the floating production, storage, and off-loading unit from the upstream oil industry. FSRUs range from converted LNG tankers to terminals planned and built specifically for the purpose. Specially designed regasification vessels transport LNG, and then vaporize it to send it through a sub-sea pipeline at the destination port.

Shipping efficiency is essential to reduce transportation costs. A typical carrier can transport 145,000–155,000 m^3 of LNG, which will become about 89–95 Mm^3standard of natural gas when vaporized. LNG carriers are similar in size to aircraft carriers, but significantly smaller than very large crude oil tankers. Because LNG ships are extremely capital intensive, they cannot afford to have idle time.

LNG vessels usually do not have a liquefaction facility on board and use boil-off gas for propulsion at a maximum of about 0.15% of cargo volume a day. Because the gas cargo supplements the fuel oil, LNG tankers arrive at the destination port with less LNG than was loaded at the liquefaction plant. LNG tankers mainly use steam turbines as their propulsion system. Although the fuel efficiency is low, they can easily be adapted to use the boil-off gas because LNG carriers also normally retain a small percentage of the cargo (the "heel") to cool the tanks down to the required temperatures before reloading.

The regasification terminal is usually the least capital-intensive link in the LNG supply chain and several systems are in operation today. Key selection factors are operational costs (fuel consumption, maintenance), environmental costs, rates of emissions, and availability of the equipment suppliers on the market. Climate and geographical constraints are also important factors.

Gas quality and interchangeability are important issues because the gas regasified from LNG goes into the pipeline system. Also, the two fastest growing importers, the United Kingdom and the United States, require gas caloric specifications that are lower than other traditional gas importers, such as Japan.

In June 2008, 80 LNG liquefaction trains at 19 sites in 15 countries had a total liquefaction capacity of 194 Mt/yr. By August 2008, 65 LNG regasification facilities in 19 countries had a total capacity of 438 Mt/yr (599 Gm^3/yr), and a total storage capacity of 28 Mm^3 of LNG (equivalent to 17.2 $Gm^3$of natural gas).

Zero CO_2 emissions for LNG terminals can be achieved by avoiding fuel consumption for regasification. Using open rack vaporizers has been the most common option for many years. Air heat exchangers are also used when climatic conditions are favorable.

Energy integration with other industries saves energy and costs. These include: "cold/hot energy" exchanges at the power plant; direct use of cold energy for industrial processes, air liquefaction, and cryogenic processes; and power production (direct expansion, Rankine cycle).

As the major gas consumption centers become more dependent on gas imports, LNG trade will play an increasing role as a transmitter of price signals between the regional markets of Europe, Asia Pacific, and North America. However, significant differences in the import structures among these markets are likely to remain until 2030 and beyond.

As Europe's indigenous production declines, the resulting deficits will be supplied by both imports of LNG and pipeline gas. North America will predominantly rely on LNG to replace its falling production, and in the Asia Pacific region, rising demand will be met by increases in indigenous production along with LNG imports (but with increased intra-regional trade). The recent findings of large amounts of shale gas will affect this. LNG will fill the supply-demand gaps in all three main gas consumption regions, but the trade of pipeline gas will remain focused on Europe.

Although most natural gas imports to Europe will still be via pipeline under contracts until 2025 and beyond, several new LNG suppliers are expected to emerge. The ability of LNG suppliers to compete in downstream markets is due to its cost-competitiveness with pipeline gas.

Historically, rising gas prices and technological developments have resulted in substantial cost reductions in the LNG business and have helped improve the competitiveness of LNG compared with pipeline gas. Between 1990 and 2000, liquefaction costs fell by 25% to 35% and shipping costs by 20% to 30%. However, more recently, this trend was reversed, with strong increases in steel prices and even stronger increases in the cost of constructing liquefaction plants.

Comparisons between the costs of gas pipeline transport onshore and offshore with the costs of LNG transport have been published since the late 1970s, when LNG transport first arose for the export of Algerian gas. A comparison included in the European Commission's Energy

Sector Inquiry report (European Commission, 2007) was based on varying throughputs of 10, 25, and 40 Gm^3/yr; and for pipeline gas, (including capital expenditure related to laying pipelines on land and building gas compressor stations); and an LNG tanker of 135,000 m^3.

This analysis between pipeline transport and LNG showed break-even gas-transport distances of 3000 km and 6500 km for projects of 10 Gm^3/yr and 25 Gm^3/yr, respectively, with shorter break-even distances for more difficult terrain, and substantially shorter break-even distances for offshore pipelines.

Recent studies suggest that a single LNG train is cheaper than all other options when the distance is over 4500 km. With further cost reductions, the break-even distance will become even shorter in the future. However, it must be kept in mind that choices between LNG and pipeline transportation are rather the exception. North African and maybe Nigerian gas to Europe as well as Middle Eastern gas to Europe are the main cases where a choice is feasible, possibly together with some gas sent from the Gulf to Pakistan and India. Even in these cases, the distances are not the same, due to differences between the shipping route and the pipeline routing onshore. For Japan and North America, LNG remains the major gas import option. Possible pipeline projects for Japan would have to originate from regions that do not supply LNG. Similarly, most gas from Russia is located in the middle of the Eurasian continent and inevitably has to be transported by pipeline.

Gas transport costs for internationally traded gas can be critical. Pricing in a tight market is based on a netback value either derived from the replacement value of gas, or alternatively from the market price of gas in a deep and liquid market. Transport costs are eventually deducted from the revenue of the exporter. For an exporter, the main question is whether or not the net present value of the compensation it receives for the depletion of its resources is attractive. The transport costs are only one element among many for the resource owner to consider when making a decision on whether, how, and where to market its gas.

15.6.4 Storage

Gas is stored during periods of low demand, and withdrawn during periods of peak demand. It is also used for a variety of secondary purposes, including:

- balancing flow in pipelines;
- leveling production over periods of fluctuating demand;
- insuring against unforeseen events; and
- meeting regulatory obligations regarding reliability.

The capacity of underground gas storage (UGS) systems among countries (Table 15.2) is highest in the United States, followed by Russia, Ukraine, and Germany. Russia's working gas volumes include long-term strategic reserves.

Table 15.2 | Number of underground storage facilities and working gas volumes (Mm^3) in 2004/2005 by nation.

Nations	No. of UGS Facilities	Total Installed Working Gas volume of UGS Facilities
		10^6 m^3
USA	385	100,846
Russia*	22	93,533
Ukraine	13	31,880

The working gas volume of regional UGS facilities in operation in 2004/2005 was 333 Gm^3 (IGU, 2006). The most important type of gas storage is in depleted gas reservoirs, aquifer reservoirs, or salt cavern reservoirs. Each possesses distinct physical and economic characteristics

that govern its suitability for a given application. Most of the working-gas volume is installed in former oil and gas fields (Figure 15.7), followed by aquifer structures, and caverns in salt. Abandoned mines and rock caverns are of little relevance on a world scale.

Depleted gas reservoirs are the most common form of storage. They are generally the cheapest to develop, operate, and maintain. Obviously, location is a very important factor in determining whether or not a depleted gas field makes an economically viable storage facility. Aquifer reservoirs can be used for natural-gas storage in some cases. Usually these facilities are operated on a single annual cycle as with depleted gas reservoirs. Salt formations are well suited to natural-gas storage. Salt caverns allow very little of the injected natural gas to escape from storage unless specifically extracted. A cavern is leached in the salt deposit.

15.6.5 Policy and Investment Considerations

Gas demand is still growing rapidly. It already provides 22% of all primary energy (compared with only 10% in 1960). According to IEA estimates, its share may reach 25% before 2030. For the foreseeable future, natural gas will continue to be used primarily for direct residential and commercial heating and cooking, as well as for electric power generation, and industrial heat processes. Power generation will continue to drive the gas market according to long-term forecasts. At the same time, new uses for gaseous fuels in new sectors (such as transport) could be achieved.

Methane is a diverse and flexible fuel which, when combusted, provides both heat and/or electricity. It can also be used in the transport sector in the form of CNG, LNG, or compressed or liquefied biomethane. The use of CNG as a transport fuel is not new, but could continue to grow (Figure 15.8), although improvements in electric vehicles may dampen any dramatic increase in CNG-powered engines. The relatively favorable environmental characteristics of combusting natural gas compared with coal and oil will certainly help it hold its position at the forefront of fossil-fuel consumption.

In countries with well-developed domestic gas markets, liberalization has privatized unbundled segments enabling consumers to choose suppliers through non-discriminatory, third-party access to gas transport systems. These policies have led to the prompt development of spot gas trading. Thus, terms of contracts have been gradually reduced, and their linkage to other energy carriers such as oil, has been replaced with a linkage to gas, with spot-market prices. The result for gas-supplying countries is negative, as it is now more difficult to guarantee returns on large-scale investments within the framework of extremely volatile spot prices. There is a real danger that this situation will destroy the financing tools for large capital-intensive projects that have developed in the last decades on the basis of long-term contracts. Nor does this situation encourage the huge investments necessary for infrastructure and production development. Participants in the gas market simply delay their investment decisions because of high uncertainty. The question of timely investments in gas project development has become more important than ever.

With institutional frameworks changing rapidly in gas-producing, -transit, and -consuming countries, there is a need for additional guarantees of contract fulfillment. The mutual distrust of many market participants makes them protect their traditional territories, leading to energy nationalism and protectionism. Competition between national energy companies (representing mainly gas-producing countries), and international energy companies (representing gas-consuming countries) are increasing.

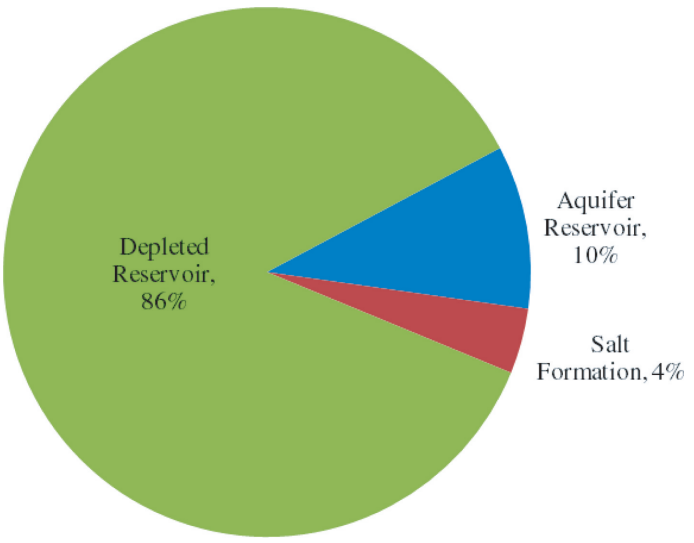

Figure 15.7 | Working gas capacity distribution by underground storage types in 2005. Source: adapted from EIA, 2006.

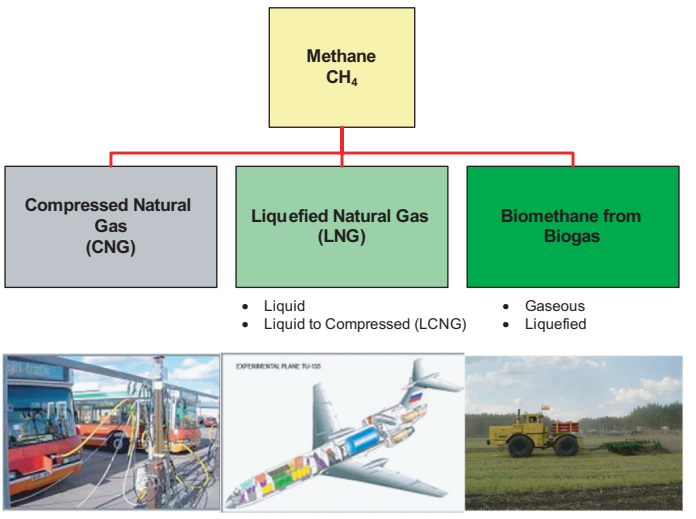

Figure 15.8 | Methane as a diverse fuel. Sources: adapted from Matic, 2006.

Gas pricing is still inconsistent: regional prices usually follow global oil prices with a slight delay. The market is currently divided into three main areas – North America, Europe, and the Asia Pacific – where different infrastructures lead to different prices, supply scheduling, and pipeline/LNG supply percentages. In Asia Pacific, demand is met mainly by LNG, with a premium over European and American prices. Future liberalization of gas markets and streamlining of trading procedures will probably eliminate the premium. LNG tankers are helping to bring regional prices down.

Solid or liquid biomass feedstocks can be converted using numerous technologies to provide more convenient energy carriers in the form of gaseous fuels, such as biogas from anaerobic digestion, landfill gas, synthesis gas from gasification, or hydrogen (see Chapter 11). Biomethane (i.e., scrubbed biogas) can be used directly for a range of local applications or injected into natural gas pipelines. The total market potential of biogas by 2020 has been estimated to be nearly 10 times the current biogas production of over 90 PJ/yr (IEA, 2007). Beneficial environmental impacts from the use of some biomass feedstocks include improving sewage treatment before discharging effluent and sludge to waterways or oceans, avoiding methane emissions from landfills, and reducing odors from direct application of animal wastes to land by first processing in a biogas plant.

Recovery of methane from modern biogas plants, following anaerobic digestion of the wet biomass feedstock, such as animal (Figure 15.9), human, food, and organic wastes and green crops, has increased in recent years. More than 4500 installations (including sewage gas and landfill gas recovery plants) were operating in Europe alone in 2002. The moisture content of slurries and wet biomass feedstocks used with anaerobic digestion plants is usually less important than for combustion of solid biomass, because the feedstock is usually not transported long distances and will not deteriorate in the short time between processing. A lower total solids content of the feedstock liquid can have an adverse effect on the biogas plant efficiency, along with the additional costs of having to store larger feedstock volumes before processing takes place.

Biogas can be directly combusted to produce heat. It can also be fed into natural gas grids or distributed to filling stations for dedicated or dual gas-fueled vehicle engines, or for power generation. For these applications, the biogas first requires scrubbing to remove any corrosive hydrogen sulfide, and carbon dioxide where gas-storage volumes are limited resulting in fairly pure biomethane gas.

Because biomass tends to have relatively low-energy density (whether as a solid, liquid, or gaseous fuel), and is organic, the storage of large volumes can be more costly than equivalent fossil fuels. For example, biogas needs either large plastic or steel storage tanks, or to be compressed and stored in cylinders, both expensive options. Therefore, matching the biogas production rate to the energy demand is the recommended approach to avoid storage costs.

Figure 15.9 | Anaerobic digestion plant and biogas storage tank on a 4000-sow pig farming in South England using two gas engines (housed in the closed shed) to provide electricity for the farm as well as low-grade heat for drying Lucerne horse feed as an ancillary farm operation. Source: courtesy of Ralph Sims.

Gasification of dry, solid biomass produces synthesis (producer) gas consisting mainly of CO and H_2. Development of efficient biomass integrated gasification combined-cycle (BIGCC) systems is nearing commercial realization, but the challenges of gas cleanup, to remove tars and condensates, remain. Several pilot and demonstration projects have been evaluated with varying degrees of success. The gas produced can be used in gas turbines, gas engines, or as feedstock for a range of liquid biofuels based on the Fischer-Tropsch process. Gas transport and storage are not usually problematic, because the gas can be converted onsite to produce heat, power, or liquid fuels as it is produced. Co-firing of biomass with coal in a gasification plant can provide increased efficiency and carbon mitigation, especially if linked with CCS, as can co-firing for heat and power generation. Torrefaction of biomass (bio-coal) using microwaves is reaching commercialization and could be co-fired (Rotawave, 2010). For an extensive discussion see Chapters 11 and 12.

15.7 Heating and Cooling

District heating systems transfer and distribute heat from one or more heating or CHP plants to individual homes, institutions, and industrial consumers, primarily in urban areas. District-heating systems are based on mature technology with a high degree of reliability. The infrastructure to deliver heat is costly, but is cost-effective when utilized efficiently. Furthermore, efficiency depends on climate and whether the infrastructure already exists. For instance, the centralized systems in the largest communities in Finland have district heating in more than 90% of homes. More than 75% of district heating in Finland is produced by CHP. In Sweden, district heating is supplied by a combination of CHP and large heat pumps. In 2008, 50 TWh district heating was produced, out of which 5.5 TWh was supplied by heat pumps and the majority of the rest (71%) from CHP fuelled mainly with woody biomass.

Major improvements in overall efficiency through CHP largely offset losses in transporting heat. In the case of heat applications in industrial processes, CHP loses less heat, as the heat transportation distances are short. Greenhouse-gas emissions are reduced because carbon-neutral wood residues and black liquor from pulp production are usually used to fuel CHP plants. In Japan, there are many cases where heating and cooling systems using heat pumps and/or induced heating have higher overall efficiency and economy than a conventional steam-based system.

Insulation material used for heat transfer pipes is now being improved continually, allowing heat to be distributed over long distances with relatively lower losses. This will facilitate using surplus heat from power plants. Further improvements in the performance of district-heating systems could develop low-temperature systems with reduced losses and more efficient operating conditions for CHP plants.

Efficiency improvements in end-use are a challenge to the district-heating sector. New low-energy houses need very little heat and only at selected times, such as cold winter nights (Larsen and Petersen, 2005). Such houses might be self-sufficient with hot water and will be unreliable consumers. In Europe, many of the district-heating systems are old and need upgrades and maintenance. General development in the electricity sector toward distributed generation works in two ways for the co-generated heat. On the one hand, generated heat is produced closer to the consumer, thereby reducing loss; on the other hand, the system gets more dispersed with smaller producers. As in the electricity sector, there is a compelling need to make the distribution system more intelligent, with closer links between producers and end-users. This is of utmost importance for the future development of sustainable heat-supply systems. Another step towards increased sustainability would be to combine district-heating systems with solar heating and heat storage, optimizing the total system.

Heating of water and building space using solar-thermal systems, ground-source heat pumps, as well as bioenergy (pellets or firewood) at the domestic and small business scale have rapidly growing markets (IEA, 2007). This is due to technological improvements and more competition, and brings the added benefit of increased reductions in greenhouse-gas emissions. Heating demands can be reduced by energy efficiency measures such as insulation, temperature adjustment, behavioral changes, etc. There is also increasing use of heat pumps, air-to-air, and air-to-water.

District-cooling systems are analogous to district-heating systems. The cooling medium is normally water from lakes and the ocean extracted at a temperature of 6–10°C, with a temperature rise of about 10°C at the consumer end before its return to the source. A water-glycol or ice-slurry-water mixture is also used. Cooling energy is produced by compressors using electricity or by absorption machines using district heating from a CHP plant or solar energy, usually at the domestic scale.

The district-heating system might drive cooling systems during the summer. Heat-driven cooling machines might also offset part of the electricity for air-conditioning, thus reducing the peak load of electricity in hotter areas of the world. Solar irradiation energy reaches its highest level around early afternoon, as building-space cooling demands peak. More direct district cooling would require the circulation of chilled water to end-users. Presently, Helsinki and Turku in Finland are among a number of cities that integrate district cooling and heating. District cooling also makes it possible to prolong the utilization period of the maximum load in CHP plants.

15.8 Electricity

15.8.1 Overview

Electricity is the key to greater energy access and more energy for sustainable development across the world, and to increasing energy efficiency throughout the energy supply-chain. Figure 15.1 vividly shows the many sources used to generate electricity and its almost universal use. By mid-century, at least two-thirds of the world's population will be concentrated in urban locations. This further underscores the importance of electricity as the primary carrier of energy from relatively remote production locations to these ever-growing urban population centers (Planck Foundation, 2009).

Electricity's capacity to transform the broad array of raw energy resources most efficiently and precisely into useful goods and services, irrespective of scale, distinguishes it from all other energy forms. Electricity also enables technological innovation and productivity growth – the lifeblood of a modern society. Electricity is indeed the equal-opportunity conversion, delivery, and end-use vehicle for all the world's energy resources (EPRI, 2003b; Yeager, 2007).

The profound impact of electricity on economic development and quality of life indicates that governments around the world will continue to place a very high priority on supplying electrical service to their citizens. Today, the annual individual consumption of electricity ranges from zero to well over 10,000 kWh. The empirical dividing line between advanced and developing economies is about 2000 kWh of annual electricity consumption per person. The resulting "electrification gap" effectively excludes nearly *half* the world's population from the potential benefits of a global economy.

Electrification offers the developing world an opportunity to "leapfrog" over the earlier, energy-intensive development of the West. For example, by 2050, if electricity provided even 40% of the world's total energy, as opposed to the 20% put forward in business-as-usual projections, improvements in global sustainability would be profound. For example, relative to business-as-usual, there would likely be at least a two-thirds reduction in global carbon emissions, made possible through higher efficiency and low-carbon fuels, and the same reduction in global oil consumption, through the use of electric vehicles. Equally important is the potential for at least a 50% increase in developing the world's economic output (IAC, 2007).

At the same time, the global electricity supply system is currently undergoing fundamental changes in its infrastructure, associated not just with the rapidly increasing amounts of renewable energy, but also with the development of new production and end-use technologies. One change is an increase in the large number of distributed production units that are significantly smaller than traditional thermal power plants. This development will include low-voltage connections from micro-distributed generation/CHP plants in individual households. Another important development is active control of this low-voltage demand, introducing a new method of providing flexibility in power balancing.

Parallel with this development is the increased use of information and communications technologies (ICT). The communications capabilities of electric devices are expanding rapidly, while also becoming less expensive. This introduces two-way communication with end-users, and is therefore an important enabling technology for future power systems. Advances in measurement technology and computational methods, e.g., for predicting weather, energy demand, and prices, create new ways to control the entire power system (Larsen and Petersen, 2009).

15.8.2 Conversion

Today's electricity supply worldwide overwhelmingly depends on centralized sources. These electricity-generating plants are designed and built to take maximum advantage of economies of scale and relatively low-cost fossil fuel (primarily coal) and hydropower. As has been the case with power delivery, short-term economics have restricted the application of innovative technology to improve the efficiency, security, and environmental performance of these centralized plants. The United States, for example, depends on thousands of centralized power plants, whose average age is approaching 40 years, because they still produce electricity at significantly lower economic cost than any newer alternative, even though the resulting environmental cost can be high.

This structure and approach has made it very difficult to achieve sustainable global energy for development. The primary issue restricting progress is not technology per se, but rather the disruptive impact new technology may have on the long-established and deeply embedded status quo. In the face of rapidly growing quantity and quality demands, it is crucial that this institutional and cultural inertia is promptly resolved so that the significant opportunities currently available to improve electricity generation are realized (Cicchetti and Long, 2003).

Increasing prices for petroleum and natural gas, along with concerns about CO_2 emissions, have contributed to increased interest in advanced coal-based power generation, including supercritical pulverized coal, circulating fluidized-bed combustion, and integrated gasification combined-cycle (IGCC) coal plants. With extensive positive experience in Europe, Japan, and Korea over the last decade, the superior efficiency and resulting improved environmental performance of supercritical plants makes them the generally preferred coal-fired power-generation choice today. Over the long run, the key to meeting the challenges of using coal to generate electricity is to refine rather than burn. Coal refining depends on the conversion of coal under reducing conditions into a synthesis gas composed principally of methane and carbon monoxide. This concentrated synthetic gas can be purified of contaminants and used, either as a clean fuel for high-efficiency combustion turbine/combined-cycle electricity generation, or as a feedstock for synthetic petroleum and chemical production (see Chapters 12 and 13). This technology is well developed and has been shown to be economically competitive with US$50/bbl, without consideration of the sizeable energy security and carbon-capture value that such plants provide (National Academy of Sciences, 2009). Ultimately, it may be feasible to extend coal refining through carbon capture and more advanced technologies, such as carbon reduction and increased nuclear and renewable energy, in order to achieve nearly zero-emission power generation. Demand side management (DSM) is today an increasingly cost and environmentally effective alternative to building new fossil fuel-fired peak generation capacity. Strategically for example, as discussed in the Appendix 15.A and Chapters 8–10, DSM through community aggregation and the decoupling of profits from electricity sales volume, also has the potential to become a much larger contributor and to effectively become an "Energy Efficiency Power Station."

The technology gap is also evident in nuclear power, preventing any realistically achievable strategy for the use of clean energy. A variety of advanced nuclear reactor, power-generation system designs are in various stages of development to address the four core issues of cost, safety, waste, and nuclear-weapon proliferation (see Section 15.3.5 and Chapter 14).

Renewable energy is also, potentially, a very important way of meeting global electrification needs in both rural and urban situations, depending on whether or not current barriers to large-scale deployment can be overcome. Despite recent gains and over one third of new power generation investments, renewable energy resources still only supply around 18% of the world's electricity, mostly from hydropower. If renewable energy is to play a greater role in the power mix, it must be reliable for the electricity system operator to use. The many options of renewable energy are technologically unrelated to each other, and, in terms of integration into present systems, each option has its own challenges. The implications for the electricity carrier and storage infrastructure are especially significant and urgent. Renewable energy power-plant capabilities, grid-planning and operation, energy and power management, and energy markets are each important to the large-scale integration of renewable energy at the system level (National Academy of Sciences, 2010). For further discussion on renewable energy, see Chapter 11.

Large proportions of wind power and other variable renewable energy generation make constantly maintaining a supply-demand balance an even larger challenge. In such cases, the system's flexibility in generation, demand management, and intra-area transmission may need to be increased (IEA, 2009b). The layout and basic structure of the grid, as well as operational practices, need to be adapted to manage the

presence of large amounts of variable supply. An energy system with large-scale integration of renewable energy, particularly wind power, is expected to meet the same requirements for the security of supply and economic efficiency as the current energy conversion and delivery systems, while delivering better environmental performance, especially with regard to CO_2 emissions and lessening dependence on fossil fuels.

Arguably the most effective mechanism to rapidly grow the renewable energy supply is locally distributed power generation. Policymakers have also set other objectives that are most effectively addressed by distributed generation (DG), since it can maximize efficiency and minimize the need for new large-scale generation plants, and upgrading of the transmission and distribution infrastructure. DG includes the incorporation of combined heat, power, and cooling for end-users, who are then able to more effectively contribute to maintaining supply-demand balance (Figure 15.10).

Isolated DG systems may be connected to the primary grid, or they may operate independently, as microgrids, or confined within a building. They are generally not centrally controlled, and with few exceptions at the present time, they cannot be switched on and off according to the needs of the grid – unless they incorporate energy conversion and storage. These current realizations of a possible "DG future" are attracting considerable interest (IEA, 2007).

The eventual goal of DG is to "reinvent" the grid itself. Instead of electricity being produced in large central plants and transmitted in one direction, DG will provide end-users with the following benefits:

- a degree of energy independence;
- opportunities for local control to improve the security of supply;
- financial optimization with energy markets;
- equal or better power quality; and
- a cleaner environment.

The perceived benefits of distributed-electricity generation systems include increased reliability of service, improved power quality, the ability to defer investment on extending the grid, and greater energy efficiency through better use of waste heat. Of these drivers, reliability of service is the most important and is linked with energy security. More and more consumers need uninterrupted electric power, yet many existing grids cannot operate without occasional blackouts. Using DG as a backup power source can largely eliminate these blackouts. Finally, the redundancy offered by a DG network, with its intertwined multitude of generators, converters, and connections, will certainly enhance the security of the power system.

To provide a reliable electricity supply, DG based on a high proportion of renewable energy will depend on a number of support technologies. These will include energy storage and load management to deal with variable power from renewable energy sources such as wind turbines. Once the concept is fully developed, DG, in addition to the obvious benefit of providing a cleaner environment, has the advantage that it is easy to add generating capacity as required, using local energy resources. The cost of such expansion is predictable over the life cycle of the generating plant, regardless of price fluctuations and shortages that may affect some fossil fuels and/or uranium in the future.

As the technology and benefits associated with it become more widely available, DG will contribute to electrification in the developing world. In this bottom-up approach, electrification can occur at the village scale, using local, renewable energy-powered "microgrids". The fundamental concept of a microgrid can be summarized as an integrated energy system having multiple distributed generation sources and multiple electrical loads, operating either in connection to, or separate from, the existing bulk power grid. A microgrid is thus a small-scale version of the electricity grid that the majority of electricity consumers rely on for power service today. Perhaps the most compelling feature of a microgrid is the ability to separate and isolate itself – known as "islanding" – from the bulk power distribution system during brownouts or blackouts. These local power cooperatives provide consumers with direct access and market transparency that traditional top-down, centralized, electricity-supply systems lack. These microgrids also offer basic building blocks for developing world electricity system expansion in the most sustainable manner. As the number of end-users (and their electricity needs) steadily grows, local microgrids can be interconnected into a regional grid combining the best of both distributed and centralized electricity supplies (Energy Business Reports, 2008).

A global future with energy for sustainable development will depend on a wise combination of both centralized and distributed generation in a system that best captures the advantages of both. The optimal balance will depend on local circumstances and the employment to best advantage of state-of-the-art technological advancements throughout the supply chain. Only in this manner can all the world's essential energy resources be made efficiently and cleanly available to serve the global population within this century.

15.8.3 Transmission and Distribution

The delivery of electricity depends on a system of overhead wires and underground cables, collectively called circuits or grids, which connect electrical loads with diverse sources of electric-power generation. This delivery and distribution system begins at the buss bar located at the generation plant, and extends to end-user meters. Today's delivery systems are largely based on technology developed in the first half of the 20th century. The strain on this aging analog, electromechanically controlled system is evident as it tries to keep pace with the precise power requirements of a digital economy – there is increasing circuit congestion, and the need for better system security. This translates into a large and growing gap between the performance capability of today's outmoded bulk-electricity delivery systems and the needs and expectations of end-users.

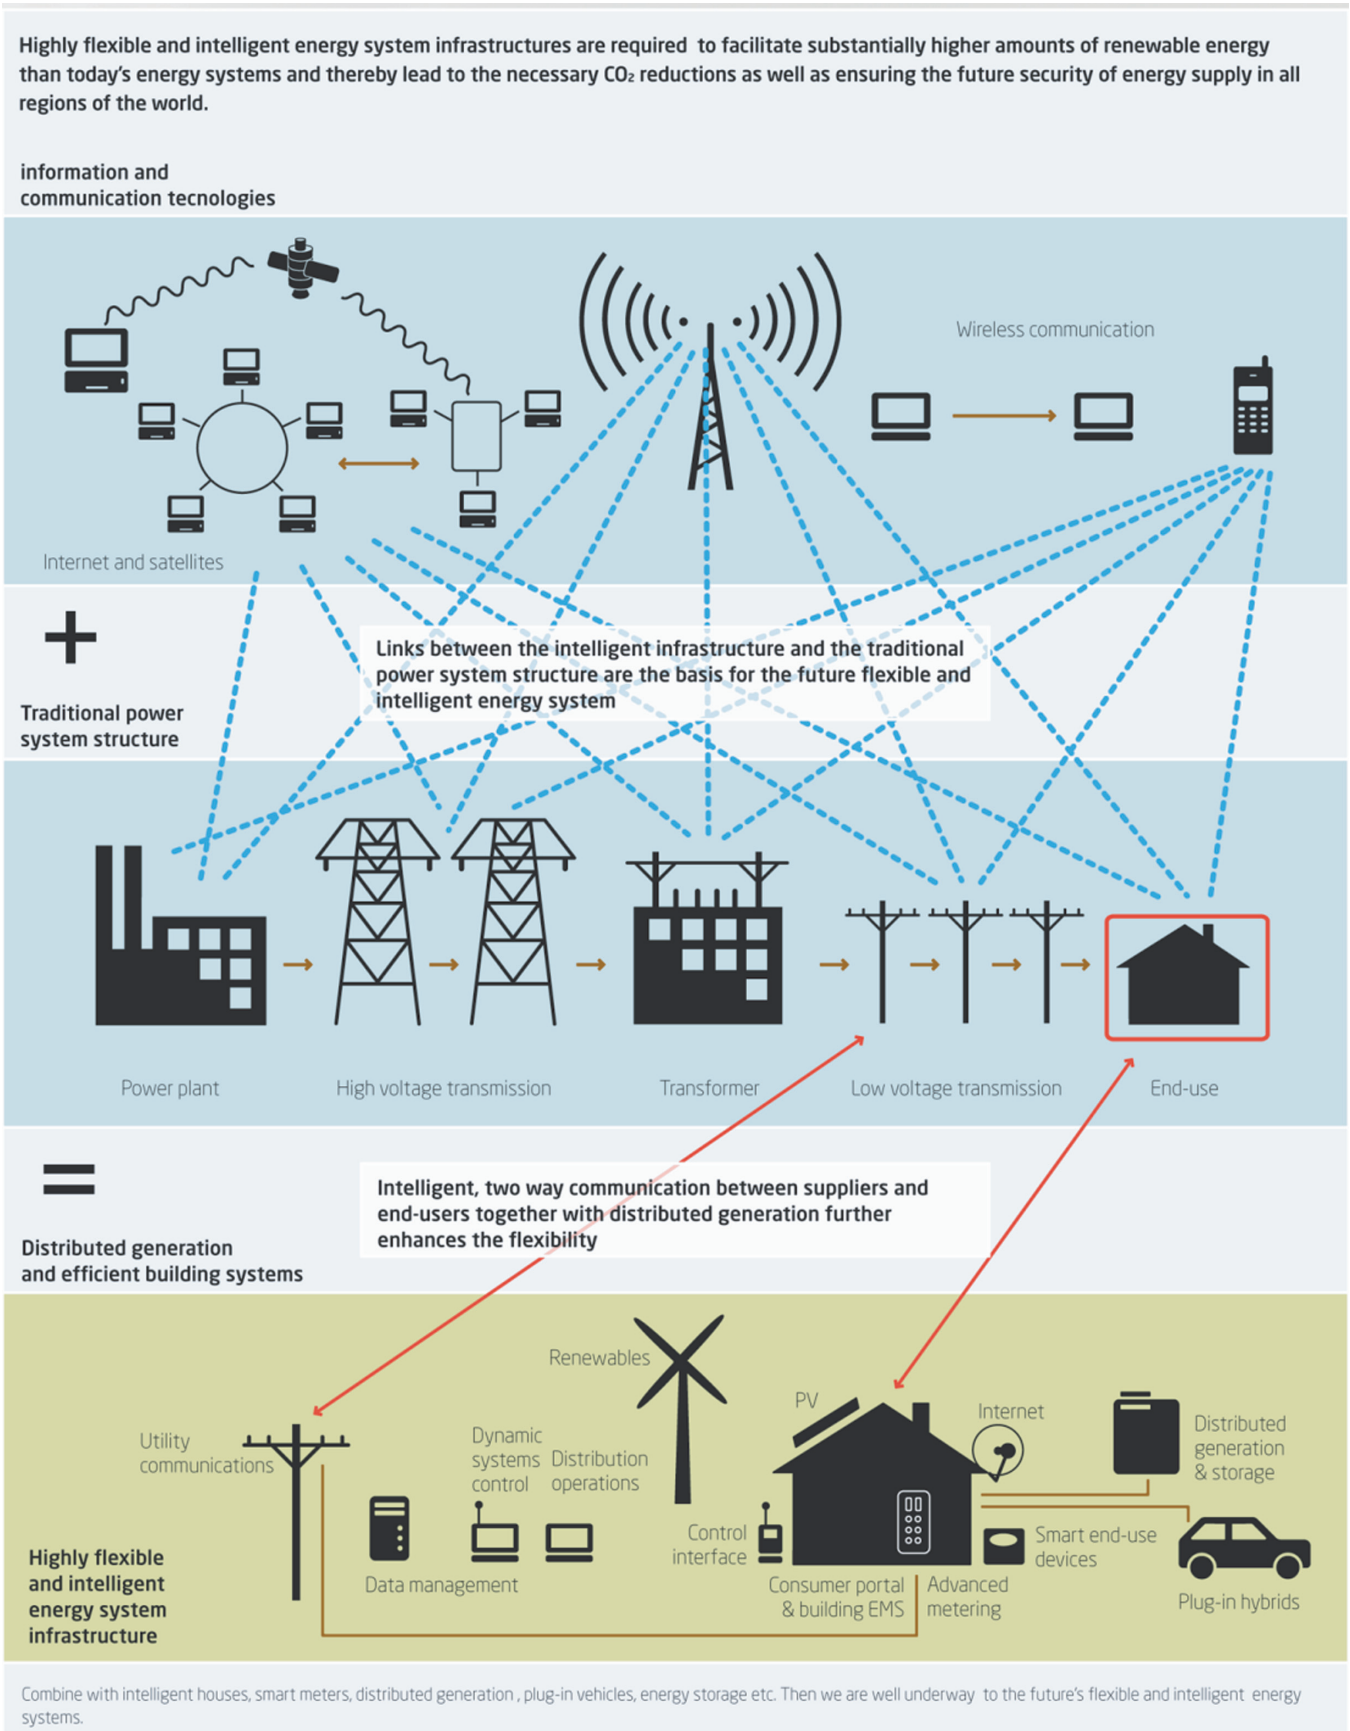

Figure 15.10 | Overview of an intelligent energy system infrastructure noting flexibility and distributed generation. Source: Larsen and Petersen, 2009.

The ultimate force pulling the transmission and distribution system into the 21st century is rapidly advancing technologies: specifically, intelligent electronic technologies that enable ever-broader consumer involvement in defining and controlling electricity-based needs. Historically, issues of reliability, security, quality, and availability have been measured and dealt with in a fragmented manner. In the future, these issues must become a highly integrated set of design and operating criteria, meeting the requirements of consumers (Nahigian, 2008).

Today's alternating current (AC) electricity delivery systems have two basic dimensions: high-voltage, long-distance transmission, and lower-voltage, local distribution. Throughout this process, voltage is raised or lowered by transformers to meet particular circumstances. Various techniques can increase the quantity of electricity carried on existing corridors. New conductors with carbon-fiber cores, for example, have higher current-carrying capacity. Because of their greater strength and lighter weight, they sag less at the line temperatures associated with high power-flow rates, and can operate continuously at temperatures above 100ºC. High Voltage Direct Current (HVDC) Light, an underground cable that moves huge amounts of power with very low losses over thousands of km, is also viewed favorably is under consideration for the European super grid (Galvin and Yeager, 2009). By doubling voltage, for example, one increases the power capacity of a transmission line by a factor of four. As load growth increases and the use of renewable power generation located far from the load center becomes more globally dominant, there will be increasing demand for HVDC technology. HVDC technology may be the only effective means of increasing power flow on an existing AC transmission corridor (Gellings, 2011). Electric power companies, government agencies, and industry are collaborating on "high-temperature" (liquid nitrogen temperature), superconducting direct current (DC) cables. As the technical and cost issues related to these are resolved, they may triple the electricity-carrying capacity of today's conventional conductors. Current technical issues include fault current susceptibility, reliability, and efficient use of cryogenics.

Renewable energy on a large scale represents a paradigm shift for the transmission and distribution system: the pacing issue is their natural variability. Because electricity supply and demand must be in constant balance, the carrier system or "grid" must be flexible, able to accommodate the sudden loss of a generation resource or an unexpected increase in demand. For small amounts of non-hydro renewable energy on a system, this can be accommodated reasonably well. However, with continued growth in such renewable energy, particularly wind, the goal to accommodate a significant fraction, 20% or more, requires new solutions. This issue has been underscored by the experience of Vattenfall, which controls northeast Germany's electricity transmission network, where the world's greatest concentration of wind-energy generation is located. In order to accommodate the unpredictable availability of the wind resource, conventional power plants have been forced to cycle on and off inefficiently, and the company has had to make emergency electricity purchases at high prices. Improved forecasting would help mitigate the problem. So would designing the grid to be more flexible (IEA, 2008a), integrating a wider portfolio of generation types (Awerbuch, 2006), and making loads responsive and active participants in power system operations. Building-integrated solar PV systems that compete with retail power prices can also have variability issues, whereas concentrating solar power (CSP) systems, combined with thermal storage, can help to overcome variability during short periods of cloud cover or darkness (UNEP, 2007).

An additional consideration is the demand that renewable energy places on the carrier system for ancillary services, such as voltage and reactive power, which must be managed to ensure the stability of the carrier system. The European Wind Integration Study, produced in 2007 by the European Transmission System Operators, focused on these issues as the amount of installed European wind capacity increased from 41 GW in 2005 to an expected 67 GW in 2008 (ETSO, 2007).

Other major upgrades to the electricity carrier system are also necessary to meet ever-growing demands, and ensure sustainability, including:

- extremely reliable delivery of high quality, "digital-grade" power, needed by a growing number of end-uses (EPRI, 2003a);
- availability of a wide range of "always-on, price smart" electricity-related consumer and business services that stimulate the economy and offer consumers greater control over their energy usage and expenses;
- a transmission and distribution infrastructure confidently protected from natural and man-made threats, which can be quickly restored in the event of an interruption;
- minimized environmental and societal impacts through the use of much more energy-efficient equipment, distributed renewable energy resources, and CHP; and
- improved economic productivity and growth, with decreased electricity intensity.

These demands, coupled with climate change concerns and increasingly involved consumers, are pushing the transmission and distribution infrastructure and its operators toward a technology and business model commonly known as "the smart grid revolution." The terms "intelligent grid," "smart grid," or "digital energy" may best be understood as the overlaying of a unified digital electronic communications and control system on the entire electricity delivery infrastructure. The goal is to provide the right information to the right entity (end-use devices, transmission and distribution controls, and consumers) at the right time to enable the right action to be taken – all at the speed of light.

The smart grid's transmission and distribution system (Figure 15.11) will constantly fine-tune itself to achieve and maintain an optimal state of

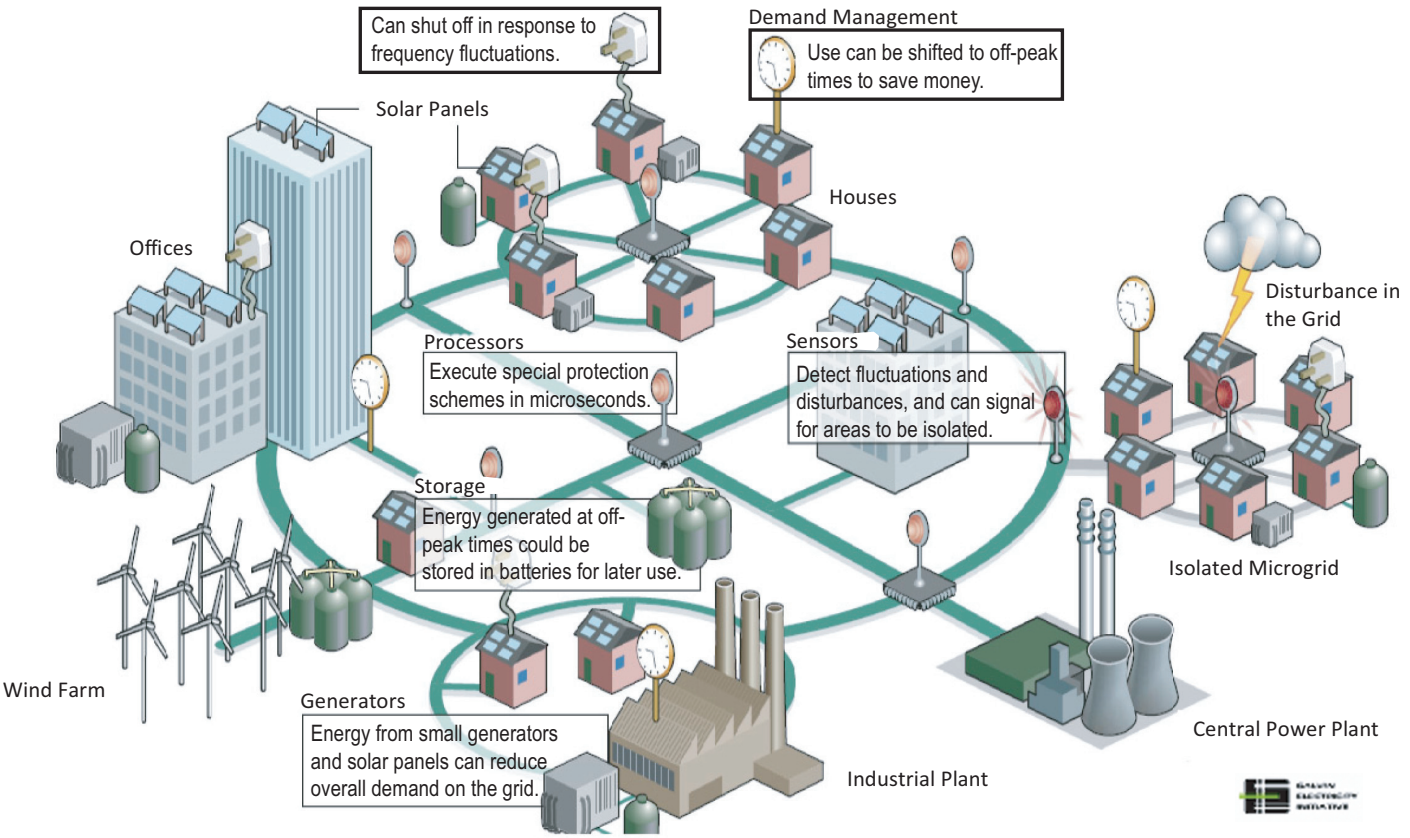

Figure 15.11 | An example of a Smart Grid, a network of integrated microgrids that can monitor and heal itself. Source: Amin, 2008.

operation, while monitoring for potential problems that could interrupt service. When a potential problem is detected, appropriate corrective action will automatically be taken. This includes "intelligent islanding," which can instantaneously separate the transmission and distribution system into self-sustaining parts, so as to maintain electricity supply under all conditions. The result is a system that optimally balances electricity supply and delivery, minimizes losses, is self-healing, and enables next-generation electricity supply, energy efficiency, and demand-response. First and foremost, it opens the door to a strong demand-side response to price signals, thereby reducing the need for peak generation, improving the use of capital, and affording better asset management throughout the entire energy chain – all with positive repercussions for the environment. This smart delivery system can also pave the way to more rapid introduction of new, more energy-efficient, end-use technology.

Perhaps the most important ultimate attribute of a smart electricity-delivery system is its capacity to assimilate significant quantities of variable renewable energy. As the National Research Council has recently concluded, the current, electromechanically controlled, electricity delivery system generally cannot reliably transport more than single-digit percentages of non-hydro, variable renewable energy without requiring self-defeating quantities of backup electricity generation or bulk-storage capacity, which is limited today to pumped hydropower (National Academy of Sciences, 2009). A green electricity system must indeed be a smart electricity system and will incorporate the following basic technological modernization improvements (NETL, 2007):

- Transitioning the electricity transmission and distribution system from what is now typically a radial design to a true network will ensure absolute connectivity from electricity generation sources to end-uses.

- Converting the transmission and distribution system from an electromechanical to a comprehensive, digitally monitored, electronically controlled network will enable continuous, instantaneous two-way communication between electricity users and suppliers, so that all consumers have the ability to move from passive to active marketplace participation.

- Incorporating locally distributed energy and CHP resources will translate into much higher efficiency and reliability, and much greater use of variable renewable energy.

All the elements of the smart grid are linked and in constant communication to optimize performance. It is indeed a supreme irony that computers, sensors, and computational ability have transformed every major industry except electric power-generation, whose product is the lifeblood of the modern global economy.

Several specific technology-related capabilities are pacing the implementation and full value operation of smart electricity-delivery systems (EPRI, 2010):

- Operating models and system impact algorithms. Simulation tools address the transient behavior of the modern grid incorporating renewable energy. These include improved operator visualization techniques, new training methodologies, and advanced simulation tools. Advanced simulations provide an accurate and complete understanding of grid behavior, as well as assisting system planners in designing reliable power-delivery systems.

- Nanotechnology sensors. Fundamental to system reliability is the comprehensive incorporation of sensors that instantaneously track conditions of the system. It is therefore surprising that nano-sensors based on magneto-resistance (the change of resistance in the presence of a magnetic field) are still not widely used in electricity carrier systems. By comparison, 250 million such sensors are produced for the hard disk industry, at a cost of a few dollars per sensor.

- Phasor measurement units (PMUs). PMUs are ideal for monitoring and controlling the dynamic performance of a carrier system in measurement systems for wide geographic areas. By 2012, for example, China plans to have PMUs throughout its electricity carrier grids, including all 500 kV substations and all power plants of 300 MW and above. All PMUs are connected via private network, and performance signals are received within 40 milliseconds on average.

- Standards and protocols for system interoperability. The lack of consistent, open standards for comprehensive system communication among all automatic components, including distributed energy resources, leads to market fragmentation, a major deterrent to smart-grid progress. The IEC 6/850 standard for substations is a valuable first step, but it falls short of addressing the interoperability requirements raised by the modernization of the entire electricity delivery system.

- Cyber-security solutions. As the control system becomes more automated, cyber security becomes a pacing issue. Although numerous security products exist on the market today, each is designed to address a specific security concern and there is no "one-size-fits-all" solution. The security for this carrier control system must provide in-depth defense, by seamlessly integrating an array of technologies to ensure that the carrier is controlled safely, securely, and meets all reliability expectations at all times.

An additional advantage provided by smart-delivery systems is greater use of direct current. DC has several advantages for distribution networks. DC-distributed links, for example, can supply power directly to digital devices at the customer's site, and connect renewable energy resources, without the need for costly and inefficient individual DC-to-AC convertors. These DC-distributed links also increase reliability by reducing the spread of disturbances from one customer to another, while enabling each facility to operate independently using distributed generation and storage. Because of its cost-saving advantages, DC distribution is becoming more widely used, especially in high-technology facilities such as data centers. Several Japanese suppliers are actively marketing DC systems for broad commercial and residential applications. Portable computers, televisions, and game consoles are all powered by DC electricity. Even washing machines, air conditioners, and fluorescent lamps convert AC into DC, and then convert it back to high-frequency AC with inverters.

Today's bulk-electricity supply and delivery systems were typically designed and built with the primary objective of keeping pace with the rapid growth in demand associated with initial electrification. Those days are long over throughout the developed world, yet little has been done in most countries to update either the infrastructure or the business incentives to focus on efficiency and quality. The electricity meter, for example, still holds retail consumers hostage to an electricity supplier monopoly over which they have essentially no market leverage. Technology is available to break down this iron curtain meter, just as the internet transformed communications. And, like the internet, consumers, suppliers, and society alike will benefit from a differentiated, service-based market business model. The incentives should be to add maximum value to each electron, not to maximize the quantity of bulk electricity sold to captive consumers (Yeager, 2008).

One of the quickest and most effective ways to achieve the greatest consumer and community benefits from the smart grid is through the microgrid – a small-scale, power-supply network, designed to provide power to a small community or a few buildings. Modern microgrids, utilizing smart grid technology, are an emerging distribution configuration. They offer significant economic and environmental benefits compared with the alternative of simply expanding the legacy electricity transmission and distribution systems. The benefits of microgrids include autonomy, stability, compatibility, flexibility, scalability, efficiency and economics. Microgrids can provide a superior match between electricity generation and load. Thus, they have a low impact on the existing electricity delivery system, despite incorporating significant amounts of variable renewable energy resources, such as photovoltaics (PVs). Because small electricity generators are also close to the users in microgrids, any waste heat can be easily recovered, and total energy efficiencies in excess of 80% can be achieved. This compares very favorably with the 30% or less efficiency for a typical electricity-generation and delivery system today (Energy Business Reports, 2008).

A key feature of the microgrid is the seamless interconnection of supply and demand. Particularly important here is the incorporation of buildings as suppliers, as well as users, of electricity. The sustainability implications here are profound because buildings are typically the largest users of electricity on a national scale, and thus also account for a large fraction of carbon emissions. Embedding intelligence into the physical fabric of each building allows all functions, appliances, and energy sources to "communicate" with one another, automatically

coordinating their activities for the greatest efficiency and economy. The result makes zero net-energy buildings a realistic goal in most regions of the world (Cheung and Wilshire, 2010; see also Chapter 10).

It is also becoming feasible to incorporate mobile electricity storage in the form of plug-in electric vehicles. Microgrids will enable an electricity delivery network strategy, where transportation can become an efficient energy-supply source, particularly during high-cost, peak-demand periods. The essential enabling policy step to realize the full benefits of DG, microgrids and plug-in electric vehicles is time-of-use electricity pricing, which encourages consumers to be efficient and to take advantage of resulting savings.

In effect, the microgrid is a local electricity refinery, raising the reliability, efficiency, and quality of the electricity supply. Although a variety of microgrid ownership and operation alternatives are possible, microgrids intrinsically lend themselves to local "co-operative" ventures, where consumers are also suppliers. Metering and billing arrangements are agreed on locally to reflect market needs within each microgrid. Microgrids can also take full advantage of currently commercial energy-storage technology, so as to accommodate rapid fluctuations in electricity demand or supply.

Microgrid development in the United States has taken a somewhat different path from similar efforts in Japan and Europe. In the United States, the emphasis has been on compensating for the relatively poor reliability and power quality provided by the nation's bulk-electricity supply system. This is in contrast to Europe and Japan, where incorporating clean, distributed electricity generation has been emphasized. In other countries DG and microgrids are seen as a means of avoiding the costly upgrades of transmission lines that are nearing capacity limits due to increasing local demand. Microgrid development efforts in the United States have been led by the Consortium for Electricity Reliability Solutions (CERTS) and, more recently, the California Energy Commission (2008) and the Galvin Electricity Initiative (2010). Prototype microgrid demonstrations range from the Fort Bragg military base in North Carolina to the Illinois Institute of Technology campus in Chicago. General Electric is also developing a Microgrid Energy Management framework to provide a unified control, protection, and energy management platform.

In the EU, several major research efforts have been devoted to DG microgrids. Demonstration sites include Kathnos Island, Greece, and Mannheim-Wallstadt, Germany. Japan is also a leader in microgrid demonstration projects that generally emphasize ensuring that the variable power of distributed renewable energy does not degrade Japan's outstanding electricity reliability and power quality.

In terms of the growing international concern regarding energy security and sustainability, modern microgrids are also attractive. In addition to providing a cost-effective approach to the modernization of transmission and distribution systems, they can be dispersed through the electricity delivery system close to consumers, where they can protect against the failure of a large power plant or bulk-electricity transmission facility. They also diversify the energy resource base by incorporating distributed renewable energy resources. However, clear policy and associated regulatory instruments are needed to capture the benefits of microgrids and to integrate them into existing electricity distribution networks. With a very high share of variable renewable energy sources, power balancing can become a huge challenge. Such a power-supply system would require the use of all potential balancing measures, including new transmission lines between regions, new flexible generating plants, demand-side management, energy storage, advanced weather forecasting, clear rules from the system operator, and the use of existing distributed resources within the system.

End-users have the potential to contribute to system balancing. Several types of demand, notably electric heating and cooling systems, can be operated in a flexible manner that responds to signals from the power company. As the number of small-scale DG units increases, many of these can also be used in ways that help balance the system. Future storage technologies, such as electric vehicle batteries, also have the potential to act as flexible balancing measures.

Power systems are currently undergoing some fundamental changes in structure and operation. These changes are associated not only with the rapidly increasing amounts of renewable energy being connected to the system, but also with the development of new types of production and end-use technologies. One such change is a general increase in the number of distributed production units that are smaller in scale than traditional thermal power plants. This development will, in the future, include low-voltage connections from micro-CHP plants in individual households. On the low-voltage side, another important trend is the active control of demand, which introduces a new way to provide some of the necessary flexibility in power balancing (UNEP, 2007).

In parallel with this development is the increased use of Information and Communications Technologies (ICT). The communications capabilities of electric devices are expanding rapidly while also becoming cheaper. This enables a power system which incorporates two-way communication with end-users, and is therefore one of the most important enabling technologies for future power systems. Advances in measuring technology and advanced computational methods, e.g., for predicting weather, energy demand, and price, create new ways to control the entire power system (Larsen and Petersen, 2009).

Few countries have a comprehensive and coordinated set of policies and incentives to promote micro-grids. Subsidies for renewable distributed generation, utility revenue decoupling, time-of-use pricing, and independent zero-energy districts all act as enablers for microgrid development.

Distributed generation comprises the cornerstone of the new microgrid paradigm. While CHP units will certainly play a role, the escalation of

renewable distributed generation will be the focal point. The microgrid development model allows the ability to maximize value from private customer investments. By far the largest and most important renewable distributed generation technology is distributed photovoltaics. Germany in particular has set the most aggressive goal, aiming to generate 25% of its total electricity capacity from solar photovoltaics. This level of penetration will require microgrid-like controls and management. Small wind turbines are also becoming a more important energy asset enabled by microgrids. Micro-scale energy-storage systems, particularly batteries, complement intermittent renewable energy sources and are also considered a key immediate driver of microgrids. These storage systems offer clear economic benefits for renewable distributed generation. When the sun is shining or the wind is blowing, a storage system builds up the electricity reserve for sale or dispatch.

Since the interest in smart-grid technologies is in dramatic ascent, microgrids are attracting considerable attention from both policy and investment sectors. While much of Europe and Japan have upgraded their grid infrastructure, these countries have traditionally emphasized more aggressive policy support for the distributed generation technologies that are driving the acceleration of microgrid developments. That said, Japan and Korea, two leaders for microgrid technology, enjoy power surpluses and therefore have limited need for microgrids today. However, within the next five years, the new generation of microgrid configurations is expected to be fully commercial, setting the stage for major global commercialization progress. Elsewhere around the world, Denmark and China are leaders in the microgrid market. An important economic advantage of microgrids is related to the payback period. Estimates of paybacks for microgrids range from two to five years. Renewable energy microgrids also offer increased co-benefits such as improved health, employment, rural development, system reliability and avoided transmission infrastructure, compared to traditional utility power, with non-renewable microgrids offering a benefit rate of three-to-five-fold over today's basic grid services (Lovins and Cohen, 2010).

15.8.4 Storage

Unlike other energy forms, electricity cannot be easily stored in large quantities where hydro capacity is not available. Without storage, there is little flexibility in managing electricity production and delivery, or in seamlessly linking electricity supply and end-use. Likewise, variable renewable energy resources are constrained in their ability to enter the bulk-electricity market and keep pace with continuously changing demands. Advanced storage technologies promise to change the nature of electricity markets by providing much greater operational and financial flexibility, and enabling carrier systems to resolve system transients and bottlenecks. The critical pacing issue is the accelerated development and implementation of more cost-effective, higher-capacity storage options, including batteries, flywheels, supercapacitors, hydrogen, and superconducting systems. Today, most of these bulk-storage options are relatively unproven, and their value proposition is complex and poorly understood (National Academy of Sciences, 2009).

Currently, the only battery commercially available for large-energy storage is the lead-acid battery. Advanced batteries being developed for large-scale applications, include nickel cadmium, sodium sulfur, sodium nickel chloride, lithium ion, and zinc bromine. Although considerable progress is being made, these generally remain too expensive for large-scale applications. The first of these advanced batteries is anticipated to be fully commercialized in the very near future, and significant cost reductions are expected as modular design and factory assembly become the norm, and production volumes increase substantially. Particularly notable from a strategic perspective are the lithium-ion battery (for electric vehicles) and the sodium sulfur battery. Japan has demonstrated a total of more than 20 MW of energy storage using sodium sulfur batteries. In August 2003, the world's largest battery energy-storage system began operating in Fairbanks, Alaska, using nickel-cadmium cells to generate 40 MW for up to seven minutes at an installed cost of US$35 million.

Over the long term, energy storage can potentially resolve the intermittency challenge of renewable energy. The types of storage under consideration range from pumped hydro and compressed air energy storage to advanced, stationary batteries. A notable example of wind-hydro synergy is Denmark's grid: this can absorb a great deal of wind because of its strong electricity transmission ties to the hydroelectric systems in Norway, Germany, and Sweden. In the absence of storage, the alternative today is to locate conventional fossil-fired power generation near to the variable renewable energy resource. This, of course, diminishes the environmental value of the renewable energy resource and raises the competitive hurdle.

Energy carriers such as hydrogen and ethanol may become important in interconnection and the storage of energy from renewable energy sources, and they have the potential to provide the interface for renewable energy sources to mobile users.

Hydrogen is an important implicit dimension of the ultimate "electrified world" scenario. The electro-hydrogen economy refers to hydrogen being generated from low-cost, clean, off-peak electricity generation, and stored and delivered as feedstock to fuel transportation, electricity generation, and industrial processes.

15.8.5 Policy and Investment Considerations

The transition to a greater use of locally distributed generation will increasingly make the local microgrid the design and operational focus of electricity supply systems, and the entire enterprise must be redesigned accordingly. The 20th century principle that an electric utility is a vertically integrated, natural monopoly has been slowly evolving under the pressure of technological progress and deregulation. Unfortunately, much of the world is still laboring under an electricity regulatory

structure. This maintains an obsolete business model with incentives to simply produce and deliver more commodity electricity, rather than compensating suppliers based on the efficiency and reliability of their electricity services.

Market reform for electricity supply and delivery is a relatively new initiative now being applied in a variety of situations throughout the developed world. As a result, sufficient experience has been gained to begin to evaluate its advantages and disadvantages as a tool in achieving universal, sustainable, global electrification. The potential of decentralized competitive markets to match supply and demand most efficiently is a well-proven principle at the heart of the developed world's commercial economic system; based on that success, it is rapidly becoming the standard for economic systems around the world.

Nonetheless, the application of market-based liberalization to the electricity sector over the past decade has had mixed results. Particularly with regard to developing regions of the world, it is important to consider the lessons learned and the possible causes of this checkered performance. Does this simply reflect a learning curve, or are there some basic limitations in applying market reforms to the electricity sector? The reforms in place typically bear little resemblance to the theoretical, market-oriented ideal. Certainly, the critical values of electricity to economic prosperity and societal welfare make it unusually susceptible to political manipulation, irrespective of governmental structure or the level of economic development (Smil, 2005).

What then can be concluded about the role of market reform in facilitating global electrification? Because surplus electricity supply is, by definition, not a circumstance facing the developing world, it is doubtful that market reform as it has been widely applied in much of the developed world, will stimulate investment on the scale required. Certainly, its initial applications have failed. Market reform is primarily a tool dependent on the more fundamental conditions of national performance. These include governmental and institutional stability, the rule of law, and sound fiscal policies. In the absence of these conditions, no amount of market reform is likely to make a difference. Where these conditions do exist, market reform can be valuable if applied to achieve its intended purpose – sustainable economic development and efficiency.

One interesting variation on market reform is the local market paradigm emerging in many rural regions of the developing world, where electrification is being initiated from the bottom-up, rather than the top-down, through village-scale microgrids under local management and control. These local cooperatives provide the direct consumer access and market transparency that top-down systems generally lack and – by virtue of their politically based institutions and commodity business culture – have great difficulty in achieving. The process of local rural electrification, whereby these distributed "PC-like" microgrids seek to network with each other to expand their capability, is also a fertile context for extending the locally established market culture. All other factors being equal, perhaps the most important advantage in building markets from the ground up, relative to reforming the status quo, is the more encouraging environment they may produce for both innovation and investment.

The lessons learned about what works and what does not show that neither the central planning approach of the 1950s and 1960s, nor the minimal government, free-market approach broadly advocated over the last 20 years will necessarily be successful. The most effective approaches to electrification will be led by the private sector in most cases, but with a stable governance framework that facilitates physical infrastructure and human capital investments, along with the social cohesion necessary for economic development and poverty reduction. Institutional development has too often been neglected in past policy discussions, but it is essential to achieve energy access and sustained poverty reduction. Successful development of this new paradigm will therefore depend on a robust, strategic public-private partnership for global development (Yeager, 2007).

Global electrification-related policies must become better at anticipating and synthesizing the revolutionary, disruptive changes underway in demographics, technology, communications, and commerce, which are currently shaping global politics, and energy and overall security in the 21st century. Because of these changes, people's aspirations – to exercise their free will and transform their lives – are rising in all corners of the globe. Policymakers must also recognize that progress is not automatic. The course of this century will be fraught with great risks. These must be wisely managed as we aim for the unambiguous goal of enabling universal wellbeing, a goal that must also be sustainable within our evolving civilization. A policy of universal electrification is the necessary energy foundation on which to resolve the pacing global "trilemma" of people, poverty, and pollution, and most importantly, to avoid failed aspirations that create intolerable levels of frustration, despair, and anger (see also Chapter 23). Failure is not an option and hope is not a strategy for addressing this global survival challenge (Patterson, 2009).

Impatience for immediate results that maximize short-term commercial returns is a lever of vulnerability impeding global electrification and modernization. Reviving the commitment to strategic investment in human and capital infrastructure is essential to sustainable global development and wellbeing, and the public-private partnerships and policies needed to realize this survival goal must be given renewed priority. Integral to this priority is the urgent need to boost development and investment in advanced energy technologies. The lag time between research and large-scale commercial deployment is sobering, yet funding for energy R&D continues to decline.

> "Civilizations decline when they stop the application of surplus to new ways of doing things. In modern terms we say the rate of investment decreases. This happens because the social groups controlling the surplus have a vested interest in using it for non-productive but ego-satisfying purposes … which distribute the surpluses to consumption but do not provide more effective methods of production" (Huntington, 1998).

15.9 Hydrogen

15.9.1 Overview

Hydrogen is a substance that may be used as an energy carrier and as a storage medium. Although hydrogen is the most abundant element in the universe, it does not exist in pure concentrations of its elemental form or as molecular hydrogen on earth. Hydrogen is abundant in the molecular structure of coal, petroleum, natural gas, biomass, and water and can be produced from these materials. Hence, hydrogen is not a source of energy, but energy is required to separate hydrogen from any of these hydrogen-containing materials. In principle, the energy source for the production of hydrogen may be any of the fossil fuels, nuclear, or renewable energy forms, although using nuclear or renewable energy enables a straightforward route to low-carbon and sustainable hydrogen, although likely at some additional cost.

Hydrogen as a complimentary energy medium offers clear benefits to the world's future energy economy. However, the potential for the hydrogen revolution still remains a speculative vision. Not the least of the challenges is the high energy-losses involved in producing hydrogen, which means that this system demands plentiful, low-cost electricity. The long-term goal is to achieve an emission-free energy system. Since the synthetic hydrogen energy carrier cannot be cleaner or more efficient than the energy from which it is produced, this means renewable or nuclear energy. High temperature gas-cooled reactors with the ability to operate at core outlet temperatures of 850ºC or above could, for example, be used to drive a variety of thermal processes for hydrogen as well as electricity production. Fuel cells are projected as the primary end-user for hydrogen with water as the byproduct. A mega-infrastructure in which liquid hydrogen pipelines also act as the cryogenic vehicle for the superconducting, zero-resistance transmission of electricity is certainly an exciting opportunity for the second half of the 21st century.

Hydrogen can be used in the same way as other gaseous fuels in combustion, or in an engine for conventional power generation, such as automobile engines and power-plant turbines. The current use of hydrogen engines is a relatively well-developed technology in the United States, with the space shuttle and unmanned engines. Vehicles with hydrogen-fueled internal combustion engines are now in the demonstration phase. However, the highest value use of hydrogen is in fuel cells, which are relatively cleaner and more efficient than conventional technologies, including onsite generation for individual homes and for businesses. Hydrogen in a fuel cell produces electricity and water with zero greenhouse-gas emissions, and efficiencies greater than when hydrogen is used in an engine.

Fuel cells are in various stages of development and efficiencies are generally in the 40 to 50% range. Phosphoric-acid fuel cells are the most developed fuel cells for commercial use. Many stationary units have been installed to support the grid with reliable backup power, and mobile units are powering buses and other large vehicles. Solid oxide and molten carbonate fuel cells operate at high temperatures and are therefore best in generating electricity in stationary, combined-cycle applications, and applications in which the excess heat can be used for cogeneration of electricity or as process heat. They are also a good fit for portable power and transportation applications, especially large trucks. Alkaline fuel cells have been used in military applications and space missions and are currently being tested for transportation applications. Polymer electrolyte membrane (PEM) fuel cells operate at low temperatures and are being demonstrated in transportation, stationary, and portable applications. Interest in PEM fuel cells has experienced a large upsurge over the past few years, and most major automobile manufacturers are developing fuel cell cars at the demonstration stage.

Nearly all major automobile manufacturers have a hydrogen fuel vehicle program, with various targets for demonstration. The early fuel cell demonstrations will consist of fleets of between 10 to 150 vehicles. To limit initial capital investment, these early vehicles were deployed in fleets with a centralized or shared refueling infrastructure. Hydrogen-fueled internal combustion engine vehicles are generally viewed as a near-term, lower-cost option, which can foster the development of a hydrogen infrastructure.

Stationary power production includes backup power units, grid management, power for remote locations, stand-alone power plants, DG, and cogeneration (see, for example, USDOE, 2002 and USDOE, 2007). The industry for commercial fuel cells for stationary applications is still in its infancy. Most existing fuel-cell systems are being used in commercial settings and operate on hydrogen reformed onsite from natural gas. Extensive use in this setting would require widespread availability of hydrogen.

The development of hydrogen as an energy carrier and storage media requires the evolution of technology for a new infrastructure consisting of three system elements: (1) conversion; (2) transmission and distribution; and (3) storage (see also Chapters 12 and 13).

15.9.2 Conversion

Hydrogen can be produced using any of the fossil fuels, nuclear power, or renewable energy, and be derived from any of the feedstock materials coal, petroleum, natural gas, biomass, or water. Most hydrogen produced today in the United States is used for chemical production, petroleum refining, metal treating, and electrical applications. Thus, hydrogen is primarily used as a feedstock, intermediate chemical, or as a specialty chemical. Steam reforming of natural gas accounts for 95% of the hydrogen produced in the United States. The least costly route to produce hydrogen is steam reforming of natural gas and is carried out in large, centralized facilities with carbon dioxide as the principle byproduct (USDOE, 2002; 2007).

Challenges include:

- high hydrogen conversion costs,
- low demand inhibiting development of production, and
- current technologies are not optimized for making hydrogen and produce large quantities of carbon dioxide.

Research, development, and demonstrations are needed to provide innovative methods of economically producing hydrogen. There is a portfolio of existing commercial processes such as steam reforming, multi-fuel gasifiers, and electrolyzers, and on the development of advanced techniques such as biomass pyrolysis and nuclear water splitting, photoelectrochemical electrolysis, and biological methods which are all promising options for the future. Renewable energy pathways offer a variety of carbon-free hydrogen that are generally longer-term but promising options (Figure 15.12).

The paths forward are different for each of the hydrogen technology areas, but recommendations for policy actions include maintaining a stable research and development funding base, providing incentives for pilot and demonstration scale tests and operating facilities, and providing market incentives as the technologies show promise.

15.9.3 Transmission and Distribution

A key element of the hydrogen-energy infrastructure is the delivery system that transports hydrogen from the point of conversion to end-use. For current applications, pipeline or trucks hauling high-pressure cylinders or cryogenic tankers are used. Rail cars or barges ship a small amount. Pipelines are currently limited to a few areas of the United States and other OECD nations where large refineries and chemical plants are concentrated and are owned and operated by merchant hydrogen producers.

The vision for hydrogen transmission and distribution is a network or infrastructure to accommodate both centralized and decentralized production facilities. Pipelines could transport hydrogen to high demand areas, and trucks and rail cars will distribute hydrogen to rural and other low demand areas. Onsite hydrogen conversion and distribution facilities could be built where demand is high enough to sustain operations.

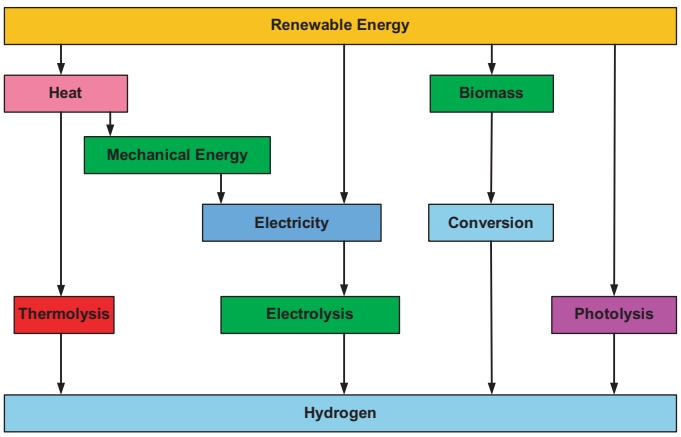

Figure 15.12 | Renewable paths to hydrogen.

The path forward is to enhance current transmission and distribution systems for safe and affordable operations through policy actions such as increasing research and development on delivery systems, developing a cost analysis of hydrogen transmission and distribution systems, and providing incentives and funding for hydrogen delivery demonstrations, such as fueling stations and power parks, in order to evaluate the hydrogen infrastructure components.

15.9.4 Storage

Storage issues cut across the conversion, transmission and distribution, and energy end-use pathways for the use of hydrogen as an energy carrier. Vehicle applications drive the development of safe, space-efficient, and cost-effective storage systems. However, other applications will benefit from all the technological advances made for these on-vehicle hydrogen storage systems (US DOE, 2002; 2007).

Hydrogen can be stored as a gas, liquid, or chemical compound. Technologies that are currently available permit the physical storage, delivery, and end-use conversion of gaseous or liquid hydrogen in tanks and pipeline systems. Compressed gaseous hydrogen storage is a mature technology and adequate vehicle range can be achieved, but with a significant volume and weight penalty. Liquid hydrogen requires less storage volume than gas, but requires cryogenic temperatures and associated insulated containers. The liquefaction of hydrogen is an energy-intensive process and results in energy losses up to approximately one-third of the energy content of the hydrogen. Other technologies in the early stage of development are reversible metal hydrides or absorption on carbon structures. Hydrogen is absorbed and released from these materials by relatively modest changes in temperature or pressure. Chemical hydrides are also being investigated as a hydrogen-storage alternative.

The vision for hydrogen storage is to achieve relatively lightweight, low cost, and low volume hydrogen-storage devices to meet the hydrogen-economy needs. Compressed hydrogen storage is a mature technology and adequate range can be achieved; however, an even better storage method would be desirable. Several automobile manufacturers are considering liquid-hydrogen storage because of its good volumetric storage efficiency. However, the special handling requirements, long-term storage losses, and cryogenic liquefaction energy requirements currently detract from its commercial viability. Metal hydrides offer the advantage of lower-pressure storage, comfortable shapes, and reasonable volumetric-storage efficiency.

Before hydrogen can become an acceptable energy option for the consumer the technology must be made transparent to end-use, similar to

today's experience with internal-combustion, gasoline-powered vehicles. Specific challenges include:

- research and development investment levels that are currently insufficient;
- costs of the round-trip, chemical hydride formation process that are too high;
- weight penalties are too high and thermal-management issues for metal hydrides are unresolved; and
- carbon materials adsorption and release of hydrogen that do not have practical processes developed.

15.9.5 Policy and Investment Considerations

Policy actions needed for the development of fuel cells include research and development to lower costs and enhance manufacturing capabilities, support for industry to develop profitable business models for distributed power systems and optimizing fuel cell designs for mobile and stationary applications, and incentives for demonstration facilities to provide information on operating performance. Policy actions for the development of hydrogen storage include increased research and development in hydrogen storage, supporting the development of innovative and high-risk technologies, and providing incentives and funding for a large-scale production process for the most promising hydrogen-storage materials.

15.10 Summary and Conclusions

Cumulative investments are needed throughout the energy sector in order to be able to meet the growth in energy demand in a sustainable manner. From 2007–2030, these investments, mainly in the power, oil, and gas sectors, have been estimated by the IEA to be over US$26 trillion (Figure 15.13). Over 65% of these investments are projected to be in non-OECD countries (IEA, 2008a). Delays in investments may result from the financial crisis that began in 2008, and there will be changes in these investments if an international agreement on greenhouse-gas emissions should come into force.

To stabilize atmospheric greenhouse-gas emissions at around 550 ppm-eq in the long term, and aim for a global temperature rise of around 3°C, would require an additional investment of US$4.1 trillion to deploy and improve existing technologies. This equates to around 0.24% of annual world GDP. Cumulative savings from concurrent energy-efficiency measures could yield US$7 trillion (IEA 2008a).

To stabilize at 450 ppm CO_2-eq will require new technologies to be developed (IEA, 2009a), as well as rapid deployment of both new and

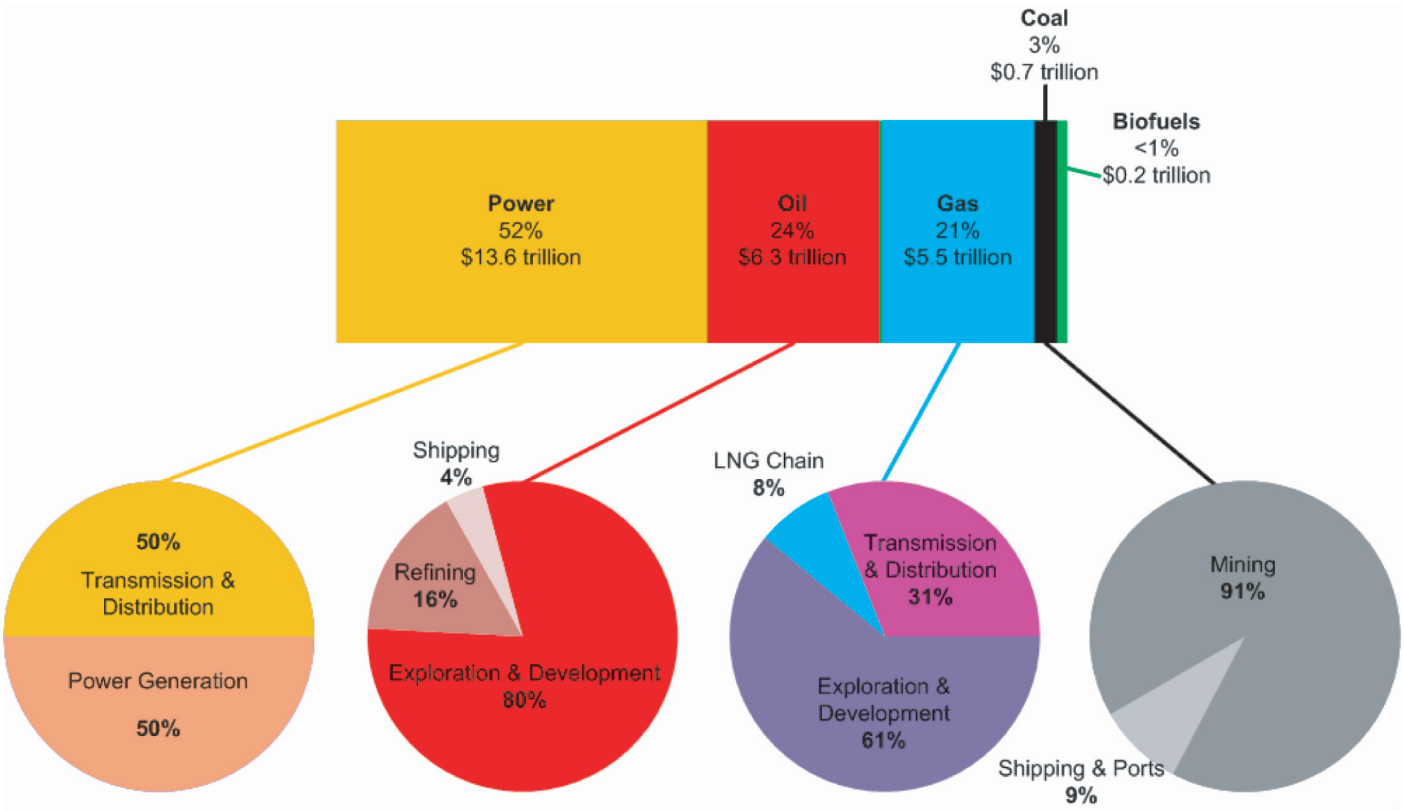

Figure 15.13 | Cumulative world investment in the energy supply sector and infrastructure under business-as-usual to meet growing energy demand and replace old plant stock at end-of life. Source: data from IEA, 2008a.

existing technologies (see Figure 15.10). An additional investment of US$2.7 trillion in more energy-efficient equipment, buildings, and appliances, together with US$2.4 trillion in low-carbon, power-generation capacity would be needed, in total equating to around 0.55% of annual world GDP by 2030. Cumulative savings would again help offset the investment costs. The GEA pathways estimates required investment needed to achieve less than 2°C compared with preindustrial times to be between US_{2005}68–87 trillion or US_{2005}1.7–2.2 trillion/yr or about 1.8–2.3% of global GDP (see Figure 17.26, Chapter 17).

Different models and pathways all show the importance of investment in renewable and end-use technologies to reach climate targets. The IEA and GEA analyses show that investments in power-generation energy technologies are necessary for all fuels, but with less emphasis on coal and gas (other than CCS) and more on renewable and nuclear (IEA, 2009a). The same investment strategy applies to end-use technologies, such as heating/cooling and conversion for transport fuels, biofuels, or hydrogen fuel cells. GEA pathways show in addition that the transformation toward the targets would be more cost-effective under pathways that focus on efficiency improvements.

15.11 Insights

In the 21st century, with a population approaching 10 billion people, it is essential that no energy resource be overlooked. By mid-century, at least two-thirds of the world's population is projected to be concentrated in urban locations (see Chapter 18). This underscores the importance of considering all sources of energy and their conversion, transmission, and perhaps most importantly, energy end-use efficiency improvements. With many and varied energy sources available, it is end-use utilizations of energy that have the most potential to achieve energy and energy-system sustainability.

In addition to energy sources, sustainable methods for conversion to carriers, along with transmission and distribution systems that can be employed for the most important end-uses, are crucial. This places particular emphasis on energy carriers to move energy from relatively remote production locations to growing urban population centers. Natural gas, as a lower-carbon fossil fuel and energy carrier, could in some situations be a bridge to the low-carbon future.

Electricity and hydrogen can be efficiently used and are critical to the availability of affordable and acceptable energy. Markets and the scale of international carbon trading will determine how much of each technology is employed in each geographic region, when this happens, and how rapidly. Heat is important to industrial processes, as well as for residential and commercial uses, and should be employed wherever feasible.

Providing integrated storage systems for this energy is essential for making optimal use of the energy sources and carriers that exist. If affordable, these energy-storage systems are key to achieving a sustainable system that is also economic and secure, and under minimum stress.

The entire energy grid for each system, from energy source through conversion to end-use must be optimized into smart grids. These will use the latest ICT in order to transition to a digital system that communicates between source and end-use continuously, employing all energy carriers and their transmission and distribution systems, heat, electricity, and hydrogen in a coordinated fashion. In this way, the operation of the entire energy system can be optimized to take advantage of the qualities, efficiencies, and productivity of each component. The production of hydrogen from surplus electricity in off-peak periods, and its conversion back to electricity for lighting or mobility, is just one example; all combinations become possible.

The capacity for competitive markets to match supply and demand most efficiently is at the heart of the developed world's economic system – and means that this model is rapidly becoming the standard for economic systems around the world. These markets will also most likely determine the future of decentralized grids worldwide.

In countries with well-developed energy markets, liberalization has often been imposed, along with privatization, unbundling, and enabling consumers to choose energy suppliers. This has led to spot-market energy trading, with the result that long-term contracts are less often the norm. The result for energy supplying countries is generally negative, as it becomes more difficult to ensure returns on large-scale investments. There is thus a threat of destroying the financing tools for large capital-intensive projects in the critical energy-supplying countries (see also Chapter 22).

15.11.1 Conclusions

The private sector will lead in developing and deploying most of the effective approaches, but will need a stable governance framework, facilitation of physical infrastructure, capital investments, and the social cohesion necessary for economic development and poverty reduction, while protecting public health and the environment. Success depends on the implementation of robust, global public-private partnerships that can achieve unprecedented cooperation and integration between governments, between businesses, and between governments and businesses. To have an effect on the changing and growing energy sector, this must happen rapidly.

In order to improve current energy systems, and their capacity to meet rapidly changing needs, it is essential to boost development and investment in advanced energy-sector technologies and integrated systems, from the energy source, through conversion and transmission, to distribution and end-use. The lag time between research and large-scale commercial deployment is long, and funding for energy RD&D continues to decline worldwide. This trend should be reversed with enhanced cooperation between private businesses, between public agencies, as well as between the public and private sectors (see also Chapter 24).

Appendix A: Demand Side Management

The term 'demand-side management' (DSM) was once coined as the utility alternative to supply-side "overspending" in energy systems. The demand-side "negawatt hour" (nWh) was made the conceptual alternative to the supply-side megawatt hour (MWh). However, DSM is not only a utility-tool, but also covers the more general large-scale deployment by use of programs to attract and raise customer interest in which utilities may be a part. Implementation of DSM is also evolving due to both new technological possibilities and requirements regarding energy security and environmental sustainability of systems.

15A.1 One System, Different Measures and Different Actors[10]

- The problem: optimization of a system that is operated by many actors, not all of whom consider (or recognize) energy as an issue.
- The solution: finding a way to deploy (mainly existing) end-use technology on a larger scale on the demand side, in order to obtain the cheapest solution for the energy services (light, climate, motive power).

Industry could be assumed to be more knowledgeable about the energy issues than, for example, residential customers. However, in industry, a great proportion of the energy used even in the energy-intensive branches is used for "trivial purposes" in motors, lighting, ventilation systems, small tools, etc. It is seldom considered and calculated in the way that is done for process-equipment.

The measures to manage demand are basically two: either (1) mandate that something should be done or (2) make use of the market and the economic instruments (Table 15A.1). Mandating is typically used to give explicit information or explicit tasks about certain technologies and certain actors that should be activated, whereas the market acceptance is used when the object cannot be easily identified, but the performance characteristic can be well defined.

The technical problem and challenge: there is a need to change the load shape (peaks and valleys) and to change the load level (conservation and growth). Whereas in the old days the objectives were formulated from the utilities need (and wish) to get a more flat and predictable load curve, the task today is more to serve societal needs and customers. The task is to keep the energy system working and to prevent blackouts and to shift from carbon-fat to carbon-lean systems, as illustrated in Figures 15A.1 and 15A.2.

15A.2 Energy Efficiency Supply Curves[11]

Since improvements in energy demand work on the energy system the same way as do additions in supply, it is necessary to compare demand-side reductions in the same terms as supply-side extensions. A revived technique is to use energy efficiency supply curves, i.e., curves that show the marginal costs for energy efficiency measures (McKinsey &

Table 15A.1 | Approaches, types of measures, suitability and examples of demand- side management to improve energy efficiency.

Approach	Type		Example of Measure	Suitability for Industry
Mandated	Standards		1. Minimum performance (MEPS)	Small motors, Lighting
			2. Top-runner standard	c.f. Energy Star computers
	"Agreed Actions"		3. Voluntary Agreements	For branches
			4. (Technology) Procurements	LCC Procurement guidelines
	Delegated Actions	By actor	5. Regional bodies	Chambers of commerce
			6. Municipalities	–
		By Means	7. Commitments	For SMEs
			8. Certificates	Quota obligations
Market Acceptance	Price-responsive customers		9. Taxes; Tax reduction	Combined with audits and agreements
			10. Price elasticity (Demand Response)	Common and neutral for all types
	Non-price responsive Customers	"Commoditizing" energy efficiency	11. Energy Services (ESCO) and Performance Contracting (EPC)	Outsourcing and facility management
			12. Labels	–

10 See also Chapter 8.

11 Early examples are presented in Fickett et al., 1990. The technique is also called Energy Conservation Supply Curves (see Worrell et al., 2003). Here the term is "energy efficiency supply curves" and is used to stress that the energy services (output) are at least similar to that of the system that uses more energy.

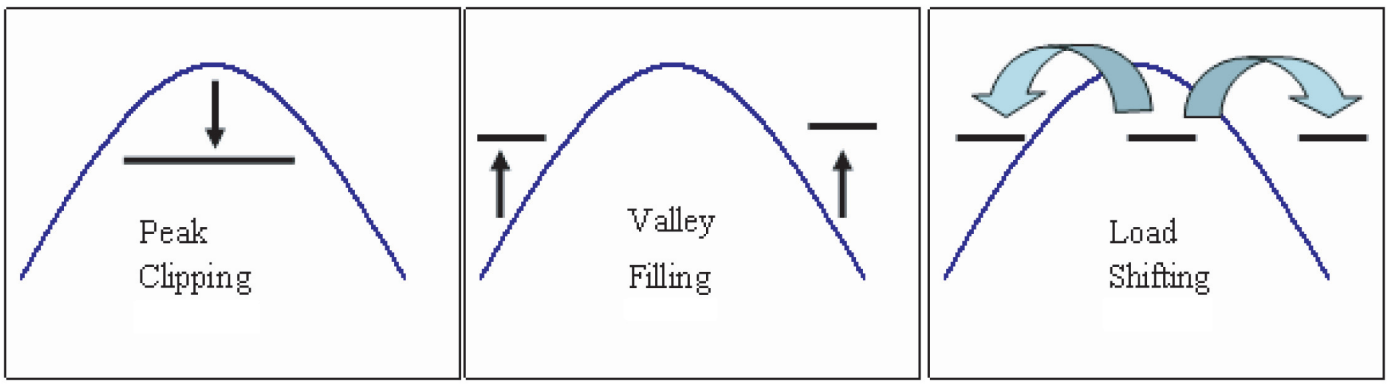

Figure 15A.1 | Load shape changes. Source: Gellings, 1982.

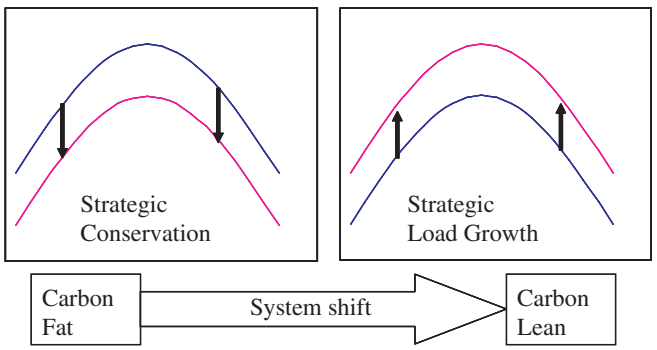

Figure 15A.2 | Load level changes. Source: Gellings, 1982.

Company, 2010). Energy Efficiency Cost (EEC) is calculated as the full cost of the alternatives minus the full cost of the reference solution divided by the annual energy savings, where:

- Full cost includes annualized capital costs over the improvement expected life-time (LCC)
- The reference solution is often the installed one and does not carry further capital costs

Changes in operating and maintenance costs are included in full costs, which also includes the cost for energy supply of each of the alternatives. Transaction costs are not included. Subsidies are generally not included, but could be added, depending on the purpose of the calculation.

Changes in productivity can be added in this calculation. This normally means a further reduction of the cost, since the basic assumption is that the pure energy services should be at least equal in the comparison.

With this formulation all economically attractive alternatives have negative costs.

The critique comprises two elements:

- Even when a calculation can show good reasons, from the point of view of the economic life-cycle, to undertake energy efficiency measures, it can still make sense for a single company to hesitate. The company may have severe difficulties and need to overlook the longer life-time of the alternative. On the other hand, they can make severe losses paying for wasted energy if they are too strict in their requirements for pay-back.
- Transaction costs and also costs for delivery of energy-efficiency measures can be quickly and substantially lowered by the "market learning process", when customers begin to demand the alternative. A programmed DSM-activity can be very useful in this process.

DSM, as a form for programmed large-scale deployment, is a useful measure to both lower the transaction costs and to release the market learning that facilitates the dissemination of cost-efficient technologies to the markets. The profitable efficiency improvements (having negative costs) are often in the range of 20–50% of the energy use. The major part of these will remain locked in without DSM-programs.

15A.3 DSM Formats

The implementation and utilization of DSM will be different in different parts of the world. In some places governments will be the operational agent, in others utilities – in some cases regulated by governments and in others operation in the free market. In any case, it is important that governments set the rules, enforce them. Rules must also not be changed very often so as to attract capital investments.

An excellent overview of the implementation of DSM, with examples from different regions and from the perspective of various government, business and consumer interests, along with costs and benefits of various approaches, can be found in IEA (2008b).

Executive Summary

This chapter examines the theme of transitions in energy systems. It assesses the literature that explores the genesis, growth, and management of transitions. This literature provides a multi-level framework for large-scale, transformative change in technology systems, involving a hierarchy of changes from experiments to niches to technology regimes.

The chapter also covers specific innovation systems and experiments in the energy sector that may have the potential for larger impact and could lead to new niches or technology regimes. These experiments include technology-driven innovations in generation and end-use; system-level innovations that could reconfigure existing systems; and business model innovations centered on energy service delivery. Experiments in generation include hybrid systems, where multiple primary energy sources help address issues such as intermittency. Experiments in end-use include technology options for the simultaneous delivery of multiple energy services, or energy and non-energy services. System-level experiments include innovations in storage, distributed generation, and the facilitation of energy efficiency by effectively monetizing savings in energy use.

In some of these experiments, technology can lead to changing relationships between actors or changing roles for actors; for example, the process of consumers becoming producers is seen in small-scale biogas projects. These changing relationships present both challenges and opportunities for influencing the transition process. The chapter also discusses policy and institutional issues that affect transitions. Finally, it is seen that although technological research, development, and innovation are important, a wide-scale, equitable, and accessible transformation to energy systems for sustainable development needs to be tackled as a socio-political issue.

16.1 Introduction

The energy sector is evolving rapidly. This evolution is shaped by the convergence of several factors, including the realization that energy is a key enabler for achieving development goals, such as the Millennium Development Goals (MDGs). Chapters 2 and 6 of this report review the link between economic growth and energy use, while the effects of energy system operation for human health and the local & global environment are reviewed in Chapters 3 and 4, respectively.

This evolution simultaneously poses a challenge and an opportunity. The challenge is to manage multiple goals and objectives, while the opportunity is to use this evolution to move society towards an energy future that promotes sustainability. The challenge is complicated by the fact that, in many countries, existing energy policy institutions were not designed for this task. Many countries have energy institutions designed for the liberalization and privatization of their energy systems in the 1990s. The challenge of investing and developing energy systems for sustainable development may require new institutional innovations (Helm, 2005; Smith, 2009).

Accomplishing the transition in energy systems will require an accelerating pace of technological change throughout the developed and developing world. Energy policies will need to facilitate this acceleration, while at the same time avoiding lock in to sub-optimal solutions. The variety of energy resources as well as end-use and supply-side technologies that may be available are assessed in earlier chapters of this assessment (Chapters 7–15). While these chapters have assessed the state of the energy system as it exists today, Chapter 17 describes possible pathways by which energy systems could be modified to simultaneously achieve multiple objectives, including environmental sustainability. In many ways, these pathways require transformative change in the energy system.

Transformative change and transitions therefore form the focus of this chapter, and the literature assessed is intended to reflect some of our learning and experience with large-scale transitions in energy systems and in other large, complex socio-economic systems; to provide insights into how transitions may be studied; and, more importantly, how they can be managed. We also review recent experiments and innovations in energy systems, which, if scaled up appropriately, could offer significant opportunities for transforming the energy system.

These experiments include approaches for generating electricity by combining different primary energy sources and approaches for the simultaneous delivery of multiple energy services. An emphasis on providing the energy services while reducing energy wastage (energy efficiency), demand-side management, and a supportive regulatory and policy environment is also encouraging innovations in business models, with energy service companies being a prime example. Finally, in many parts of the developing world, the challenge of achieving energy access goals more rapidly is leading to efforts aimed at supporting a new generation of energy-sector entrepreneurs. Taken individually, each of these trends might be seen as an isolated example, with little significance for the large-scale context. But taken together, and governed effectively, they offer a possibility of creating new transformation pathways for energy systems. In this way, the chapter serves to connect the assessment of the expectations from, and the current state of, the energy system (Clusters I and II) with the pathways to energy systems for sustainable development (Clusters III and IV).

The remainder of this chapter is structured as follows. Section 16.1 reviews literature on transitions and transition management that underpins the importance of considering ancillary and complementary factors while examining policy-driven or autonomous change. Several examples of experiments that may have the potential to influence future energy transitions are grouped into two broad categories. The first section (16.2) includes technology-driven experiments in electricity generation and end-use. Then Section 16.3 considers innovative systems experiments in overall energy system optimization, configuration, and operation. The final section (16.4) looks at a number of policy and institutional issues that may positively or negatively influence energy system transitions.

16.1.1 Transitions and Transition Management

A detailed historical perspective on the long-term evolution of energy systems is given in Chapter 1, including the way in which the industrial revolution changed the fabric of human society and our natural environment. Chapter 1 also discusses the characteristics of historical energy transitions, such as the change in resource use from traditional biomass to coal, oil, and gas. These long-term transformations were driven by both endogenous factors, such as the emergence of electricity after the invention of the dynamo by Michael Faraday, and by exogenous factors, such as the 1973 Oil Crisis. Endogenous technological change is a key element of these long-term transitions. A combination of historical analysis and new modeling techniques can help in identifying predictable patterns of technological change and innovation (Grubler et al., 1999) and thus improve the treatment of technology in models used to project trends in energy and economic and environmental futures.

16.1.1.1 Determinants and Drivers of Transitions

Transformations in energy systems are long-term change processes (decadal or longer) in technology, the economy, institutions, ecology, culture, behavior, and belief systems. They typically cover all aspects of energy systems, including resource extraction, conversion, and end-use. While these transitions are not deterministically caused by technology, technological change is a useful entry point through which long-term transitions may be analyzed and explained. In relation to the transport sector, for example, transitions have been explained as changes in the mode of transport, such as from sailing ships to steamships (Geels, 2002) and from horses to motorcars (Grubler et al., 1999).

A recent approach to understanding transitions is the "multi-level perspective" (Rip and Kemp, 1998; Geels, 2002; Geels and Schot, 2007; Markard and Truffer, 2008). Combining insights from evolutionary theory and the sociology of technology, this perspective conceptualizes major

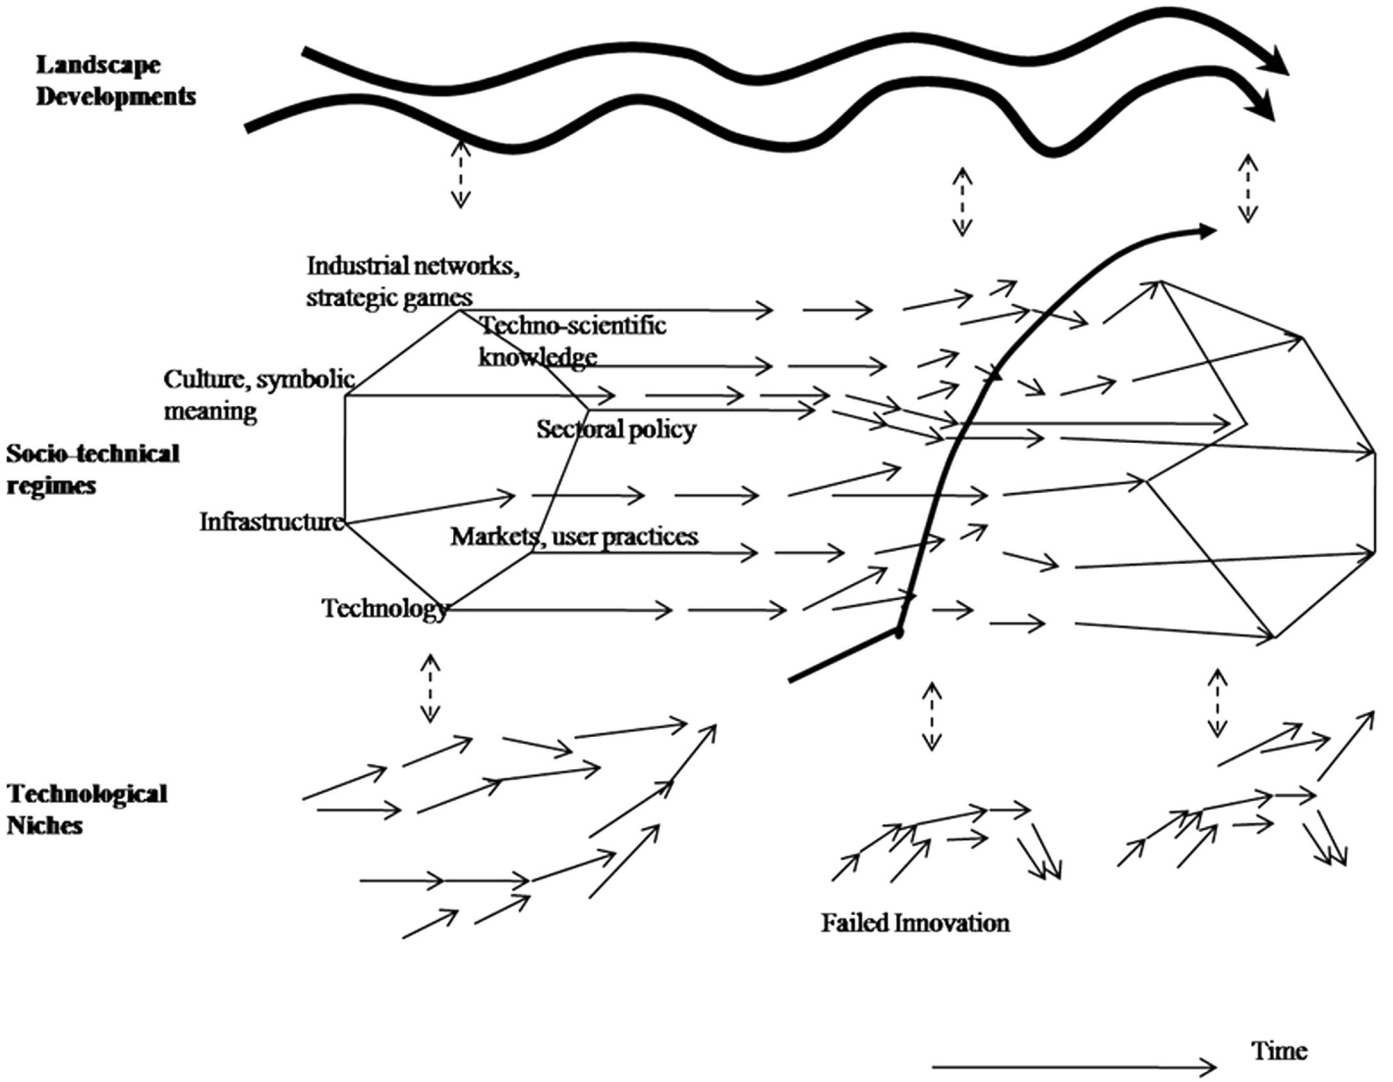

Figure 16.1 | A dynamic representation of the multi-level perspective on transitions. This perspective distinguishes between the micro-level of niches, the meso-level of socio-technical regimes, and the macro-level of landscapes. Innovations and experiments can only break through when there is sufficient pressure on the socio-technical regime. The small arrows at the bottom represent the niche innovations and experiments, which join together, become powerful (as in the thicker arrows), start influencing the socio-technical regimes, leading to major changes in technology, market, user practices, etc., and eventually become part of the landscape. Source: Geels, 2002.

transformative change as the product of interrelated processes at the three levels of niche, regime, and landscape. The framework emphasizes the incremental nature of innovation in socio-technical regimes. A niche is a network of similar projects carried out by innovating actors who seek to challenge the incumbent and dominant socio-technical practice (regime), such as a distributed generation using renewable energy versus a regime of centralized electricity generation. Regimes and niches develop in the context of a socio-technical landscape, which consists of both hard geographical features, such as resource availability and infrastructure, and "soft" elements, such as political conditions, societal trends, and economic fluctuations. The socio-technical landscape provides the exogenous environment for regime change and is a source of major selection pressures on prevailing regimes. Transitions, i.e., shifts from one stable socio-technical regime to another, occur when regimes are destabilized through landscape pressures, which in turn provide breakthrough opportunities for niche innovations. Figure 16.1 visualizes the multi-level model.

Similar frameworks have been developed by other authors. For example, Van Dijk (2000) defines the technological regime as a particular combination of opportunity, appropriateness, cumulativeness, conditions, and properties of the knowledge base that are common to specific activities of innovation and production and are shared by a population of firms undertaking those activities. Stier (1983) and Kathuria (1998) have used examples from product/process and system diffusion to describe changes in technologies and technology systems. Technology products or processes form part of technology systems, which in turn form part of technology regimes.

The transitions literature has advanced from an initial one-pathway conceptualization of transitions, in which niches grow and change regimes, to distinguishing between pathways, depending on different configurations and multi-level interactions (Smith et al., 2005; Geels and Schot, 2007), as summarized in Box 16.1.

Box 16.1 | Pathways that Represent and Characterize Transitions

1. Reorientation/transformation

This pathway is characterized by external pressure (from the landscape level or outsider social groups) and gradual adjustment and reorientation of existing regimes. Although external pressures create windows of opportunity for wider change, niche innovations are insufficiently developed to take advantage of them. Change is therefore enacted primarily by regime actors, who reorient existing development trajectories. Outside criticism from social movements and public opinion is important because it creates pressure on regime actors, especially when they spill over towards stricter environmental policies and changes in consumer preferences. Although regime actors respond to these pressures, the changes in their search heuristics, guiding principles, and research and development investments are modest. The result is a gradual change of direction in regime trajectories. New regimes thus grow from older ones through cumulative adjustments and reorientations. Regime actors survive, although some change may occur in social networks. Furthermore, regime actors may import external knowledge if the distance with regime knowledge is not too large. Such symbiotic niche innovations add to the regime, rather than disrupting the basic architecture.

2. Reconfiguration

In this pathway, niche innovations are further developed when regimes face problems and external landscape pressures. In response, the regime adopts certain niche innovations into the system as add-ons or component substitutions. This leads to a gradual reconfiguration of the basic architecture and changes in some guiding principles, beliefs, and practices. In the reconfiguration pathway, the new regime also grows out of the old regime. But it differs from the transformation pathway insofar as the cumulative adoption of new components changes the regime's basic architecture substantially. The main interaction is between regime actors and niche actors, who develop and supply the new components and technologies. This is therefore a more radical transition than that of the transformation pathway.

3. Technological substitution

Here, landscape pressures produce problems and tensions in regimes, which create windows of opportunity for niche innovations. Niche innovations can use these windows when they have stabilized and gathered momentum. Diffusion of these new technologies usually takes the form of niche-accumulation, with innovations entering increasingly bigger markets and eventually replacing the existing regime. In this pathway newcomers (niche actors) compete with incumbent regime actors.

4. De-alignment and re-alignment

Major landscape changes lead to huge problems in the regime. The regime experiences major internal problems, collapses, erodes, and de-aligns. Regime actors lose faith in the system's future. The regime's destabilization creates uncertainty about dimensions on which to optimize innovation efforts. The sustained period of uncertainty is characterized by the coexistence of multiple niche innovations and widespread experimentation. Eventually, one option becomes dominant, leading to a major restructuring of the system (new actors, guiding principles, beliefs, and practices).

Source: Smith et al., 2005; Geels and Schot, 2007.

The multi-level perspective on transitions is still under active development and has raised some criticisms. In their review of current transitions research, Genus and Coles (2008) have identified limitations of this perspective that need to be addressed to improve the understanding of processes of innovation affecting the transformation. Few case studies presented in the literature systematically identify or analyze the meso-level socio-technical regimes said to be central to stability and change in socio-technical systems, not least with respect to the rules and routines acknowledged as key to the activities of groups in those regimes. There has also been a tendency to focus on successful technologies and

methodological issues concerning the multi-level perspective's functionality, and the poor record of historical case studies appears to have been undervalued. Moreover, there is a danger that some ideas implicit in this treatment of the perspective can seep into the policymaking domain, so that the reality of a neat, mechanistic model of transition could become the dominant interpretation of the perspective. Markard and Truffer (2008) suggest that the multi-level perspective approach is largely confined to the niche level in its analysis of emerging technologies. Frameworks for the analysis of transitions need to:

- consider more explicitly the innovation processes perceived at the micro-level of organizations (strategies, agency);
- take account of mutual dependencies between actors and institutions;
- develop consistent performance comparisons to recommend how to support the development of particular innovations; and
- facilitate systematic identification and assessment of the broad range of factors (e.g., events, developments, institutional effects, actor behavior) that influence innovation processes.

Fouquet (2010) attempts to analyze the role of economic drivers in past energy transitions in order to identify commonalities that may be useful in anticipating future transformations. The analysis proposes that the same micro-economic drivers that were important in the past, such as better and cheaper services, will be relevant in the future. In terms of policy findings, governments and regulatory agencies will have to protect niches rather than rely solely on consumers' willingness to pay for niche technologies. This would involve incentivizing the provision of ever cheaper services and highly valued additional attributes, and minimizing the problem of negative aspects of new technologies. The study further suggests that the periods of niche development, refinement, and large-scale adoption will probably spread over decades.

16.1.2 Managing Transitions

The emerging understanding of transitions and transformations have raised the possibility that they may be actively influenced or managed through policy and other interventions. For example, strategic niche management (SNM) conceptualizes innovation projects with novel technologies as sustainability experiments taking place in real-life contexts (Hoogma et al., 2002; Raven, 2005; Schot and Geels, 2008). SNM also emphasizes the critical role of social network dynamics, articulating expectations, learning processes, and clever niche regime interfaces. The perspective has been applied to a large number of case studies in the field of sustainability, such as sustainable transport (Hoogma et al., 2002), photovoltaic cells (Van Mierlo, 2002), sustainable food supply chains (Wiskerke, 2003; Smith, 2006), bioenergy technologies (Raven, 2005), biofuels (Van Eijck and Romijn, 2008; Van der Laak et al., 2007), wind turbines (Kemp et al., 2001; Healey, 2008), the hydrogen economy (Agnolucci and Ekins, 2007), and low-energy housing (Lovell, 2007; Smith, 2007).

Another part of the literature deals with specific social groups as niches for sustainable technologies, such as Non Governmental Organizations (NGOs), civil society, and social entrepreneurs (Verheul and Vergragt, 1995; Seyfang and Smith, 2007; Witkamp et al., 2011). More fundamentally, Hegger et al. (2007) and Monaghan (2009) suggest that rather than emphasizing technology, niche management could include experimentation with concepts and guiding principles. Ieromonachou et al. (2004) propose an adapted version of strategic niche management based on policy niches, rather than technological niches, to investigate urban road pricing schemes.

A similar method of conceptualizing the role of experiments is the Bounded Socio-Technical Experiment, in which the mapping and monitoring of the learning process can be conceptualized into four levels (Brown and Vergragt, 2008):

- problem solving using pre-determined objectives;
- problem definition in relation to the particular technology-societal problem coupling;
- dominant interpretive frames; and
- worldview, which denotes deeply held values with regard to the preferred social order.

A detailed case study by Brown and Vergragt (2008) of a zero-fossil-fuel residential building led them to conclude (though by no means generic) that the learning involved in bringing about system changes takes place at both the individual and team levels, that it mainly involves changes in problem definition, and that the process involved is just as important as the product obtained. However, a study of several green niches by Smith (2007) found that different actors drew different lessons from projects in niches, depending upon their institutional position and interests. Learning is important, but so too is translating lessons between actors operating in very different contexts. Low-carbon construction techniques that work for green builders may be less amenable to mainstream volume house-builders, for instance, who adopt only elements of the greener techniques. Policy has to support more effective translation processes between niche actors and those in the incumbent regime. Smith et al. (2005) have downplayed the role of niches as instruments in transition governance and introduced the concept of transition contexts to better understand how regimes might adapt to changing selection pressures, such as emerging sustainability preferences in society. They argue that governance must be understood as articulating selection pressures and coordinating and providing resources for adaptation.

The management of transformations could be considered as the transformation of complex adaptive systems (Kemp et al., 2007; Loorbach,

2007), where governance is a process of envisioning sustainable futures in a participatory manner, with front-runners in policy, industry, and society.

Another approach examines the functions of technological innovation systems. This approach conceptualizes transformative change towards sustainability as a process of fulfilling a set of different system functions that are developing and interacting over time. Change occurs through motors that produce either virtuous or vicious cycles, causing system growth or system collapse (Suurs, 2009). Governance advice following an analysis of the functioning of a specific technological innovation system often entails arguments to support certain system functions that are preventing further growth and breakthrough.

Since technology is an important element of transitions, the planning and coordination of research and development efforts may be relevant for guiding transitions. Shafiei et al. (2009) have developed a mathematical and conceptual model of energy research and development resource allocation with an explicit perspective of developing countries (in their case, Iran), which has been linked to a bottom-up energy-systems model and can help in determining the optimal allocation of research and development resources. A similar effort was produced for the United States energy system through a recent project involving several US national laboratories. This model, an open source, long-range Stochastic Lite Building Module, which is part of a larger economic model for the US energy system (the Stochastic Energy Modeling System), estimates the impact of different policies and consumer behavior on the market penetration of low-carbon building technologies (Stadler et al., 2009). The tool can be used, among other things, to simulate the impact of different levels of research and development funding for energy-related technologies. Recent work from the Lawrence Berkeley National Laboratory using the Stochastic Energy Modeling System assesses the impact of research and development levels for photovoltaic technology and solid-state lighting (Stadler et al., 2009). These models can also be helpful in getting at least an approximation of the expected duration of a major energy transition.

As the variety of technology options and combinations increases, there is a greater need for assessment, evaluation, and planning tools. Azevedo (2009) has developed a flexible and transparent, user-friendly tool that assesses the most cost effective way to provide residential end-use energy services (heating, cooling, clothes washer, dishwashers, hot water, cooking, clothes dryer, refrigerator, freezers, and lighting) from different fuels (natural gas, electricity, kerosene, wood, geothermal, coal, solar, distillate, and LPG). With this tool, known as the Regional Residential Energy Efficiency Model, simulations can be performed in any number of the following US census division regions: New England, Middle Atlantic, East North Central, West North Central, South Atlantic, East South Central, West South Central, Mountain and Pacific. The model considers different energy and climate policy constraints.

Transition processes have been studied in the context of national policies. Marinova and Balaguer (2009) present a comparative study of photovoltaic industry growth in three countries – Australia, Germany, and Japan. While Australia has seen successes in sophisticated photovoltaic off-grid systems, it has not been able to achieve great success in the development of on-grid systems, due to the lack of market development and also because of a shortage of funding available to smaller or newer research groups emerging in the photovoltaic domain. In contrast, the growth in Germany and Japan has been more successful, because development took place in a more business-like and industrial environment. In Germany, the strong industrial environment in sophisticated manufacturing allowed the vertical integration of the photovoltaic industry from feedstock materials to module fabrication. In Japan, meanwhile, the existing and huge electronics industry served as a natural base for solar cell technology. In both these countries, the photovoltaic industry was directed towards on-grid applications and was well nurtured by subsidies that helped create markets and mainstream the technologies. These studies suggest the importance of considering energy, industrial, and technology policies in an integrated manner.

In the developing world, an important transition is the replacement of traditional non-commercial energy carriers by modern energy sources. A recent analysis of the household energy transition in India and China reported that, despite sharp differences in the absolute amount of energy used and penetration of electric infrastructure, the overall trends in energy use and the factors influencing a transition to modern energy in both nations are similar (Pachauri and Jiang, 2008). Compared with rural households, urban households in both nations consume a disproportionately large share of commercial energy and are much further along in the transformation to modern energy. However, total energy use in rural households exceeds that of urban households because of a continued dependence on inefficient solid fuels, which contributes to over 85% of rural household energy needs in both countries. It has been found that, in addition to urbanization, key drivers of the transition in both nations include income, energy prices, energy access, and local fuel availability. Similar trends have also been observed in other parts of the developing world.

The study of transitions is an active area of research, and may provide many useful insights into the way that emerging trends and options for meeting energy-related goals might be facilitated and accelerated into larger-scale system transitions. This will require careful identification, documentation, and analysis of experiments that may have a potential to enhance sustainability, and that may be replicable and scalable. Crucially, research also shows that opportunities for these experiments to influence wider changes may depend upon processes that destabilize the incumbent energy regime and its institutions, and it may be necessary to consider the creation of sustainable alternatives in tandem with tensions within prevailing energy systems (Smith, 2005; Smith et al., 2005; Geels and Schot, 2007).

16.2 Technology-Driven Innovations Experiments

Experiments play an important role in long-term, large-scale transitions, particularly where there is a supportive policy environment that allows for promising experiments to evolve into niches that could challenge incumbent regimes. The challenges of access, cost, security, environmental, and health concerns are pushing for new ideas and technologies to emerge in the energy sector, creating a range of possibilities. This section assesses emerging experiments that are largely driven by technology innovation. Three categories of experiments are considered. The first consists of experiments that combine multiple primary energy sources for electricity generation, to overcome problems such as intermittency, and to increase reliability and availability. The second considers multiple energy end uses that may be addressed together, while the third category addresses experiments in which energy and non-energy services are provided simultaneously.

16.2.1 Combining Different Primary Energy Sources

Renewable energy technologies are A key element of all energy system evolution pathways that meet the GEA normative goals for sustainability (see Chapter 17). However, renewable energy sources, such as biomass, wind, and solar, vary greatly in intensity and availability, both diurnally and seasonally. This intermittency is an important constraint to their use. Performance may be improved by connecting non-correlated, multiple sources together, to create a hybrid system. A hybrid system typically consists of two or more energy sources, together with power conditioning equipment and optional energy storage. There is increasing experience with the design and operation of such hybrid systems. Mohamed et al. (2004) have demonstrated that hybrid energy systems can significantly reduce the total lifecycle cost of stand-alone power supplies in many situations, whilst providing a more reliable supply of electricity through the combination of energy sources. An example of hybrids that combine multiple renewable energy technologies are solar-wind LED-based lighting systems that are being used extensively in China for street lighting (Liu and Wang, 2009).

Sometimes, for reasons of resource availability, landscape, climate, or investment difficulties, it is not possible or feasible to harness more than one source of renewable energy. In such situations, conventional fossil fuels could be used to supplement the electricity generated through renewable options. For example, hybrid dual-fuel engine pumps using biogas obtained from community biogas plants are often the least expensive option for pumping irrigation water. The unit cost is further reduced for large-capacity biogas plants, reflecting the effect of an economy of scale in their capital cost, in comparison to pumps operating on-grid electricity, wind power, solar photovoltaic, and stand-alone biogas plants (Purohit, 2007). Similarly, Shaahid and El-Amin (2009) have discussed the techno-economic feasibility of using a hybrid solar photovoltaic-diesel battery power generation system for off-grid supply to Saudi Arabia's remote, unelectrified villages. Another approach to issues of variability and intermittency is the addition of storage or coproduction of another energy carrier, such as hydrogen. Energy storage technologies and related issues are covered in Section 16.3.1, while Chapter 15 examines the generation, storage, and use of hydrogen as a future energy carrier.

Hybridization may offer not only greater reliability, but also optimize the utilization of various energy resources. To maximize revenue from such systems, the optimum configuration will depend on resource availability, the capital and fuel input prices, and the prices of electricity generation from different sources (Dufo-López et al., 2009).

One interesting review by Paska et al. (2009) lists various hybrid combinations that are commercially available (see also Chapter 11), in development, or, at least, plausible (Figure 16.2). Potentially, hybrid energy systems are proving capable of adding reliability and quality to the existing power generation system, particularly as renewable energy systems seem to offer distinct, technology-specific advantages. This approach can be extremely useful in addressing region-specific power issues.

It is clear that most technologies mentioned above have been demonstrated successfully at the research and development stage, and even in small-scale application. To achieve an economy of scale, appropriate policy and enabling environment interventions may be needed.

Research into hybrid systems has focused mostly on the actual design and operation of generation technologies. However, constructing even a pilot plant or innovative, experimental system to evaluate the economic feasibility for each new location where a hybrid or renewable energy system is being proposed can be very cumbersome and capital intensive and can lead to disinterest among decision makers. In such situations, the use of mathematical modeling and simulation techniques may be an attractive alternative for assessing techno-economic feasibility. For example, Deshmukh and Deshmukh (2008) have produced mathematical models of hybrid solar and wind energy systems, including a diesel generator and a battery.

16.2.2 Addressing Multiple End-uses

The idea of hybridization could also be used to address multiple energy end-uses. The most common example is the use of heat produced during electricity generation for thermal applications or the use of waste heat for electricity production, i.e., cogeneration, or combined heat and power (CHP).

Low temperature heat produced by heat engines has very few applications, because most applications require heat at high temperature.

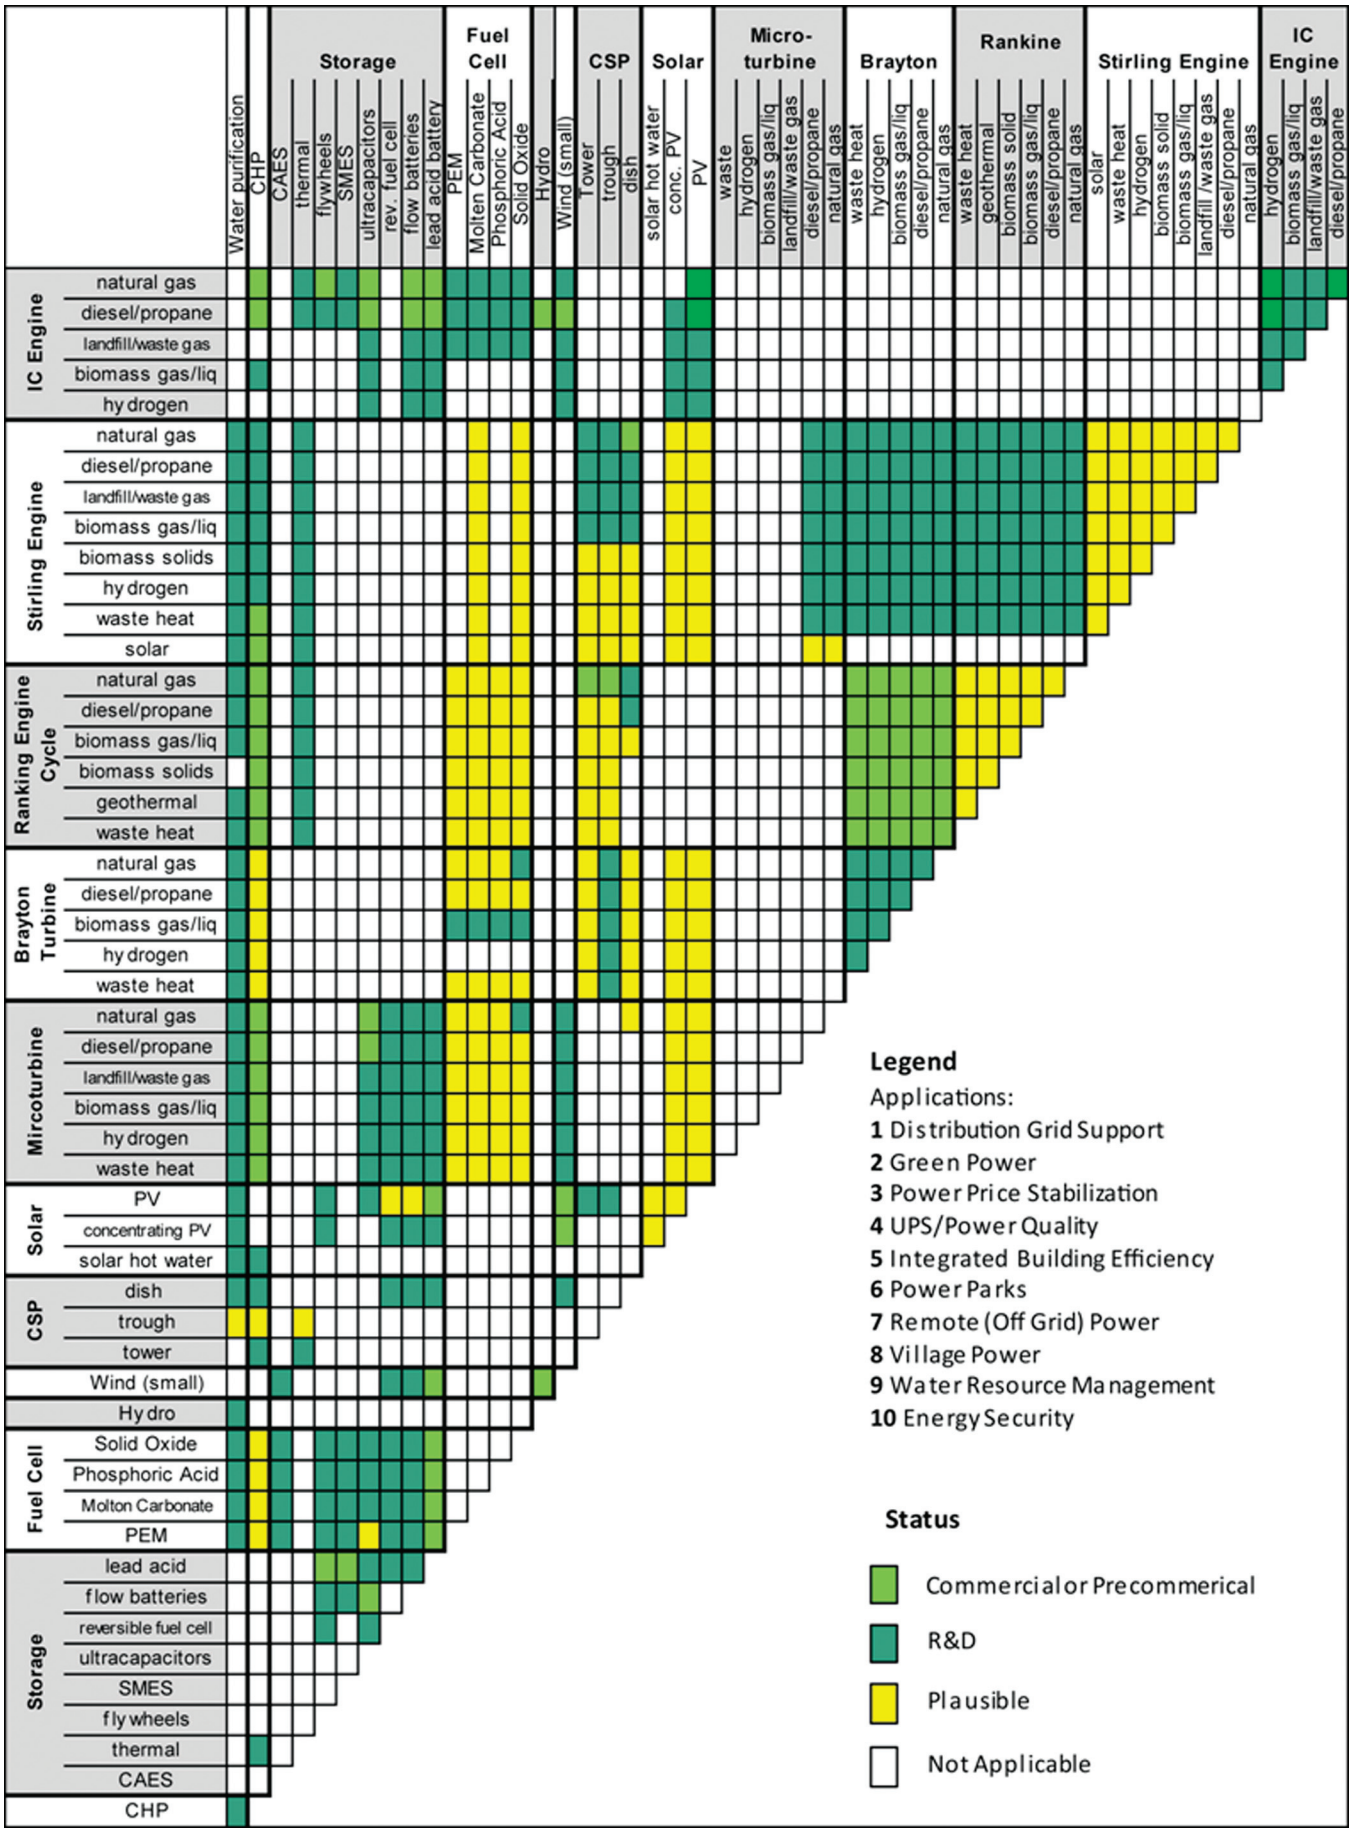

Figure 16.2 | Matrix showing overview of commercialized, research and development stage, and plausible combinations of hybrid technologies, including storage. Source: Paska et al., 2009.

However, if this heat can be harnessed to produce electricity on-site, which is technically possible, a CHP system is obtained. This category of micro-CHP system is generating much interest (Laughton, 1996; Hinnells, 2008). Such systems can operate in homes or small commercial buildings and are driven by heat-demand, delivering electricity as the by-product. Micro-CHPs have the added advantage of being able to run on renewable energy sources, such as wood, biomass, and solar thermal systems, as well as on fossil fuels. Gas turbines are used in most small systems because of their high efficiency, small size, clean combustion, durability, and low maintenance requirements. Natural gas is normally used to provide heat in a boiler or furnace by combustion, and the waste heat (usually from the waste gas stream) is used to generate electricity from a dynamo (generator). Marbe et al. (2004) show the economic advantage of cooperation between an industry and an energy company when a biofuel CHP plant delivers both process stream and district heating. District heating systems transfer and distribute heat from one or more centralized heating plants or CHP plants to individual homes, institutions, and industrial consumers for space heating and industrial processes. In Europe many heating systems are old and need upgrades and maintenance. The general development in the electricity sector towards distributed generation may have two advantages for the cogenerated heat. On the one hand, the generated heat is produced closer to the consumer, thereby reducing the losses. On the other hand, the system gets more dispersed with widespread smaller producers. As in the electricity sector, there will be a strong future need for making the distribution system more intelligent, with closer links between producer and end-user. One further development of district heating systems toward higher levels of sustainability is to combine the systems with solar heating systems and storage facilities, allowing a higher degree of overall optimization of the total system.

The district heating system might, in summer, be used for heat-driven cooling systems. Heat-driven cooling machines might also be used to offset part of the need for electricity for air- conditioning and thus reduce the peak load of electricity in the world's hot regions. A more direct way of district cooling is to develop specially piped chilled water circulating inside the cooling systems to end-use customers. Presently, the integration of district cooling and heating systems is used in the Finnish cities of Helsinki, Turku, and Lahti (Finnish Energy Industries, 2004). District cooling also makes it possible to prolong the utilization period of the maximum load in CHP plants.

Another interesting approach for the simultaneous delivery of heat and electricity is the use of fuel cells based on natural gas, where household needs for electricity and space heating could be met simultaneously. Brown et al (2007) describe micro-CHP using fuel cells in Japan. Simultaneous production of heat and electricity by hybrid solar photovoltaic and thermal systems could reach higher rates of solar energy conversion than stand-alone solar photovoltaic systems. Evaluation of relative payback time periods for both the systems demonstrate that the hybrid systems are cheaper (Kalogirou and Tripanagnostopoulos, 2006). End-use hybrids could also include systems where two different thermal end-uses are provided simultaneously without the intermediate production of electricity. For example, Rane and Dasgupta (2003) report a Multi-utility Vapor Compression System that simultaneously produces hot and cold water streams for different end-use applications, such as bathing and air-conditioning.

16.2.3 Delivering Energy and Non-energy Services

New opportunities may arise from the possibility of combining the delivery of energy services with non-energy services. One example that has attracted much recent attention is that of plug-in hybrid vehicles (PHEV), which create interesting possibilities around the combination of transport and electricity. Other examples include the use of waste heat for desalination of water for domestic and industrial use, the integration of waste management with electricity production, and more generally, the concept of energyplexes, where multiple energy carriers and other byproducts may be produced simultaneously.

The PHEV contains an internal combustion engine as well as batteries that can be recharged by connecting a plug to an electrical power source. It therefore shares characteristics with both traditional hybrid electric vehicles (HEVs), having an electric motor and an internal combustion engine, and battery electric vehicles (BEVs), also having a plug to connect to the electric grid. Depending on the vehicle control design, a PHEV can be driven solely on electricity until the storage battery charge is depleted, after which the vehicle can be operated as a traditional HEV powered primarily from petroleum (Bradley and Frank, 2009). This gives users the advantages of driving on electricity as with a BEV, without the limitation of a shorter range.

Benefits of the PHEV include reduced carbon emissions, economic operating costs, and more efficient use of existing electric system capacity (EPRI, 2007; Shiau et al., 2009). Even when the production of the vehicle's storage battery is included, the life cycle amount in gCO_2-eq/km of a PHEV are below that of a conventional hybrid vehicle, when the PHEV is charged with electricity that has about 650–750 gCO_2-eq/kWh (Samaras and Meisterling, 2008). Other benefits include fewer fill ups at service stations, the convenience of home recharging, opportunities to provide emergency backup power in the home, and vehicle to grid applications. Disadvantages include a battery pack with increased size and cost, the requirement of public and home electrical outlets, potentially increased peak electrical loads, and increased pollution in some areas from increased electricity production from coal, although overall pollution declines (Simpson, 2006; EPRI, 2007). The availability of a distributed system of PHEVs may create the opportunity for large-scale storage and integration of variable renewable energy in the future (Kempton and Tomic, 2005).

The user cost, fuel use, and greenhouse gas emissions of PHEVs also depend critically on the size of the battery and the distance traveled. Further efficiency can be added to PHEVs by using newer batteries, such as closed-system regenerative fuel cells, instead of the regular battery. The regenerative fuel cell uses the conversion of water into its

Box 16.2 | The Future of Solid-state Lighting for General Illumination

The International Energy Agency has estimated that worldwide lighting is responsible for emissions of approximately 1900 $MtCO_2$/year, with 80% of these emissions being associated with electricity generation, and 20% from the 1% of global lighting that is produced by the direct combustion of paraffin and oil lamps used (IEA, 2006). Dramatically improved lighting system efficiency, together with electrification, could make a large contribution to controlling global CO_2 emissions. The most widely used technology, the incandescent bulb, converts only between 1% and 5% of the electricity into usable light. To address and overcome such inefficiency and concerns for the environment, energy security, and affordability, legislatures and regulators in the European Union (EU), Australia, Brazil, Canada, Ireland, Italy, New Zealand, the United States, and Venezuela have all recently moved to implement a mandatory phase-out of most standard incandescent bulbs over the coming decade. Most remaining countries in the EU are likely to adopt similar policies. Solid-state lighting uses technology based on a light-emitting diode, which has the potential to achieve such objectives.

Monochromatic LEDs have seen a very sharp increase in efficacy over a very short period of time when compared with other lighting technologies. Today, red and green LED efficacies are as good as, or better than, fluorescent and high intensity discharge technologies. Commercialized white solid-state lighting is expected to reach those levels in just the next few years, and still is far from reaching theoretical limits that have already constrained future improvements in incandescent and fluorescent lamps.

Solid-state lighting shows great promise as a source of efficient, affordable, color-balanced white light. Azevedo et al. (2009) have shown that, assuming market discount rates, white solid-state lighting already has a lower annualized cost than incandescent bulbs. The annualized cost for white solid-state lighting will be lower than that of the most efficient fluorescent bulbs by the end of this decade. However, much of the literature suggests that households do not make their decisions in terms of simple expected economic value. Assuming higher discount rates on consumer decision-making will delay the adoption of solid-state lighting technology. Successful consumer adoption will depend on, among other things, the availability of solid-state lighting products providing high color quality, high efficiency, and a low up-front cost.

Sources: IEA, 2006; Azevedo et al., 2009.

components, hydrogen and oxygen gases, whose recombination (again, to produce water) generates energy. The gasoline consumption of the vehicle can be reduced by over 80%, whilst reducing the operating cost of the vehicle by about US$200/year by 2010 and US$500/year if less expensive air-cooled engines are used in plug-in fuel cell hybrid electric vehicles (PFCHEV) (Suppes, 2006). A further advantage is found in solar chargers to recharge these plug-in hybrid vehicle systems during the day, when most people are at work (Birnie, 2009). Parking lots can thus become large solar recharging stations for commuters.

The use of low-energy lighting can also provide co-benefits (Box 16.2).

Another interesting example is the use of industrial waste heat, generated in a power plant or a chemical plant, to desalinize water from the sea and make it potable. Desalinization is a highly energy-intensive process, where seawater is distilled by heat from coal- or oil-fired boilers. Multi-stage flash distillation currently accounts for over 85% of the world's desalinized water, while the rest uses mostly membrane-based reverse osmosis process (Water Technology, 2009). The heat currently generated by fossil fuels dedicated solely to desalinization units can alternatively come from waste heat from power plants. Chacartegui et al. (2009) examine one example. Their research, taking a thermal power plant in Spain as a case study, shows that desalinization is actually the most efficient and most economically and technically feasible option of cogeneration that can be obtained from a power plant. This is because the waste heat from the power plant is at a temperature that is too low for most other options, such as residential and district heating/cooling and oil-refining. The desalinization unit can be installed with minor configuration changes, such as increasing the plant's condenser pressure and installing a heat exchanger at the top of the stack.

Mahmoudi et al. (2008) have assessed the feasibility of using hybrid (wind and solar) energy conversion systems to meet the energy needs to power a seawater greenhouse.[1] Examination of the data collected confirms that it is technically feasible to take advantage of renewable energy to run the seawater greenhouse and produce freshwater without the back-up support of fossil fuel energy sources. An attempt to scale-up these concepts in practice is the Sahara Forest Project, a collaborative effort of the Jordanian and Norwegian governments. The project, targeted to commence in 2015, attempts to simultaneously provide water for a greenhouse for growing crops, desalination for drinking water, and solar thermal for electricity

1 Seawater Greenhouse: The seawater greenhouse is a method of cultivation adopted in arid coastal areas that provides desalination, cooling, and humidification in an integrated system. Its purpose is to provide a sustainable means of agriculture where scarcity of fresh-water and expense of desalination make agriculture unviable (Davies et. al, 2004).

production and is a good example of an integrated system that attempts to generate energy and non-energy co-benefits.

Waste-to-energy projects are gaining popularity in the developing as well as the developed world. These experiments and niches offer the opportunity of generating electricity and heat as well as assisting in waste management, thus generating non-energy related co-benefits. A recent experiment in India illustrates the interaction of social, technological, economic, and policy-related aspects around electricity generation using cattle-waste as a primary fuel (Patankar et al., 2010). This experiment represents local technology adaptation of bio-methanation and electricity generation technologies prevalent in other applications, and independent plant management as success parameters to ensure waste collection and energy throughput. In addition to electricity generation, the experiment contributes to waste management and greenhouse gas mitigation.

Solid waste management offers opportunities to simultaneously meet waste management, climate mitigation, and electricity generation objectives. Landfills are the primary mode of disposal for municipal solid waste in developing countries. Methane emissions from landfills, occurring as a result of the natural decomposition of waste, are estimated to account for between 3% and 19% of anthropogenic emissions globally (Mor et al., 2006). The landfill gas generated can be extracted from the landfills through a gas recovery system. Once collected, this gas can be utilized for electricity generation or used as an alternative vehicle or industrial fuel such as in Sweden (Lantz et al., 2007). Municipal solid waste could also be converted into refuse-derived fuel, for use in electricity production or other industrial applications as a substitute for coal or traditional biomass. This conversion helps in higher and constant heating value; homogeneity of physical-chemical composition; ease of storage, handling, and transportation; lower pollutant emissions; and a reduced excess air requirement during combustion. While the production and sale of refuse-derived fuel alone might not be economically viable, there are benefits associated with regard to waste management and the reduction of pressure on landfills. The economics may improve further if the refuse-derived fuel is used for downstream electricity production, as that offers additional opportunities for incentivization (Caputo and Pelagagge, 2002a; 2002b).

Another promising alternative is the development and deployment of integrated energy conversion and end-use systems. In energy conversion, these integrated systems are also known as energyplexes. They are highly efficient and incorporate advanced technologies that may have fuel flexibility and allow for various combinations of electricity, liquid fuels, hydrogen, chemicals, and/or heat. Yamashita and Barreto (2005) have explored three co-production strategies based on coal gasification, namely hydrogen and electricity, Fischer-Tropsch (F-T) liquids and electricity, and methanol and electricity. Using these examples, they have highlighted the important role that integrated energy systems and enabling poly-generation strategies may play in long-term global energy supply systems. Specifically, emphasis has been laid on the role of synthesis gas (or syngas) as a key energy carrier for a multi-fuel, multi-product system based on carbonaceous feedstocks. Since syngas can be obtained not only from natural gas but also from solid energy carriers such as coal and biomass, this allows for its conversion into higher quality, cleaner, and more flexible energy carriers. Because syngas production systems are similar, or at least compatible to some extent, this could facilitate the introduction of multi-fuel systems, provided that technical issues over the quality and variety of feedstocks can be overcome. Hu et al. (2011) have attempted a techno-economic evaluation of coal-based polygeneration systems. China is abundant in coal reserves but deficient in oil and gas, which poses a challenge of utilizing the fossil fuels efficiently and cleanly. Polygeneration system technologies for chemical and power coproduction are therefore becoming more important. When compared with conventional synthetic fuel production systems and power generation technologies, with system integration, the polygeneration technology can achieve a trade-off between primary installed capital cost and fuel savings. That can effectively reduce the cost penalty for CO_2 avoidance. The polygeneration system, without shift reaction and the adoption of a partial recycle scheme, can achieve the optimal primary cost saving of over 10%. Another novel technique proposes the synthetic utilization of coal and natural gas through a combined cycle process of dual fuel-reforming. In this technique, the thermal heat released from burning coal is absorbed by the reforming reaction and transformed into chemical energy of the syngas (Han et al., 2007). Since the chemical energy of natural gas and coal is used more efficiently, the net thermal efficiency of coal to power can reach from 43.5% to 46.3%, which is almost equal to the efficiency of the integrated gasification combined cycle. Sensitivity analysis shows that the performance of the new cycle can be improved further to about 50%. Further, the net specific investments of coal to power, and the operating cost of the new combined cycle, are also lower than the integrated gasification combined cycle.

16.3 Experiments and Niches in System Configuration and Operation

Technological change and innovation is also creating opportunities for improvements in overall system operation. For example, the smart grid is an umbrella term used for a range of technologies to enhance system operation and performance and perhaps transform the grid from a centrally controlled entity to several self-controlled sub-networks (Hamidi et al., 2010). The array of technologies observed in today's smart grid ranges from smart metering to simulating business models with variations in configuration and operation. The improvements in computer communications and networks enhance the ability to optimize generation, demand management, and integration of renewable energy resources (Rahman, 2009).

Amongst the range of experiments related to system configuration and operation, four emerging ideas seem to have significant transformational potential for the future. These include energy storage, distributed generation, micro-grids, and business models around energy service delivery.

16.3.1 Energy Storage

Although the present electric grid operates effectively without storage, cost-effective ways of storing electrical energy can help make the grid more efficient and reliable. The amount of load in most electrical grids changes from hour to hour and from day to day (Figure 16.3). In most regions, system operators typically try to meet this demand by using least-cost economic dispatch, based on available generation and transmission. Electric energy storage (EES) can be used to accumulate excess electricity generated at off-peak hours and discharge it at peak hours, thus reducing the need for peak generation and reducing the strain on transmission networks. EES can also provide critically important ancillary services such as grid frequency regulation, voltage support, and operating reserves, thereby enhancing grid stability and reliability.

Unlike other energy forms, electricity cannot be easily stored in large quantities. Without storage, there is little flexibility in managing electricity production and delivery. Likewise, intermittent renewable energy resources such as solar and wind are constrained in their ability to practically enter the bulk electricity market and keep pace with its continuously changing demands (see Chapter 11). Advanced storage technologies promise to change the nature of electricity markets by providing much greater operational and financial flexibility and enabling carriers to resolve system transients and bottlenecks. The accelerated development and implementation of more cost-effective, higher capacity storage options, including batteries, flywheels, super-capacitors, hydrogen, and super-conducting systems, is the critical issue underlying further diffusion. Today, most of these bulk storage options are relatively unproven, and their value proposition is complex and poorly understood.

For example, the lead acid battery is the most used for large energy storage as well as all types of stationary applications (Perrin et al., 2005). However, advanced batteries being developed for large- scale applications include nickel cadmium, sodium sulfur, sodium nickel chloride, lithium ion, and zinc bromine. Advanced batteries are moving towards commercialization[2], although they remain too expensive for large-scale electricity carrier and storage system application. However, significant cost reductions are expected as modular design and factory assembly become the norm and production volumes increase substantially. Particularly notable from a strategic perspective is the lithium ion battery, being targeted for electric vehicle applications, and the sodium sulfur battery, with the latter being used in Japan for more than 200 MW of energy storage installations (Baker, 2008). The total worldwide market for energy storage products was estimated at around US$26 billion in 2005 (Frost and Sullivan, 2006). About 59% of this market came from

2 A recent commercial-scale deployment of Na-S batteries is a project in Texas, US, where a 4 MW Na-S was energized to the grid in March 2010, with the objective of providing transmission backup in the event of a transmission line outage, along with additional benefits of improvement in power quality. For more information, see ETT, 2011.

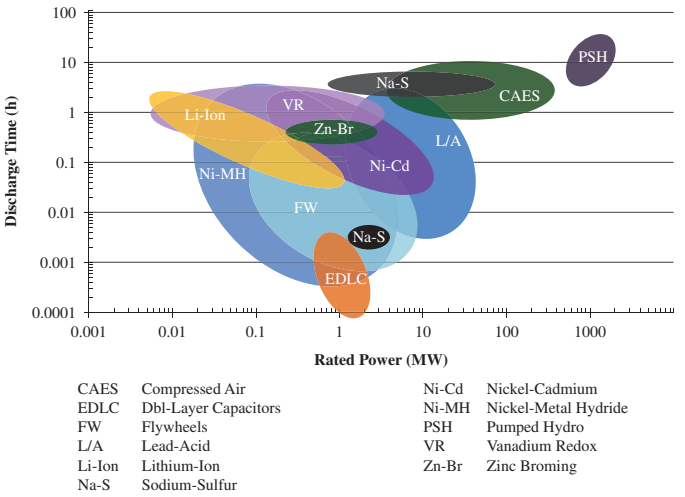

Figure 16.4 | Energy storage system ratings (rated power vs. discharge time) for installed systems (November 2008). Source: Roberts, 2009. © Energy Storage Association.

sales of automotive starting batteries. Another 27% of the total market was concentrated in portable electronics, while motive power (batteries for, e.g., forklifts, golf carts, and electric vehicles) constitutes about 6.6%. Only about 6% of the market, or around US$1.5 billion, came from stationary power products (Frost and Sullivan, 2006). Most of these sales were for backup power applications, such as UPS systems, substation and generating plant backup batteries, and telecom backup batteries. The market for energy storage in utility applications, other than their use as backup batteries, is relatively small. EES technologies can be grouped as electrochemical and non-electrochemical EES technologies. The most common EES technologies are:

- Electrochemical EES
- Lead Acid Battery
- Sodium-Sulfur Battery
- Flow Batteries
- Vanadium Redox Battery
- Zinc Bromine Battery
- Nickel Cadmium Battery
- Nickel Metal Hydride Battery
- Lithium Ion Battery
- Non-Electrochemical EES
- Pumped Storage Hydroelectric
- Compressed Air Energy Storage
- Flywheel
- Ultra-Capacitor
- Superconducting Magnetic Energy Storage (SMES)

The EES technologies listed above and shown in Figure 16.4 are described in detail in EPRI (2003; 2004) and Gyuk et al. (2005). In general, large-scale applications of energy storage have been limited to the utility industry. Utility-scale projects based on storage technologies other than pumped hydroelectric storage have been built, though they have not become common. Existing US facilities include one Compressed Air Energy Storage system, several plants based on lead-acid batteries, one based on nickel-cadmium batteries, and recent installations of sodium sulfur batteries. There are also recent installations of lithium ion batteries and flywheels for frequency regulation in regions where there are spate markets for frequency regulation through Independent System Operators/Regional Transmission Organizations (ISO/RTOs). In all, some 2.5% of the total electric power delivered in the US passes through energy storage, largely pumped hydroelectric. The percentages are somewhat larger in Europe and Japan, at 10% and 15%, respectively (EPRI, 2003). The most widespread form of electricity storage used for utility scale applications is pumped hydroelectric storage, with over 90 GW of installed capacity throughout the world. According to the US Energy Information Administration, the United States had 150 pumped storage plants with a total nameplate capacity of 19.5 GW in 2005 (US EIA, 2005).

There are technical as well as market barriers for the wide-scale integration of energy storage for wholesale market applications. At present, most energy storage technologies have higher capital costs than peaking power alternatives, such as gas turbines. While capital costs are falling somewhat due to technology improvements, significant manufacturing economies of scale have not yet been realized (EPRI, 2003; 2004).

In the longer term, the introduction of energy storage can potentially resolve the renewable energy intermittency challenge. The type of storage under consideration ranges from advanced stationary batteries to other emerging technologies, such as electrochemical capacitors, thermal storage using ice, pumped hydro technology, and compressed air energy storage (Roberts, 2009). The advanced compressed air energy storage system essentially uses the concept of compressing air and storing it during off-peak hours when energy prices are very low and running a turbine with the released air to produce electricity when needed. Because the compressed air is blended with the input fuel in the turbine, it produces much more power than conventional stand-alone gas turbines. Such systems have already been installed in places like Handorf, Germany, and McIntosh, AL, United States. Locations considered ideal for these systems are underground geological formations, such as mines, salt caverns, or depleted gas wells. The largest of these, with a capacity of 800 MW, was proposed to be installed in the United States as of August 2009 (Roberts, 2009). While these systems have mostly been built on the principle of using energy from a conventional electricity grid, they can also be designed as a hybrid to use renewables like wind energy (from turbines) to compress the air.

16.3.2 Decentralization of Power: Distributed Generation

The provision of electricity remains a major challenge in many developing countries. The typical policy response has been to mount aggressive and large-scale rural electrification schemes. Advances in technology and the possibilities provided by hybrid systems may make it more attractive technically and economically to provide these modern energy

services through distributed, off-grid generation options. Recent studies have tried to make explicit the trade-offs and choices between these two modes for electrification and energy service delivery.

Distributed generation is the concept of having decentralized, small generating units that may or may not be connected to the main grid, but are usually located close to the point of end-use (Bayod-Rújula, 2009). Distributed systems may be connected to the grid, or they may operate independently. They are generally not centrally controlled and, with few exceptions at the present time, are not dispatchable; that is, they cannot be switched on and off according to the needs of the grid unless they incorporate suitable grid support technologies, such as energy conversion and storage (Larsen and Peterson, 2005).

Distributed generation provides consumers with opportunities to gain benefits, such as a degree of energy independence, opportunities for local control to improve security of supply, financial optimization, equal or better power quality, and a cleaner environment. It also offers a possibility of including millions of small suppliers, providing a high proportion of renewable energy sources. With distributed generation, homes and businesses could produce their own electric power and heat using various technologies or a mixture thereof. Excess power would be sold to the grid, and consumers could obtain from the grid any power that they did not generate themselves.

Distributed generation is often described as 'integrated' and 'decentralized' to distinguish it from traditional centralized systems, in which power is generated at large, centrally located, and centrally controlled plants. Electricity is presently the dominating medium of exchange in distributed generation, although heat from, for example, combined heat and power (CHP) plants also plays an important role in district heating and other kinds of energy supply. In the long run, energy carriers such as hydrogen and biofuels are expected to contribute very significantly to the energy exchange in distributed generation. Regardless of size, fuel, or technology, the central issue in distributed generation is the large-scale integration of decentralized energy resources.

The generating technologies and energy sources behind distributed generation include wind, solar, micro-hydro, biomass, geothermal energy, and wave or tidal power. These share several attributes:

- energy resources that are geographically dispersed and unevenly distributed;
- energy resources that are typically intermittent, varying by the hour or the season, and not available on demand (some technologies, such as fuel cells and micro turbines, are not intermittent);
- energy that is typically produced as electricity, rather than some other energy carrier that is easier to store; exceptions include biomass and hydropower based on reservoirs; and
- in electricity-driven technologies, heat may be a by-product; in the same way, electricity may be a by-product in heat-driven technologies.

These characteristics, and the inflexibility of most renewable energy technologies, pose important constraints on and requirements to energy systems based on distributed generation. As the share of renewables grows, energy systems (and their necessary support technologies) will face increasing challenges to their operation and future development, affecting both the supply and demand side. Information and Control Technology will be very important to the successful integration of these renewable energy options.

The perceived benefits of distributed power systems include increased reliability of service, improved power quality, the ability to defer investment in extending the grid, and greater energy efficiency, e.g., through better use of waste heat. Of these drivers, reliability of service is one of the most important. Increasingly, consumers need uninterrupted power supplies, yet many existing grids cannot operate without occasional blackouts. Finally, the redundancy offered by a distributed generation network, with its intertwined multitude of generators, converters, and connections, will certainly enhance the security of the power system to deal with acts of terrorism.

Distributed generation based on a high proportion of renewable energy will depend on a number of support technologies that include energy storage and load management to deal with the fluctuating power and intermittency from renewable sources such as wind turbines. Once the concept is fully developed, distributed generation, in addition to the obvious benefit of providing a cleaner environment, has the advantage in that it is easy to add generating capacity as required, using local energy resources. The cost of such expansion is predictable over the life cycle of the generating plant, regardless of price fluctuations and shortages that may affect fossil fuels in the future.

Of the various barriers to a robust implementation of distributed power, key factors include the need for reliable interconnections between distributed generation systems and the grid, and the quality assurance that includes the testing and certification of distributed generation systems and components. Developing standards, procedures, and techniques for the design, testing, and certification of distributed generation systems is relatively new, but it can draw on experiences developed in the wind industry over the last two decades for both systems and projects. Other pacing issues include the lack of experience in understanding how various distributed generation systems interact when a variety of designs are broadly deployed, and the increasing complexity of physical and cyber security issues as the number of electric system participants grows. Proper availability and provision of skills for the maintenance and repair of such systems is also an issue.

New electricity pricing and electricity supplier business structures will be needed in many jurisdictions to remove the reduced bulk electricity sales

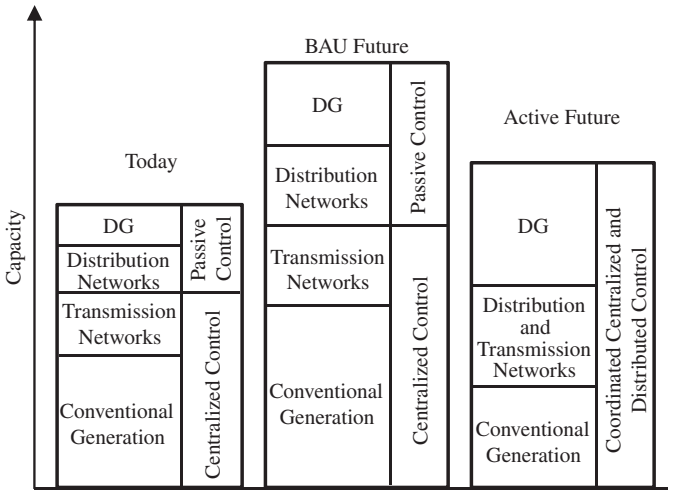

Figure 16.5 | Passive vs. active management of distribution networks. Note: BAU = Business As Usual. Source: Cossent et al., 2009.

disincentives that monopoly electricity suppliers now experience when they encounter user-sited distributed generation. These can be replaced with incentives that encourage distributed generation investments that achieve widely accepted societal benefits such as carbon reduction. The use of a more distributed power generation system will be an important element in protecting consumers against power interruptions and blackouts, whether these are caused by technical faults, natural disasters, or terrorism. Figure 16.5 proposes a Coordinated Centralized Control Mechanism for better control of grids that use distributed generation (Cossent et al., 2009).

Distributed generation appears to be a more promising approach where grid connectivity does not exist. In such regions, distributed generation offers an alternative to grid extension. One such case study identifies niche areas in India where renewable energy-based decentralized generation options can be financially more attractive than grid extension for providing electricity (Nouni et al., 2008). They estimated the cost of delivering electricity in remote areas, considering the cost of electricity generation, and also the cost of its transmission and distribution in the country, where about 70% of the population live in rural areas (see Chapter 24).

Nouni et al. (2008) also analyze the relative contributions of different factors to the levelized unit cost of electricity. At any location receiving electricity through the grid, the delivered cost of electricity consists of three components: (a) cost of generating electricity at the bus bar of the centralized plant; (b) cost of transmitting electricity through the transmission network; and (c) cost of distribution. For electricity generated from coal thermal power plants, the delivered cost of electricity in remote areas located in the distance range of 5–25 km was found to vary from INR[3] 3.18–231.14/kWh (US_{2005}0.073–5.32/kWh), depending on the peak electrical load up to 100 kW and on the load factor (Nouni et al., 2008). The paper concluded that all renewable energy-based decentralized electricity supply options (such as micro-hydro, dual-fuel-biomass gasifier systems, small wind electric generators, and photovoltaics) could be more financially attractive than grid extension in providing access to electricity in remote villages.

A similar study in Cameroon (Nfah and Ngundam, 2009) uses software simulation to examine the breakeven distances for grid extension compared to distributed generation using hybrid systems. Pico-hydro and photovoltaic hybrid systems incorporating a biogas generator were simulated for remote villages in Cameroon based on a load of 73 kWh/day and 8.3 kW peak. For a single wire grid extension cost of €5000/km (US_{2005}6329/km), operation and maintenance costs of €125/km (US_{2005}158/km) per annum, and a grid power price of €0.10/kWh, the breakeven grid extension distances were 12.9 km for pico-hydro/biogas/battery systems and 15.2 km for photovoltaic, biogas, and battery systems, respectively.[4]

By giving more emphasis to distributed generation, the United Kingdom can potentially reduce its energy losses in the transmission and distribution system of electricity. Including the waste heat generated during electricity production, this currently amounts to about 65% of the energy input (Allen et al., 2008). However, technical barriers still cause significant impediments to their growth. These include grid integration, planning permission, and licensing issues, because the main grid is designed for large-capacity centralized power generation (Sauter and Watson, 2007). Financial and economic barriers also exist, notably including the poor performance of the Low Carbon Buildings Programme grant given directly to home owners to encourage distributed generation using renewables. For instance, according to the UK Department of Trade and Industry, a domestic solar photovoltaic installation in 2006 could cost up to £10,400 (US_{2005}19,259),[5] and it could supply about 51% of the average annual electricity demand of the house. However, the maximum available Low Carbon Buildings Programme grant for this is £2500 (US_{2005}4630), which is too little to make the distributed generation system an economic option (Allen et al., 2008). Wolfe (2008) has also described the Low Carbon Buildings Programme grants as too limited in nature to cause a significant surge in distributed generation. A general lack of monitoring and information on distributed generation also prevents a faster growth of successful commercialization of these new systems.

Nevertheless, many European Union countries have managed to achieve appreciable distributed generation contributions using renewable energies in their electricity supply. Figure 16.6 shows the percentage

3 US$1.00 = INR45.80 (October 20, 2006)

4 US$1.00 = €0.71 (July 01, 2009)

5 US$1.00 = £0.54 (July 01, 2006)

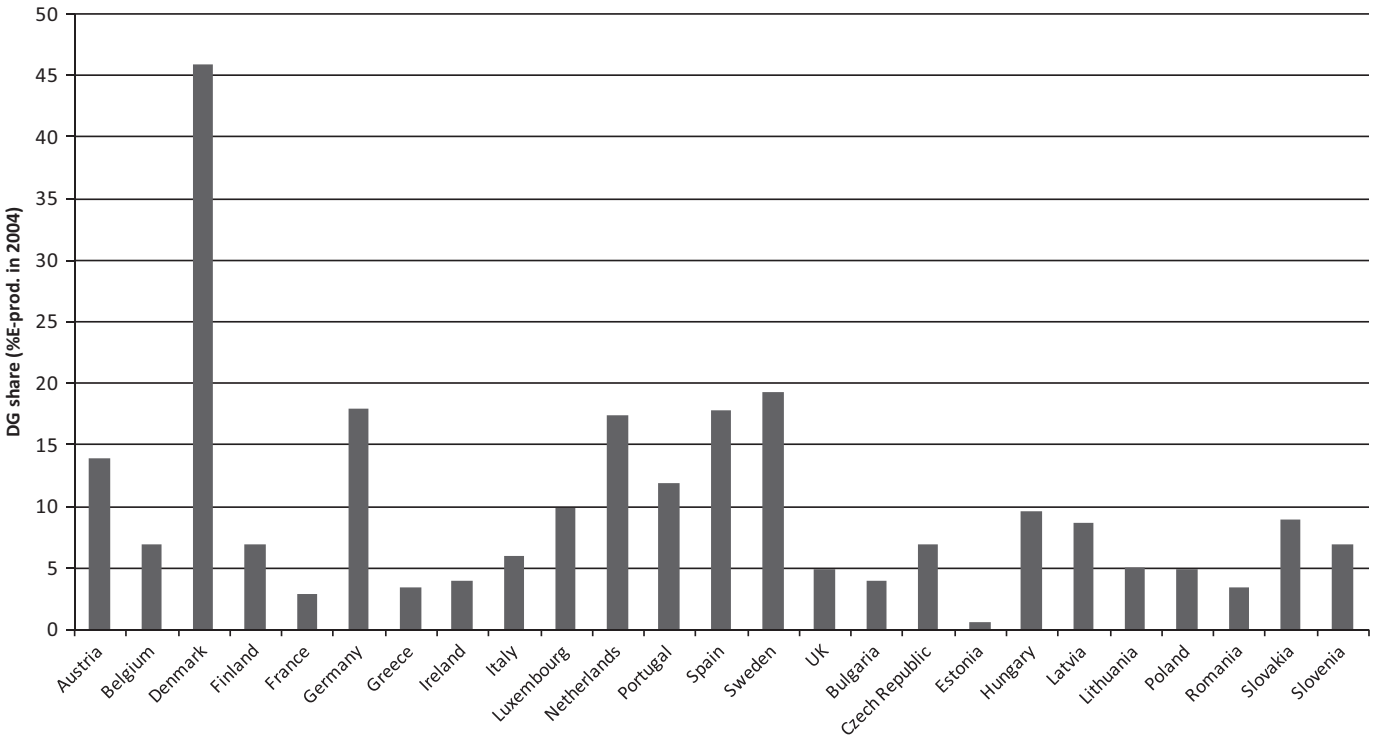

Figure 16.6 | Distributed generation shares in total electricity production in 25 EU countries (2004). Source: Cossent et al., 2009.

contribution of distributed generation in each EU member's total electricity generation in 2004 (Cossent et al., 2009). Denmark scores the highest, with over 45% of its electricity coming from distributed generation resources. It is interesting to note that historical circumstances, next to favorable policies, have played a critical role in the success of distributed generation in Denmark, particularly the role of the cooperative movement in the Danish power industry (van der Vleuten and Raven, 2006).

16.3.3 Aggregating the Distributed Energy Resources (DERs): The Micro-grid

Distributed generation has many benefits and, although it is commercially stable, its growth has been rather slow. DERs can be much more economic if they are realized as a micro-grid. A micro-grid is systems architecture: an aggregate of DERs in a small power network that can provide electric power and often heating and cooling to a small group of closely located customers (King, 2006). This combines the advantages of DERs with those of the micro-grid, the latter being aggregated demand, increased reliability, and an ability to share the capital costs.

Intelligently interconnected buildings and distributed electricity generation are the most critical elements of the micro-grid architecture. It is also becoming feasible to incorporate mobile electricity storage in the form of plug-in electric vehicles (PHEVs). Micro-grids will enable an electricity delivery network strategy where transportation can become an efficient energy supply source, particularly during high cost, peak demand periods. The essential enabling policy step to realizing the full benefits of distributed generation, micro-grids, and PHEVs is time-of-use electricity pricing, which incentivizes consumers to be efficient and to take advantage of the resulting savings.

The interface between the micro-grids and the wider electricity distribution network is through a well-defined and controlled interface utilizing smart grid technologies. The micro-grid is designed and operated to best serve the needs of its customers, ensuring a precise quantity and quality of electricity supply that most efficiently and cost-effectively meets the needs of those customers at all times. In effect, the micro-grid acts as a local electricity refinery, raising the reliability, efficiency, and quality of the bulk electricity supply system.

Although there are a variety of potential micro-grid ownership and operation alternatives, micro-grids intrinsically lend themselves to local cooperative ventures where consumers may also be suppliers (Sauter and Watson, 2007). Metering and billing arrangements are agreed upon locally to reflect the market needs for power within each micro-grid. Micro-grids can also take full advantage of current commercial energy storage technology to accommodate rapid fluctuations in electricity demand or supply.

Micro-grid development in the United States has taken a somewhat different path than similar efforts in Japan and Europe. In the United

States, the emphasis has been on compensating for the relatively poor reliability and power quality provided by the nation's bulk electricity supply system. This is in contrast to Europe and Japan, where the emphasis has been on incorporating clean distributed electricity generation. Micro-grid development efforts in the United States have been led by the Consortium for Electricity Reliability Solutions and, more recently, by the California Energy Commission and the Galvin Electricity Initiative. Prototype micro-grid demonstrations include the Fort Bragg military base in North Carolina, the Beach Cities Micro-grid project in San Diego, CA, and the Illinois Institute of Technology campus in Chicago (GalvinPower, 2010). General Electric is also developing a Micro-grid Energy Management framework to provide a unified control, protection, and energy management platform. Unfortunately, micro-grids are still not defined in most US states' regulatory laws and are usually subject to case-by-case interpretation of regulatory laws for the main power grids, their suppliers, and their customers (King, 2006). Steps such as formalizing the definition and legal rights of micro-grids, adopting formalized procedures for their interconnection with the main grid, and formalizing the responsibilities of the micro-grid owner would greatly help to encourage this new power architecture, along with the great scope for innovation and creativity that it potentially has.

In the European Union, several major research efforts have been devoted to distributed generation micro-grids. These include a consortium led by the National Technical University of Athens, along with utilities, equipment suppliers, and research teams from many EU countries. Demonstration sites include Kythnos Island, Greece, and Mannheim-Wallstadt, Germany. Japan is also a leader in micro-grid demonstration projects. These generally serve the purpose of ensuring that the fluctuating power of distributed renewable energy resources does not degrade Japan's outstanding electricity reliability and power quality. These projects are demonstrating the technical feasibility of micro-grids incorporating renewable energy, while providing multiple levels of power quality and reliability with constant bulk electricity delivery system inflows.

16.3.4 Business Models for Energy Service Delivery

Optimization across demand and supply has created the possibility of new business models centered on the energy service companies (ESCOs). ESCOs are private or public companies that can provide the technical, commercial, and financial services needed for energy efficiency projects. ESCOs may assume a variety of risks, including project performance risk (technical risks associated with the project), arrange financing for the project, and, depending on their reach and agreement with the client, may also take customer credit risk (financial risks). This is done through a performance contract between the ESCO and customer. Two popular models of ESCO operation are:

- *Shared saving contracts*: the ESCO finances the project either from its own fund or by borrowing from a third party. Thus, the ESCO assumes the performance as well as the credit risk.

- *Guaranteed savings contracts*: the customer finances the project by borrowing funds from a third party. Finance is usually arranged by an ESCO, but the loan contract is between the bank and the customer. The ESCO takes only the performance risk by guaranteeing the savings.

In general, the services provided in the two models above are characterized in Table 16.1.

ESCO models may be evaluated with regard to their business sustainability and viability, attractiveness to entrepreneurs, technology linkages and requirements, and the enabling environment required. At the level of firms or in the public systems (buildings, water pumping, streetlighting), the role of ESCOs has proven to be successful at various levels. ESCOs provide multiple services related to the diagnostics of existing energy-use patterns and the implementation of identified technical interventions, including technical, operation, and maintenance services.

Different levels of success characterize the maturity of the ESCO industry in North America and Europe, compared to the evolving ESCO industry in Asia and Africa. ESCOs are still at a nascent stage in developing countries. Painuly et al. (2003) describe a number of barriers to ESCOs in developing countries, including market barriers, institutional barriers, financing barriers, and knowledge and information barriers. They suggest that market development through the active involvement of governments as a customer, information provider, and policymaker is required to promote ESCOs. Local financing markets need to be boosted through the development of special energy efficiency financing windows in appropriate financial institutions such as banks. Skills for energy efficiency project appraisal and for the development of financial products to execute energy efficiency projects also need to be developed. In some cases, specialized energy funds and guarantee funds may be needed to kick-start the investment in energy efficiency projects.

ESCOs have a much longer history and a richer knowledge base in developed countries. Vine (2005) reports that, based on an international

Table 16.1 | Two models of energy service companies.

	Energy auditing	Project structuring	Project financing	Implementation	M&V	Stake in perpetual savings
Guaranteed savings	Yes	Yes	No	Yes	Yes	Limited
Shared savings	Yes	Yes	Yes	Yes	Yes	High

survey, the total amount of ESCO activity outside the United States in 2001 was between US$560 million and US$620 million. This is approximately half to one-third of the ESCO revenues in the United States for 2001.

Goldman et al. (2005) present a detailed empirical analysis of project data and market trends in the United States. They estimate that industry investment for energy efficiency related services reached US$2 billion in 2000, following a decade of strong growth. ESCO activity is concentrated in states with high economic activity and strong policy support. Typical projects save 150–200 MJ/m^2/year and are cost-effective, with median benefit to cost ratios of 1:6 and 2:1 for institutional and private sector projects, respectively. The median simple payback time is seven years among institutional customers; three years is typical in the private sector. They conclude that appropriate policy support, both financial and non-financial, can jump-start a viable private sector energy efficiency services industry that targets large institutional and commercial or industrial customers.

The ESCO market is quite diverse. Historically ESCOs were distinguished from other energy efficiency providers by their use of performance contracting as a core business activity. Increasingly, however, ESCOs are moving away from performance contracting, instead installing energy efficiency projects on a design/build or fee-for-service basis and offering additional services such as energy consulting and information services. Other ESCOs also provide performance-based services beyond the traditional shared savings and guaranteed savings mechanisms, such as build/own/operate contracts for major energy facilities at customer sites. Some ESCOs have pursued new business opportunities in restructured electricity and natural gas markets, combining commodity procurement with energy price risk management and energy efficiency services in a single, bundled product.

Although the ESCO concept has been working well globally, there are challenges facing ESCOs in developing countries, including:

- the creditworthiness (technical and financial) of ESCOs;
- the availability and acceptability of well-drafted energy service contracts and/or agreements;
- arranging finances for the implementation of projects (both equity and loans) for successful demonstration projects;
- performance guarantees: users want the ESCO to indemnify them if promised energy savings do not materialize;
- a lack of minimum performance standards; and
- a lack of clear measurement and verification protocols.

Box 16.3 describes a specific ESCO case study from India (Kalra and Shekhar, 2006).

Box 16.3 | Case Study of an ESCO with Nasik Municipal Corporation, India

A specific example of an ESCO in India is the experience of Nasik Municipal Corporation (NMC). In 2003, ICICI Bank financed an ESCO project implemented, following a tender process, by Sahastratronic Controls Private Limited (SCPL) for NMC in the city of Nasik, Maharashtra. The NMC project, based on shared savings, had SCPL as the borrower work to upgrade the existing street lighting facilities on NMC's premises. The contract was for SCPL to supply 460 energy-saving devices, which represented almost half of NMC's total requirement. Under the Energy Services Agreement, SCPL was required to invest in establishing energy efficiency measures, namely Street Light Controllers, including capital assets, and maintain the same for five years.

ICICI Bank provided financial assistance of INR8.3 million (US_{2005}190,900) in two installments (INR4.5 million and INR3.8 million [US_{2005}103,500 and US_{2005}87,400]) to meet part of the project's cost, from a INR20.0 million (US_{2005}460,000) Line of Credit facility sanctioned to the ESCO through USAID's ECO Programme. Repayments were secured by a direct payment mechanism to NMC through an escrow arrangement. Energy audit studies had estimated an energy savings potential of at least INR7.5 million per year (US_{2005}172,500). SCPL had guaranteed a minimum 25% in energy savings. A large part of the saving was supposed to be shared with SCPL as compensation for their establishment and maintenance of the energy saving devices. The first phase, which consisted of 361 panels with a total load of 4000 kVA, was commissioned in December 2004. Subsequent to the successful implementation of this project, NMC awarded the second contract to the ESCO for 125 panels for which ICICI Bank sanctioned a term loan of INR3.8 million (US_{2005}87,400).

NMC draws about 5000 kW of energy per hour in a 12-hour day, throughout the year for its street lighting application. This amounts to an energy bill of about INR5.5 million per month (US_{2005}126,500) payable to the Maharashtra State Electricity Board (at a tariff of INR3 per kWh), for an annual expenditure of around INR65 million (US_{2005}1,495,000) on street lighting alone. The SCPL area had an actual load of 2700 kW. On this basis, the monthly energy bill payable to the Maharashtra State Electricity Board was about INR35

million (US_{2005}805,000). On the basis of 25% assured savings, the savings for this area was estimated to be 0.25 x 35.0 = INR8.8 million (US_{2005}202,400). In line with this, the NMC project has realized energy savings of about INR11 million (US_{2005}253,000) on a total load of 4000 kVA in one year, with a capital investment of INR12 million (US_{2005}276,000). The average savings per year have worked out at 31% with peak savings on some sub-sections as high as 44%. SCPL has so far received INR7.8 million (US_{2005}179,400) as its share of savings, while NMC's share was INR3.2 million (US_{2005}73,600).

Impact

The project was the first of its kind in India. It has served as a model for other ULBs, municipalities, and government organizations to follow. Successful execution of the project and timely repayments to the bank has not only convinced other banks to lend to similar ESCOs but has also encouraged other municipal corporations to undertake similar street lighting projects.

16.4 Policy and Institutional Issues

The previous sections (Section 16.3 and 16.4) enumerate several emerging experiments both with regard to technological innovations as well as changes in systemic configuration and business models. Many of the experiments can become niches, provided they are suitably nurtured and supported. One of the key factors influencing the scaling up of niches to larger regimes is the existing policy environment. Energy transitions are as much affected by policy and institutional issues as they are by technological and systemic ones. Subsequent chapters (see Chapters 22 – 25) in this Assessment cover energy policies and related policies for innovation and capacity-building. This section focuses on the role of policies in facilitating and guiding transitions.

16.4.1 Role of Policy in Transition Management

To appreciate the role of policy in energy transitions, it is important to note that only very few historical regime transitions were explicitly directed by collective, socially deliberated, long-term goals like sustainability (Smith and Stirling, 2010). Nevertheless, there have been historical studies that trace the emergence of new regimes back to originating niches, and they do inspire ideas for sustainability transitions. Transition management focuses on facilitating an evolution of sustainable regimes from green niches. This should include helping green niches by putting incumbent regimes under significant pressure to reach sustainability targets through policy building, and thereby favoring the environment for these niches, although these are often underplayed in transition policy recommendations (Smith and Stirling, 2010).

Niches, by their very nature, provide protective settings that are less susceptible to prevailing market pressures. Radical innovations pertaining to those niches that carry systemic implications typically need this kind of space to develop, improve, and get much needed support. Transition management puts this niche-based, evolutionary view of change within an iterative, four-stage cyclical governance framework (Smith and Stirling, 2010):

1. *Problem structuring and goal envisioning*: In this step, the development of a shared vision for attaining sustainability goals by multi-stakeholder transition arenas is often facilitated by a government department. Practical visions are formed from the sustainability goals by scenario-building techniques, and these visions then provide a basis and a direction for subsequent government policies.

2. *Transformation pathways and experiments*: Pathways toward transition visions are identified by the participants using back-casting methods, which provide a framework for the development of the niche experiments. Successful pre-development of those niches is followed by a period of take-off and acceleration, before culminating in stabilization within a more sustainable regime.

3. *Learning and adaptation*: This step provides the essential links between long-term goals, socio-technical pathways, and short-term actions in niche experiments. Lessons are learnt for both the improvement of the niche and the institutional reforms. Understanding the institutional constraints and opportunities for the sustainable practices is central to the niche experiments.

4. *Institutionalization*: Institutionalization is often given the least consideration in transition management literature, despite the fact that it is the most important factor in transition management. Institutionalization involves the mobilization of serious selection pressures against the incumbent regime, and the redirection of vast institutional, economic, and political commitments into promising niches along certain feasible pathways. This is the point at which serious commitments are needed, to the extent that the incumbent regime suffers and is undermined as a result. This step is difficult politically as well as economically.

A promising approach for transformative change appears to be strategic niche management, which suggests that such transformative

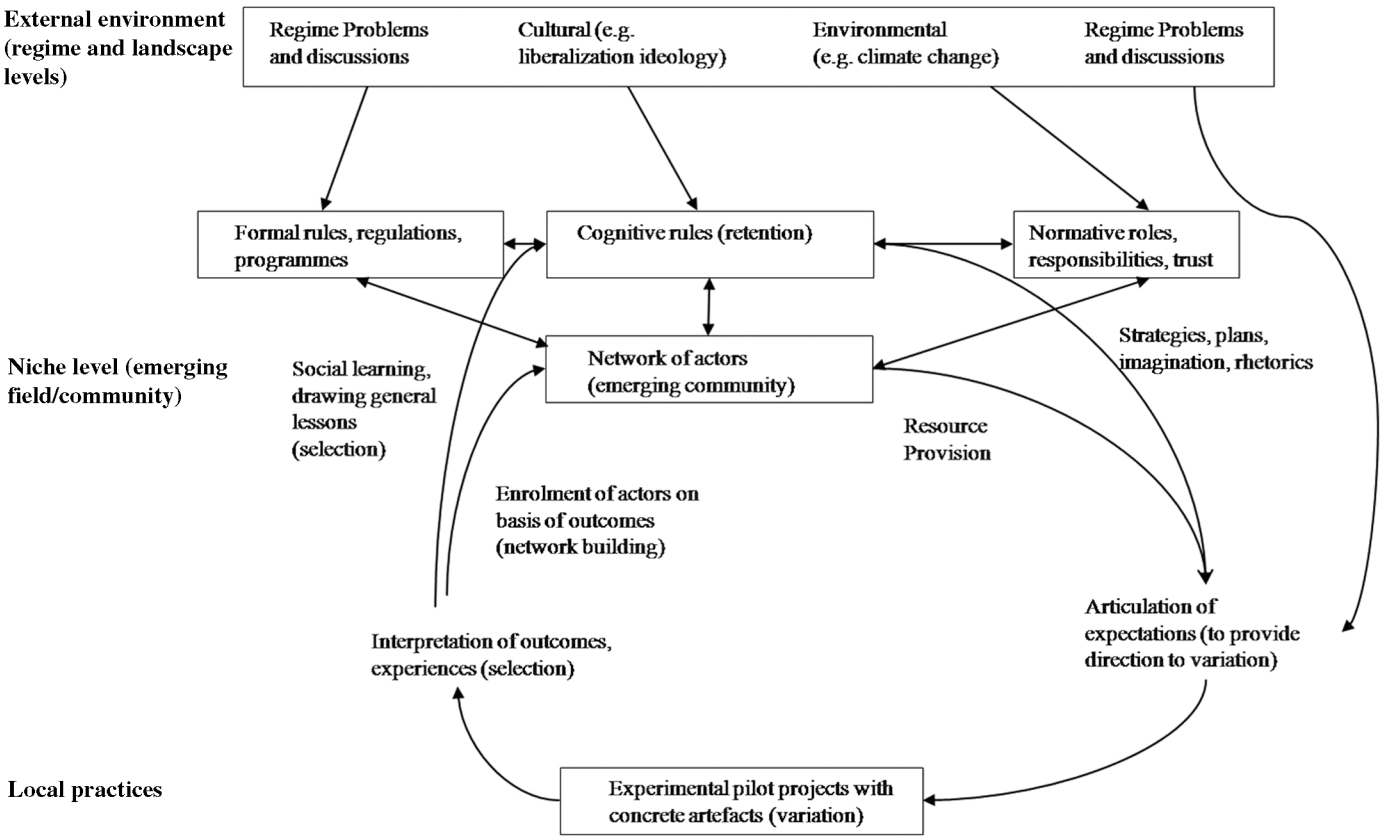

Figure 16.7 | Dynamics in socio-cognitive technology evolution. Source: Raven and Geels, 2010.

change could be facilitated by the creation of technological niches, i.e., protected spaces that allow experimentation with the co-evolution of technology, user practices, and regulatory structures (Geels and Schot, 2007). While the understanding of the evolution of a technological niche to a regime shifts, the following three internal niche processes have been distinguished (Elzen et al., 1996):

- The articulation of expectations and visions provides direction to the learning processes.
- The building of social networks becomes important for developing a constituency behind the new technology and facilitating interactions with relevant stakeholders.
- To facilitate alignments between variation and selection and create "configurations that work," the projects and experiments in technological niches should provide learning processes on dimensions such as:
  - Technical aspects and design specifications
  - Market and user preferences
  - Cultural and symbolic meaning
  - Infrastructure and maintenance network
  - Industry and production networks
  - Regulation and government policy
  - Societal and environmental effects

A further broader, more recent view of the role of niches in regime shift has led to the principle of multi-level perspective, which distinguishes three analytical levels. The niches form the micro-level, where the novelties emerge; the socio-technical regime forms the meso-level, which accounts for the stability of existing large-scale systems; and the socio-technical landscape depicts the macro-level, an exogenous environment beyond the direct influence of the niche and regime actors (Figure 16.7).

The manner in which transitions occur in the real world is a function of the dynamics between the three levels, as well as of internal niche interactions. The attributes that influence the transitions change depending upon the niche's setup and location. The following sections attempt to analyze transitions in practice which have occurred at different settings and scale.

16.4.2 Creating Policy Environment for Transitions

Overall, transition management incorporates goal-directing processes into socio-technical transformations. This approach is attracting increasing interest in many countries' environmental policies, such as

in the Netherlands and Finland. The European Commission is funding research into transition foresight under its seventh framework program. Think tanks in the United Kingdom and elsewhere are advocating the approach. The Austrian Program on Technologies for Sustainable Development promotes the so-called Energy Regions, which can be considered niche spaces for experimentation within a larger systemic perspective (Smith and Stirling, 2010).

The Swiss Energy program offers an interesting case study. It has been highlighted by Geels et al. (2008) as a systems-transformation approach to energy policy for sustainability. Switzerland's energy policy is characterized by strong vertical policy linkages, including both top-down initiatives and bottom-up engagement. The top-down initiatives include the Federal Energy Act 1998 and the CO_2 Act 2000, which encourage environmentally friendly energy sources and the reduction of CO_2 emissions. The bottom-up engagement is facilitated by the Swiss tradition of decentralization of power, so that the cantons (the provincial units) have a great say in decisions pertaining to energy matters and in their implementation. Furthermore, there is an emphasis on using voluntary measures to enhance cooperation between the state and industry. Lastly, the Swiss tradition of direct democracy empowers people to influence the local, cantonal, and federal policies by referendums and initiatives. Because of these vertical linkages, the Swiss energy policy is characterized by a combination of regulatory instruments and process-based implementation. The Swiss Energy program has focused on five key areas: modernization of buildings, renewable energy, energy-efficient appliances, efficient use of waste heat, and energy-efficient, low-emission transportation. Overall, Geels et al. (2008) believe that the Swiss Energy program should be considered a success, because without it, Swiss CO_2 emissions would have been about 2.8 $MtCO_2$ higher than present day levels, and fossil fuel consumption, about 8% higher. The key message here is how the strong vertical policy linkages have been utilized as an instrument to bring about a significant transition.

Nykvist and Whitmarsh (2008) provide a comparative analysis of sustainable transport-related policies in two countries, the United Kingdom and Sweden. In Sweden particularly, where the major historical focus of transport policy was on safety, a remarkable change is seen in the way it has embraced sustainability goals. Swedish policies, such as a law in operation since 2006 that requires filling stations above a certain size to supply biofuels, highlight the government's efforts to reduce dependence on traditional fuels. In the United Kingdom, there is graduated vehicle excise duty and a company car tax, which reduces the tax in line with carbon emissions. The governments of both countries have also been exploring the options of creating a modal shift from cars to public transport systems and car pools or car clubs. A decrease in the registration for driving licenses can also be possibly linked to an overall societal change of moving from private to public modes of transport. The authors note that there are several reasons for the emergence of such policies. Key amongst the determining factors are landscape pressures – including environmental (e.g., climate change), economic (e.g., oil prices, automotive and Information and Communication Technoloy markets), and cultural (value/behavior change) factors – which in turn have an impact on policies at the national and European level. At the niche level, there is interest in exploiting opportunities arising from these trends, e.g., among agricultural and emerging biofuel industries. Networks are starting to emerge in some areas (e.g., biofuels), supported by a favorable policy system. Regime actors are also beginning to respond to landscape pressures and exploit technological opportunities and new markets (e.g., biofuels, HEVs, and small, fuel-efficient cars).

Van der Laak et al. (2007) have studied three recent experiments on biofuels in the Netherlands in order to develop policy guidelines. The strategic niche management approach has been used to explain the success and failures of the three projects, and thereby develop key policy pointers. The guidelines have been categorized into three broad areas: shaping expectations, network building, and learning processes. Their analysis suggests that sustainable technologies often lack a clear advantage for individual entrepreneurs or users (e.g., financial gains), because advantages are at the wider level of society (e.g., reduction of greenhouse gases). Nevertheless, in particular situations (niche markets, local benefits, and ideological arguments) there might be local entrepreneurs willing to nurture and develop a technology that is potentially sustainable. These bottom-up initiatives are important, because they can trigger a process of increasing societal awareness, enable the emergence of local demand, and benefit from wider diffusion. Also, additional (unanticipated) advantages may prove to be viable. Issues such as new job creation, reinforcing local economies, and visual improvements to the countryside may render first generation biofuels socially and economically attractive, despite their limited potential for reducing greenhouse gas emissions.

16.4.3 Examples of Sectoral Transitions

16.4.3.1 Rural Energy Sector

Rural communities across the globe rely on cheap and inefficient fuels, such as traditional biomass. With rapid population growth and the absence of reliable alternatives to traditional fuels, these communities face a grave situation. Renewable energy options or other modern energy technologies are almost non-existent, either due to their high cost implications or because they are unreliable. Field experience has shown that energy, such as electricity, should be employed in enterprises that employ local people or add value to local resources (Bastakoti, 2003).

The energy sector and, in particular, energy service delivery could be an important source of new economic opportunities, including livelihood options. Many hybrid systems described in this chapter offer opportunities for new enterprises based around more sustainable energy solutions, and create the possibility of achieving energy, developmental, and economic goals. Innovation support programs of national governments and multilateral institutions may be used to target energy related sectors. Decentralization of power can be a possible solution to the problem of introducing clean energy technologies to rural areas of developing

nations. Distributed generation provides consumers with opportunities to gain a number of benefits, such as a degree of energy independence, opportunities for local control to improve security of supply, financial optimization, equal or better power quality, and a cleaner environment.

The *Uttam Urja* project was developed by TERI (2009) as a field project for dissemination of photovoltaic lighting technologies in rural India. The project developed a novel business model that promoted the delivery and management of energy services through the development of a local entrepreneurial chain. By customizing the financial assistance, providing affordable quality products teamed with good after-sales service through local energy service networks, this model has been able to function and sustain effectively without any foreign aid (financial/technical) (Rehman et al., 2010).

Another example is the African Rural Energy Enterprise Development (AREED) which demonstrates a partnership based model that accomplishes multiple objectives: new venture creation, support to small and medium enterprises, and energy service delivery (AREED, 2009; see also Chapter 25). An entrepreneur and an energy business are at the heart of the REED (the UNEP Rural Energy Enterprise Development) model, which seeks to tap and support the entrepreneurial spirit and help create sustainable energy businesses through appropriate financing, business development, technology support, and enabling government policies. Following the successful examples of AREED model, the REED approach has been applied in Yunnan province and neighboring areas of western China. China Rural Energy Enterprise Development (CREED) functions through coupling Enterprise Development Services (EDS) with closely targeted start-up financial for entrepreneurs, enabling them to deliver cleaner and higher quality energy services through new business ventures. CREED also offers support for consumer credit and income-generation loans through Green Village Credit. It creates strong links with local government agencies, NGOs and financial institutions active in the areas of energy, environmental protection, consumer credit, and income generation. Through these links, CREED aims to influence broader energy and development shifts underway in China, and redirect existing sources of finance and support to sustainable energy activities.

In general, the rural poor are willing and able to pay for energy services if they have appropriate financing options and are able to meet the first costs of access and/or of the appliance (Rehman et al., 2010).

16.4.3.2 Transport Sector

Delhi and Mumbai are the economic hubs of urban India. As a result of fast-paced economic development, the cities have seen a substantial increase in transport infrastructure and services. The existing transport technological regime, characterized by the use of low-efficiency fuel, was pressurized by public interest groups to improve local air quality. This triggered the development of institutions involved in clean technologies in the transport sector. These institutions analyzed various technological innovations to achieve the goal of better air quality, and consequently improved health conditions.

An increased awareness and concern over the deteriorating air quality was demonstrated through Public Interest Litigations and NGO movements. This resulted in actions taken at the policy level to address the issue. The transport authorizing bodies issued specific directives which resulted in phasing out older vehicles that depended on inefficient fuel. These directives were further supported through court interventions. These legal directives acted as a market pull for technology developers and service providers.

The transition in the transport sector for the two cities is characterized by both top-down initiatives and bottom-up engagement. The top-down approach includes the transport authority directives and court judgments. The bottom-up approach involves NGOs and citizen groups, who expressed their concerns through Public Interest Litigations, plus the interest shown by public and private organizations to develop ancillary infrastructure to support the transition. This is an example of an established technology regime that is supported by infrastructure, finance, and user interest, with clearly defined roles for policymakers and regulators.

The co-benefits associated with the change in the technological regime provided a major impetus to the entire transition phase. The concerns of citizens led technology and service providers, policymakers, and the judiciary to mobilize the implementation process rapidly. Although fuel switching in the transport sector is a micro-change, it has triggered the use of natural gas in the industrial and domestic sectors. Therefore, through the application of a supporting policy structure, a micro-change can be successfully converted into a large-scale technological regime (Patankar and Patwardhan, 2006).

16.4.3.3 Small and Medium Enterprises Sector

For governments and manufacturing companies, global warming, rising energy prices, and increasing customer awareness have pushed energy efficient manufacturing to the top of the agenda (Bunse et al., 2010). Energy management is the judicious and effective use of energy to maximize profits, to enhance competition through organizational measures and optimization of energy efficiency in the process. Realizing the importance of energy efficiency, many developing countries have initiated policy and regulatory mechanisms focusing exclusively on conservation of energy. These policies are a mix of both obligating and voluntary approaches (Lindhqvist, 2001).

Lack of financial and technical assistance is the most prominent hindrance in the adoption of energy efficient technologies in small to medium enterprises (SMEs). Most of the existing conservation policies provide some form of incentives to the existing industries, to motivate them to adapt efficient and clean technologies. This may be in the form of soft loans and/or tax incentives. Long-term, low interest funding

from international institutions like the World Bank and GEF can be utilized by countries to establish a separate dedicated financial institution with equity participation from the government to address the financial issues. One such example is the Pollution Control and Abatement Fund, a US$5 million fund established in Sri Lanka to provide financial assistance to financially viable industrial enterprises towards waste minimization, resource recovery, pollution control, and abatement.

The scheme has two components: (a) Technical assistance and (b) Credit component. The loan can be obtained from any of the six participating credit institutions. Loan disbursement is affected only after obtaining the Environmental Protection Licence. Under the Technical Assistance component, reimbursement up to 75% of cost towards cost of consultancy services for the investigation of waste minimization, preparation of designs, selection, supervision, installation, and operation of the equipment is affected. Under the Credit Component, finance up to a maximum amount of US$128,000 per industry at zero real rate of interest is provided. Maximum repayment period will be seven years including a maximum of one year of grace period. Security needed for the loan is a mortgage over the project assets. For projects that involve investment for modernization entailing a financial return in addition to the desired environmental effects, a loan amount of 50% of such costs would be provided and for all other cases it could be 100%. This loan could be used for purchase of equipment or phasing out of hazardous substances. Over 75 industries have benefited from this scheme (Thiruchelvam et al, 2003).

Demonstration projects in energy intensive sub-sectors undertaken as a part of government led initiatives can also act as an example of successful implementation of EE activities.

For example in India, The Energy Research Institute (TERI) has been involved in improvising the foundry segment of the SMEs. Energy efficient divided blast cupola (DBC), developed by the British Cast Iron Research Association (BCIRA), has been promoted by TERI. The implementation of these DBCs has improvised the profitability through reduced fuel costs. Further, it also delivers molten metal at higher temperatures and substantially reduces other (silicon and manganese) losses, thereby further reducing production costs (Patel et al., 2009).

For SMEs, energy is usually a small portion of the total production cost and therefore receives relatively little attention. Barriers to the introduction of energy management in SMEs are lack of innovation, information availability, and expertise of entrepreneurs. Further absence or lack of data on benchmarks, good practices, and standards makes comparative analysis difficult (Kannan and Boie, 2003).

Executive Summary

Chapter 17 explores possible transformational pathways of the future global energy system with the overarching aim of assessing the technological feasibility as well as the economic implications of meeting a range of sustainability objectives simultaneously. As such, it aims at the integration across objectives, and thus goes beyond earlier assessments of the future energy system that have mostly focused on either specific topics or single objectives. Specifically, the chapter assesses technical measures, policies, and related costs and benefits for meeting the objectives that were identified in Chapters 2 to 6, including:

- providing almost universal access to affordable clean cooking and electricity for the poor[1];
- limiting air pollution and health damages from energy use;
- improving energy security throughout the world; and
- limiting climate change.

The assessment of future energy pathways in this chapter shows that it is technically possible to achieve improved energy access, air quality, and energy security simultaneously while avoiding dangerous climate change. In fact, a number of alternative combinations of resources, technologies, and policies are found capable of attaining these objectives. From a large ensemble of possible transformations, three distinct groups of pathways (GEA-Supply, GEA-Mix, and GEA-Efficiency) have been identified and analyzed. Within each group, one pathway has been selected as "illustrative" in order to represent alternative evolutions of the energy system toward sustainable development. The pathway groups, together with the illustrative cases, depict salient branching points for policy implementation and highlight different degrees of freedom and different routes to the sustainability objectives. The characteristics of the pathways thus differ significantly from each other, depending on the choices made about technologies, infrastructures, behaviors, and lifestyles, as well as on future priorities with respect to the portfolio of supply- and demand-side policies. These choices, in turn, have broad implications for issues of technological availability and scale-up, institutional and capacity requirements, and financing needs.

The analysis in this chapter shows that achieving all the objectives simultaneously remains an extremely ambitious task. Although a successful transformation is found to be technically possible, it will require the rapid introduction of policies and fundamental political changes toward concerted and coordinated efforts to integrate global concerns, such as climate change, into local and national policy priorities (such as health and pollution, energy access, and energy security). An integrated policy design will thus be necessary in order to identify cost-effective "win-win" solutions that can deliver on multiple objectives simultaneously.

The transition can be achieved from different levels of energy demand as well as through alternative combinations of energy resources. An in-depth modeling sensitivity analysis shows, however, that efficiency improvements throughout the energy system are the most important options to achieve the energy transformation toward a more sustainable future. Under assumptions of high energy efficiency (the GEA-Efficiency pathways), it is feasible to achieve the transformation under any of the analyzed supply-side portfolio restrictions. This includes in particular the feasibility of the transformation in absence of carbon dioxide (CO_2) capture and storage in combination with the phase-out of nuclear as well as cases without bioenergy with carbon capture and storage, or without relying on carbon sink management. Under the contrary assumption of high energy demand (the GEA-Supply pathways), however, the rapid and simultaneous growth of many advanced technologies is required. For instance, with high energy demand the sustainability targets remain out of reach if the supply of intermittent renewables or carbon capture and storage (CCS) is restricted, thus making these two "options" in effect mandatory in the absence of important improvements on the demand side. Assuming a nuclear phaseout, on the other hand, was found compatible with the transformation also at high energy demand.

1 The target is "almost universal access" because reaching the remotest rural populations is exceedingly expensive.

Despite the flexibility and choices available to direct the energy system transformation, a large number of robust and nondiscretionary components of an energy transition would need to begin being implemented now. These are referred to in the chapter as necessary conditions, summarizing the commonalities across all pathways to achieve the objectives. They include the following:

- Future improvements of at least the historical rate of change in the energy intensity of the economy, to reduce the risk that the sustainability objectives become unreachable. Further improvements in energy intensity, entailing aggressive efforts to improve end-use efficiency, increase the flexibility of supply and the overall cost-effectiveness of the energy system transformation.

- A broad portfolio of supply-side options, focusing on low-carbon energy from non-combustible renewables, bioenergy, nuclear energy, and CCS, achieving low-carbon shares in primary energy of at least 60–80% by 2050. These include:
  - strong growth in renewable energy beginning immediately and reaching 165–650 exajoules (EJ) of primary energy by 2050;
  - an increasing requirement for storage technologies to support system integration of intermittent wind and solar energy;
  - growth in bioenergy in the medium term to 80–140 EJ by 2050 (including extensive use of agricultural residues and second-generation bioenergy to mitigate adverse impacts on land use and food production);
  - nuclear energy plays an important role in the supply-side portfolio in some transition pathways, but the assessment of pathways with "restricted" portfolios suggests that it is also feasible to phase out nuclear and still meet the sustainability targets; and
  - fossil CCS as an optional bridging or transitional technology in the medium term, and increasing the contribution of biomass with CCS in the long term, unless energy demand is high, in which case cumulative storage of up to 250 gigatons of carbon dioxide ($GtCO_2$) by 2050 would be needed in order to limit global average temperature change to below 2°C.
- Aggressive decarbonization in the electricity sector, reaching low-carbon shares of 75% to almost 100% by 2050; phase-out of conventional coal power (i.e., without CCS); natural gas power could act as a bridging or transitional technology in the short to medium term.

- Enhancements of the transportation sector through electrification or the introduction of hydrogen vehicles to improve end-use efficiency, increase the flexibility of supply, and improve the overall cost-effectiveness of the energy system transformation.

- A peak in oil use in the transportation sector by 2030, followed by a phase-out over the medium term; a strong growth of liquid biofuels in the short to medium term, after which the mix of liquid and gaseous fuels depends on transportation system choices and technological breakthroughs.

- Availability of energy resources (fossil and non-fossil) does not limit deployment on an aggregated global scale but may pose important constraints regionally, particularly in Asia, where energy demand is expected to grow rapidly.

The analysis of the GEA pathways shows, similarly to earlier assessments, that the transformation of the energy system would require dedicated efforts to increase global energy-related investments to between US$1.7 trillion and US$2.2 trillion annually, compared with about US$1.3 trillion in annual investment today. Out of this total, about US$300 to US$550 billion of efficiency-related investments are required on the demand-side of the pathways. This includes only the efficiency-increasing part of the investment to improve energy intensity beyond historical improvement rates. The full demand-side investments into all energy components of appliances might thus be significantly higher. Total investments into energy supply and efficiency-related investments at the demand-side correspond in sum to a small fraction

(about 2%) of global gross domestic product (GDP). Future transitions with a focus on energy efficiency achieve the targets at more modest cost and thus represent the lower bound of the investment range.

Meeting the sustainability objectives will require the further tightening of present and planned legislation and the introduction of new policies:

- *Universal access to electricity and clean cooking* requires the rapid shift from the use of traditional biomass to cleaner fuels and/or clean cooking technologies. This is feasible over the next 20 years, provided that sufficient financial resources are made available for investments on the order of US$36 billion to US$41 billion/year (half of it in Africa).

- *Pollution control measures* across all sectors need to be tightened beyond those in present and planned legislation so that the majority of the world population is meeting the World Health Organization (WHO) air quality guideline (annual PM2.5 (particulate matter less than 2.5 μg in size) concentration < 10 $\mu g/m^3$ by 2030), while remaining populations are staying well within the WHO Tier I-III levels (15–35 $\mu g/m^3$ by 2030). Estimated global costs to meet the air pollution target are about US$200 billion to US$350 billion/year to 2030 (about 10–20% of energy costs). This estimate accounts for ancillary benefits of stringent climate change mitigation policies that reduce overall pollution control costs by about 50–65%.

- *Limiting global temperature change to less than 2°C over preindustrial levels* (with a probability of > 50%) is achieved through rapid reductions of global CO_2 emissions from the energy sector, which peak around 2020 and decline thereafter to 30–70% below 2000 emissions levels in 2050, reaching finally almost zero or even negative CO_2 emissions in the second half of the century.

- *Enhanced energy security* for regions can be achieved by increasing the use of domestic energy sources and by increasing the diversity and resilience of energy systems. A focus on energy efficiency improvement and renewable deployment increases the share of domestic (national or regional) supply in primary energy by a factor of 2 and thus significantly decreases import dependency. At the same time, the share of oil in global energy trade is reduced from the present 75% to under 40% and no other fuel assumes a similarly dominant position in the future.

Achieving society's near-term pollution reduction and health objectives is greatly furthered by climate change mitigation, and similarly, stringent climate policy can help further the energy security goals of individual countries. The simultaneous achievement of climate change mitigation, energy security, and air pollution control comes thus at a significantly reduced total energy cost when the multiple economic benefits of each are properly accounted for. This concerns:

- the added costs of future air pollution control measures at the global level, which can be cut significantly (by up to US$500 billion annually to 2030) in the case of stringent climate policy;

- energy security costs, which can be substantially decreased under increasingly stringent levels of decarbonization, approaching almost zero for very stringent climate policies and translating to an annual cost savings of about US$130 billion annually in 2030; and

- subsidies of carbon-intensive oil products and coal amount at present to about US$132 billion to US$240 billion/year. Rapid decarbonization of the energy system reduces the need for these subsidies by about US$70 billion to US$130 billion/year by 2050.

The transformation toward the sustainability objectives offers multiple benefits that cannot be assigned monetary values at a detailed level, but are nevertheless important to account for. The following are some important nonpecuniary benefits of the transformation:

- Universal access to electricity and clean cooking increases the productivity of the poorest people and thus contributes to overall well-being and more equitable economic growth. In addition, such access results in significant health benefits of more than 24 million disability-adjusted life years (DALYs) saved in 2030.

- Stringent pollution control policies to meet the WHO air quality guidelines for the majority of the world population result in health benefits on the order of 20 million DALYs saved in 2030.

- Limiting climate change to less than 2°C compared with preindustrial times reduces the risks of a number of different types of climate impacts, summarized by five main reasons for concern: the risk to unique or threatened systems; the risk of more frequent episodes of extreme weather; an inequitable distribution of impacts (given that some regions, countries, and populations may face greater harm from climate change); large aggregate damages (assessing comprehensive measures of impacts through efforts to aggregate into a single metric, such as monetary damages); and the risk of large-scale discontinuities (e.g., tipping points associated with very large impacts, such as the deglaciation of the West Antarctic or the Greenland ice sheet).

- Rapid decarbonization and thus stronger reliance on efficiency improvements and low-carbon energy (e.g., renewables) may create new job opportunities, thus providing additional economic benefits.

17.1 Introduction

17.1.1 Scenarios and Energy Transformations

Chapter 17 represents an integrative module of the Global Energy Assessment (GEA). It builds on Clusters I and II of this report to shed light on the question of how future energy systems can address multiple challenges and sustainability goals, ranging from issues of energy access to climate change mitigation. Specifically, the analysis of integrative future energy pathways presented in this chapter aims at illustrating how the energy system components, technologies, and resources described in Cluster II can be combined to address the challenges and realize the sustainability goals identified in Cluster I. The resulting energy transitions achieve multiple goals simultaneously and include various combinations of policy measures and instruments as well as lifestyle and value changes. The results of this scenario analysis thus prepare the ground for Cluster IV, which assesses policy packages and institutional and governance changes for realizing the different sustainable futures.

The two main objectives of developing the transformational pathways are, first, to provide a quantitative and qualitative framework for the identification of policies and measures for a transition toward an energy system that supports sustainable development, and second, to facilitate the integration of diverse energy issues and consistency across the different chapters of the GEA.

The existing literature contains a large number of scenarios, following different traditions in scenario design, development process and objectives. Broadly, one can distinguish between scenarios along "qualitative versus quantitative" lines or along "normative versus descriptive" lines. Whereas quantitative scenarios provide detailed numerical information about underlying processes and dynamics, qualitative scenarios aim at a textual and narrative description of how the future might unfold, thus providing an overarching story (see, e.g., Schwartz, 1991). A few scenario exercises have combined the two traditions and developed quantitative scenarios with so-called underlying storylines (among the first of which were those in the IPCC (Intergovernmental Panel on Climate Change) Special Report on Emissions Scenarios (SRES) (Nakicenovic and Swart, 2000) and the scenarios developed by the Millennium Ecosystem Assessment (Carpenter and Pingali, 2005). Descriptive scenarios usually aim at exploring a wide scenario space and thus improving our understanding of future uncertainties (given the variation of underlying assumptions about driving forces). Prominent examples include the IPCC reference greenhouse gas (GHG) emissions scenarios, such as the IS92 (Leggett et al., 1992; Pepper et al., 1992) and the SRES. Normative scenarios, by contrast, explore the underlying dynamics of change in order to achieve specific desirable outcomes or targets, usually assuming the deployment of a certain set of measures or policies. Consequently, normative scenarios usually do not aim at exploring the whole uncertainty space of possible future developments, but rather focus on the main characteristics of the transition that are considered necessary to achieve specific objectives.

Although various combinations of the above scenario designs are possible, a descriptive or a qualitative scenario design would not be sufficient to address the main aim of the GEA scenario analysis, which is to identify specific measures and policies that would enable the transformation of the energy system. Instead the GEA adopts a combination of a normative and a quantitative scenario approach, whereby specific targets for various energy objectives are defined and formal modeling approaches are used to quantify how, over what time frame, and at what costs those objectives can be achieved.

The GEA energy transition pathways presented in this chapter are designed to describe transformative changes toward a more sustainable future. A specific feature of these pathways is that they simultaneously achieve normative goals related to all major energy challenges, including the environmental impacts of energy conversion and use, energy security, and how to provide access to clean and affordable energy services for growing populations and higher standards of living (particularly for the world's poorest 3–4 billion people). Emphasis is given to the identification of potential synergies, or in other words, of integrated solutions and "win-win" strategies in addressing multiple energy objectives at the same time. One possible way of understanding the GEA pathways is to regard them as alternative interpretations of one overarching GEA scenario in which the energy system is transformed under normative, sustainable goals. The pathways highlight different degrees of freedom and routes to these goals.

17.1.2 Roadmap of the Chapter

The chapter is structured as follows (Figure 17.1). First, the GEA scenario logic and taxonomy are introduced, followed by assumptions about the main sustainability objectives and targets as defined by various chapters of Cluster I of the report. Next, the main characteristics of

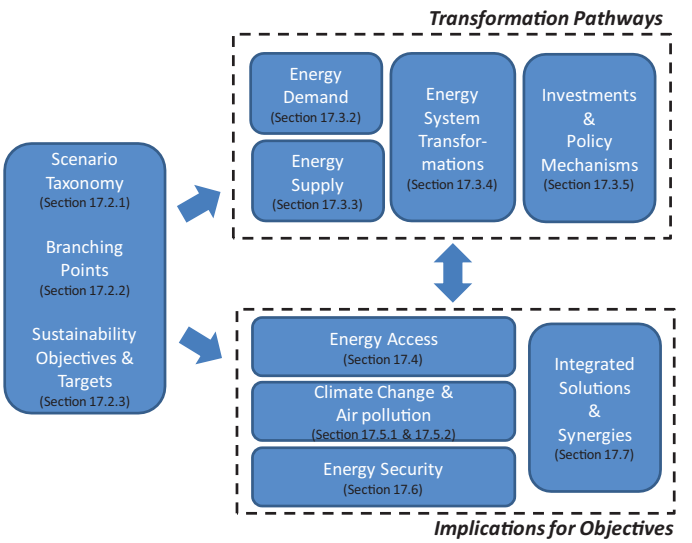

Figure 17.1 | Roadmap of Chapter 17.

Box 17.1 | Definitions of Key Terms Used in Chapter 17

GEA scenario	An overarching storyline of energy system transformation to meet normative sustainability objectives
Pathways	Qualitative and quantitative descriptions of demand- and supply-side energy system transformations falling within the overarching GEA scenario
Pathway groups	Groups of pathways distinguished by their level of energy demand and used as an organizing framework for the modeling of specific supply-side pathways
GEA-Efficiency	Pathway emphasizing demand-side and efficiency improvements
GEA-Supply	Pathway emphasizing the supply-side transformation at relatively high energy demand
GEA-Mix	Pathway emphasizing regional diversity at an intermediate level of demand between GEA-Efficiency and GEA-Supply
Illustrative pathway	A single pathway selected from one of the three pathway groups to illustrate in more depth the similarities and differences between pathways and to explore further implications
Branching points	Substantive alternatives or "choices" causing a divergence of pathways and contrasting characteristics:
	level of demand (low, intermediate, or high)
	transportation system transformation (conventional or advanced)
	portfolio of supply-side options (full or restricted)
Counterfactual	Hypothetical no-policy baseline describing the evolution of the energy system in absence of any transformational policies for the demand- or supply-side of the energy system

the energy transformation, including demand-side efficiency enhancements, supply-side transitions, technology deployment, and investment needs are analyzed. In the first instance, a wide range of possible transformation pathways and associated uncertainties are identified and explored. From the resulting ensemble of pathways, three illustrative cases are selected to represent salient differences in choices of how to meet the sustainability objectives. After addressing the issue of how the transition can be achieved, the chapter moves to the individual objectives and elaborates on what can be improved through which measures. Specific attention is given to identifying cost-effective policy portfolios for addressing energy access, environment (climate and pollution), and energy security objectives. The chapter concludes with a synthesis of how multiple sustainability indicators can be reached simultaneously. Box 17.1 sets out the key terms to be explained and used throughout the chapter.

17.2 GEA Scenario Logic

17.2.1 Scenario Taxonomy

The GEA comprises essentially a single normative scenario of the sustainability transition. Within this single scenario, alternative pathways are developed that describe transformations toward normative objectives related to the environmental impacts of energy conversion and use, energy security, and energy access. All pathways fulfill these objectives by reaching specific and clear targets. For example, they all limit the future global mean temperature increase to not more than 2°C above preindustrial levels, and they all lead to almost universal access to clean energy services throughout the world by 2030. Another feature common to all pathways is that all economic and demographic changes within them are consistent with the GEA's aspirational goals with respect to sustainable development.

Achieving all these goals simultaneously is an enormous challenge that requires substantial effort and fundamental change in the energy system. Although the direction of change in the GEA is clearly defined by the sustainability objectives, the specific characteristics of the transition pathways may differ significantly and will depend on choices about technologies, infrastructures, behaviors, and lifestyles, as well as future priorities with respect to the portfolio of supply- and demand-side policies. These choices, in turn, have broad implications for issues of technological availability and scale-up, institutional and capacity requirements, and financing needs.

A fundamental assumption underlying the pathways is that the coordination required to reach the multiple objectives simultaneously can be

achieved. The pathways thus illustrate the extent of coordination that is necessary and the benefits of policy integration across local and global concerns. By doing so, they inform decision making about the impacts of successful policy implementation. They do not, however, aim at developing recommendations of how the favorable political environment that is also necessary for successful policy coordination and implementation should be achieved (see Chapters 22 and 24).

The main aim of the GEA pathways is thus to provide a better understanding of what combination of measures, over which time frames and at what costs, is needed to deliver the necessary solutions. Although some combination of both supply- and demand-side measures is needed to transform the energy system, emphasis on one side or the other constitutes an important point of divergence between different policy choices that may drive the energy system in alternative directions. Thus, a critical factor is to what extent demand-side efficiency measures, together with lifestyle and behavioral changes, can reduce the amount of energy used for mobility, housing, and industrial services, and thus help fulfill the GEA's aspirational goals across virtually the whole range of sustainability objectives. If energy demand is low, any of a number of alternative supply-side configurations might be able to fulfill the goals. By contrast, a lower emphasis on reducing energy demand will require a much more rapid expansion of a broader portfolio of supply-side options. Hence, the successful implementation of demand-side policies increases the flexibility of supply-side options, and, vice versa, more rapid transformation of the supply side increases flexibility on the demand side.

Figure 17.2 illustrates this concept, which is the logical basis of the overarching GEA scenario and of the different GEA pathways. Three GEA pathway groups, labeled GEA-Efficiency, GEA-Mix, and GEA-Supply, are constructed to represent different emphases in terms of demand-side and supply-side changes. Each group varies in particular with respect to assumptions about the comprehensiveness of demand-side policies to enhance efficiency, leading to pathways of comparatively low energy demand (GEA-Efficiency), intermediate demand (GEA-Mix), and high demand (GEA-Supply). Within each group, a range of alternative pathways for the supply-side transformation are explored. These include a large diversity of supply portfolios in the GEA-Efficiency group of pathways, exploring, for example, the implications of the transformation with limited contributions of either nuclear, carbon capture and storage (CCS), or renewable technologies. In contrast, the GEA-Supply pathways involve much less flexibility with respect to supply-side measures, as most options need to expand pervasively and successfully, given the assumed high level of demand. By the same token, the GEA-Supply pathways show the most flexibility on the demand side of the energy system, requiring, for example, a much less pervasive introduction of efficiency measures to reduce energy demand for services. The pathways thus explore not only alternative combinations of supply- and demand-side policy portfolios, but also different choices with respect to overall strategy and level of implementation. In this context, the GEA-Mix pathways explore the degrees of freedom offered by more diverse energy systems, from resource extraction to services delivered to end users. The emphasis

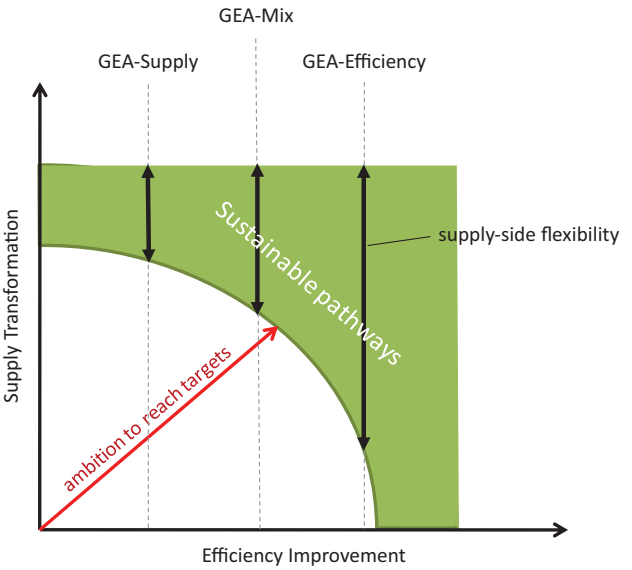

Figure 17.2 | Schematic illustration of the GEA pathways. The different pathways (GEA-Supply, GEA-Mix, and GEA-Efficiency) explore alternative combinations of efficiency improvements and supply-side transformations to achieve ambitious targets for sustainable development. The ambitiousness of the targets defines the feasibility frontier for the combinations of supply and efficiency measures. High levels of efficiency improvements, as depicted by the GEA-Efficiency pathways, increase the supply-side flexibility to reach the targets, and vice versa, the rapid transformation of supply increases the flexibility for the required efficiency improvements to limit energy demand.

of GEA-Mix is on the diversity of the energy supply mix, to enhance the system's resilience against innovation failures or technology shocks. This emphasis also implies that the GEA-Mix group of pathways is not necessarily intermediate between the other two groups in terms of other salient scenario characteristics (e.g., the required policy portfolio,[2] costs, fuel choices, or deployment of individual technologies).

17.2.2 Branching Points and the GEA Pathways

Many alternative GEA pathways fulfill the normative objectives set out for the global energy system. Moving from these objectives to a specific pathway entails three critical choices or "branching points." The first branching point involves a choice among alternative levels of energy demand and efficiency improvements, leading to distinct pathway groups of low, high, and intermediate demand (GEA-Efficiency, GEA-Supply, and GEA-Mix, respectively).

Another branching point explores alternative transformations on the supply side with the main aim of testing the flexibility of different supply-side configurations to fulfill the GEA sustainability objectives, given the levels of energy demand resulting from the choice at the first branching point. One aim was specifically to use the GEA Integrated Assessment Models to explore whether any of the supply options were mandatory.

2 The emphasis on policy in GEA-Mix is on developing and maintaining a diversity of demand- and supply-side options through a diversity of policy choices.

To do this, constraints were set on the portfolio of supply-side options by prohibiting or limiting the availability of specific technologies, including nuclear, CCS, biomass, and other renewables.

A third branching point, whose importance was revealed by this supply-side analysis, concerns changes in the transportation system. A "conventional" transportation system relying on liquid fuels has substantively different implications for supply flexibility than an "advanced" system dominated by electric or hydrogen-powered vehicles. Although any major transformation in an end-use sector that entails fuel switching will impact the energy supply, the magnitude of the impact of such a transformation in the transportation system alone warranted its inclusion as an explicit branching point.

The sequencing of these branching points is important and reflects a central tenet of an integrated, systemic approach to efficient environmental design that is equally applicable to wider technological systems (von Weizsäcker et al., 1997). In the context of energy systems, it is the demand for energy services such as mobility, heating, and industrial processes that drives the system. Hence, systems design should begin with the demand for energy services, emphasizing efficiency improvements and other means of reducing demand. This "sizes" the overall system and forms the basis for exploring supply-side options to meet this demand.

Whereas the first branching point thus addresses the main question of which level of resources needs to be mobilized in order to make the provision of energy services more efficient as well as reduce overall demand for those services, the other two branching points address issues of technological risk and uncertainty related to potential barriers to the deployment of specific supply technologies, which would hinder their adoption at full scale. These barriers might include, for example, the high investment requirements of a hydrogen distribution and refueling infrastructure, system constraints on the scale-up of specific technologies (e.g., integrating large amounts of power from intermittent renewable energy sources into electricity grids), potential public opposition (e.g., to the widespread deployment of CCS or nuclear power), and other specific risks of individual technologies (e.g., proliferation in the case of nuclear).

The branching points also depict irreversibilities, "lock-ins," and path dependencies within the system, reflecting the fact that once technological change is initiated in a particular direction, it becomes increasingly difficult to change its course. A prominent historical example of lock-in is the success of the internal combustion engine; in the same way, the two branches for the transportation sector – toward either electric or hydrogen-powered vehicles or clean liquid fuels – depict two alternative and not easily reversible directions of technological change for the future.

These branching points generate a wide range of alternative GEA pathways exploring different interactions between possible energy demand- and supply-side changes; these are summarized in Table 17.1 and illustrated in Figure 17.3. The first branching point, as already noted, leads to three pathway groups of low, high, and intermediate demand (GEA-Efficiency, GEA-Supply, and GEA-Mix, respectively). The other two branching points, relating to the transportation system and supply-side flexibility, in reality do not occur in a neat sequence, but rather are elaborated through an iterative process of pathway modeling and analysis. However, it is convenient to present them sequentially so that the pathways can be more easily understood; doing so in no way affects the underlying scenario logic. Thus, the second branching point, relating to the transportation system, gives rise to two scenarios, labeled Conventional Transportation and Advanced Transportation, in each of the three pathway groups. Conventional Transportation refers to the continuation of a predominantly liquid-based transportation system, whereas Advanced Transportation requires either fundamental changes in infrastructures (in the case of high penetration of electric vehicles) or major breakthroughs in transportation technology (e.g., in hydrogen fuel cells). The third branching point, relating to supply-side flexibility, then generates 10 alternative pathways in each of these six scenarios, giving a total of 60 alternative GEA pathways. Of these, 19 were rejected as they failed to fulfill the GEA objectives. That is, no feasible solution could be found within these pathways that would meet the "stringent" sustainability objectives described in Section 17.7. The issue of feasibility is discussed further in Section 17.3 and summarized in Section 17.3.6.

Table 17.1 | Branching points and GEA pathways.

Branching point 1: *What is the level of energy demand?*	Branching point 2: *What are the dominant transportation fuels and technologies?*	Branching point 3: *How diverse is the portfolio of supply-side options?*
GEA-Efficiency (low demand) GEA-Supply (high demand) GEA-Mix (intermediate demand)	Conventional (liquid fuels) Advanced (electricity, hydrogen)	Full portfolio (all options) Restricted portfolio (excludes or limits particular options):[1] No CCS No BioCCS No sinks No nuclear No nuclear and no CCS Limited renewables Limited biomass Limited biomass and renewables Limited biomass, no BioCCS, no sinks

1 For further details and rationales of specific restrictions, see Table 17.9 and Section 17.3.3.5.

17.2.3 Energy Goals and Targets of the Sustainability Transition

There is a large body of literature on different types of objectives for sustainable development that addresses the environmental and social,

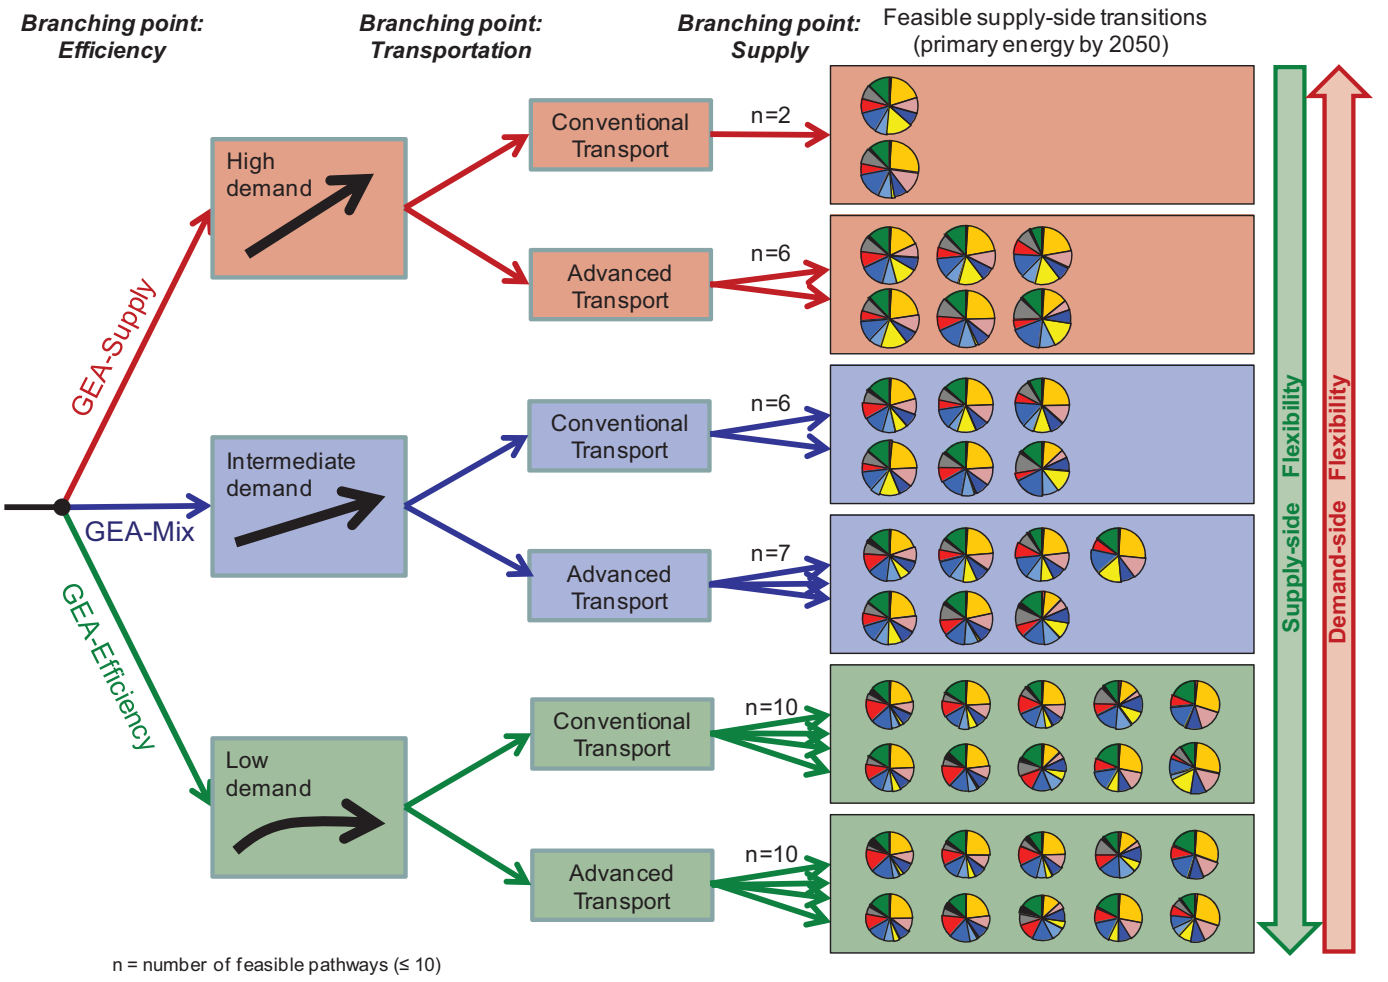

Figure 17.3 | Schematic illustration of the GEA pathways and the three branching points. The scenario setup features alternative choices for the combination of demand-side efficiency improvements and supply-side transformations, describing alternative policy emphases that would enable the transformation of the energy system. The pie charts represent primary energy portfolios of feasible transformation pathways under different branching point assumptions.

as well as the economic, dimensions of sustainability (Hirschberg et al., 2007; Vera and Langlois, 2007). This section does not intend to be comprehensive with respect to all these dimensions but instead focuses on the main energy challenges, and thus on selected objectives that are directly or indirectly affected by energy use. The targets identified here thus refer only to the necessary changes in local and global energy systems; much more is required in other sectors of societies for overall sustainability to be realized.

The definition of the targets builds upon the assessment of the objectives presented in the chapters of Cluster I of this report. Their selection has, to the extent possible, been guided by agreements and aspirations expressed by the international community or by United Nations actions and resolutions.

The targets are of central importance, since they define the ambitiousness and the magnitude and pace of the required transformation. The targets are thus major drivers of the pathways, defining the policy stringency and portfolio of measures to respond to the energy challenges (see Sections 17.3 to 17.7). The model-based assessment in this chapter focuses predominantly on the technological feasibility, required policies, and associated costs and benefits of reaching the targets. The political feasibility of the assessed pathways will depend, in addition, on whether international and regional agreements for the implementation of the policies are put in place (see Chapters 22 and 26).

Table 17.2 summarizes the main target levels. These are used in the analysis of pathways to sustainability as the main boundary conditions or formal constraints in the integrated assessment modeling frameworks MESSAGE and IMAGE (see Box 17.2). The targets are defined in quantitative terms and prescribe a specific time schedule for meeting certain goals. They cover goals for all four principal energy challenges: energy access, air pollution and health, climate change, and energy security. In addition to these goals, the GEA also adopted adequate energy services to support economic growth as a normative goal (see Chapter 6).

Table 17.2 | Targets for the four main energy challenges and key characteristics of the corresponding transition pathways. In addition to these targets, the GEA also adopted adequate energy services to support economic growth as a normative goal (see Chapter 6).

Objective/Goal	Target and timeline	Pathway characteristics	Further details
Improve energy access	Almost universal access to electricity and clean cooking fuels by 2030 (see also Chapters 2 and 19)	Diffusion of clean and efficient cooking fuels and appliances. Extension of both high-voltage electricity grids and decentralized microgrids. Increased financial assistance from industrialized countries to support clean energy infrastructure.	Section 17.4
Reduce air pollution to improve human health	Achieve global compliance with WHO air quality guidelines (annual PM2.5 concentration < 10 μg/m^3) for the majority of the world population, and the remaining populations staying well within the WHO Tier I-III levels (15–35 μg/m^3) by 2030 (see also Chapters 3 and 4)	Tightening of air pollution legislation across all energy sectors (e.g., vehicles, shipping, power generation, industrial processes). Decarbonization to support pollutant emissions controls. Fuel switching from traditional biomass to modern energy forms for cooking in developing countries.	Section 17.5.2, 17.7
Avoid dangerous climate change	Limit global average temperature change to 2°C above preindustrial levels with a likelihood > 50% (see also Chapter 3)	Widespread diffusion of zero- and low-carbon energy supply technologies, with substantial reductions in energy intensity. Global energy-related CO_2 emissions peak by 2020, are reduced to 30–70% of 2000 levels by 2050, and approach almost zero or negative levels in the very long term. Globally comprehensive mitigation efforts covering all major emitters. Financial transfers from industrialized countries to support decarbonization.	Section 17.5.1, 17.7
Improve energy security	Limit energy trade; increase diversity and resilience of energy supply (both by 2050; see also Chapter 5)	Increase in domestic energy supply options (e.g., renewables to provide 30–75% of primary energy by 2050), and reduction of the share of oil in global energy trade from the present 75% to under 40% (and no other fuel assumes a similarly dominant position). Increase in diversity of energy supply as well as all endues sectors and regions by 2050. Infrastructure expansion and upgrades to support interconnections and backup, including increased capacity reserves, stockpiles, and energy storage technologies.	Section 17.6, 17.7

Note: For further details see Section 17.3.

Box 17.2 | Scenario Development Process

The GEA scenarios were developed in parallel by two integrated assessment modeling frameworks and through an iterative and participatory process so as to achieve integration across various chapters of the GEA. Figure 17.4 illustrates the scenario development process, showing the flow of information from individual chapters to the scenario development team and the iterations across various knowledge clusters.

Important inputs to the GEA scenarios include quantitative technoeconomic information such as technology costs, energy resources, and potentials provided by other GEA clusters. In addition, a series of workshops and a scenario questionnaire were prepared by the GEA writing team and external experts to solicit input for defining the main characteristics of the GEA scenario taxonomy and the set of objectives for a sustainable energy system with specific targets and timelines. These inputs are used by two modeling frameworks for the development of the GEA pathways:

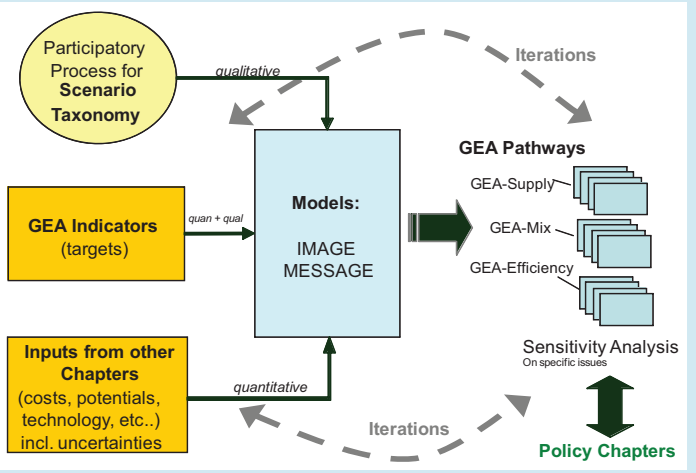

Figure 17.4 | The GEA scenario development process.

MESSAGE (Model for Energy Supply Strategy Alternatives and their General Environmental Impact) is a systems engineering optimization model used for medium- to long-term energy system planning, energy policy analysis, and scenario development (Messner and Strubegger, 1995; Riahi et al., 2007). The model provides a framework for representing an energy system with all its interdependencies from resource extraction, imports and exports, conversion, transport, and distribution to the provision of energy end-use services such as light, space heating and cooling, industrial production processes, and transportation. The framework covers all GHG-emitting sectors, including agriculture, forestry, energy, and industrial sources, for a full basket of greenhouse gases and other radiatively active gases: CO_2, methane, nitrous oxide, nitrogen oxides, volatile organic compounds, carbon monoxide, sulfur dioxide, black carbon and organic carbon, tetrafluoromethane, hexafluoroethane, various hydrofluorocarbons (HFC125, HFC134a, HFC143a, HFC227ea, HFC245ca), and sulfur hexafluoride. MESSAGE is used in conjunction with MAGICC (Model for Greenhouse Gas Induced Climate Change) version 5.3 (Wigley and Raper, 2001) for calculating internally consistent scenarios for atmospheric concentrations, radiative forcing, annual-mean global surface air temperature, and global-mean sea level implications.

IMAGE is an integrated assessment modeling framework consisting of a set of linked and integrated models (Bouwman et al., 2006). Together the framework describes important elements in the long-term dynamics of global environmental change, such as air pollution, climate change, and land use change. Important subcomponents of the model are the global energy model TIMER, the land use and land cover submodels of IMAGE, the detailed description of the carbon cycle, and the MAGICC 6.0 (Meinshausen et al., 2009) model that is included as the climate model within IMAGE. The model focuses on several dynamic relationships within the energy system, such as inertia, learning-by-doing, depletion, and trade among the different regions. Technological choices are made on the basis of relative costs (using multinomial logit equations). The land cover submodels in the earth system simulate the change in land use and land cover at a resolution of 0.5×0.5 degrees (driven by demands for food, timber and biofuels, and changes in climate). The earth system also includes a natural vegetation model to compute changes in vegetation in response to climate change feedbacks from changes in temperature, precipitation, and atmospheric CO_2 concentrations.

Both models use a set of harmonized assumptions about future drivers of change (including targets) to generate the GEA pathways. Many of these drivers are specified externally to the modeling frameworks and were provided by other chapters of the GEA report (Table 17.3). The pathways thus also aim to integrate information (e.g., on resources, technologies, costs) provided elsewhere in the GEA.

Although the models were applied to develop the three illustrative pathways within each of the pathways groups, the assessment relies on the strengths of the individual models with respect to specific sensitivity analysis. For instance, both models explored the sensitivity of the results with respect to energy access; however, the assessment mostly builds upon simulations from IMAGE for detailed land use projections and mainly uses the MESSAGE model to explore supply-side flexibility and to calculate pollutant emissions. The atmospheric chemistry and dispersion modeling for the assessment of health impacts from air pollution were conducted with the TM5 model hosted

Table 17.3 | Model structure and assumptions used to generate GEA pathways.

Examples of externally specified or harmonized variables across models	Constraints on model outputs or "boundary conditions" for least-cost model solutions	Examples of internally generated or "endogenous" model outcomes
Population growth	Energy access target	Diffusion of supply-side technology options and their shares in primary energy
Reference economic growth	Environmental impact targets	Demand-side portfolios and fuel consumption
Reference energy intensity improvements	Energy security targets	Price-induced changes in energy demand
Resource availability and costs		Changes in land use and land cover
Technology availability and costs		Exposure to pollutant emissions
		Energy system investments
		Costs of alternative policy packages for energy access, environment, and security
		Costs of emissions reductions
		Carbon price

at the Joint Research Centre of the European Commission (Dentener et al., 2006; Stevenson, 2006; Kinne et al., 2006; Textor et al., 2007; Bergamaschi et al., 2007). As with any model-based assessment, any specific conclusions are conditional on the applied methods and assumptions.

Detailed scenario data for the individual GEA pathways are publicly available in the GEA database at www.iiasa.ac.at/web-apps/ene/geadb. The GEA database provides interactive features for data visualization and a user interface for the download of scenario information in different formats.

Because the GEA objectives are strongly normative, the targets are all designed to be ambitious. The elaborated GEA pathways suggest that all the targets can be reached, if appropriate policies are introduced and energy investments are scaled up considerably. Table 17.2 lists some general characteristics of the GEA pathways as influenced by each of the objectives.

The target of ensuring *almost universal access to electricity and clean cooking by 2030*[3] is driven by the current reliance of a large fraction of the population in developing countries on traditional biomass to satisfy basic energy needs. Their lack of access to electricity and to affordable and clean fuels for cooking has vast impacts on human health, productivity, and land conservation. Section 17.4 presents a comprehensive analysis of the combinations of policies that can achieve the GEA goal of universal access by 2030. Specific focus is given to microcredits or grants to finance appliances as well as subsidies to improve the affordability of clean fuels for cooking. In addition, the same section assesses the need for infrastructure investments for transmissions and distribution networks to connect the rural poor to the grid (see also Chapters 2 and 19).

The target of *reducing air pollution in compliance with WHO (World Health Organization) air quality guidelines*[4] *by 2030* is explored in depth in Section 17.5.2 through a bottom-up, technology-based assessment of main measures across main pollutant emissions sources and sectors. Many countries around the world have adopted antipollution legislation and have specific plans for further implementation of legislation in the short term. As the analysis in Section 17.5.2 indicates, however, current legislative plans in the aggregate are not sufficient to achieve the GEA target. Hence, a major focus of that section is on identifying specific policy levers for individual sectors and regions, and the associated costs, to deliver further improvements consistent with the overall objective (see also Chapter 4).

3 The target is "almost universal access" because reaching the remotest rural populations is exceedingly expensive.

4 The WHO air quality guidelines are given for an annual PM2.5 concentration $< 10\ \mu g/m^3$. In the GEA pathways the majority of the population meets this guideline by 2030, while the remaining populations stay well within the WHO Tier I-III levels of 15–35 $\mu g/m^3$.

With respect to climate change, the GEA adopts the target of *limiting global average temperature change to 2°C above preindustrial levels with a likelihood of more than 50%*.[5] This target is consistent with various scientific assessments of the increasing risk of climate-related impacts above that threshold (Smith et al., 2009) as well as with EU and UN policy recommendations (European Commission, 2007; United Nations Conference of the Parties, 2009). Such a global target calls for globally comprehensive and stringent GHG emissions reductions. Section 17.5.1 analyzes the required emissions pathways, measures to reduce emissions, costs, and equity implications of the transition (see also Chapter 3).

Last but not least, the GEA objective of improving energy security is achieved partly as a convenient co-benefit of decarbonization, which is illustrated in the GEA transition through two related objectives on *limiting energy trade across major importing regions* and *increasing the diversity and resilience of energy supply*. Although many different types of energy security indicators are summarized in the literature (e.g., Jansen et al., 2004; Scheepers et al., 2007; Kruyt et al., 2009; Sovacool, 2009; Sovacool and Brown, 2010), the GEA uses a relatively simple dual taxonomy to define security: sovereignty of the energy system based on the degree of energy trade, and resilience based on the degree of diversity of types of energy sources. The sovereignty dimension is incorporated by limiting energy trade as a fraction of total primary energy at a regional scale (discussed in Section 17.7). Although the resilience dimension is not a direct limitation in the GEA pathways, the analysis in Section 17.6 shows that diversity increases in all energy subsystems (total primary energy supply, fuel supply for end uses, and regional mixes). Section 17.6 elaborates on these indicators and on the different strategies to improve energy security and their implications for the transition (see also Chapter 5).

Without policies to enable the sustainability transformation, the energy system would continue its heavy reliance on fossil fuels. This is illustrated by the hypothetical no-policy baseline (counterfactual) of the GEA, which describes the evolution of the energy system in absence of any transformational policies to meet the GEA objectives. In the GEA counterfactual fossil fuels more than double their contribution by 2050 (reaching about 900 EJ). As a consequence greenhouse gas emissions would continue to grow at present rates for many decades to come, leading to an average global mean temperature change of about 5°C in the long term. Increasing use of fossil fuels would also increase import dependency and worsen energy security, particularly in resource poor regions in Asia. Lack of incentives to strengthen policies to control the emissions of air pollutants would result in an increase of outdoor air-pollution induced health impacts from 23 million disability-adjusted life years (DALYs) lost globally in 2005 to more than 33–40 million by 2030. In addition, the lack of financing for clean cooking fuels and electricity for the poor would leave the energy access problem unresolved, leading to health impacts from household fuel pollution of about 40 million DALYs by 2030.

Changing the energy system to support sustainable development requires thus dedicated policies so that all the GEA goals are met concurrently. Hence, a major focus of the assessment is to explore integrated and holistic solutions that take into account potential trade-offs and help to identify *synergies* from achieving all the different objectives simultaneously. These are discussed in detail in Section 17.7.

17.3 The GEA Energy Transition Pathways

This section describes the main underlying dynamics and transformational changes featured on both the demand and the supply side of the energy system. The pathways are described initially in a disaggregated way, separating out macro drivers, demand-side improvements, and supply-side transformations. Then the pathways are reintegrated using three illustrative pathways to provide comprehensive storylines of what the energy system transformation might look like if the overarching GEA scenario is to be fulfilled. Once these "what" questions are answered, the chapter turns to questions of "how." The section that follows sketches out an answer to the question of how such a transformation might come about, pointing the way to more detailed analysis later in this chapter as well as in the remainder of this report.

This part of the chapter is organized as follows. Section 17.3.1 describes the main socioeconomic and demographic trends common to all the GEA pathways. Section 17.3.2 covers changes in energy intensity and final energy demand and draws together evidence from other parts of the GEA on the potential for efficiency improvements in different end-use sectors. Based on this demand-side analysis, three groups of pathways are set up corresponding to low, high, and intermediate levels of demand: these are the GEA-Efficiency, GEA-Supply, and GEA-Mix pathways, respectively. Section 17.3.3 turns to the supply side of the energy system. The lowest-cost portfolio of supply-side transformations (assuming the full availability of all advanced future technologies on a large scale) is described, followed by an analysis of the importance of fuel and technology transformations in the transportation sector. This leads into a broader analysis of flexibility in supply-side portfolios and the potential for specific supply-side options to be either limited or omitted completely. Section 17.3.4 integrates the analysis of macro drivers, efficiency improvements, and supply transformations to present the GEA pathways in an integrated form. Initially, three illustrative pathways are explored in depth to establish key characteristics, similarities, and differences. Then the full diversity of pathways is compared and contrasted, with particular emphasis on regional-level analysis and on the implications for land and food supply,

5 The likelihood of 50% refers to physical climate change uncertainties, including climate sensitivity, aerosol forcing, and ocean diffusivity. It thus depicts the chances that a specific GHG pathway would stay below the 2°C temperature target. The likelihood does not imply any probability of the political implementation of the targets, nor does it correspond to the likelihood of specific technologies becoming available in the future.

given bioenergy's potential contribution to the transformation. Section 17.3.5 is concerned with how the pathways might be implemented. Two critical issues are addressed: costs and investments, and policies. Because the overarching GEA scenario is strongly normative, all the pathways analyzed within this scenario require strong interventions to induce and direct the energy system transformation.

17.3.1 Economic Growth and Demographic Change

The GEA pathways share a common median demographic projection whereby the global population increases from almost 7 billion today to about 9 billion by the 2050s before declining toward the end of the century (UN DESA, 2009). Figure 17.5 illustrates this population projection in the context of the full range of global demographic developments from a very low to an improbably high number of people by 2100. The median development path is a challenging one, as the global population will be aging rapidly through the century and concentrating ever more in urban areas.

The GEA pathways also share a median economic development path, expressed in terms of world GDP that allows for significant development in the 50 or so poorest countries in the world, while at the same time reflecting increased resource productivity and demand growth in the richest countries, dampened by changing consumption patterns and lifestyles. This GDP development path builds on the updated IPCC B2 scenario projection by Riahi et al., (2007); for details see also the GEA database at www.iiasa.ac.at/web-apps/ene/geadb. Main changes include updates of short-term trends and revisions of regional projections consistent with the sustainability objectives of the GEA. The economic projection used in all the GEA pathways is illustrated in Figure 17.6, which also shows the full range of economic trajectories for the global energy scenarios in the literature (Nakicenovic et al., 2006).

The socioeconomic development pathway is chosen to be consistent with global aspirations toward a sustainable future while also attaining this goal with a high degree of confidence. Global real per capita income in the GEA pathways grows at an annual average rate of 2% over the next 50 years, but with significant differences in the pace of development across regions. Today's developing and emerging economies continue to grow at a relatively rapid pace, with their combined economic output surpassing that of the industrialized world by around 2040 (see inset in Figure 17.6). This pathway is also consistent with other central projections in the literature (Nakicenovic et al., 2006) and hence provides a good reference point for placing the GEA energy pathways within a comparative context.

17.3.2 Energy Demand and Services

The adequate provision of energy services is a prerequisite for human well-being and productivity, and ultimately it is the demand for these

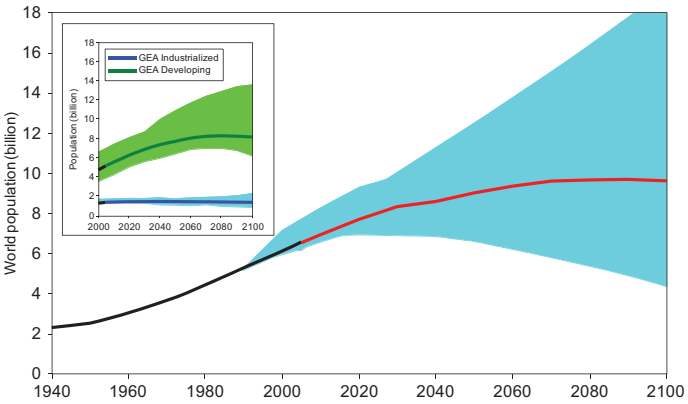

Figure 17.5 | Global population projections. The line indicates the median GEA development pathway and the fan indicates the range of population projections from the literature (Nakicenovic et al., 2006). The insert shows the median projections and ranges for the industrialized and developing regions separately.

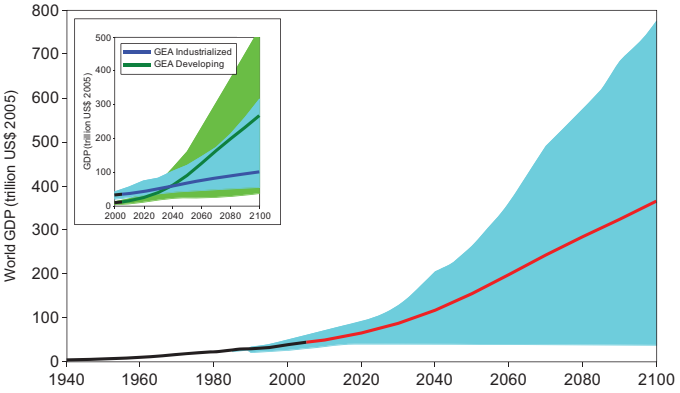

Figure 17.6 | Global economic development projections. The line indicates the median GEA development pathway and the fan indicates the range of economic projections from the literature (Nakicenovic et al., 2006). The insert shows the median projections and ranges for the industrialized and developing regions separately.

services that drives the energy system and its continuing expansion. Increasing affluence has historically been one of the major drivers of energy demand, and both the quantity and the quality of energy services determine in turn the magnitude of environmental and social impacts associated with the energy system. It is these impacts that are addressed by the normative objectives enshrined in the overarching GEA scenario.

Energy services are typically provided by end-use technologies, which convert energy from a particular form (biomass, petroleum, natural gas, electricity, and so forth) into services useful to a final consumer (heating and cooking, mobility, industrial processing, entertainment, and others). Consequently, end-use technologies and the efficiency with which they convert energy into useful services are inseparably connected with the levels and types of energy services demand. As a result, one can identify three broad and interrelated approaches to tackling demand-side challenges in the energy system:

- *improve technological efficiency*, e.g., increase vehicle fuel efficiency;
- *change the structure of energy services demand*, e.g., substitute physical mobility with "virtual" mobility enabled by electronic communications; and
- *reduce the level of energy services demand*, e.g., reduce travel needs by living closer to work or amenities.

Although all three of these approaches are explored in the GEA pathways as means of reducing final demand for energy, the emphasis throughout this section is on efficiency improvements. As a means for potentially decoupling energy demand from economic growth, energy efficiency represents a central lever for policy to target. Moreover, efficiency contributes to all the sustainability objectives. The degree to which efficiency improvements can limit energy demand growth is – by design – one of the main distinguishing characteristics of the GEA pathways. It should be noted, however, that efficiency improvements can be offset by both rebound effects and scale effects (Greening et al., 2000; Birol and Keppler, 2000; Hanley et al., 2009). Rebound effects describe an increase in demand for energy services as improvements in efficiency lower their effective cost. These effects can be direct (the savings from greater efficiency are spent on the same energy service), indirect (the savings are spent on a different energy service), or economy-wide (the savings contribute to economic and income growth, which increases demand). Rebound effects can be mitigated by price and other policies, which are discussed further in Section 17.3.5. Scale effects describe an increase in demand for energy services due to rising population or to rising economic output. Both rebound and scale effects make it important to consider the other approaches to demand-side transformation described above. Hence, both the structure and the level of energy services demand are also important parts of the GEA pathways described in this section.

The rest of this section is organized as follows. First, the headline trends in each group of pathways are discussed, covering the efficiency of the economy as a whole as well as on a per capita basis. Second, the GEA-Efficiency group of pathways is explored in more depth, sector by sector, drawing on material from the corresponding chapters of this report. Third, similarities and differences in the structure of energy demand (e.g., its distribution between end-use sectors) are considered.

17.3.2.1 Energy Intensity Improvements

Energy intensity is energy used per unit of output, typically expressed in megajoules per US dollar (MJ/US$) of GDP or value added. Energy intensity metrics are widely used to represent the overall energy productivity of an economy or sector. The final energy intensity of the global economy has fallen historically at a rate of about 1.2%/year since the early 1970s. However, some regions have experienced substantially more rapid reductions over certain periods. For example, China's energy intensity declined at a rate of about 4%/year between 1990 and 2000 (followed by a slower decline in the subsequent period). The causes of the energy intensity declines are many. They include, first, technological improvements in individual energy end-use appliances and technologies combined with substitution among fuels, such as the replacement of fuelwood with electricity or liquefied petroleum gas (LPG) for cooking. They also include changing patterns of energy end use; urbanization, which is characterized by generally higher system efficiencies: changes in the structure of the economy, including shifts toward higher shares of the less energy-intensive services sector; and finally, changing lifestyles, which affect both the type and the level of energy services demanded. Although not every such change has resulted in declining energy intensities in the past, taken together the overall trend is persistent and pervasive (Nakicenovic et al., 1998).

Energy intensity improvements can continue for a long time to come. Despite the energy efficiency and intensity improvements that have already been implemented to date, the efficiency of the energy system remains far from the theoretical potential. Although the full realization of this potential may never be possible, many estimates indicate that energy intensity reductions of a factor of 10 or more may be possible in the very long run (see Nakicenovic et al., 1993; Gilli et al., 1995; Nakicenovic et al., 1996).

The degree of energy intensity improvement is a crucial uncertainty for the future. All three groups of GEA pathways depict energy intensity futures that are driven by policies to improve energy efficiency, leading to global energy intensity improvement rates at or above historical experience. This is partly a result of the increasing importance of some low-income regions with relatively high rates of intensity improvement, but it is also partially due to the assumed move away from inefficient traditional fuels in the developing world. Energy intensity improvements thus vary significantly at the regional level, with some regions also developing more slowly than the historical rate, particularly in the GEA-Supply and -Mix pathways. The resulting global average reduction in energy intensity varies across the GEA pathways between about 1.5% and 2.2% annually to 2050. The lower end of the range is slightly faster than the historical experience, whereas the higher end is roughly double that and corresponds to a reduction in energy intensity of 60% by 2050. Cumulatively, these intensity improvements lead to substantial differences in per capita energy demand across the three pathway groups (see Figure 17.7).

Studies have shown that it is possible to improve energy intensity radically through a combination of behavioral changes and the rapid introduction of stringent efficiency regulations, technology standards, and environmental externality pricing, which mitigates rebound effects (see also Chapters 8, 9, and 10). The group of GEA-Efficiency pathways depicts such a development with a radical departure from historical trends. This group of pathways thus deliberately explores the consequences of demand-side interventions that lead to substantial declines

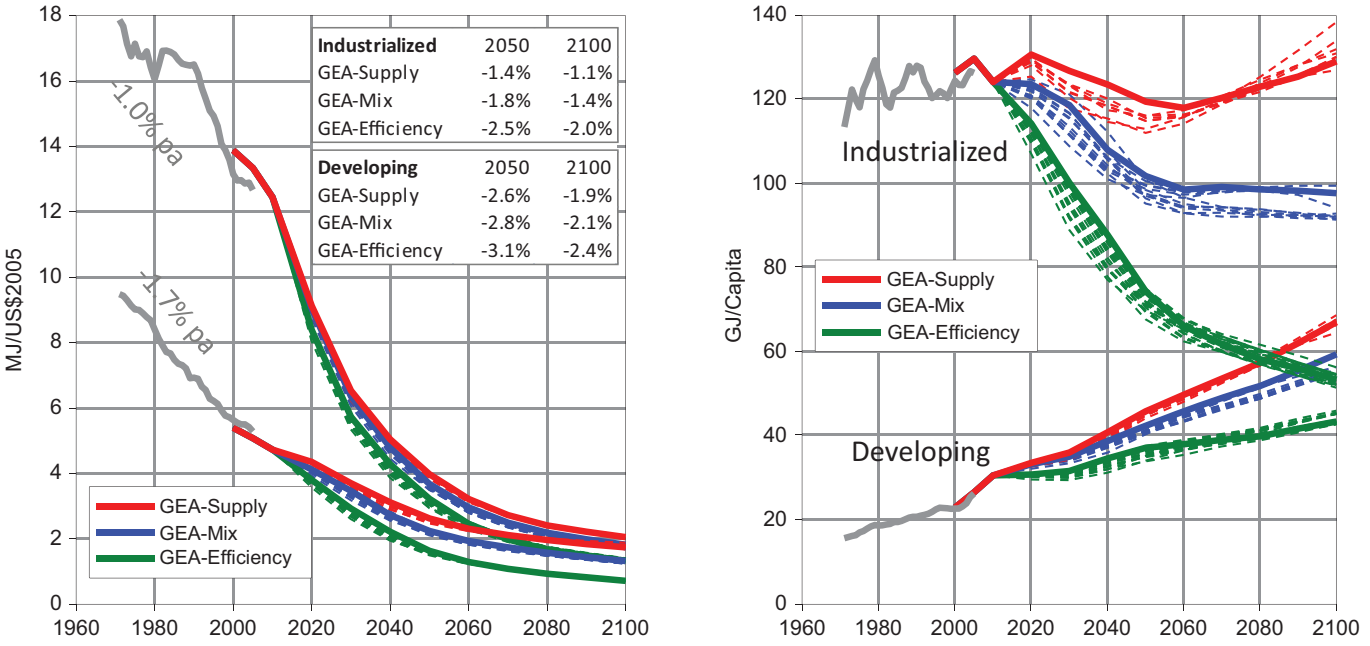

Figure 17.7 | Historical and projected energy intensity (left panel) and per capita final energy use (right panel) in the developing world and the industrialized world. Solid lines denote the illustrative GEA pathways within each of the three pathway groups; dashed lines show changes in energy intensity due to supply-side variations (discussed further in Section 17.3.3). The inset in the left panel shows rates of improvement in energy intensity (calculated using GDP at market exchange rates) between 2005 and 2050 and between 2005 and 2100. Source of historical data: IEA, 2010.

in per capita energy use in the industrialized world of about 45% in 2050 (from 130 GJ per capita in 2005 to about 75 GJ by 2050). Energy intensity rates in the developing world under the GEA-Efficiency pathways decline at 3.1%/year between now and 2050, and then slow down corresponding to an average of 2.4%/year over the course of the century. These rates are also considerably higher than historical experience. Given expected economic growth in the developing world, however, per capita energy demand continues to increase over the course of the century, although at a considerably slower pace than in the other GEA pathways groups (0.75%/year in the GEA-Efficiency pathways compared with 1.3%/year in the GEA-Supply pathways to 2050).The magnitude and pace of these efficiency improvements in the GEA-Efficiency pathways will undoubtedly require concerted and dedicated demand-side policies and measures. These are discussed in general terms through the remainder of this section and in more detail in Section 17.3.5.

As noted, the GEA-Efficiency pathways group depicts the upper bound of potential efficiency improvements and thus the lower bound of energy demand in the GEA pathways. The GEA-Supply pathways group depicts the opposite, that is, the lower bound of potential efficiency improvements giving rise to an upper bound of energy demand across all GEA pathways. The GEA-Supply pathways thus place much less emphasis on efficiency and other demand-side measures, focusing instead on supply-side transformations, which are discussed further in Section 17.3.3. In the GEA-Supply pathways, the long-term improvement rate in global energy intensity over the course of the century is slightly above the historical record of 1.2%/year. Over the medium term to 2050, however, both developing and industrialized regions experience intensity improvements about 40% higher than in the past (1.4%/year and 2.6%/year compared with 1%/year and 1.7%/year in the past, respectively). As a result, per capita energy use in the industrialized world stays at roughly 2005 levels, while per capita demand in the developing world catches up, increasing by almost a factor of 2 in the long term (Figure 17.7). The GEA-Mix pathways group is characterized by intermediate efficiency improvements, giving rise to energy intensities both economy-wide and per capita that lie between the aggressive GEA-Efficiency pathways and the less prescriptive demand-side trends of the GEA-Supply pathways.

17.3.2.2 Sectoral Measures to Improve Energy Efficiency

Introduction

Increasing affluence typically results in additional demand for energy. However, per capita energy use today varies widely even between countries at comparable income levels (see Table 17.4). The reasons include differences in the type and amount of energy services demanded, in the efficiency of end-use technologies, and in the way these services and these technologies form part of broader structural patterns of behavior and lifestyle.

The use of energy for mobility provides a prominent example of these differences in energy use across countries. The average North American consumes about 54 GJ annually traveling by car, compared with about half of this amount in the other member countries of the Organisation

Table 17.4 | Final energy use and income per capita for Industrialized and Developing Regions, 2005 Actual and 2050 under GEA-Efficiency and GEA-Supply.

	2005		2050			
			Industrialized[1]		Developing[2]	
	Industrialized[1]	Developing[2]	GEA-Efficiency	GEA-Supply	GEA-Efficiency	GEA-Supply

Total final energy (GJ per capita)	73–219	7–46	62–98	104–156	28–50	32–71

1 Aggregated ranges of five GEA regions representing the industrialized world: North America, Western Europe, Pacific OECD, Eastern Europe, and Former Soviet Union. For full regional definitions see the electronic appendix to this chapter.

2 Aggregated ranges of six GEA regions representing the developing world: Centrally Planned Asia and China, South Asia, Pacific Asia, Middle East and North Africa, sub-Saharan Africa, and Latin America. For regional definitions see the electronic appendix to this chapter.

for Economic Co-operation and Development (OECD). Three main factors, in addition to the slightly higher per capita income in North America, explain the difference: the lower fuel economy of the typical individual vehicle (3 MJ/km in North America versus 2.6 MJ/km in the other OECD countries), longer distances traveled (as a result of both preferences and structural characteristics of urban form and land area), and more individualized use of cars (average occupancy is about 1.3 passengers/vehicle in North America compared with up to 1.5 passengers/vehicle in Eastern Europe, for example). This illustrates well the combined effect of efficiency and of behavior and lifestyles (levels and types of energy service demanded) on fuel consumption (see also Chapter 9).

Similar differences in per capita energy use can be found between other regions of the world as well as for other sectors, such as residential and industry. Large-scale improvements in the energy intensity of an economy therefore require a portfolio of measures that stimulate the adoption of highly efficient end-use technologies, complemented by policies to promote changes in energy services demand through behavioral and lifestyle shifts. In addition, structural changes in the economy play an important role.

The overarching finding from the sectoral analysis is that the rapid energy intensity improvements depicted by the GEA-Efficiency group of pathways are feasible with currently available technologies. The necessary magnitude of change, however, requires a fundamental shift in the way energy is used across all major sectors of the economy. The following sections summarize the nature of these shifts and the policies that might drive them in the GEA-Efficiency pathways.

The Residential and Commercial Sector in the GEA-Efficiency Pathways

In the residential sector, economic growth is expected to further increase the floor areas of dwellings by increasing living standards, particularly in developing countries. This will result in additional energy demand for space heating and cooling. As noted in Chapter 10, however, the potential for efficiency improvements in the use of energy for this purpose is vast. In the GEA-Efficiency group of pathways, a large fraction of this potential is successfully tapped. Policies to improve thermal insulation as well as retrofits to advanced building types (passive house standards or lower) lead to improvements in energy use per unit of floor area by a factor of 4 in the industrialized world, from about 400–900 MJ/m^2 down to 100–230 MJ/m^2 by 2050 (Table 17.5). Improvement rates are similar in the developing world, on the order of a factor of 2 to 3.

The potential efficiency gains from buildings in terms of energy use avoided are among the highest across all end-use sectors. Achieving these gains requires the rapid introduction of strict building codes and retrofit standards for almost the complete global building stock. The rate of retrofit would need to increase to about 3% annually to 2050, about three times the historical rate.

In the GEA-Efficiency pathways, demand for energy from centralized sources and grids is further reduced by the adoption of technologies that enable space heating and cooling with net zero use of centralized energy. These include solar water heating, solar heating, air-source or ground-source heat pumps powered by solar photovoltaics, and biomass-based heating. Combined with efficiency improvements to building shells, these technologies would significantly reduce the need for centralized solutions for thermal comfort; centralized energy infrastructure would largely provide the additional energy required for lighting, cooking, and appliances.

Per capita electricity use in the residential and commercial sector is expected to grow significantly because of rising incomes and the adoption of modern household appliances and other electric devices. This trend is particularly pronounced in the developing world. Despite high efficiency standards, electricity use in the developing world increases in the GEA-Efficiency pathways group by a factor of 3 to 8 by 2050 (Table 17.5). The increase is more modest in the lower-income countries of the industrialized world, whereas in the higher-income countries of North America and Western Europe, per capita electricity use peaks and then declines toward 2050 to levels below that of 2005. Although overall demand for electricity continues to increase in the residential sector,

Table 17.5 | Energy service indicators for the residential and commercial sector in Industrialized and Developing Regions, 2005 Actual and 2050 under GEA-Efficiency pathways.

	2005, actual		2050, GEA-Efficiency	
	Industrialized[1]	Developing	Industrialized	Developing

3 Includes two- and three-wheeled vehicles.

efficiency improvements significantly slow this growth. As a result, per capita consumption across all income groups is about 25–50% lower in the GEA-Efficiency pathways group than it would be without a concerted emphasis on the demand-side transformation.

The Transportation Sector in the GEA-Efficiency Pathways

The slow growth of energy demand in the transportation sector in the GEA-Efficiency pathways results in part from efficiency improvements in the vehicle fleet, but also from structural shifts toward public transport (including rail and bus) and limits to car ownership, with implications for behavior and lifestyle (see also Chapter 9). In the GEA-Efficiency pathways group, about half of the overall improvement in energy intensity by 2050 comes about through technical efficiency improvements across all modes of passenger transportation. The compound global effect of these efficiency gains reduces fuel consumption from about 1.7 MJ/km in 2005 to 1.3 MJ/km by 2050. Gains are largest for vehicles, with some significant differences across world regions (the range is from 1.9 to 0.9 MJ/km). The other half of the overall intensity improvement is achieved by reducing demand for mobility as an energy service (e.g., by substituting travel with teleconferencing) and shifting demand for mobility to public transportation (e.g., trains and buses). Large differences in modal split across countries already exist world-wide. Although demand is thus significantly lower in relative terms in the GEA-Efficiency pathways than in the GEA-Supply pathways, in absolute terms mobility continues to increase.

In the industrialized world, the proportion of total mobility (expressed in passenger-kilometers) provided by cars declines from about 60% in

2005 to 40% in the GEA-Efficiency pathways (Table 17.6). Trends are different in the developing world, where a large fraction of the population already relies on public transportation. Increasing affluence will make cars more affordable and thus increase reliance on individual mobility. As a result, car ownership in the developing world is expected to increase by almost a factor of 5 even in the GEA-Efficiency pathways (from 2 to 11 cars per 100 people by 2050). Although this is a considerable increase, the expected growth in the absence of any policies to support public transportation and limit car ownership would be some 30% higher still. Also, despite this large increase, transportation by bus and train in 2050 in the GEA-Efficiency pathways covers a much larger fraction of total passenger transport demand in the developing world than in the industrialized world (35% versus 20%; see Table 17.6).

In addition to individual mobility, freight transport continues to be a strong driver of energy demand in the transportation sector. An important feature of the GEA-Efficiency pathways group is therefore the switch toward higher shares of railway transportation (Table 17.6) combined with improvement in the overall efficiency of freight transportation by about a factor of 2 by 2050, from 1.3 MJ/t-km (tonne-kilometers) on average in 2005 down to 0.7 MJ/t-km in 2050. In the industrialized world this leads to relatively constant per capita energy use for freight transportation despite the near doubling of transport volume from 8,200 t-km per capita to about 16,000 t-km per capita by 2050. Although efficiency gains are of a similar order of magnitude in the developing world, increases in freight demand more than offset those gains, leading to an increase in per capita energy use for freight by about 20% to 2050. In absolute terms, however, by 2050 energy demand for this purpose in developing countries remains considerably below that of today's industrialized countries.

The Industry Sector in the GEA-Efficiency Pathways

In the GEA-Efficiency pathways, energy efficiency in the industrial sector improves by about 1.5%/year, resulting in an overall demand of about 200 EJ in 2050. This is around 20% below what it would be in the absence of a concerted approach to demand-side transformation, and it equates to a 50% reduction in the overall energy intensity of industrial production (see Table 17.7 for related data in per capita terms).

The demand-side emphasis of the GEA-Efficiency pathways features a number of different measures in the industrial sector to improve energy efficiency, promote structural change, and optimize industrial systems design to reduce energy demand. These measures can be broadly split into the following categories:

- widespread adoption of best available technology for new investments;
- retrofit of existing plants to improve energy efficiency;
- optimization of energy and material flows through systems design, quality improvements, lifecycle product design, and enhanced recycling; and
- further electrification and a switch to renewable energy.

Table 17.7 | Energy service indicators for the industry sector in Industrialized and Developing Regions, 2005 Actual and 2050 under GEA-Efficiency pathways.

	2005, actual		2050, GEA-Efficiency	
	Industrialized[1]	Developing	Industrialized	Developing

Feedstock	6–23	0.3–6	6–14	1–7
Other (nonthermal, e.g., electric)	4–15	1–4	12–16	5–9

1 Industrialized and developing regions are defined as in Table 17.4.

The adoption of best available technology for industrial processes can yield an efficiency improvement of around 15% (IEA, 2007; Saygin et al., 2010). More systemic approaches to optimizing the use of combined heat and power, pumps, fans, compressed air and steam systems, and so on can yield another 15% (IEA, 2007; Price and McKane, 2009). Further reductions in energy intensity in the industrial sector can be achieved through the optimization of material flows and the widespread adoption of new high-efficiency technologies currently at niche scales (WBCSD/IEA, 2009). Moreover, a switch to 25% renewable energy throughout the manufacturing industry yields a 10% "efficiency" gain through electrification and reduced used of fossil resources, although this is balanced by a similar loss from widespread adoption of CCS (see Chapter 8). The efficiency potentials of the five most energy intensive industrial subsectors (iron and steel making, chemicals and petrochemicals, cement making, pulp and paper, and aluminum), which account for about two-thirds of industrial energy use, are discussed in more detail in the online electronic appendix to this chapter, as well as in Chapter 8.

Energy Efficiency by Sector in the GEA-Supply Pathways

The sectoral analysis above provides some specific detail as to how the fundamental demand-side transformation represented by the GEA-Efficiency pathways can be achieved. Central to this effort is the rapid and pervasive introduction of energy efficiency measures throughout the world. However, technical measures alone will not be sufficient. They need to be complemented by measures to both shift and limit the underlying demand for energy services, build institutional capacity (see Chapter 25), remove market and nonmarket barriers to increased energy efficiency (see Chapters 22 and 26), and mobilize the substantial investment needed (see Chapter 6). These policy and investment needs are discussed further in Section 17.3.5

but are emphasized here as an integral and essential feature of the GEA-Efficiency group of pathways.

The GEA-Supply pathways, in contrast, represent the extent of potential demand-side transformation without this concerted policy and investment emphasis, and without many of the specific efficiency measures described in the sectoral analysis above. However, the GEA-Supply pathways group is not simply a business-as-usual continuation of historical trends. All the GEA-Supply pathways fulfill the sustainability objectives of the overarching GEA scenario set out in Section 17.2.3. As noted, these pathways are implemented through the achievement of highly ambitious targets relating to energy access, environmental impacts, and energy security. Reaching these targets requires a raft of policy and other initiatives, discussed in detail in Sections 17.4–17.7 of this chapter, that lead to a transformation of the global energy system. Whereas the GEA-Efficiency pathways emphasize the transformative potential on the demand side, the GEA-Supply pathways concentrate on supply-side measures. However, the latter also impact energy demand, albeit indirectly. To take one simple example, a carbon tax implemented to reduce the share of fossil fuels in electricity generation might indirectly raise the cost of final energy and so reduce demand. The more general point is that the level of energy demand and energy intensity improvements in the GEA-Supply pathways shown in Figure 17.7 falls well below the upper bound of demand projections found in the scenario literature to represent business as usual. Compared with, for example, the extensive scenario database of the IPCC Fourth Assessment Report (IPCC AR4) (Fisher et al., 2007), energy intensity improvement rates in the GEA-Supply pathways correspond roughly to an intermediate demand projection close to the median of the scenario distribution by 2050. Compared with the upper 90th percentile of the full scenario set reviewed in the IPCC AR4, the GEA-Supply pathways achieve more than double the intensity improvements by 2050 (1.5%/year compared with 0.6%/year in the scenarios reviewed by the IPCC).

Table 17.8 summarizes indicators of per capita energy use for the GEA-Efficiency and GEA-Supply groups of pathways in all end-use sectors: residential and commercial, transportation, and industrial. Projections for 2050 are compared with efficiencies of energy use as of 2005. The table combines information from the detailed bottom-up technology assessments of each sector in Chapters 8–10 with information from the global GEA pathways discussed in this chapter.

In the residential and commercial sector, floor area as an underlying determinant of energy services demand is the same in both pathway groups. However, the penetration of advanced buildings combining major efficiency improvements with decentralized energy technologies is minimal in the GEA-Supply pathways. Resulting heat demand per unit of floor space is consequently a factor of 2 to 3 higher, with per capita consumption around double that in the GEA-Efficiency pathways in both industrialized and developing countries.

In the transportation sector, total passenger demand for mobility is around 20–30% higher in the GEA-Supply pathways, because the measures described above to limit and shift services demand in the context of the GEA-Efficiency pathways are not implemented. Car ownership is also around a factor of 7 higher than current levels, compared with the factor of 5 increase in the GEA-Efficiency pathways. Although levels of car ownership increase proportionally more in developing countries, they remain at far higher absolute levels in the industrialized world. Meanwhile, although overall demand for freight mobility is similar, the GEA-Supply pathways have a higher proportion of freight moving by road than rail, the opposite of the case in the GEA-Efficiency pathways. Together with lower efficiency gains in the vehicle fleet, this results in 15–20% higher per capita fuel use. Demand for aviation is assumed to be the same in both the GEA-Supply and the GEA-Efficiency pathways.

In the industrial sector, the absence of major new efficiency policies in the GEA-Supply pathways results in energy demand more than doubling, to 260 EJ, in 2050 compared with 210 EJ in the GEA-Efficiency pathways. Energy intensity does improve, by about 1%/year, but this is lower than the 1.5%/year improvements achievable from the concerted demand-side transformation that occurs in the GEA-Efficiency pathways.

These large differences in efficiency improvements between the GEA-Supply and the GEA-Efficiency groups of pathways have major implications for the required transformation of the supply side of the energy system. The higher level of demand in the GEA-Supply pathways means fewer degrees of freedom in terms of supply options. This interdependency between the demand- and the supply-side features of the pathways is discussed in detail in Section 17.3.4.

17.3.2.3 The Structure of Final Energy Demand

Despite the large differences in efficiency improvements between the GEA-Efficiency and the GEA-Supply groups of pathways described in the previous section, certain structural characteristics of final energy use are remarkably consistent across all GEA pathways, including the group of GEA-Mix pathways. These relate to the provision of energy services using higher-quality forms of energy. All GEA pathways depict a demand-side transformation toward ever more flexible, more convenient, and cleaner forms of energy at the point of final use (see also Nakicenovic et al., 1998). Figure 17.8 presents the same findings graphically by distinguishing the share of final energy provided by solid, liquid, and grid-based or on-site-generated forms of energy. The low variation across the three groups of GEA pathways is shown by the limited extent of cross-hatching or overlap.

A pervasive characteristic of all the GEA pathways is the continuing shift from energy used in its original, often solid form, exemplified by

the traditional direct uses of coal and biomass, to more sophisticated systems of energy conversion and delivery. All the GEA pathways include the phase-out of traditional biomass in the residential and commercial sector by 2030, due to dedicated energy access policies in the developing world (see Section 17.4). In addition, stringent climate policies (see Section 17.5.1) lead to the phase-out of the direct use of coal in both the industrial and the residential sectors by 2050. The share of solid fuel shown in Figure 17.8 after 2050 is predominantly biomass in the industrial sector, as a substitute for coal in industrial processes where carbonaceous fuels are required (e.g., iron and ore reduction processes).[6]

A second major transformation is the increasing degree to which energy is delivered by dedicated transport infrastructures, such as pipelines and networks. This enables similar end-use patterns across regions, as end

6 In addition, the possibility of direct reduction with hydrogen is considered by the pathways as a long-term option for the substitution of coal in these processes.

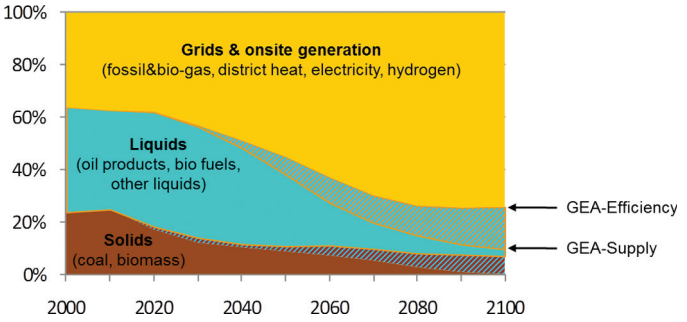

Figure 17.8 | World final energy shares of solid fuels, liquid fuels, and grids and on-site generation. Overlapping hatched areas indicate variations across the GEA-Efficiency and the GEA-Supply pathways. The GEA-Mix pathways lie in between the two others.

uses can be linked to fundamentally different and potentially distant primary energy supplies (see Section 17.3.3 for more details). An additional and related transformation, represented particularly in the GEA-Efficiency pathways, is the increasing development of on-site generation of both heat and electricity by renewable energy technologies.

These transformations in the use of final energy also involve changes in the economic structures that underpin the pathways. Continued industrialization of the developing world and increasing demand for industrial goods as incomes rise, result in comparatively larger shares of industrial energy demand in the future. This trend is most pronounced in the GEA-Efficiency group of pathways because aggressive efficiency programs in the residential and transportation sectors limit their shares of final energy demand, as shown in Figure 17.9.

In sum, all the GEA pathways share some key features in terms of the structure of final energy demand: a shift away from traditional solid forms of energy; an increase in modern, cleaner, grid-delivered and on-site-generated forms of energy; and a rising share of industrial sector energy use as incomes rise. There is, however, one major point of difference among the GEA pathways. This relates to the nature of transformation in the transportation sector. The environmental and energy security objectives of the overarching GEA scenario necessitate a lower reliance on oil in all GEA pathways. By 2050, oil use in the transportation sector is reduced by 35–50% from 2005 levels. However, the substitution away from oil branches into alternative transportation systems, as described in Section 17.2.1. Broadly speaking, these alternatives can be described as "conventional" and "advanced" transportation.

A future conventional transportation system would rely predominantly on liquid fuels (including some oil), biofuels, liquefied natural gas, and potentially the direct use of biogas and natural gas. This represents the least discontinuity from current trends in terms of both end-use technologies and fuel supply and distribution infrastructure. In contrast, an advanced transportation system involves a more fundamental transformation, requiring largely new infrastructure systems in the case of hydrogen fuel cell vehicles, or new uses for existing infrastructure in the case of plug-in hybrids or fully electric vehicles.

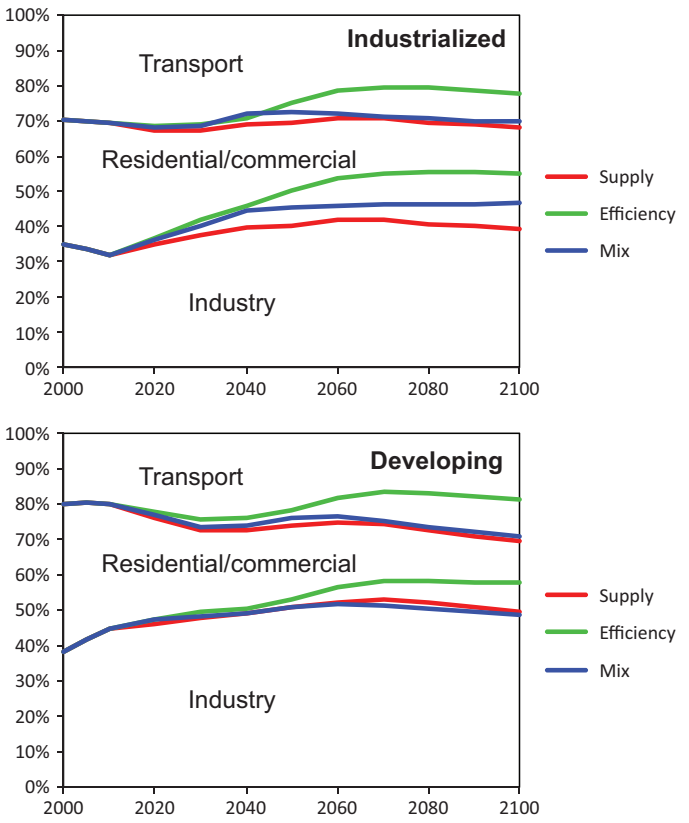

Figure 17.9 | Shares of final energy by sector in the three pathway groups in industrialized and developing countries.

Both these alternatives are feasible within all three of the GEA pathway groups. Their outcome is essentially one of choice and direction rather than necessity. This is why they are explicitly included as a branching point in the scenario taxonomy. The importance of this branching point stems from the magnitude of the implications on both the demand and the supply sides. On the demand side, for example, vehicle technologies would follow very different innovation and development paths, either reducing the costs and improving the reliability of fuel cells in the hydrogen-based Advanced Transportation system, or improving the flexibility of engines to use both biofuels and fossil-derived liquids in the Conventional Transportation system. However, the impacts of the transportation branching point are felt particularly strongly on the supply side, as they potentially reduce the flexibility of supply-side portfolios given the GEA sustainability objectives. Similarly, any changes on the supply side can have major implications for the choice of demand-side technologies. These interdependencies are discussed further in the next section, which turns to consider the supply side of the energy system transformations represented in the GEA pathways.

17.3.3 Energy Supply

17.3.3.1 Introduction

The level of energy demand determines the flexibility of supply-side portfolios. This is particularly the case given the ambitiousness of the

GEA sustainability objectives and the energy transition required to reach the associated targets. Across all the GEA pathways, energy access objectives constrain the use of traditional fuels in developing countries; energy security objectives limit the amount of energy trade and foster the increasing diversity of energy supply; climate change objectives constrain the use of carbon-intensive energy forms in electricity generation; and so on. Within these already tight constraints, low energy demand allows a greater number of viable options for energy supply, whereas high energy demand reduces the choices available and makes it more difficult to limit or omit specific supply options. Similarly, the future fuel needs of the transportation sector have a further impact on the extent to which supply-side portfolios can be varied in response to political, resource, land, or other requirements.

Having established and analyzed the different levels of demand in the GEA-Efficiency, GEA-Supply, and GEA-Mix groups of pathways, this section explores variability in the corresponding supply-side transformations, including transmission and distribution infrastructure.[7] The aim is twofold: to enrich the storylines represented by the GEA pathways in fulfilling the sustainability objectives, and to identify both the necessities and the choices available on the supply side of the energy system if these sustainability objectives are to be met.

This section is organized using the branching point approach set out in Section 17.2.2. First, the principal options on the supply side are set out, covering both energy forms and relevant technologies. Second, the viable portfolios of supply-side options across the GEA-Efficiency, GEA-Supply, and GEA-Mix groups of pathways are assessed, given the different levels of energy demand in each group – the first branching point. Third, the effect of alternative transportation system transformations, either Conventional or Advanced, is explored in terms of supply-side portfolio flexibility – the second branching point. Fourth, the potential for further limiting or omitting specific options from the supply-side portfolio is assessed through an extensive sensitivity analysis – the third branching point. Through this process, the three groups of GEA pathways become first 6 and then 60, although ultimately they are reduced to the 41 that are feasible. The feasibility analysis indicates how important certain supply-side options are for a the energy transition. However, the results should not be mistaken for predictions. Rather, they can be interpreted as an assessment of the necessary technological changes, exploring the "option values" of different technology clusters that might, for example, guide future investment decisions.

17.3.3.2 Supply-Side Options and Portfolios

There is a large portfolio of options on the supply side to provide the energy needed to meet the demand for energy services. These options comprise different forms of energy and their attendant conversion technologies: crude oil converted into petroleum products by refineries to provide transportation fuel and thus mobility, for example, or wind energy converted into electricity by wind turbines to provide lighting. Throughout this section, supply-side options are distinguished in terms of both the primary energy form (e.g., bioenergy, coal, solar energy) and the conversion or processing technology (e.g., biomass-to-liquids, biomass power generation, coal power generation with CCS, solar photovoltaic). Each option also has implications for the transmission and distribution infrastructure: rigs, pipelines, and filling stations in the case of the energy conversion chain from crude oil to mobility; electricity grids and transformer stations in the case of conversion from wind energy to lighting. These, too, will be considered here.

In scenario studies (as well as historically), there are also a wide range of factors that shape and constrain the shares of final energy provided by different supply-side options. The clearest determining factors relate to cost, efficiency, and other performance attributes. Availability, based on the underlying resource potential, is another factor, although a detailed assessment of the bioenergy and other renewable, fossil, and uranium resources in the context of the GEA pathways show that none of these supply-side options face an absolute resource constraint at the global level (see Box 17.3 and the electronic appendix to this chapter on resource potentials). At the regional level, however, some resource categories could become scarce.

In the context of sustainability assessments like the GEA, other factors also come into play, including environmental impacts (e.g., air pollution, GHG emissions), social impacts (e.g., electrification and clean cooking), and geopolitical considerations (e.g., energy security). The supply-side options used in all the GEA pathways must allow the GEA sustainability objectives to be fulfilled within the timelines and to the extent set out by their associated targets (see Section 17.2.3). This means that certain supply-side options are preferred over other options in the energy transition toward its objectives. For instance, technologies like bioenergy and other renewable energy sources, nuclear energy, and CCS have the potential to help meet the climate target. CCS can also be used in combination with bioenergy (BioCCS) to produce net negative carbon dioxide (CO_2) emissions (see Chapter 11, Section 11.3 for more details about the technology). This is another potentially important option in the context of climate stabilization objectives.

An alternative option to reduce CO_2 emissions is carbon sink enhancement through afforestation. As both BioCCS and carbon sinks can significantly affect the magnitude and timing of emissions reductions on the energy supply side, both are included in this analysis.

Cost, performance, resource availability, and sustainability criteria are not the only factors influencing the projected success of these supply-side options. Some options require advanced technological knowledge, which is not universally available (and which has contributed to historical differences in primary energy supply patterns at the country or regional level). Other options face barriers to a rapid scaling up (Wilson,

7 The supply-side flexibility analysis relies primarily on the MESSAGE modeling framework, but the findings have been checked for consistency with the pathways generated with the IMAGE model.

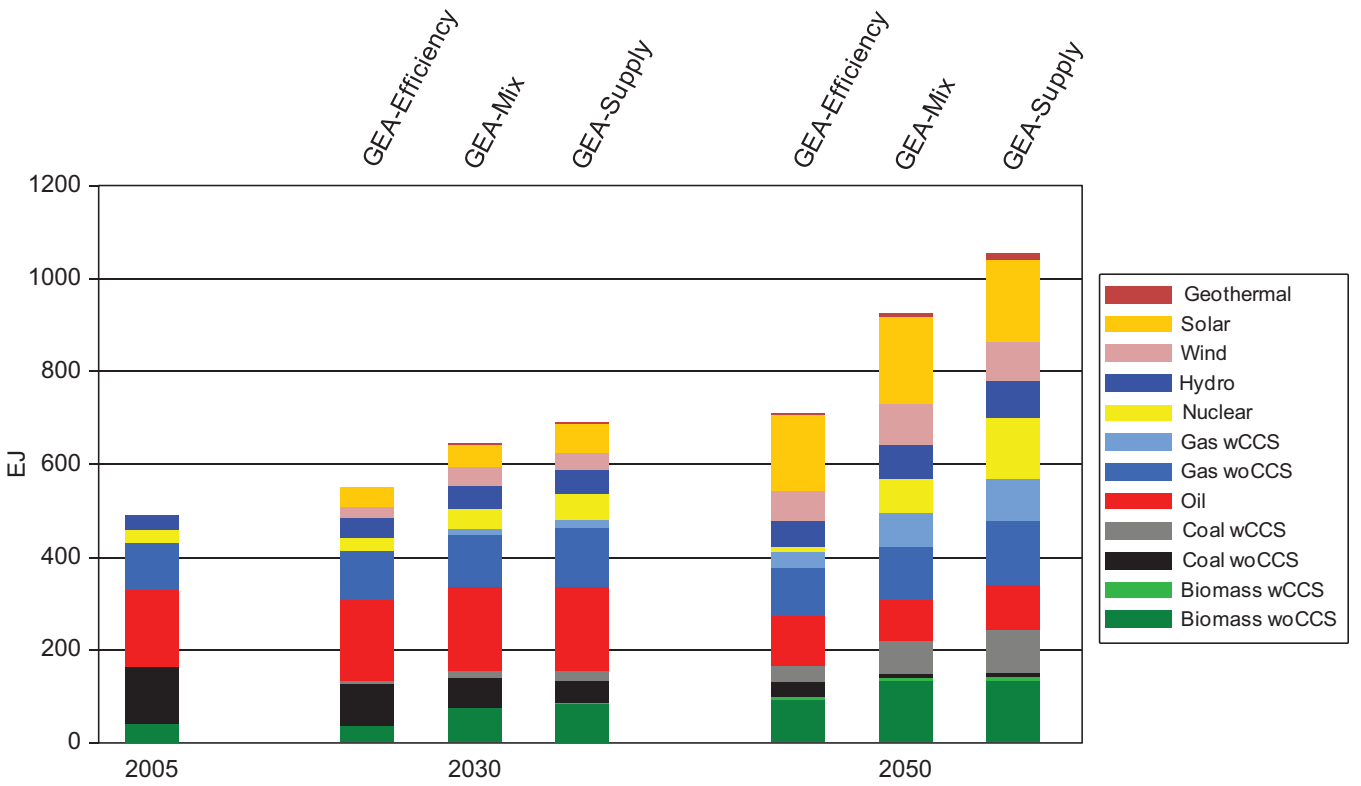

Figure 17.10 | Composition of global primary energy supply in 2005, 2030, and 2050 across pathway groups under an unrestricted supply portfolio and Conventional Transportation setup.

2009). Integrating high proportions (e.g., 20% or more) of intermittent energy sources such as wind or solar in electricity grids is an example. Still other options face issues of public acceptance. Nuclear energy in some countries is an obvious example, but some forms of renewable energy, such as large-scale hydropower, bioenergy, on-shore wind, and CCS, are others. Some options, such as nuclear, entail also other societal risks due to accidents or proliferation of fissile material for weapons use. The overall conclusion of the GEA assessment on nuclear is thus that until the proliferation potential is better controlled and safer reactor designs are available, countries (especially those considering building their first nuclear power plants) should consider other climate-friendly power supply options first (for a further discussion, see Chapter 14). Finally, the requirements of some supply-side options in terms of new physical infrastructure and distribution systems are highly capital intensive but face initially low overall demand, and thus are often unattractive to both private investors and resource-limited public investors.

In light of all these potential issues, the approach taken here begins by elaborating the broadest possible decision space, or range of possibilities, in terms of supply-side portfolios in each of the three GEA pathway groups (GEA-Efficiency, GEA-Mix, and GEA-Supply). First, the full range of supply-side options is considered, subject to cost, performance, and system integration constraints but always respecting the overarching need to comply with the GEA targets. As noted earlier, the level of demand has a significant impact on supply-side flexibility: the greater efficiency improvements and reductions in energy services demand of the GEA-Efficiency group of pathways leave more options open on the supply side. Next, this maximal decision space is reduced in stepwise fashion. The impacts of major changes in the transportation system on this unrestricted supply portfolio are explored. Finally, the impacts of specific restrictions or omissions of particular supply-side options are considered, to reflect the sensitivities or concerns surrounding their widespread deployment. These restricted supply portfolios, as well as the transportation analysis, provide a broad sensitivity analysis around the unrestricted supply portfolio, illustrating which options are "musts" and which others are choices.

17.3.3.3 Supply-Side Options under Different Levels of Demand

Figure 17.10 summarizes the result of the unrestricted supply portfolio analysis for the three levels of energy demand represented in the GEA-Efficiency, GEA-Mix, and GEA-Supply pathway groups. It compares the primary energy supply mix in 2030 and 2050 under each of the three groups with that in 2005.[8] Each future primary energy supply mix depicted can be interpreted as the least-cost portfolio subject to

8 A well-recognized problem with reporting primary energy supply is how to include noncombustible energy forms (e.g., nonbiomass renewables and nuclear energy). Here the substitution method is used to back-calculate primary energy by assigning a 35% efficiency for electricity generation from noncombustible sources and an 85% efficiency for heat generation (see Chapter 1 for details).

the cost and performance characteristics of the different supply-side options and the need to fulfill the GEA objectives with respect to access, environment, and security.

The most striking difference across pathway groups is in the total demand provided by the energy system. In terms of supply-side options, the figure also shows the breadth of the supply portfolio needed to meet the GEA sustainability objectives: most if not all options contribute across all three pathway groups. Nuclear energy makes a greater proportional contribution in the GEA-Supply pathways group than in the other groups, which has less flexibility in terms of portfolio restrictions.[9] Conversely, as will be explored further below, the GEA-Efficiency pathways group can tolerate the restriction or even omission of various individual supply-side options.

An equally important difference across pathway groups is the varying degree of urgency for change on the supply side in the medium term. With the ambitious effort on the demand side in the GEA-Efficiency pathway, the change from current supply-side structures can be less rapid. In 2030, with the exception of wind and solar (which grow considerably in absolute terms), the primary energy supply mix in the GEA-Efficiency pathway is only modestly different from that of today. In contrast, the GEA-Mix and, in particular, the GEA-Supply pathways require more radical changes in energy supply. This includes a more rapid scaling up of all renewable supply options, and CCS, which by 2030 needs to remove up to 10% of CO_2 emissions from fossil fuel combustion in the GEA-Supply pathways, increasing to about 50% by 2050. The same is true for nuclear energy, which in the GEA-Efficiency pathway (with an unrestricted supply portfolio) continues to contribute about the same amount of energy as today or less through 2050, whereas in the GEA-Mix and GEA-Supply pathways a two- to fivefold increase up to 2050 is observed. For pathways with a nuclear phase-out see sections 17.3.3.5 and 17.3.4.

17.3.3.4 Supply-Side Options under Different Transportation Systems

As noted in Section 17.3.2, the structure of the transportation sector decisively influences the feasibility of supply-side portfolios. Therefore, the analysis below distinguishes between two sets of assumptions about the transportation sector transition, labeled Advanced Transportation and Conventional Transportation. The Advanced Transportation setup is characterized by a transition to electricity or hydrogen, or both, as main transportation fuels in the medium to long term. By 2050 these two fuels would have to deliver between roughly 20% and more than 60% of the transportation sector's final energy, depending strongly on overall transportation demand. This implies a massive buildup of new infrastructure over the coming decades. Whereas such a transition could proceed more gradually in the case of electrification, the transition to hydrogen is more challenging, because bulky investments in a new distribution infrastructure would need to be made. On the other hand, hydrogen would be more compatible with the existing refueling infrastructure and business model, which might have to change significantly in a largely electrified transport sector (Andersen et al., 2009). In contrast, the Conventional Transportation story would stay mostly within current modes of operation, largely relying on liquid fuels and, in some regions, on gas. Still, a growing share of electricity would also be needed in this conventional world, reflecting a combination of a modal shift toward public transportation and some electrification of at least short-distance individual transport.

Two different interpretations of the Advanced Transportation setup are realized in the GEA scenario analysis: an electric route and a hydrogen route. These have in common that numerous additional energy sources (e.g., nonbiomass renewable energy, nuclear energy) become available to the transportation sector on a large scale.[10] The electric route leads to a substitution process, dominated by electric vehicles and plug-in hybrids in combination with biofuels. The alternative route, hydrogen, explores a transition toward a long-term transportation sector that is dominated by hydrogen fuel cell vehicles after 2050. In contrast, the Conventional Transportation setup tends to follow a regionally more diversified path, depicting the coevolution of a wide portfolio of fuels and technologies with similar shares, including hybrid vehicles, flexible cars using biofuels in conjunction with fossil liquids from natural gas (in combination with CCS to reduce carbon emissions), and direct use of biogas and natural gas. These alternative transportation sector configurations also have important implications for the required technological innovation and improvements in vehicle engines. R&D and deployment incentives are needed in the Advanced Transportation setup to reduce costs and improve the reliability of either fuel cells or the next generation of batteries. The transition under the Conventional Transportation setup relies more heavily on advanced and more flexible designs of internal combustion engines.

As illustrated by Figure 17.11, the differences between the alternative transportation sector assumptions tend to play out more severely in the GEA-Mix and particularly the GEA-Supply groups of pathways, simply because demand is significantly higher by 2030 and still higher by 2050. Total primary energy supply is lower in an Advanced Transportation world than in a Conventional Transportation world, because the well-to-wheel efficiency of the electric and hydrogen routes is generally higher than that of the liquid route (van Vliet et al., 2010; 2011). A more subtle difference concerns the higher uptake of the available bioenergy potential under the Conventional Transportation option by 2030 across the three groups of

9 The main reasons for the high nuclear contribution in the GEA-Supply pathways is the high demand of energy, which reduces the flexibility of supply (see Section 17.3.3.5) and thus results in comparatively higher prices for energy. The higher energy prices, in turn, increase the demand for more costly energy options, such as nuclear. Different phase-out pathways for nuclear, however, show that the transformation toward the sustainability objectives are in principle technically possible also in the GEA-Supply pathways (Section 17.3.3.5).

10 The Advanced Transportation sector in the GEA-Supply pathways relies largely on hydrogen, whereas in the GEA-Efficiency pathways the electric route is chosen. The GEA-Mix pathways rely to a greater extent on electricity in their MESSAGE interpretation and more on hydrogen in the IMAGE interpretation.

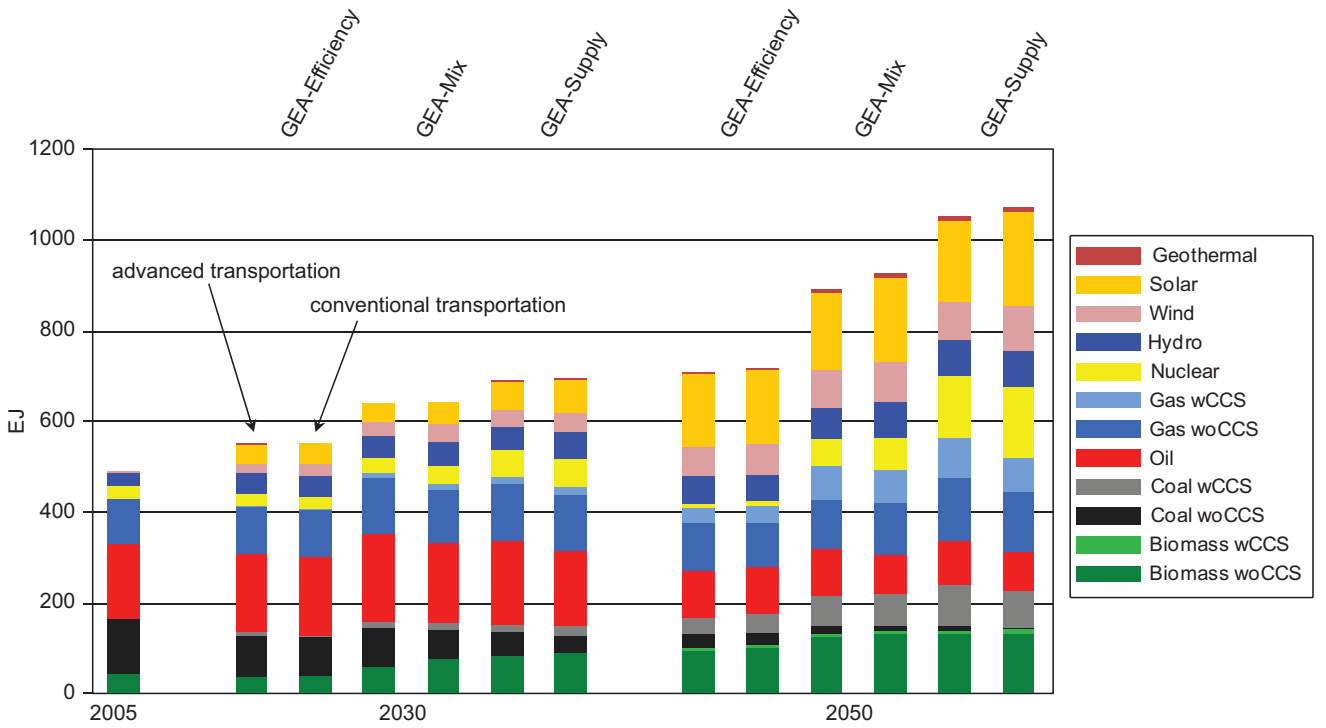

Figure 17.11 | Composition of global primary energy supply in 2005, 2030, and 2050 across pathway groups under an unrestricted supply portfolio and alternative transportation sector assumptions.

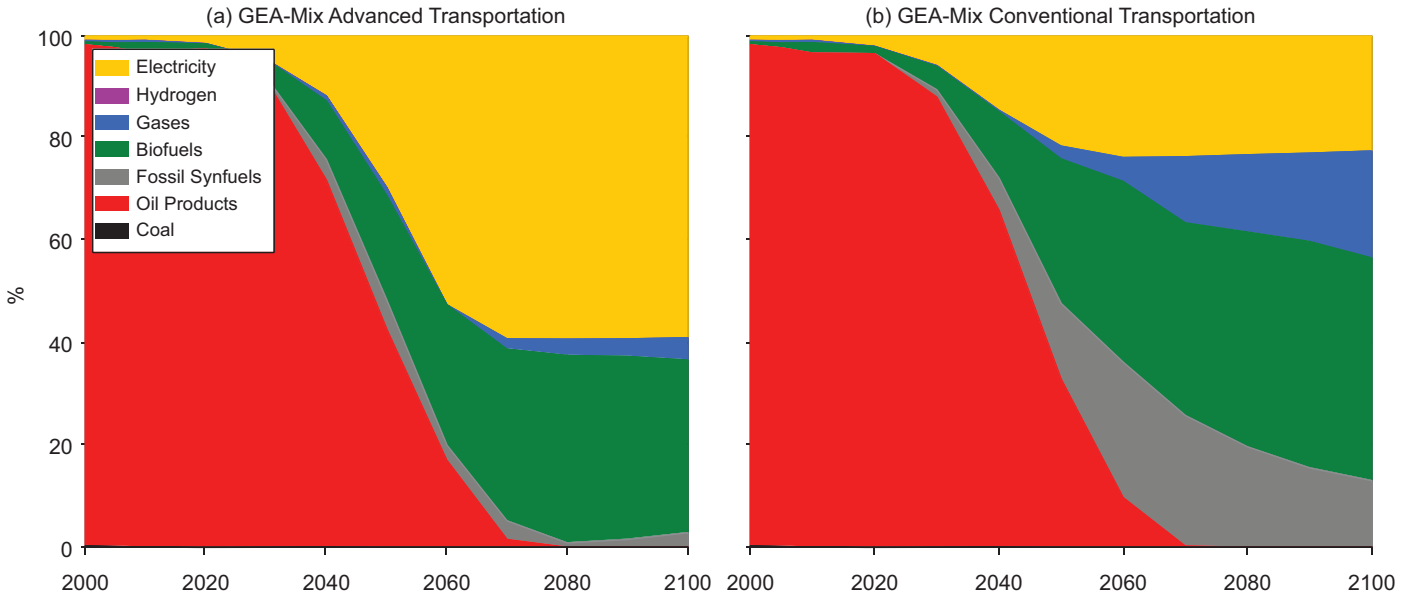

Figure 17.12 | Development of global final energy fuel shares in the transportation sector under Advanced and Conventional assumptions for the GEA-Mix pathways group.

pathways. The different final energy patterns of the two transportation sector configurations are shown in Figure 17.12 for the GEA-Mix pathway.

Given the ambitious goals of the energy transition, this difference in the transportation sector has profound implications for the supply-side choices, particularly for the GEA-Mix and GEA-Supply groups of pathways. The Advanced Transportation setup generally opens additional supply routes for transportation fuels such as electricity and hydrogen from non-biomass renewables or nuclear energy, whereas Conventional Transportation offers fewer routes, to a large extent relying on fossil

fuels and bioenergy and leading to reduced flexibility on the supply side. The limited potential of sustainable bioenergy is the main determinant of the reduced number of feasible transition pathways under the Conventional Transportation assumption (see Section 17.3.4.3 for details), because bioenergy is one of the few remaining ways to reduce GHG emissions in the transportation sector and in selected other parts of the energy system (e.g., bioenergy feedstocks for nonenergy use; see Dornburg and Faaij, 2005).

17.3.3.5 Supply-Side Options under Different Portfolio Restrictions

Portfolio Restrictions as a Sensitivity Analysis

The analysis presented here relies on a set of "restricted portfolio" pathways in which selected supply-side options are either limited or excluded completely, in order to focus on overall questions of feasibility and on economic and resource implications. These pathways should therefore be interpreted as sensitivity analyses around the central case of the full or "unrestricted" portfolio for each of the three GEA pathway groups.[11] An important assumption underlying this restricted portfolio analysis is that the level of energy demand in each group of pathways is fixed.[12]

In total, nine different restricted supply portfolios are explored for each of the six possible combinations of GEA-Efficiency, GEA-Mix, and GEA-Supply pathway groups and two transportation system transformations (Conventional and Advanced). Together with the unrestricted portfolios, this results in 60 different possible pathways (3 levels of demand $\times$ 2 transportation systems $\times$ 10 supply portfolios).

Issues, concerns, and potential constraints facing different supply-side options were the basis for the choice of restricted portfolios analyzed. Six supply-side options were either limited or excluded, either in isolation or in combination with other options.[13] These options and the corresponding restricted portfolio pathways are shown in Table 17.9. Also presented are summaries of the rationales for including these particular restricted portfolios.

Table 17.9 | Overview of restricted supply portfolios.

Supply-side option	Main rationales for restriction	Restricted portfolio pathways	Description
CO_2 capture and storage (CCS)	Storage availability Social acceptability Infrastructure requirements Environmental risks	No CCS[1]	CCS excluded
Bioenergy with CCS (BioCCS)	See entries for CCS and bioenergy	No BioCCS[1]	Bioenergy used only for co-firing in fossil CCS facilities (no dedicated BioCCS facilities)
Carbon sinks (afforestation)	Resource availability Land use impacts Political acceptability	No sinks	No additional afforestation beyond baseline assumption of no net global deforestation from 2070 onward
Bioenergy	Resource availability Land use impacts Food security risks Environmental risks	Limited bioenergy	Bioenergy potential reduced to 50% of central estimate to reflect potential implementation issues for sustainable bioenergy
Nuclear energy	Environmental risks Social acceptability Proliferation risk	No nuclear[1]	No new nuclear power plants built after 2020, leading to full phase-out after 2060 (assuming 40-year plant lifetime)
Renewable energy	Systems integration	Limited renewables	Intermittent renewables (wind, solar) restricted to 20% of final electricity consumption
Combinations[2]		Limited bioenergy + Limited renewables No nuclear[1] + No CCS[1] No BioCCS[1] + No sinks + Limited bioenergy	

1 Option was fully excluded from the portfolio; for other options the restriction was implemented in terms of limited potentials.

2 See individual options for rationales and descriptions.

The results of the portfolio analyses are shown in Figure 17.13 for the $3 \times 2 \times 10$ matrix of pathways. The 19 blank columns, each marked with an X, show those pathways that were not feasible given the portfolio restrictions.

A headline conclusion of the portfolio analysis is that the low level of energy demand in the GEA-Efficiency group of pathways makes it possible to reach the sustainability objectives in the absence of both nuclear energy and CCS. For the intermediate and high levels of energy demand under the GEA-Mix and GEA-Supply pathways, respectively, excluding either nuclear or CCS is typically possible, but in the high-demand case this requires transforming the transportation system away from liquid fuels. In the context of climate change mitigation, only a limited number of studies (e.g., Krewitt et al., 2009; Teske et al., 2010; Delucchi and Jacobson, 2011; Føyn et al., 2011; Jacobson

11 Similar analyses, mostly in the context of climate change mitigation, have been done in the ADAM (Edenhofer et al., 2010b) and RECIPE (Edenhofer et al., 2010b) modeling comparison studies and in several individual publications (Krey and Riahi, 2009).

12 Generally, excluding options from the supply portfolio leads to increased prices of energy services, because more expensive supply options have to be utilized. In this situation, standard economic theory suggests a price-induced demand response, which in this analysis is not considered, because by design the supply-side flexibility is investigated given a fixed level of demand for energy services.

13 An additional potential option would have been to limit the availability of unconventional fossil resources. This has not been implemented, however, since the stringent climate target allows unconventional resources no significant role in the pathways (even if no restriction is assumed).

Box 17.3 | Resource Potentials

Integrated Assessment Models like IMAGE and MESSAGE typically do not consider the full technical potential of energy resources but include additional criteria, such as sustainability or economic criteria, which are not fully captured within the models but which lead to a significant reduction of the technical potential. For the GEA pathways, the ranges of these deployment potentials are summarized in Table 17.10. The resource assumptions for all sources are within the ranges of resource uncertainties assessed in Chapter 7 (see also the electronic appendix to this chapter for more details).

Table 17.10 | Fossil fuel resources and renewable energy potentials.

	GEA pathways:	Chapter 7	
Energy source	reserves and resources (ZJ)[1]	Reserves (ZJ)	Resources (ZJ)
Fossil fuels			
Coal	259 – 376	17.3 –21.0	291 –435
Conventional oil	9.8– 11.1	4.0 –7.6	4.2 –6.2
Unconventional oil	8.9 – 23.0	3.8– 5.6	11.3– 14.9[2]
Conventional gas	11.6 –16.8	5.0 –7.1	7.2 –8.9
Unconventional gas	23.0– 96.4	20.1 – 67.1	40.2 – 122
	Deployment potential in 2050 (EJ/year)	Technical potential (EJ/year)	
Renewables			
Bioenergy	145–170	160–270	
Hydro	18.7–28	50–60	
Wind	170–344	1250–2250	
Solar photovoltaic	1650–1741	62,000–280,000	
CSP	990[3]	810–1400	
Geothermal	23[4]		

Notes: The deployment potentials for noncombustible renewable energy sources in the pathways are specified in terms of the electricity or heat that can be produced by specific technologies (secondary energy perspective). By contrast, technical potentials from Chapter 7 refer to the flow of energy that could become available as inputs for technology conversion (e.g., the technical potential for wind is given as the kinetic energy available for wind power generation, whereas the deployment potential as reported in this chapter gives the electricity that can be generated by wind turbines). In addition to the renewable energy potentials stated in this table, technology diffusion and systems integration constraints may apply in the pathways and prevent the potentials from being fully utilized. Note that elsewhere in Chapter 17 the substitution method is used to report primary energy from non-combustible sources and therefore primary energy numbers can exceed those reported as deployment potential in this table.

1 One zettajoule (ZJ) equals 1000 EJ, or 10^{21} joules.

2 Estimates for unconventional oil that are not separated into reserves and resources reach significantly higher values than reported in this summary from Chapter 7 (see Table 7.8a/b).

3 The potential is from MESSAGE as the IMAGE modeling framework does not include CSP.

4 Geothermal energy is exogenously determined in the IMAGE scenarios; therefore no deployment potential can be specified.

and Delucchi, 2011) have looked at ambitious climate stabilization scenarios that exclude nuclear and CCS completely from the supply-side portfolio, thus relying exclusively on a combination of renewable energy and energy efficiency.

Another important insight from the portfolio analysis is that the low energy demand in the GEA-Efficiency pathways also enables an energy transition with limited contributions from bioenergy, without BioCCS and without relying on carbon sink management. All of these land use-related supply options have potentially adverse impacts and are controversial in the literature (see Section 17.3.4.7 and the electronic appendix to this chapter).

Furthermore, how the transportation sector is configured has profound implications for supply-side flexibility. Under the Advanced Transportation setup, the GEA-Supply group of pathways is still feasible if either BioCCS, carbon sink enhancement, nuclear energy, full bioenergy supply, or the large-scale deployment of other renewable energy is not considered an option. Under the Conventional Transportation setup, only nuclear energy can be excluded to keep the GEA sustainability targets within reach.

The situation is somewhat improved in the GEA-Mix group of pathways, where the Conventional Transportation setup still allows for the same choices as the Advanced Transportation setup under high energy demand. CCS turns out to be a crucial technology under these conditions, because

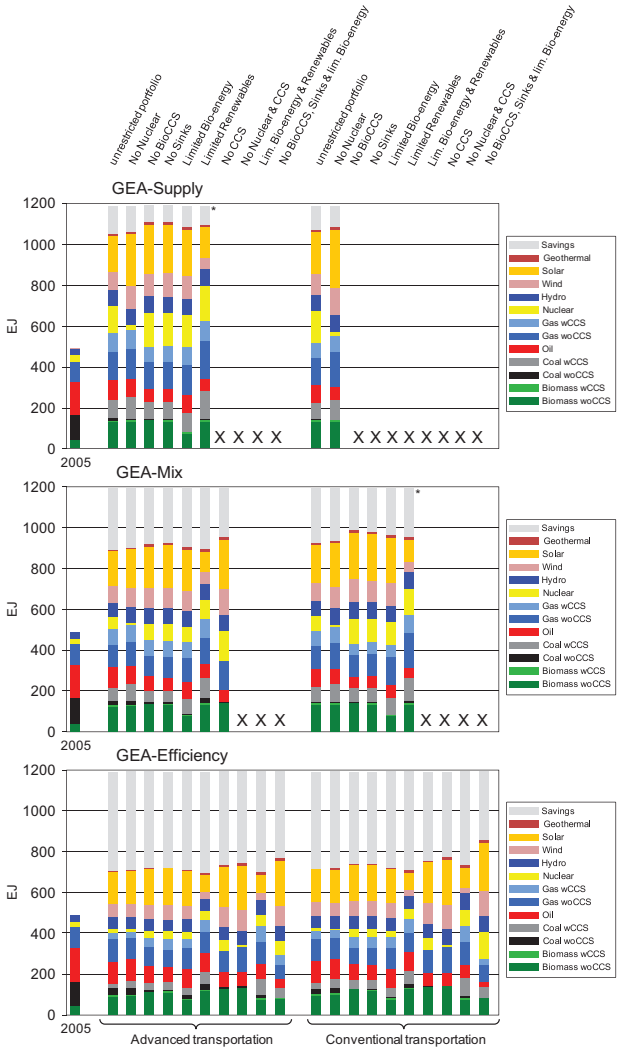

Figure 17.13 | Composition of global primary energy supply in 2005 and 2050 for the three pathway groups under alternative transportation sector assumptions and supply portfolios. See Table 17.9 for details of the restricted supply portfolios. Xs indicate infeasible pathways. Pathways marked with an asterisk are bordering on infeasibility, with carbon prices slightly higher than defined in the note below. Energy savings are calculated by comparison with a hypothetical case with energy intensity improvements compatible with historical trends and no additional climate and energy policies (see also Section 17.3.2.1).

Note: Feasibility is technically defined here as the inability of the supply side to deliver the (fixed) useful energy demand. As uncertainties grow over time, modest undersupply of service demands of up to 5% beyond 2050 is still interpreted as feasible. As in other studies (e.g., Clarke et al., 2009), this concept is operationalized by declaring pathways with carbon prices higher than US$1000/tCO$_2$ in 2012 (as a result of so-called demand backstop penetration) infeasible. This relaxation may lead to limited comparability of economic indicators (e.g., energy-related investments) across the restricted portfolio pathways after 2050.

in the absence of a major transition to electricity or hydrogen, or both, biofuels are the only alternative available to decarbonize the sector. As in the GEA-Supply groups of pathways, the limited sustainable bioenergy potential is a constraining factor, and CCS is important to remove the carbon from bioenergy feedstocks that does not end up in the liquid biofuel itself.

In contrast, the strong focus on energy efficiency, to some extent combined with lifestyle changes (transportation demand is most affected; see Section 17.3.2 on energy demand), in the GEA-Efficiency group of pathways allows the greatest flexibility on the supply side, essentially independent of the transportation sector assumptions – at least for the portfolio of options examined within this analysis.

Restrictions on CO_2 Capture and Storage

Background to Restrictions – Although CCS has not been deployed in energy applications beyond the demonstration level, the scenario literature indicates that it could play an important role as a bridge or transitional technology under stringent climate targets (Edenhofer et al., 2009; Krey and Riahi, 2009; Luderer et al., 2009; Edenhofer et al., 2010a).[14] However, the use of CCS raises various issues. First, the deployment potential is limited by storage capacity at both the global and the regional scale (see Section 17.3.4.4 on regional analysis). Second, even relatively low leakage rates (e.g., between 0.1% and 1%) can compromise CCS as a climate stabilization option (van der Zwaan and Smekens, 2009). Third, upstream emissions from fossil fuel extraction (including of non-CO_2 gases) reduce the comparative effectiveness of fossil CCS as a low-carbon supply-side option. Fourth, in contrast to other low-carbon options, CCS is a single-purpose technology with limited or no ancillary benefits, and it imposes an energy penalty, thus increasing resource consumption (see also Section 17.7 on multiple benefits).

Results of Restrictions – Figure 17.13 shows the importance of CCS as a transitional supply-side option. For all pathways with high levels of energy demand (the GEA-Supply pathways group), including those with Advanced Transportation, the No CCS restricted supply portfolio is not feasible. The No CCS restriction is feasible for the GEA-Mix pathways group (with intermediate levels of energy demand), but only if the transportation system does move away from the currently dominant liquid fuels.

In other words, the supply-side analysis shows that CCS is a necessary supply option if the level of demand and the associated energy intensity improvements remain on current trajectories, and if the transportation sector remains more or less compatible with existing infrastructures and business models. These infrastructures can continue to serve a large fraction of energy demand, and the required decarbonization of the energy system is accomplished using CCS in an "end of the pipe" mode.

Restrictions on BioCCS and Sinks (Negative GHG Emissions Options)

Background to Restrictions – Supply-side options that can produce considerable amounts of net negative GHG emissions include carbon sink enhancement and BioCCS (bioenergy in combination with CCS). Capture of CO_2 from the atmosphere (CO_2 air capture, artificial trees) is another option but is not addressed here (for details see, e.g., Baciocchi et al., 2006; Keith et al., 2006; Zeman, 2007). Although the current emphasis with CCS is on fossil fuel conversion technologies, large-scale biomass cofiring (practiced today in coal-fired power plants typically at the level of a few percent; see, e.g., De and Assadi, 2009) could become an attractive

14 CCS can also become economically feasible in non-intervention scenarios, because of the benefits of the captured CO_2 for use in enhanced oil and gas recovery, for example. However, the potential for these applications is limited, and therefore CCS deployment in baseline scenarios is typically constrained to a relatively low level compared with climate stabilization scenarios.

supply-side option, helping to reduce residual emissions from coal CCS toward zero without having to increase the capture rate to 100%, which currently appears to be economically unattractive. Once infrastructure has been built to transport CO_2 from its place of origin (e.g., a power plant or cement production plant) to a suitable storage location, the building of smaller-scale BioCCS plants may also become an option.

Results of Restrictions – As can be seen from Figure 17.13, the No BioCCS and No Sinks restricted portfolio pathways produce fairly similar primary energy supply mixes by 2050, in particular within the GEA-Efficiency and GEA-Mix pathways groups. In both cases, cumulative negative carbon fluxes are similar. In contrast to BioCCS and atmospheric CO_2 capture, carbon sink enhancement is a supply option that is available immediately, but large annual reductions in carbon emissions result only with relatively long lag times. Although their deployment occurs at scale only after 2050, the availability of net negative GHG emissions options is crucial for near-term targets, as they reduce the need for immediate GHG mitigation while still allowing the 2°C climate stabilization target to be reached by 2100.[15] So, in contrast to the other supply-side options considered here, these negative net emissions options affect the supply portfolio throughout the time period of the analysis.

The No BioCCS and No Sinks restrictions require a more aggressive deployment of other low-carbon options in the first half of the century, in particular nuclear energy and renewables (Figure 17.13). In combination, however, with the additional restriction of Limited Bioenergy, this can only be achieved at low levels of energy demand (the GEA-Efficiency pathways).

Restrictions on Bioenergy

Background to Restrictions – Bioenergy could play an important role in future energy systems and can contribute to multiple objectives, such as increased energy security (e.g., Brazilian ethanol program; (Goldemberg, 2007)) and GHG mitigation. Biofuels in the transportation sector represent a relatively low cost alternative to fossil fuels that (unlike hydrogen, for example) also requires less additional infrastructure. Even in scenarios that aim to limit bioenergy use, it might still be attractive to use biofuels for specific transport modes (e.g., air traffic, shipping, or long-distance freight (LBST, 2008). In the power sector, bioenergy also represents a relatively low-cost option to reduce GHG emissions. Unlike other renewable energies, it does not pose intermittency challenges. In ambitious climate stabilization scenarios, bioenergy is particularly attractive because of the possible combination with CCS (see Section 17.3.3.5). Despite these potential benefits, however, if bioenergy production is not implemented in a sustainable way, multiple adverse effects can occur, including competition with food production, net increases in GHG emissions from deforestation, and biodiversity losses (Rajagopal and Zilberman, 2007; Wise et al., 2009); see also the electronic appendix to this chapter). Estimates of bioenergy available in 2050 range as high as approximately 360 EJ, a sevenfold increase over current use (Dornburg et al., 2010). Under stricter sustainability criteria and less favorable assumptions about water scarcity and yield improvements, however, the estimated potential can be as low as 60–70 EJ in 2050 (van Vuuren et al., 2010).

Results of Restrictions – Limiting bioenergy in the supply portfolio is feasible in all but the GEA-Supply (high demand) pathways group with Conventional Transportation (see Figure 17.13). Limited bioenergy implies about 80 EJ/year of sustainable bioenergy, including agricultural residues, by 2050, and less than 125 EJ/year by 2100. The 2050 level would mean less than a doubling of total bioenergy use compared with today, taking into account a substitution of traditional biomass for clean forms of bioenergy as required by energy access objectives.

Restrictions on Nuclear Energy

Background to Restrictions – Although nuclear energy can potentially contribute to energy security objectives (by reducing the imported share of primary energy) as well as to climate stabilization and air pollution objectives, it is a controversial supply-side option for various reasons, including the unresolved problem of long-term waste disposal, the risk of catastrophic accidents and the associated liabilities, and the possible proliferation of weapons-grade fissile material (see also the electronic appendix to this chapter). An additional concern at present is the imbalance of R&D portfolios in favor of nuclear energy, leading to a diversion of government resources from other important options. Compared with actual nuclear generation capacity, R&D spending is, for instance, among the highest levels of government support across all supply-side options (Grubler and Riahi, 2010). The overall conclusion of the GEA assessment on nuclear is thus that until the proliferation potential is better controlled and safer reactor designs are available, countries (especially those considering building their first nuclear power plants) should consider other climate-friendly power supply options first. For a further discussion of risks and concerns, see Chapter 14.[16] The extent to which nuclear energy can contribute to the GEA objectives is, given the risks and concerns described above, thus very uncertain at the global scale, and even more so at the regional or country level.

Results of Restrictions – The No Nuclear restricted portfolio pathway is feasible under all levels of demand and transportation system alternatives. Although Figure 17.13 shows a continued contribution of nuclear energy to the supply mix in 2050 in these pathways, after 2060 this has largely been reduced to zero as the last plants built in 2020 under the No Nuclear restrictions are retired. Most importantly, nuclear energy can in general be seen as a choice rather than a necessity. In other words, alternatives can substitute nuclear energy at a global scale without endangering a successful energy transition, which also implies that

15 The potential for future BioCCS to allow a postponement of more costly supply-side options (in present value terms) comes at a price in the form of a reduced likelihood of staying below a certain temperature threshold (see Section 17.5.1 on climate change for details).

16 It should be noted that following historical experience (see Grubler, 2010), all pathways assume that the cost of nuclear power is at best stable or even increasing further over time. In response to addressing proliferation risks, the analysis is restricted to light water reactors, i.e., a plutonium fuel cycle including fast breeder reactors is not considered to be an option, which can have implications for uranium resource availability at some point (see electronic appendix to this chapter).

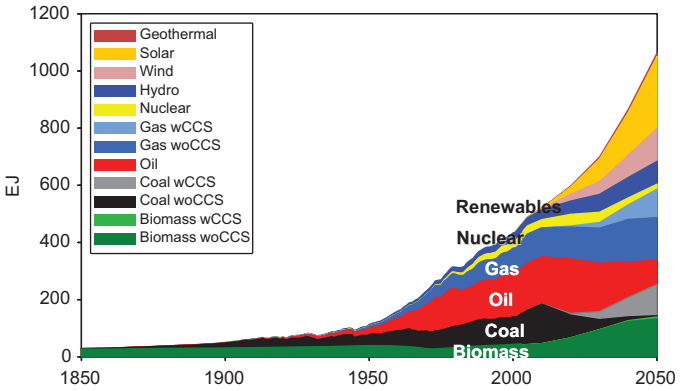

Figure 17.14 | Development of primary energy in the GEA-Supply pathway with a nuclear phaseout shortly after 2050.

different attitudes toward nuclear energy at the national or the regional level can be facilitated. Hence, the phaseout of nuclear is even possible under the relatively high energy demand projection of the GEA-Supply group of pathways (see Figure 17.13 and Figure 17.14). The phase-out of nuclear might lead, however, to somewhat higher costs (see, e.g., investment needs of restricted portfolios in Section 17.3.5, and IEA, 2010).

Restrictions on Other Renewable Energy

Background to Restrictions – Like demand reductions, renewable energy can contribute to all the energy system objectives, including energy access (by decentralizing supply), climate stabilization, and energy security (by reducing energy imports and diversifying supply). Although the global renewable energy resource base (technical potential) vastly exceeds projected future primary energy use (see Box 17.3), harvesting renewable resources may be limited by factors including land competition and systems integration. The latter issue is discussed further in Chapter 15, Section 15.8 and in a number of wind energy integration studies, which conclude that penetrations of wind-generated electricity of up to – and, in a limited number of cases, exceeding – 20% are technically feasible, but not without challenges (see, e.g., Gross et al., 2007; Smith et al., 2007; Holttinen et al., 2009; Milligan et al., 2009). In addition, institutional challenges to the expansion of transmission, including cost allocation and siting, can be substantial (Benjamin, 2007; Vajjhala and Fischbeck, 2007; Swider et al., 2008). In interpreting the results of this restriction, it needs to be taken into account that 20% of electricity from wind and solar would be a substantial increase from today's level, which essentially only Denmark has reached.

Results of Restrictions – The Limited Renewables portfolio restriction reduces the contribution of wind and solar to electricity generation, and thus to the primary energy supply mix (Figure 17.13). The effect is somewhat less pronounced for solar energy, because solar thermal (e.g., solar rooftop collectors) and concentrating solar power (CSP) with thermal storage at the power plant level are affected less or not at all by systems integration issues. Restrictions on wind are intermediate in their impact, whereas the reduction of output is strongest for solar photovoltaic, as the curtailment of electricity generation from this source at peak hours (around noon) can occur at a relatively low installed capacity compared with the system's overall size.[17]

A related and counterbalancing effect of the pathways that assume limited potential of intermittent renewables is that dispatchable renewables (hydro, geothermal, and bioenergy) and other low-carbon electricity generation sources (nuclear and fossil CCS) are deployed to a larger extent.[18]

17.3.4 The GEA Pathways: Energy System Transformations

17.3.4.1 Introduction

The pathways analysis presented in the previous sections focused on several different dimensions of a successful energy transformation toward a more sustainable future. These dimensions correspond to the branching points of the scenario design process described in Section 17.2.2. This analysis led to a total of 60 pathways, of which 41 were feasible alternative representations of an energy transition that fulfills the GEA objectives. The approach taken here is to use a selection of three illustrative GEA pathways, interpreted by two different modeling frameworks – IMAGE and MESSAGE – to integrate the demand-side analysis of Section 17.3.2 with the supply-side analysis of Section 17.3.3. Narrowing the task down to these three pathways clarifies the important points of similarity and difference within the broader range of 41 pathways. Having firmly established the characteristics of these three illustrative pathways, the section turns in more detail to questions of supply-side flexibility and to regionally disaggregated findings.

17.3.4.2 Three Illustrative GEA Pathways

The three illustrative GEA pathways were selected to combine specific choices at the different branching points. They are *not* intended to be central cases, most likely cases, or even representative cases. Rather, their intent is to illustrate the types of options available throughout the energy system and to explore critical choices in terms of the magnitude and direction of policies, investments, and broader efforts to transform the energy system.[19]

17 The lower penetration of intermittent renewables in the Limited Renewables portfolio pathways also leads to reduced demand for technologies to address load management issues (such as backup generation capacities, hydrogen electrolyzers, pumped hydro, or compressed air storage).

18 There appear to be no insurmountable technical barriers to high penetration rates of renewables if ancillary changes to system management and infrastructure are implemented appropriately (see, e.g., the high penetration rates of renewables in the GEA pathways with unrestricted renewables).

19 The overarching criterion for the selection of illustrative cases is that they reflect the main characteristics of each of the groups of GEA pathways (Efficiency, Mix, Supply). In addition, the selection of illustrative cases is guided by the ranges of different energy options in the peer-reviewed scenario literature (eg the recent assessment by

The main distinguishing dimensions of the three illustrative GEA pathways are as follows:

- *Demand versus supply focus.* While the assessment shows that a combination of supply- and demand-side measures is needed to transform the energy system, emphasis on either side is an important point of divergence between different policy choices. A critical factor is thus the extent to which changes in demand for energy services, together with demand-side efficiency measures, can reduce the amount of energy to provide mobility, housing, and industrial services and thus help meet the goals across virtually the whole range of sustainability objectives. This dimension is one of the main distinguishing characteristics, and it motivates the naming of the three illustrative pathways.

- *Global dominance of certain energy options versus regional and technological diversity.* Once technological change is initiated in a particular direction, it becomes increasingly difficult to change its course. Whether the transformation of the future energy system follows a globally more uniform or a diverse path has thus important implications, given irreversibility, "lock-in," and path dependency of the system. GEA-Efficiency and GEA-Supply depict worlds with global dominance of certain demand/supply options, while GEA-Mix is characterized by higher levels of regional diversity.

- *Incremental versus radical new solutions.* Given the ambitious sustainability objectives, transformational changes need to be introduced very rapidly across all GEA pathways. For instance, all pathways feature decreasing shares of presently dominant fossil fuels. The pathways differ, however, with respect to the emergence of new solutions. Some rely more heavily on today's advanced options and infrastructures (such as biofuels in GEA-Mix), while others depict futures with radically new solutions (such as hydrogen in GEA-Supply).

In terms of the supply mix that provides for overall levels of energy demand across the three illustrative pathways, Figure 17.15 shows the ongoing transition from primarily fossil fuels, which have dominated since the late 19th century (see Nakicenovic et al., 1998) to the low-carbon options – nuclear energy, renewable energies, and fossil energy with CCS – of the second half of the 21st century.[20] The two alternative interpretations of these illustrative transition pathways have been harmonized to a great extent. They start from identical socio-economic assumptions, but the development of final energy is very close as a result of largely harmonized service demand levels (see Box 17.2). However, despite sharing many characteristics, there are three dimensions in which the interpretations are quite different, and this allows for important insights:

- The counterfactuals (or business-as-usual scenarios) underlying these successful transition pathways are considerably different, which materializes in different levels of energy savings across the MESSAGE and IMAGE interpretation (as shown in Figure 17.15). While the MESSAGE counterfactual is more optimistic about the future availability of hydrocarbons and, consequently, many sectors will continue to rely on this option, the IMAGE counterfactual features a transition to coal and nuclear energy becoming the dominant primary energy sources and inducing a shift to synthetic fuels in, for example, the transport sector. Both share, however, similar characteristics when it comes to environmental problems, as well as an inability to successfully address energy access and security issues. This illustrates that a successful transition can be achieved from very different starting points.

- While the demand-side changes, in particular the role of energy efficiency, have been largely harmonized, the supply-side portfolios are different across the two interpretations of the illustrative GEA pathways. The MESSAGE interpretations rely to a much greater extent on renewable energy, while in IMAGE, fossil CCS tends to be of greater importance, particularly over the second half of the century.[21] The role of nuclear energy is very similar in the GEA-Efficiency and GEA-Supply pathways in both frameworks while in the GEA-Mix pathway, MESSAGE foresees a significantly larger role for nuclear after 2050 than IMAGE.

the IPCC (2011)). Each of the illustrative cases represents a distinctly different pathway, and together they illustrate the different types of transformations that were explored in more detail through sensitivity analysis of the wider set of 41 feasible pathways. (1) The group of GEA-Efficiency pathways is characterized by the highest degree of "supply-side flexibility". This is illustrated by sensitivity cases with respect to supply-side technology restrictions, all of which were found technologically possible under the GEA-Efficiency conditions. To illustrate this high degree of supply-side flexibility and the feasibility to reach the GEA objectives under even restricted portfolios, a pathway with a restriction for nuclear was selected as illustrative for the GEA-Efficiency group of pathways. (2) The group of GEA-Mix pathways is intermediate with respect to many pathway characteristics (eg, energy demand and the required pace for the upscaling of supply-side options). A major characteristic of the Mix pathways, which distinguished this group from the others, is the diversity of options that contribute toward reaching the GEA objectives. This diversity is most pronounced in the GEA-Mix pathway that assumes restrictions for the electrification of transport, and thus require a variety of "conventional transport" options to satisfy the increasing demand for mobility. Hence, this pathway was selected as the illustrative case for the group of GEA-Mix pathways. (3) The GEA sustainability goals become out of reach in most of the GEA-Supply sensitivity cases with restricted supply-side options. The GEA-Supply pathways are thus characterized by the least supply-side flexibility, requiring the more rapid and pervasive upscaling of supply-side options compared to the other groups of pathways. To illustrate the limited supply-side flexibility and the need of rapid upscaling of supply-side options, an unrestricted portfolio case that allows all options to penetrate the market was selected as the illustrative pathways for GEA-Supply.

20 The reporting convention for primary energy in the GEA follows the substitution method. It cannot be overemphasized that for transition pathways towards a sustainable energy future that imply fundamental change in the energy system, the accounting method can introduce a significant perception bias. A more detailed discussion of this issue can be found in Chapter 1.

21 It should be noted that the representation of solar energy in the IMAGE modeling framework is restricted to solar photovoltaic, which leads to significantly lower solar energy contributions in the IMAGE interpretation of the GEA pathways. For other forms of renewable energy, the differences between the IMAGE and MESSAGE interpretations are much less pronounced.

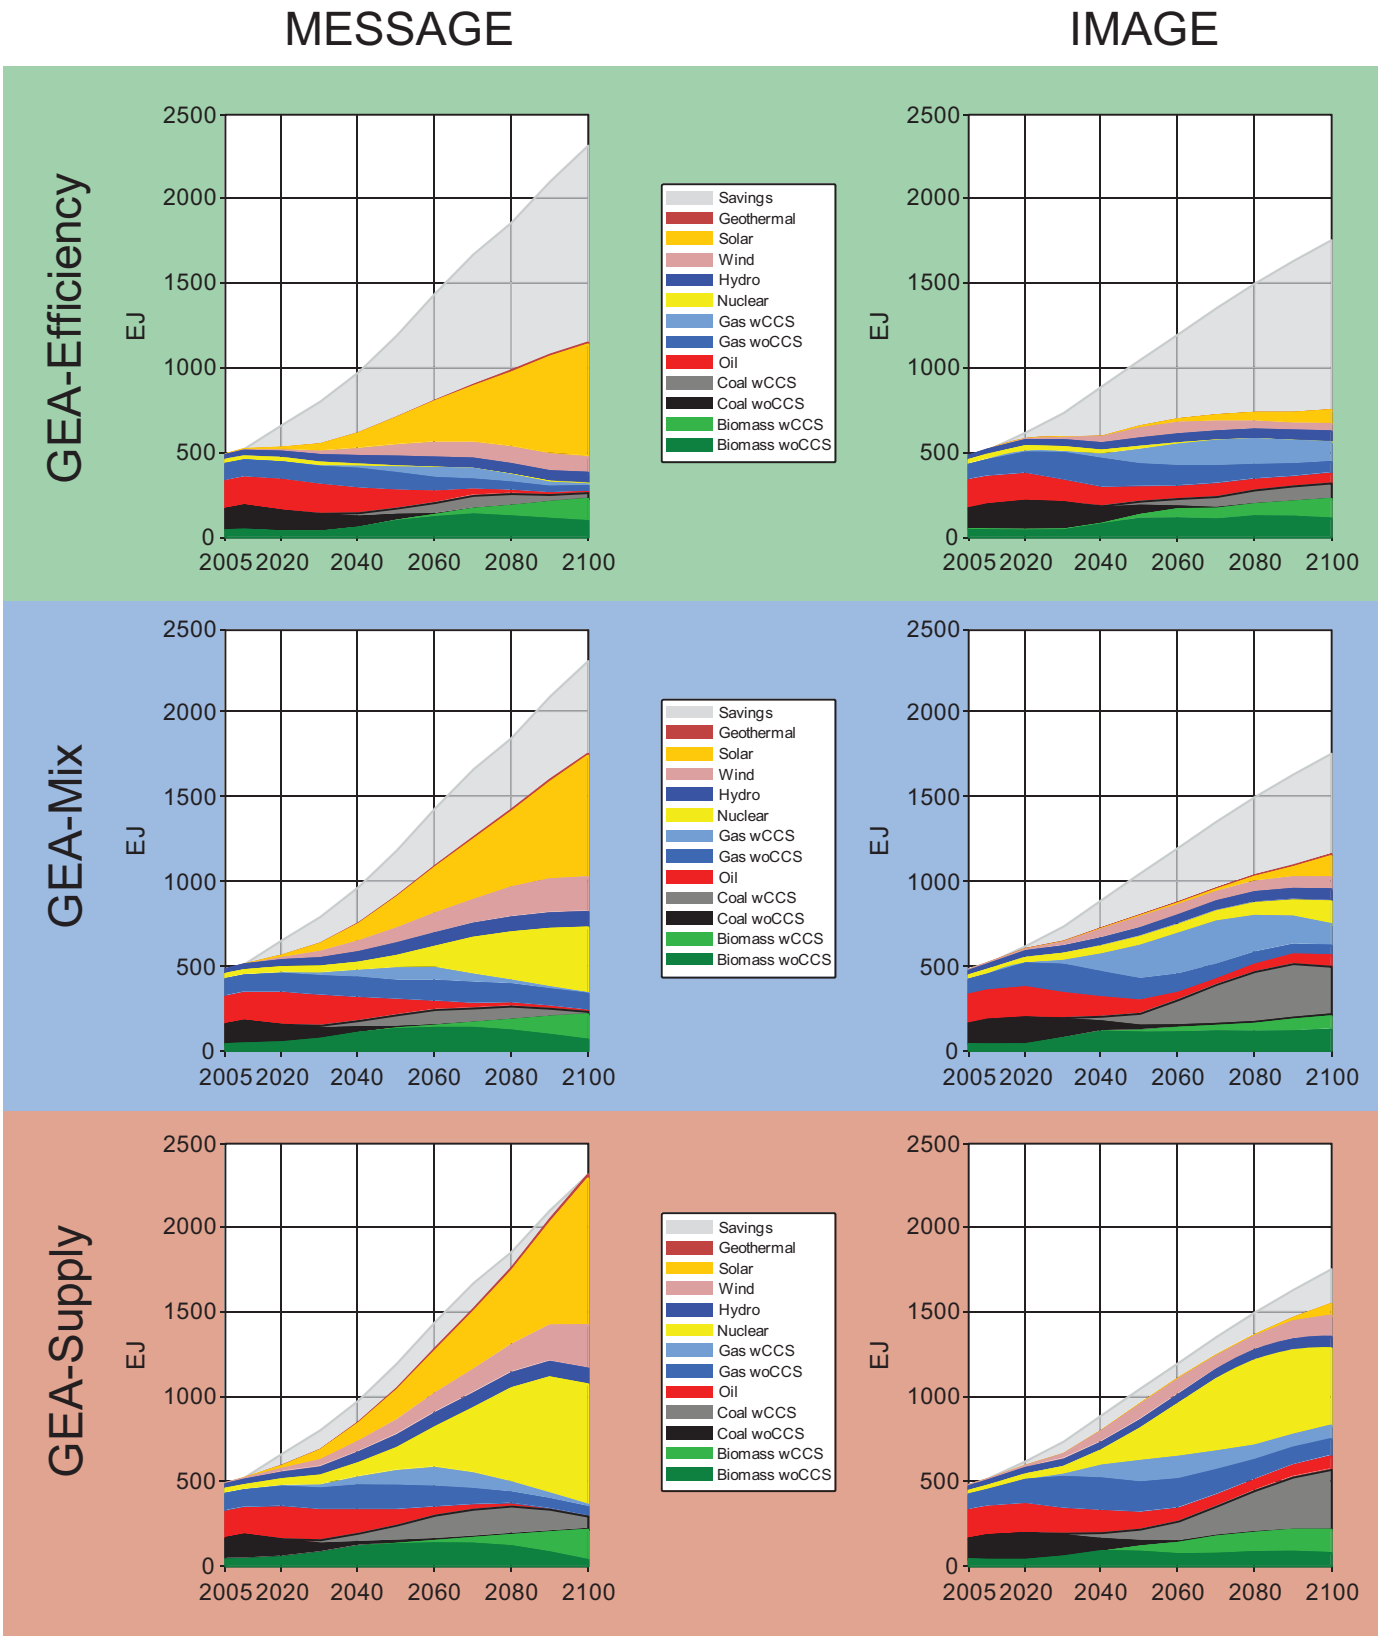

Figure 17.15 | Development of primary energy supply in the three illustrative GEA pathways in both their MESSAGE (left-hand side) and IMAGE (right-hand side) interpretations.

Notes: Energy savings were calculated compared to hypothetical cases without climate or any other energy policies – the so-called counterfactuals – and are roughly compatible with historical energy intensity improvements.

- The level of final energy use is very similar in the respective IMAGE and MESSAGE interpretations of a particular GEA pathway, but due to the primary energy reporting convention adopted in this report – the substitution method (see Chapter 1 for details) – the resulting primary energy supply mix appears very different across the two interpretations.

Specific characteristics of the illustrative GEA pathways are summarized below, followed by a more detailed discussion of the commonalties and choices across all pathways in the next section.

- The illustrative *GEA-Efficiency* pathway features a strong emphasis on efficiency and a heavy reliance on renewable energy, with a share of between 50–90% of primary energy in the long term (2100). Nuclear is assumed to be phased out over the lifetime of existing capacities to reduce the proliferation risk, and CCS provides an optional bridge for the medium-term transition toward a renewables-based energy system. The strong emphasis on efficiency reduces the growth of energy demand over the course of the century by about a factor of 2 (see comparison of the GEA-Efficiency and GEA-Supply pathways in Figure 17.15). This corresponds to roughly doubling the energy intensity improvement rate over historical experience and requires policies in the buildings sector to improve by a factor of 4 by 2050 (a global retrofit rate of 3%/year); in the industry sector, it requires the rapid adoption of best available technology, retrofitting of existing plants, enhanced recycling, and lifecycle product design; in the transportation sector, it requires reducing energy demand through both aggressive efficiency standards (in both freight and passenger transport) and behavioral and lifestyle changes (a switch to public transport and the reduction of demand for private mobility). Table 17.11 recalls the relative contributions of different demand-side transformations in the illustrative GEA-Efficiency pathway, whose absence in the GEA-Supply pathways explains the higher primary energy supply trend. Although efficiency improvements make the largest contributions toward the lower levels of demand in the GEA-Efficiency pathways, these are not viable without complementary policies and measures (including direct and indirect energy pricing) to mitigate demand for energy services.

- The illustrative *GEA-Supply* pathway has a major focus on the rapid upscaling of all supply-side options. The more modest emphasis on energy efficiency and conservation leads to energy intensity improvement rates slightly above historical experience. Massive upscaling of R&D and deployment investments leads to the emergence of new infrastructures and fuels (such as hydrogen vehicles in the transportation sector). Fossil CCS becomes an essential building block to decarbonize fossil fuels, and new nuclear power plants gain a significant market share after 2030.[22] A prerequisite of the GEA-Supply pathway is thus that the associated proliferation risks of weapons-grade fissile material are addressed successfully through, e.g., internationalization of the nuclear fuel cycle. Renewable energy contributes significantly in the long term, with bioenergy playing a more important role in the developing world while wind deployment is occuring in about half of today's OECD countries. The role of other renewable energy sources is more heterogeneous in the two different interpretations by MESSAGE and IMAGE.

Table 17.11 | Approaches to reducing energy demand in the GEA-Efficiency pathways.

Approach	Relative contribution to reducing energy demand		
	Residential and commercial sector	Transport sector	Industrial sector
Improvements in technological efficiency	High	High	High
Structural changes in the type of energy services demanded	Low	Medium	Low
Reductions in the level of energy services demanded	Low	Medium	Low

- The illustrative *GEA-Mix* pathway is intermediate with respect to many scenario characteristics, such as the focus on efficiency and the pace of supply transformation (i.e., upscaling of advanced and clean supply-side technologies). The main emphasis is on diversity of the energy supply mix, thus enhancing system resilience against innovation failures or technology shocks. Large differences in regional implementation strategies reflect local choices and resource endowments. Whereas the absolute level of nuclear energy deployment is different between the MESSAGE and IMAGE interpretations, the regional focus of its deployment is Asia in both frameworks where more than two thirds of new capacity is commissioned. In the MESSAGE interpretation of the pathway, this results in the co-evolution of multiple fuels, particularly in the transport sector where, for example, second generation biofuels (in Latin America, Former Soviet Union, North America, and Pacific OECD), liquid fossil fuels with CCS (China and the Middle East), and electricity (which gains importance globally, although the generation portfolio differs significantly across regions)

22 In the illustrative GEA-Supply case nuclear energy grows to the level of 1850 GWe installed capacity, which is above the IAEA high projection of 1228 GWe, and the present (May 2011) level of 366 GWe of mostly relatively aged capacities. This level of expansion might be increasingly difficult to achieve in the aftermath of the Fukushima accident. In the past, nuclear growth has been below the IAEA's high projection – and, until 2000, even below its low projections. The range of nuclear in the GEA pathways is similar to the ranges found in other studies in the peer-reviewed scenario literature. For example, the IPCC Report on Renewable Energy (Fischedick et al, 2011) has assessed the recent literature on mitigation scenarios. The nuclear deployment of the underlying scenarios was collated by Clarke and Krey (personal communication, 2012). An analysis of the underlying data shows that 25% of the 137 mitigation scenarios assessed by the IPCC Report on Renewable Energy have higher nuclear deployment by 2050 than the GEA-Supply pathway. The lower bound of the GEA is representative of other low nuclear pathways from the literature that explore GHG mitigation in case of a nuclear phase-out.

gain importance in different regions. The same interpretation of the pathway using the IMAGE model shows less transport fuel diversification and feeds into a hydrogen-dominated transportation sector much as in the GEA-Supply storyline. The IMAGE interpretation, in turn, shows a stronger diversification of electricity generation and hydrogen production, particularly in the long term.

17.3.4.3 Commonalities and Choices across the GEA Pathways

Introduction

Despite major differences in the levels of energy demand and in the nature of transportation system transformation, the three illustrative GEA pathways share certain supply-side characteristics. All show a decarbonization of the supply mix away from conventional fossil fuels, particularly coal. All show an ever-increasing share of energy services demand being met by renewable energy, particularly by the end of the century. All show a substitution of traditional biomass for clean forms of bioenergy.

These commonalities are pervasive features of all the transition pathways for the global energy system toward the sustainability objectives. They can be interpreted as "musts" – that is, required elements of the supply-side transformation if the access, environmental, and security objectives are to be fulfilled.

In other areas, the three illustrative pathways have major points of difference. The most obvious, and the most influential, is the level of energy demand, which distinguishes the pathways by design. Emphasis on demand-side transformation varies massively between the GEA-Efficiency pathways and the GEA-Supply pathways at the extremes. Another point of difference, again by design, is the nature of transformation in the transportation sector, either Conventional, with an ongoing reliance on liquid fuels, or Advanced, a more radical departure from historical trends and existing infrastructures and technologies.

These points of difference are analogous to broad, systemic choices about how and where to direct attention, investment, and policies in order to transform the energy system. None of the outcomes of these choices precludes a transition pathway that fulfills the GEA sustainability objectives: all are therefore feasible within these normative bounds. However, the interdependencies within the energy system mean that choices made in one part of the system have potentially major enabling or constraining effects elsewhere. This was most clearly demonstrated in the comparison of the illustrative GEA-Efficiency and GEA-Supply pathways as to their degree of supply-side flexibility.

This section moves from an analysis of the three illustrative GEA pathways using both IMAGE and MESSAGE to the full suite of pathways, including those 41 feasible pathways based on additional MESSAGE analysis, to establish further commonalities and choices. These are organized in six related sections: the first three relate to the major energy conversion chains of electricity generation, the "other" conversion sector (mainly liquid and gaseous fuels), and the upstream sector that supplies fuels; the other three relate to supply-side decarbonization, looking at low-carbon energy in general and CCS and bioenergy in particular.

Commonalities and Choices: Electricity Generation

The commonalities in primary energy supply with respect to decarbonization also hold for electricity generation. First, across all GEA pathways, the fossil electricity generation technologies that dominate today's system are on the retreat. Second, low-carbon alternatives, taken together, grow across the board. As a group of supply-side options, these low-carbon alternatives include fossil CCS, nuclear power, and renewable electricity generation.

Beyond these commonalities (which are largely intuitive given the challenge of climate stabilization), electricity generation has three further common features across all GEA pathways. First, conventional coal power generation has to decrease very soon, and by 2030 should not supply more electricity than today. This implies that new construction of coal power plants without CCS must stop, and that some existing plants will have to be retired prematurely or, if possible, retrofitted with CCS (see Chapter 12, Section 12.6.3 for a discussion of CCS retrofitting).

Second, gas power generation, mostly in combined-cycle configurations but also as gas turbines for load balancing, sees considerable growth until around 2030 and only thereafter faces a decline. This is also a commonality across most GEA pathways. In other words, whereas coal power without CCS must phase out rapidly, gas power can be considered a short- to medium-term bridge or transitional technology until longer-term options become more available at scale.

Third, renewable power technologies show significant increases compared with the role they play in electricity generation today. This is clearly visible in Figure 17.16. This finding is consistent with a recent large-scale analysis of renewable energy in long-term transition scenarios by Krey and Clarke (2011). The GEA pathways analysis did not consider scenarios that exclude renewables completely, but limitations of various options were explored. Under these constraints, relatively mature technologies such as hydropower and onshore wind experience strong growth to 2030 and to 2050, with limited variability between pathway groups. Solar photovoltaic and CSP[23] are more variable and show stronger deployment after 2030, although by 2020 the average deployment shows a multifold increase compared with today's levels. Biomass and geothermal electricity generation show much lower deployment levels on average compared with these other renewable technologies.

Three important points relating to these common trends in renewable power should be noted. First, even the lower end of market volumes

23 Note that IMAGE does not include CSP and therefore the above statement only refers to the MESSAGE interpretation of the pathways.

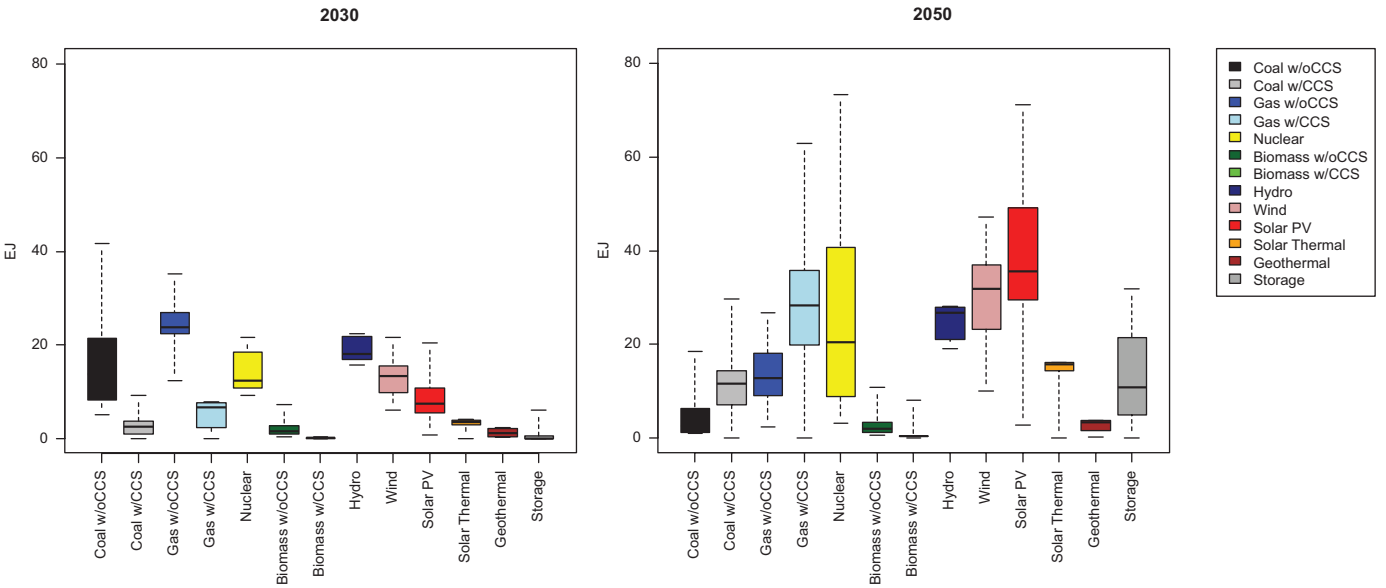

Figure 17.16 | Electricity supplied by different generation technologies in 2030 and 2050 in the GEA pathways. The boxes represent interquartile (25th-75th percentile) ranges, and the horizontal lines within boxes represent medians across all feasible GEA pathways from MESSAGE and IMAGE. Error bars indicate the full range across all feasible pathways.

shown for 2020 will require effective and stable policy frameworks, extending those that are increasingly observed in the current situation. Second, deployment levels vary greatly by region according to local resource potentials. This is discussed further in Section 17.3.4.4. Third, increasing requirements of storage technologies are characteristic for pathways with very high deployments of intermittent sources (wind, solar photovoltaic, and to a lesser extent CSP).This trend is more pronounced in the medium and long term,, when renewable energy become the dominant source of energy supply in some of the regions. Storage can be supplemented with demand-side management and/or so-called smart-grids. These requirements also depend on the availability of negative carbon options (BioCCS and carbon sinks). If negative emissions technologies do not become available on large scale, more rapid early action, including larger contributions of wind and solar photovoltaic are needed. The same is true if nuclear power is excluded, with the slack taken up by intermittent renewable sources again. Like the renewables themselves, storage technologies are diverse, unevenly distributed (e.g., pumped storage hydropower), and in some cases less mature, more costly, and more dependent on new infrastructures (e.g., hydrogen electrolyzers and fuel cells) and business models.

Fossil CCS provides a bridge or transitional option for the power sector. However, in contrast to conventional gas power generation, this is not common to all pathways, as the most efficient pathways do not necessarily include CCS. The most attractive option to combine with CCS in power generation is natural gas, with its cleaner fuel supply chains, lower upstream GHG emissions, higher conversion efficiencies, and significantly lower capital intensity. However, this is not entirely consistent with current R&D activities, which are focused on coal power generation with CCS. The focus on coal is, in turn, driven by the relative cost and abundance of the resource, as well as concerns over dependence on imported gas. The global preference for gas with CCS is particularly weak in coal-rich regions such as China. Although bioenergy with CCS plays an increasingly important role under more stringent climate stabilization targets, the deployment focus can be in either the electricity or the synthetic fuels sector, depending on the overall system configuration (on advanced designs of BioCCS technologies see also Chapter 11, Section 11.3).

The major choice in terms of supply-side flexibility to emerge from the pathways analysis relates to nuclear power. Nuclear energy can become one of the central sources of electricity generation by 2050, and it is among the supply-side options with the highest deployment across all GEA pathways. Such a development can only materialize if effective technological, institutional, governance, and legal frameworks are introduced to avoid present risks of nuclear energy, including in particular the risk of proliferation. It is thus important to emphasize that in all pathways nuclear power can also be fully phased out after 2060, with no new plants built after 2020. The global "choice" of excluding nuclear power from the supply mix has implications for energy costs, as do any of the other restricted portfolio options (as, by definition, the unrestricted portfolio has the lowest cost). This is discussed further in Section 17.3.5.

Some of the trends observed between 2030 and 2050 in Figure 17.16 continue into the second half of the century, namely, considerable growth in electricity generation from solar and wind energy as well as nuclear power. On the other hand, fossil fuel-generated electricity with CCS tends to decline again toward the end of the century, because of non-negligible GHG emissions in the entire fuel supply chain.

Commonalities and Choices: Liquid and Gaseous Fuels

Today the processing of liquid and gaseous fuels is a very different energy conversion chain than the generation of electricity from primary

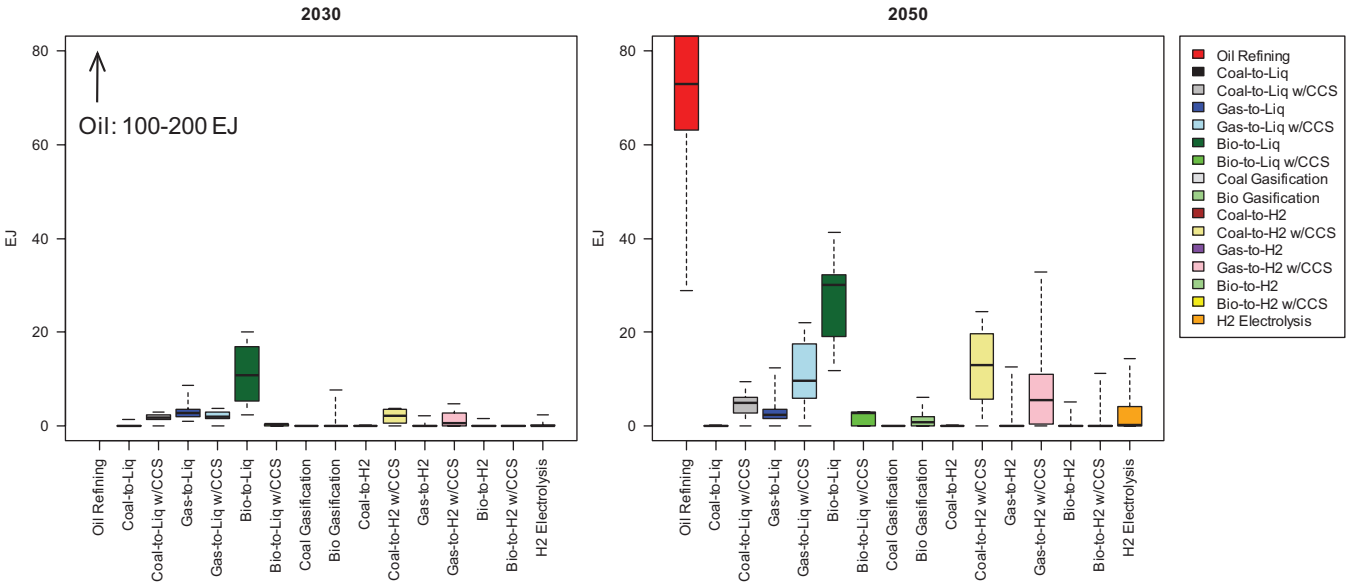

Figure 17.17 | Deployment of liquid and gaseous fuel production technologies in 2030 and 2050 in the GEA pathways. Boxes represent interquartile (25th-75th percentile) ranges, and horizontal lines within boxes represent medians of all feasible GEA pathways from MESSAGE and IMAGE. Error bars indicate the full range across all feasible pathways.

energy sources, as it is almost entirely dominated by oil products. Only about 1.3% of liquid fuel production – about 2.2 EJ out of a total of about 165 EJ in 2007 (IEA, 2009b) – originates from biofuels. In addition, this minor biofuel contribution is regionally very heterogeneous and is essentially dominated by Brazil, the United States, and the European Union, all of which have specific biofuel policies in place. As a result, in the left-hand panel of Figure 17.17, which shows the situation by 2030, the contribution of oil refining is still outside the range of the figure (oil products contribute between 100 and 200 EJ in 2030), while all other technologies contribute less than 20 EJ, even in the most extreme case. The first major commonality, therefore, is the short-to-medium term dominance of oil in the production of liquid and gaseous fuels as energy carriers destined primarily for the transportation sector.

The second commonality is that in the medium term, the biofuel contribution grows substantially. This occurs in regions that already have supportive policies in place, as well as in regions with advantageous conditions for biofeedstock production (e.g., sub-Saharan Africa and Australia/New Zealand). By 2030, the range will be somewhere between today's level and approximately 20 EJ, which corresponds to almost a 10-fold increase over 20 years. The higher end of this range is driven by transportation sector assumptions: the higher deployment range typically comes from scenario variations with a Conventional Transportation setup. Nevertheless, even in the transformation process under an Advanced Transportation setup, biofuels play an important transitional role, and in the very long term (beyond 2050), liquid biofuels may still have an important role in, for example, aviation and heavy freight transport. Once second-generation biofuel technologies become available at a larger scale, sometime between 2020 and 2030, a continued diversification of biofuel production is foreseen.

Unlike liquid biofuels, the potential substitution of oil products with synthetic fuels from natural gas (gas-to-liquid conversion) is a choice rather than a common feature across all pathways. However, this depends on related choices made with respect to CCS.[24] Coal-to-liquid conversion, on the other hand, plays a less important role at the global scale even with CCS, except in regions with abundant coal resources.

In terms of gaseous fuel production, biomass gasification will be limited even in 2050 (depending on the choices made with respect to bioenergy production), although it could be readily integrated into existing natural gas infrastructures. The major choices with respect to gaseous fuels concern hydrogen; but again, these depend on the choices made with respect to Conventional versus Advanced Transportation systems and, within the latter, whether electricity or hydrogen is the preferred route (although hydrogen can also supply some industrial applications). If the build-up of a hydrogen-only infrastructure turns out to be too ambitious, the injection of hydrogen into the gas grid is a favorable (relatively low-cost) option that helps reduce direct CO_2 emissions in the end-use sectors (Riahi and Roehrl, 2000; Midilli et al., 2005; NATURALHY, 2010). If it is derived from fossil fuels, however, hydrogen is an attractive option only in combination with CCS. In the longer term its predominant source would be nuclear or renewable energy. In the latter case, hydrogen electrolyzers would offer the opportunity to deal with the intermittency of wind and solar electricity and thus serve as a storage technology (Sherif et al., 2005; Yang, 2008).

24 CCS is usually a low cost add-on for gas-to-liquid and coal-to-liquid technologies because one of the predominant processes, Fischer-Tropsch synthesis, produces a concentrated CO_2 stream that can be captured at little extra cost (see Chapter 12).

Commonalities and Choices: Fossil Resource Extraction

Currently the upstream sector is dominated by fossil fuel extraction, most importantly oil but increasingly natural gas and coal, which has seen considerable expansion over the last several years, largely driven by significant price increases for hydrocarbons. Compared with these three groups of fossil fuels, renewable energy sources, such as purpose-grown bioenergy as well as agricultural residues and byproducts from other uses of biomass feedstock (e.g., in paper and pulp production), are small today.

However, it needs to be emphasized that the sustainability goals built into the GEA scenario, in particular the climate target, put limitations on the use of fossil fuels. This implies that resource limitations for fossil fuels are generally not a concern for the GEA pathways (Figure 17.18). Therefore, the pathways in general show peak oil and gas behavior, however, not because of the assumed physical scarcity of hydrocarbons, but because of the limited carbon emission budgets under, for example, the 2°C target (see also Verbruggen and Al Marchohi, 2010).

The extraction of conventional hydrocarbons lies within a smaller range than that of the unconventional categories,[25] largely because they still play an important role during the energy transition over the coming decades. The largest part of the ranges in oil and gas extraction shown in Figure 17.18 is due to variations in the deployment of unconventional resources, which tend to play a significant role only under specific conditions because of their relatively more energy- and emissions-intensive extraction processes. Unconventional oil plays a limited role in the GEA-Efficiency group of pathways and in the unrestricted portfolio pathways with the Advanced Transportation option of both the GEA-Mix and the GEA-Supply pathway groups, because here the transition away from oil to other fuels is permissible at a steadier pace (see Section 17.3.3.3). In contrast, unconventional gas extraction is most relevant in the GEA-Mix and GEA-Supply groups of pathways under the No Nuclear and Limited Renewables pathways, where CCS is elevated in importance compared with the unrestricted supply portfolio.

Coal extraction declines significantly over the next couple of decades across almost all transition pathways. However, after 2030, when CCS could become available at a larger scale, two distinct developments are possible, leading to a very wide range of possible levels of coal extraction by 2050. If CCS is excluded as a supply-side option, which is a possibility under the GEA-Mix and GEA-Efficiency groups of pathways, then coal extraction has to almost completely disappear by the middle of the century. On the other hand, if CCS can be successfully deployed at scale, a revival of coal extraction, reaching current levels and even going beyond, is an option. The absolute level depends on overall demand: in general, coal extraction is highest in the GEA-Supply group of pathways, followed by the GEA-Mix and the GEA-Efficiency groups.

25 The definition of conventional and unconventional hydrocarbon resources used here follows Rogner (1997). For a comprehensive discussion of the difficulties in the distinction of conventional and unconventional hydrocarbons see Chapter 7, Section 7.2.

Commonalities and Choices: Low-Carbon Energy Shares

Figure 17.19 shows low-carbon energy shares for total primary energy supply, electricity generation, and final energy demand (overall and in the transportation sector) in 2020, 2030, and 2050 for the different energy demand levels of the three GEA pathway groups. At the primary energy level and in electricity generation, nuclear energy, renewables, and fossil with CCS are counted as low-carbon energy. At the final energy level, fuels without direct CO_2 emissions (i.e., electricity, district heat, and hydrogen) as well as solid biomass and biofuels are counted as low-carbon energy.[26]

One important finding shown clearly by Figure 17.19 is that the low-carbon energy share is consistently lowest in the GEA-Efficiency group of pathways. From a climate perspective, what matters is not the share of GHG-emitting fuels but the absolute amount of emissions. Therefore, at a lower level of total energy demand, the share of GHG-emitting fuels can obviously be higher (see Section 17.5.1 on climate change).

A consequence is that the required speed of decarbonization is very ambitious under the GEA-Supply pathways with high energy demand; up to a doubling of the low-carbon energy share is needed within the decade to 2020. In the GEA-Efficiency pathways, a less aggressive decarbonization of global primary energy supply is permissible. Across all pathways, 60–90% of primary energy supply has to come from low-carbon sources by 2050.[27]

By far the most complete decarbonization has to be achieved in electricity generation; the threshold is in the range of 40–60% globally by 2020, starting from today's share of around 35%, largely due to nuclear and hydropower. By 2050 almost full decarbonization of electricity generation (80–100%) is required. This implies the need for a continued expansion of renewable electricity generation and of nuclear power, or a rapid commercial deployment of CCS, or both (see the discussion in Section 17.3.4.3). Financing for these mostly very capital intensive technologies (Section 17.3.5) and technology transfer mechanisms to enable deployment in developing countries (Section 17.5.1.4) are major challenges.

At the final energy level, the transition appears less challenging, at least in the short term. However, traditional biomass is included as a low-carbon energy source, accounting for some 30 EJ or about 10% of final energy

26 Note that the latter definition implies the assumption that the generation of electricity, heat, and hydrogen is decarbonized to a large extent, although in a transition period (in particular 2020–2030) significant carbon emissions in the conversion sector may be implied. In addition, it is noted that biomass and liquid biofuels cause direct CO_2 emissions, but if derived from sustainably grown biomass their lifecycle carbon emissions can become close to zero or even negative (in combination with CCS).

27 These values are comparable with those from a study conducted by O'Neill et al. (2010b) that systematically analyzes mid-century targets for keeping long-term climate stabilization options open. O'Neill et al. (2010b) identify low-carbon primary energy shares above about 65% by 2050 to achieve a similar probability (>60% based on uniform prior climate sensitivity probability density function by Forest et al. (2002)); see Section 17.5.1 on climate change for details on staying below 2°C warming by 2100 compared with preindustrial levels.

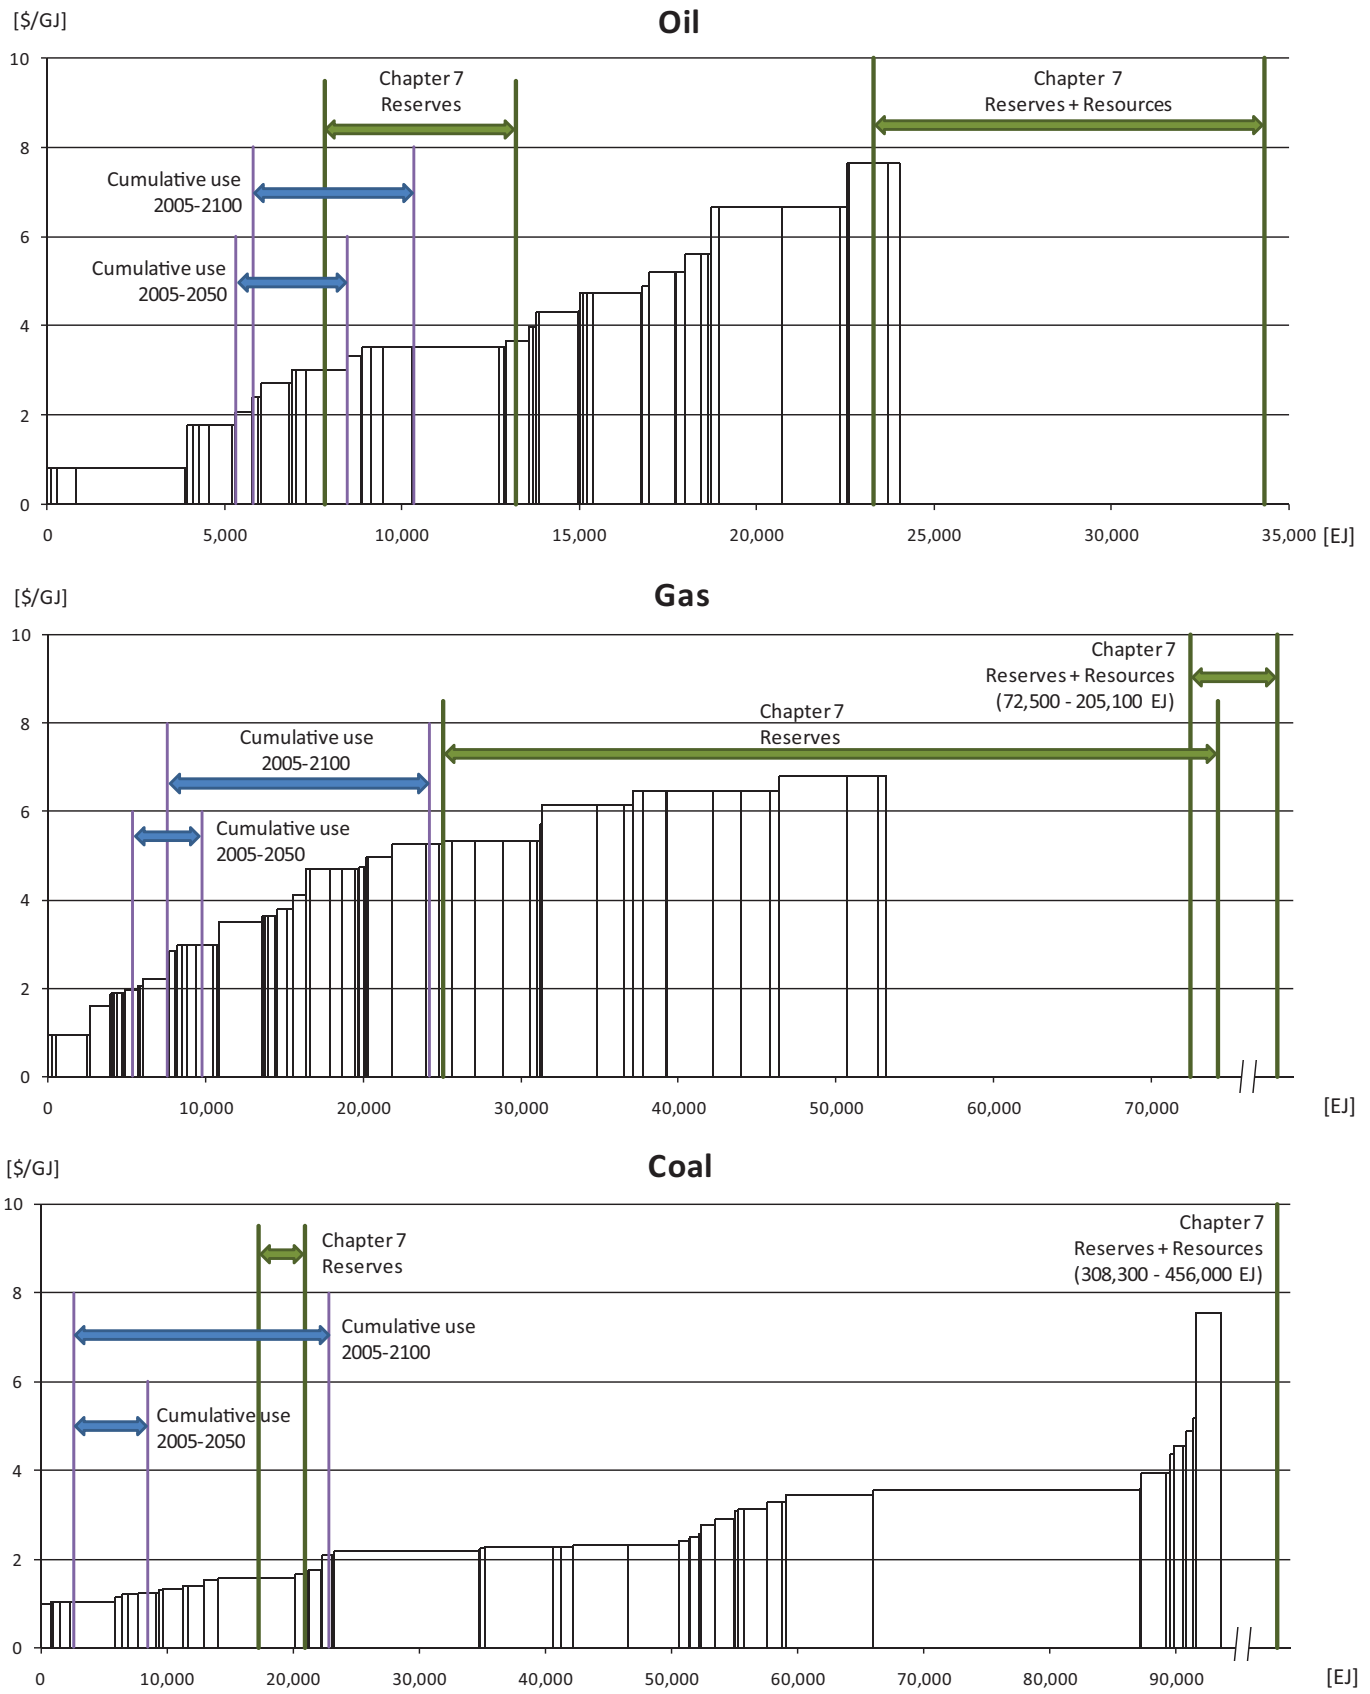

Figure 17.18 | Cumulative global resource supply curves for oil, gas, and coal in the MESSAGE model. The double-headed arrows show the range of cumulative fuel extraction across all feasible GEA pathways from MESSAGE and IMAGE between 2005 and 2050 and between 2005 and 2100. Vertical lines show the central reserve and resource estimates from Chapter 7.

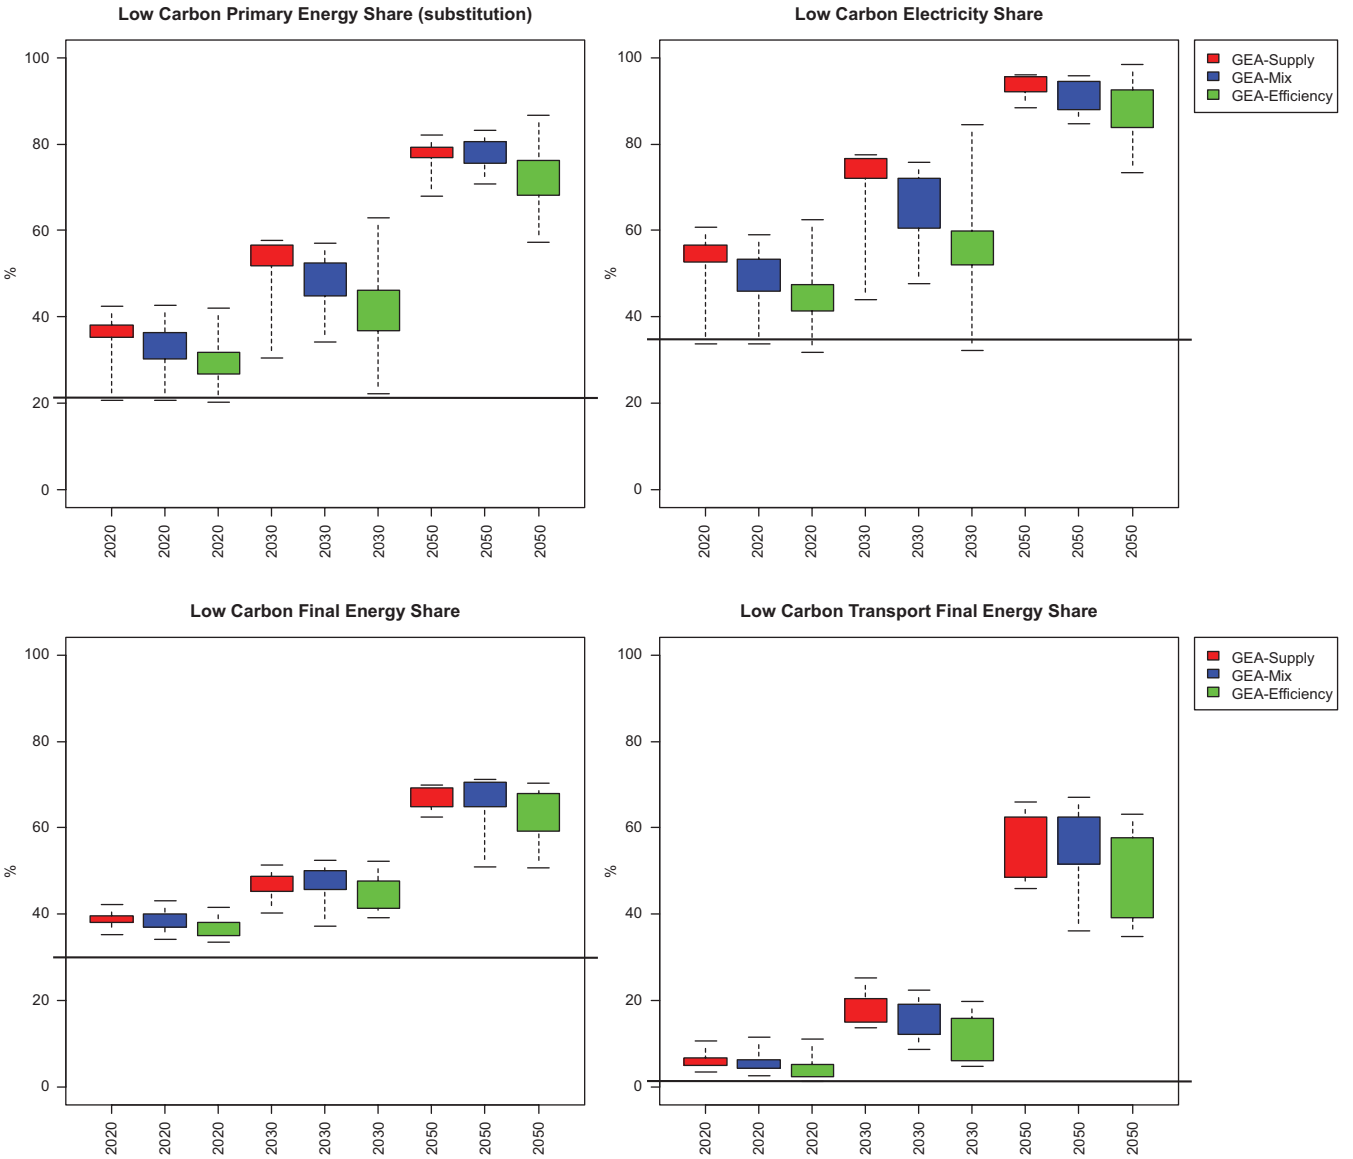

Figure 17.19 | Low-carbon shares in primary energy supply, electricity generation, total final energy use, and transportation sector final energy use by 2020, 2030, and 2050 across GEA pathways from MESSAGE and IMAGE. Boxes represent the interquartile (25th-75th percentile) range and error bars the full range across all feasible pathways in the indicated group. The black horizontal lines indicate low-carbon shares in 2005.

use in 2005. The energy access objective requires that traditional biomass be replaced with cleaner energy forms; in this light, the decarbonization challenge with respect to final energy demand becomes clearer.

In the transportation sector, the threshold level of a less than 10% low-carbon energy share to be reached by 2020 appears relatively modest compared with the low-carbon fuel shares in the other sectors, although it has to be kept in mind that the starting point is close to zero at present. Also, this required development is opposite to the historically observed downward trend in the share of public and rail-bound freight transport (see Chapter 18, Section 18.6.3). By 2050, low-carbon energy shares in transport have to reach a range of 35–75%, depending on the demand level.

Commonalities and Choices: CO_2 Capture and Storage

In those pathways that do not exclude CCS as an option, considerable amounts of CO_2 would need to be stored between 2020 and 2030, quickly rising to 2050, by which time cumulative storage needs to be no less than 55 $GtCO_2$ and closer to 250 $GtCO_2$. The bulk of this would come from fossil CCS (see above); bioenergy in combination with CCS takes off only around 2040 but increases its contribution in the latter half of the century.

By mid-century, cumulative CO_2 storage is strongly determined by the demand level, with relatively little overlap across the high, intermediate, and low demand levels that are assumed in the GEA-Supply, GEA-Mix, and GEA-Efficiency pathway groups, respectively (Figure 17.20). This observation accords well with the fact that under low demand, the need

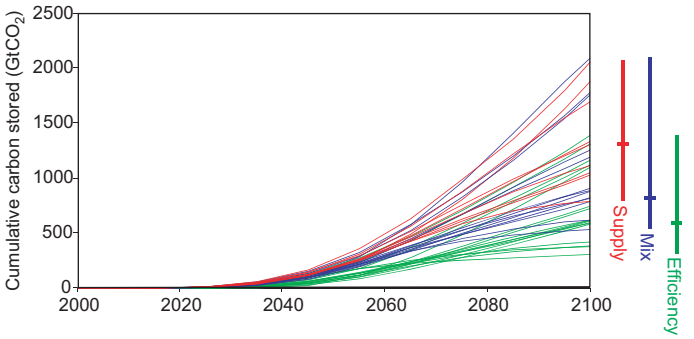

Figure 17.20 | Cumulative global CO_2 storage in the GEA pathways between 2020 and 2100. The vertical bars to the right of the chart show the range of cumulative storage needed within each group of pathways, with the median pathways marked as horizontal bars.

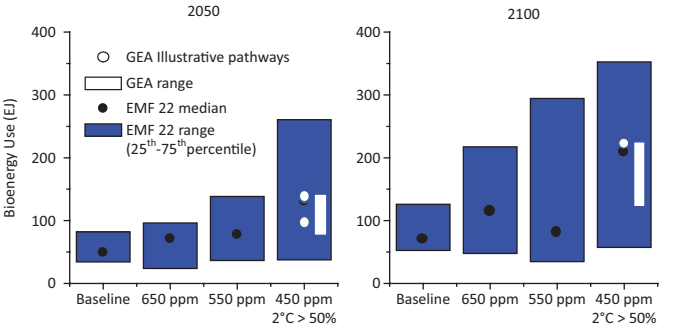

Figure 17.21 | Bioenergy use in 2050 and 2100 for alternative CO_2-equivalent atmospheric concentration targets in scenarios submitted to Energy Modeling Forum 22 (Clarke et al., 2009). Concentration targets (horizontal axis) are in parts per million. White squares and circles indicate the relative positions of the three GEA illustrative pathways. Fewer than three white squares and circles indicate that the pathways overlap.

for CCS is even independent of the transportation sector setup; that is, CCS is a choice, not a "must."

The above figure for global CO_2 storage by 2100 is compatible with the best estimate of 2000 $GtCO_2$ storage capacity, as presented in the IPCC Special Report on CCS (IPCC, 2005), although a few cases come close to this estimate: the GEA-Supply and GEA-Mix pathways with limited renewable energy and those without nuclear energy and the IMAGE interpretations of these two pathways that generally rely to a greater extent on CCS than their MESSAGE counterparts. In these cases, the demands placed on CCS would rely on the more optimistic storage estimates – including saline aquifers, in particular – to materialize, which is supported by more recent studies (see Chapter 13, Section 13.4.3 on CO_2 storage estimates). The high levels of storage and the continued growth toward the end of the century are mostly due to bioenergy with CCS; fossil CCS is generally a bridge technology for application within the medium term, although in the absence of other mitigation options it may have to serve throughout the entire century.[28]

Commonalities and Choices: Bioenergy and Land

The range of bioenergy used in the GEA pathways reaches up to almost 150 EJ by 2050 and 225 EJ by 2100 (in the IMAGE and MESSAGE models). A considerable part of this energy is assumed to be supplied from residues, thus conforming to sustainability criteria. Figure 17.21 shows the use of bioenergy in the three illustrative GEA pathways, set within the broader context of bioenergy estimates from a range of modeling studies exploring increasingly stringent climate change stabilization targets. As is immediately evident, all three illustrative pathways show a similarly high use of bioenergy on the order of 150 EJ in 2050, rising to around 225 EJ in 2100 unless bioenergy use is further restricted.

The main commonality, therefore, with respect to bioenergy is its increasing role in the global energy system. Most studies using energy scenarios under stringent climate policy targets show that it is attractive to use bioenergy as a feedstock to create biofuels, electric power, or hydrogen, possibly in combination with CCS. Bioenergy might also be attractive as a feedstock for the production of materials. The impacts of this increased bioenergy production depend on several factors. First and foremost, first-generation bioenergy production routes may lead to extensive land use (either directly or indirectly) and are therefore likely to have negative impacts on biodiversity and food security. These impacts are expected to be considerably less for second-generation biofuels and electricity generation feedstocks (Dornburg and Faaij, 2005). However, second-generation bioenergy could also lead to significant GHG emissions. In the longer term, biomass can also play an essential role in achieving low GHG concentration targets by making negative emissions a possibility if combined with CCS. Nevertheless, the potential impacts of bioenergy on other policy and sustainability objectives imply that additional policies and strict monitoring of bioenergy and its land use implications will be necessary.

A key factor associated with bioenergy expansion relates to the availability of land.[29] As the GEA pathways use similar levels of bioenergy (see Figure 17.21), the illustrative GEA-Mix pathway is used here to indicate relevant trends in land use and food production.

As shown in Figure 17.22, grassland use (pastures) in the GEA-Mix pathway is more or less stable. This is the result of two opposing trends: an increase in meat consumption and an intensification of animal husbandry. The use of cropland for food production in the GEA-Mix pathway is expected to increase slowly up to 2050 and then stabilize. The land use trends for food production in the GEA pathways are therefore within, but somewhat on the low side of, the range of projections in the literature, which typically show a 0–40% increase (see, for instance, van Vuuren et al., 2009).

28 Even these high levels will need to be phased out some time during the first half of the 22nd century to avoid atmospheric CO_2 concentrations falling below pre-industrial levels, which appears to be neither desirable nor justifiable based on the argument that dangerous anthropogenic interference with the climate system should be avoided. In addition, within this time frame storage capacity could become a problem even at the global level.

29 The IMAGE modeling framework was used to assess the land use implications of the GEA pathways.

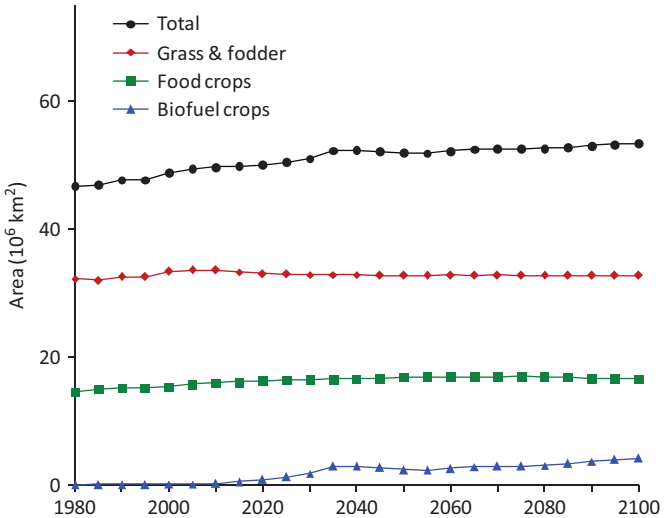

Figure 17.22 | Land use in the illustrative GEA-Mix pathway.

The increase in modern bioenergy use in the GEA scenarios implies an increase in land use for bioenergy production. The exact amount of land used depends strongly on assumed yield increases (see the electronic appendix to this chapter) and the types of bioenergy that are used. Still, as most other studies (e.g., van Vuuren et al., 2010) have found, bioenergy remains a relatively small category compared with other forms of land use. At the same time, the increase in land for bioenergy production in the GEA pathways is about equal to the total increase in agricultural land use. This implies that increases in global land use will lead to some further biodiversity loss and land scarcity. In the context of the GEA sustainability objectives, it will thus be particularly important that policies be put in place that can avoid a strongly adverse impact on crop prices (or the risk of such impacts in a situation of sharply rising energy prices).

17.3.4.4 Regional Analysis of the GEA Pathways

Thus far, the discussion of the GEA pathways has focused predominantly on the transition at the global scale, with regional issues raised in only a few cases. The following sections present explicit regional detail. The starting point of the analysis is energy demand, which starts from a very heterogeneous basis and is tightly linked to economic development in the different regions. On the supply side, three different topics with important regional implications are highlighted: renewable energy deployment, bioenergy use and related land use issues, and CCS, which links fossil energy resources and geological CO_2 storage potential.

This regional analysis is limited in scope and usually remains at the level of illustrative examples rather than being fully comprehensive. Full regional detail of the quantitative GEA scenario analysis is, however, available in the web-based GEA scenario database at www.iiasa.ac.at/web-apps/ene/geadb (see also Box 17.2 on scenario development).

Regional Analysis of Energy Demand

A core concern of the GEA transition pathways is to explore strategies to overcome the current, extremely inequitable distribution of incomes and the associated lack of access to clean and efficient energy services worldwide, while at the same time improving the environmental performance of energy end use and supply. This illustrates the comprehensive nature of the GEA transition pathways under the three main dimensions of sustainability: economic, social, and environmental.

This discussion illustrates some generic patterns in the regional development of energy demand in the GEA transition pathways. In an ideal case, such an analysis would first of all concentrate on actual levels of energy services provided to people, as the ultimate driver of energy systems. However, the diversity of energy end uses and their correspondingly different metrics (thermal comfort, distances traveled, industrial output, etc.) do not allow their aggregation into a commensurable uniform metric. Therefore, this section focuses on final energy demand, which has the advantage of being well covered by current statistics and available modeling and scenario methodologies.

Figure 17.23 summarizes per capita final energy demand as of 2005 as well as the situation in 2050 for the three illustrative GEA transition pathways. Final energy demand is disaggregated by major end-use application type: residential and commercial, industrial, and transportation. For the scenario projections to 2050, an additional efficiency (improvement) potential (grey shaded areas in the bottom panel of Figure 17.23) is shown, corresponding to the difference in final energy use between the lowest energy demand scenario, that of the illustrative GEA-Efficiency pathway, and the more supply-side-focused illustrative GEA-Supply pathway. All three GEA transition pathways achieve comparable levels of energy services provision. Their different levels of final energy use do not represent a difference in energy demand proper, but rather a difference in the efficiency with which comparable levels of energy demand can be provided. These levels of efficiency of energy end use across pathways can be compared with current levels as ranging from efficient (GEA-Supply) to extremely efficient (GEA-Efficiency). For greater legibility, Figure 17.23 summarizes the scenarios for only six of the 11 GEA world regions.

The current disparities in income and energy use across low-income (Africa and South Asia), middle-income (Latin America), and high-income countries (Western Europe and North America) are immediately apparent, as are important differences in the structure of final energy use (a very low industry share in Africa versus a high share in China and Centrally Planned Asia) and the much greater importance of transport energy use in North America than in Latin America. The figure also demonstrates the importance of energy end-use efficiency: Western Europe and North America currently enjoy comparable levels of income, but Western Europe uses only about half as much final energy per capita.

The world in 2050 will look decidedly different from today when viewed through the lens of the GEA transition pathways. Current distinctions between low- and higher-income countries will be largely obsolete, as

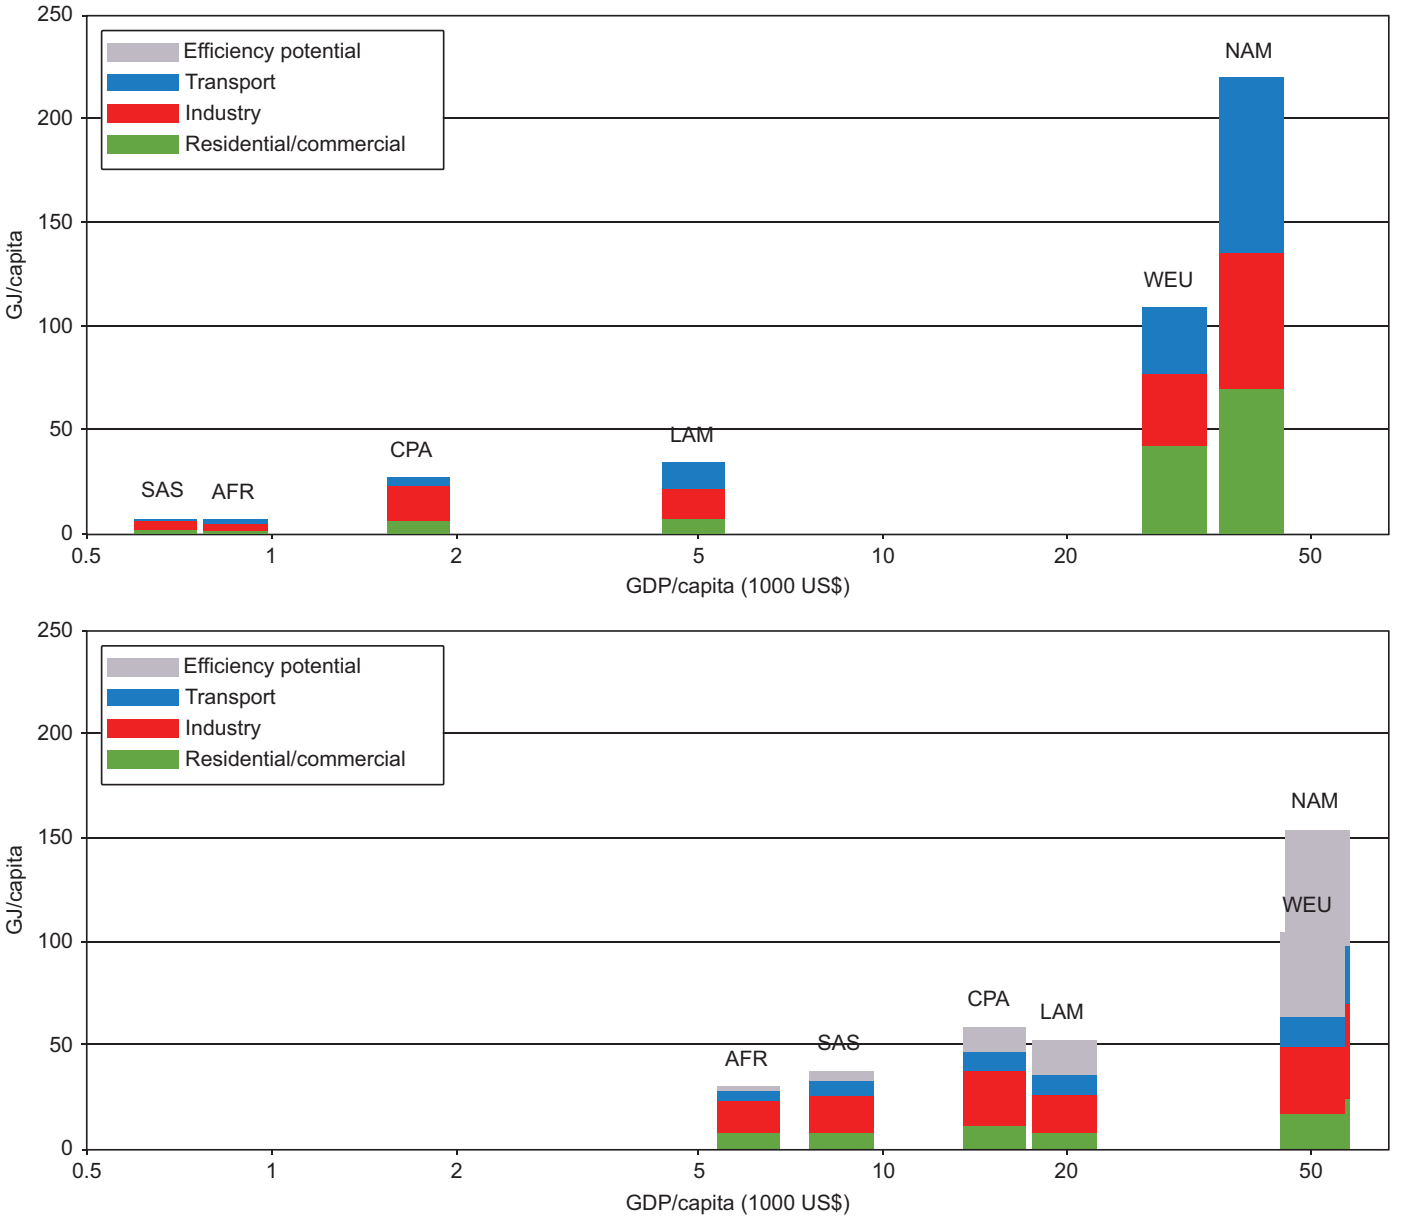

Figure 17.23 | Per capita final energy use and income for selected world regions in 2005 (top panel) and in the illustrative GEA-Efficiency pathway in 2050 (bottom panel). The efficiency potential is calculated from the difference in final energy use between the illustrative GEA-Efficiency and the GEA-Supply pathway. Income is in thousands of 2005 US dollars.

even the regions with the lowest per capita incomes today (sub-Saharan Africa and South Asia) will have advanced to lower-middle-income levels (annual per capita incomes in 2005 dollars of US$5000–10,000), while other developing regions (Centrally Planned Asia and China, Latin America and the Caribbean) will have attained middle-class incomes and lifestyles (US$15,000–20,000) characteristic of the affluent OECD countries in the 1990s. The GEA transition pathways thus describe a pattern of conditional convergence in incomes. This tendency is even more pronounced when one considers that corresponding final energy use per capita remains below roughly 50 GJ per capita across all currently developing regions and transition pathways, because of significant improvements in energy end-use efficiency that combine appropriate policies at the local to regional scale with globalized availability of energy-efficient technologies and devices. Nor will the potential for improvement have been exhausted even by 2050, as indicated by the scenario differences between the GEA-Efficiency and the GEA-Supply pathways.

Undeniably, the biggest transition challenge will face today's high-income OECD countries, above all in North America. The much-discussed "factor 4" (see von Weizsäcker et al., 1997) – a simultaneous doubling of income and halving of energy use – characterizes the GEA-Efficiency

Table 17.12 | Ranges of renewable energy deployments across GEA Pathways, by region, 2050 (in Exajoules unless otherwise stated).

Region	Bioenergy	Hydropower	Wind	Solar[1]	Geothermal	All renewables	All renewables as % of total
Sub-Saharan Africa	8.8–40.5	2.0–5.5	0.0–19.6	0.5–25.5	0.0–0.3	11.4–91.4	31–94
Centrally Planned Asia and China	6.9–24.7	9.7–10.3	3.7–8.8	0.9–40.1	0.0–0.3	21.2–84.2	24–50
Eastern Europe	1.3–2.8	0.8–1.0	0.7–5.0	0.2–6.1	0.0–0.3	2.9–15.3	23–85
Former Soviet Union	2.9–10.1	2.7–15.8	1.4–7.4	0.3–9.7	0.0–1.0	7.4–43.9	25–93
Latin America and the Caribbean	10.5–22.5	10.7–17.6	3.6–12.4	0.5–21.8	0.0–1.8	25.3–76.1	40–100
Middle East and North Africa	1.2–5.1	0.8–1.2	1.3–8.7	0.5–15.8	0.0–0.3	3.8–31.1	17–40
North America	10.0–21.5	7.2–7.9	2.6–36.7	1.2–41.6	0.0–3.4	21–111	38–89
Pacific OECD	3.4–11.3	1.4–1.7	0.6–4.9	0.2–5.4	0.1–0.8	5.7–24	26–89
Pacific Asia	5.0–11.9	1.9–7.2	1.0–2.0	0.4–14.5	0.2–1.3	8.6–36.9	15–63
South Asia	5.2–20.8	3.5–4.3	1.1–6.7	1.0–79.0	0.0–0.2	10.7–111	21–65
Western Europe	3.9–11.0	5.7–7.6	3.0–30.2	0.7–28.9	0.1–2.1	13.4–79.8	34–83
World	78.3–139	49.9–80.1	28.5–134	7–285	0.6–11.9	164–651	28–74

Note: Ranges include restricted supply portfolios and are calculated as primary energy supply using the substitution method.

1 The representation of solar energy in the IMAGE modeling framework is restricted to solar photovoltaic, which leads to significantly lower solar energy contributions in the IMAGE interpretation of the GEA pathways that typically mark the lower end of solar deployment in this table.

pathway for this region. Although challenging, such a major transition both is technologically feasible by 2050 (see Section 17.3.2.1), considering historical rates of capital turnover, and entails significant benefits in terms of increasing energy security, improving local and regional environments, and avoiding damages from climate change. Compared with these benefits, the required adjustments in energy end-use patterns and lifestyles (toward more energy-efficient, more compact vehicles and greater use of high-quality public transit) will be either modest or nonexistent (e.g., in the case of zero-energy homes that do not compromise living space and comfort).

The biggest challenge revealed by the transition pathways faces not consumers, who can confidently expect expanded and improved levels of energy services in the future, but rather entrepreneurs and policymakers. They need to embrace decidedly different views from those widely held today, focusing on energy services provision rather than mistakenly viewing technology- and policy-dependent levels of primary energy use as immutable, given consumer demand. Policymakers must also embark on different policies that combine both carrots and sticks in order to include stricter building, appliance, and vehicle efficiency standards and changes in relative prices through taxes, subsidies, feed-in tariffs, and other measures. This would open up new business opportunities (e.g., for energy services companies), thereby creating new markets (e.g., for efficiency technologies) and leveraging the power of market forces to meet social concerns and public policy choices.

Regional Analysis of Renewable Energy Sources

Renewable energy sources play an important role in essentially all GEA transition pathways, as discussed at length in Section 17.3.3. Even under the Limited Bioenergy and Limited Renewables pathways (see Table 17.9), renewable energy sources reach some 40% of total global primary energy supply by 2050. Regionally, however, the contribution of renewables varies considerably, as Table 17.12 illustrates for 2050. Several reasons deserve mentioning in this context. First, the resource supply curves (i.e., technical potential as well as resource quality) for the various renewable energy sources differ significantly across regions (see Box 17.3 and the electronic appendix to this chapter). Second, the availability of low-carbon supply-side alternatives (nuclear energy and fossil CCS), which ultimately determine the economic potential for renewable energy sources, is also strongly region dependent. Third, the tradability of renewable energies or of secondary energy carriers derived from them is very heterogeneous. Whereas liquid biofuels are easy to trade and can even rely on existing infrastructures, the scope for trading electricity (e.g., from wind, solar photovoltaic and CSP, and hydropower) at the global scale is much more limited, and for heat (e.g., solar thermal, geothermal), trade is not an option at all. This generally leads to higher exploitation rates of bioenergy potentials than of other renewables. For example, sub-Saharan Africa and Latin America, with the largest sustainable bioenergy potentials, export significant quantities of liquid biofuels starting after 2020 across almost all GEA pathways.

Beyond bioenergy, the relative contribution of the other renewable energy sources varies considerably. In regions with advantageous wind conditions, such as North America and Europe, wind power becomes the largest or second-largest source in terms of secondary energy provided. In most other regions, by 2050 solar energy can become the dominant renewable energy source.[30] Hydropower continues to provide a sizeable share in North America, Latin America, Europe, the Former Soviet Union countries, Centrally Planned Asia and China, and Pacific Asia. Geothermal energy deployment is less pronounced globally and most relevant in North America, Western Europe, Latin America and the Caribbean, and Pacific Asia, in that order (see Chapter 7, Section 7.4.5).

The largest variation in deployment across GEA pathways naturally occurs for those renewable energy sources that are explicitly constrained in the restricted supply portfolio analysis: bioenergy, wind, and solar. For hydropower, deployment ranges tend to be narrower, with a few exceptions. The role of renewable energies generally varies greatly across regions. However, two points are worth noting. First, sub-Saharan Africa and Latin America have the highest renewables deployments by 2050, which, even at the lower end, means that about 40% of primary energy supply comes from renewables; this rises to more than 90% if other supply options are not available. These high shares are related to the bioenergy potentials in these regions not being solely exploited for domestic use, but also being converted to liquid biofuels for export. Second, all of the Asian regions lie toward the lower end of the spectrum, with renewable shares of typically less than 50% by 2050. This is primarily due to those regions' high population density and to potential land use and other conflicts that limit, for example, their sustainable bioenergy or wind energy potential.

Regional Analysis of Bioenergy and Land Use

The use of bioenergy is expected to lead to an expansion of agricultural land. As Figure 17.24 (which is meant only for illustration purposes) suggests, this expansion may occur in many parts of the world. In today's high-income regions such as Europe, North America, and Russia, the GEA-Mix pathway shows a small decrease in agricultural area leading to land abandonment. This decrease in land use results from a stabilizing population, further increases in yields, and increasing food imports. The pathway thus shows that some land could be abandoned for agricultural purposes, to be compensated for by the expansion of agricultural land in low-income areas. These abandoned agricultural areas are used in the GEA-Mix scenario for bioenergy production, which also provides alternative rural income.

Land use for production is also expected to expand in low-income regions such as sub-Saharan Africa, Latin America, and Southeast Asia. Here, an important driver is relatively low production costs. Again, this opens up routes for bioenergy production. Figure 17.24 shows important bioenergy production areas developing in Latin America and sub-Saharan Africa (which also retain vast forest areas). The trends in the other GEA pathways are broadly comparable to those shown here and are therefore not discussed in detail.

Regional Analysis of CCS

As discussed in previous sections, the role of CCS is very heterogeneous in the electricity and liquid and gaseous fuel sectors as well as across the globe. Regionally, the situation depends on available alternatives such as nonbiomass renewable energy sources, but it depends even more so on the resource basis and costs of fossil fuels and bioenergy. As a result, the amount of CO_2 captured and stored, or shipped to appropriate storage elsewhere, also varies widely. Figure 17.25 shows regional cumulative CO_2 storage over the century in the three illustrative GEA pathways in their IMAGE and MESSAGE interpretations.

The regions with the highest storage volumes are those with large coal resources and correspondingly high utilization of coal with CCS (Centrally Planned Asia and China), large bioenergy potential (sub-Saharan Africa), a combination of the two (North America) or a lack of alternatives (South Asia). Regional CO_2 storage potentials reported in the literature (see Chapter 13, Section 13.4.3; IPCC, 2005; and Hendriks et al., 2004) indicate that in some regions, storage beyond the best estimate may be needed under the higher CCS deployment levels derived in the present analysis.[31] Particularly difficult is the situation in South Asia, where even the comparatively modest need for CO_2 storage under conditions of low demand comes close to the higher estimate by Hendriks et al., (2004). It must be acknowledged that the global best estimate of Hendriks et al. (2004), about 1660 $GtCO_2$, is almost 20% lower than the best estimate of the IPCC Special Report on CCS (IPCC, 2005) published shortly afterward. The overview of CO_2 storage estimates presented in Chapter 13, Section 13.4.3 indicates that uncertainties of storage estimates in saline aquifers – potentially the largest storage option by far, with up to more than 20,000 $GtCO_2$ at the global scale – are very large and that reliable estimates at the regional level are often missing.

17.3.5 Energy Investments

Having presented the main transformational changes of the GEA pathways, the discussion moves now to financial resources, and specifically to the energy investments that need to be mobilized to transform the system.

An important characteristic of the energy sector is its long-lived capital stock, with lifetimes for infrastructure and energy conversion facilities of

30 Note that this only holds for the MESSAGE interpretation of the GEA pathways because the representation of solar energy in the IMAGE modeling framework is restricted to solar photovoltaic, which leads to significantly lower solar energy contributions in the IMAGE interpretation of the GEA pathways.

31 Because of the large uncertainties in the regional CO_2 storage potentials, no explicit limitations were imposed in the scenario generation process with the MESSAGE model, whereas IMAGE explicitly includes limitations for CO_2 storage based. This section presents an ex post comparison of storage needs in the GEA pathways with ranges from the literature undertaken here.

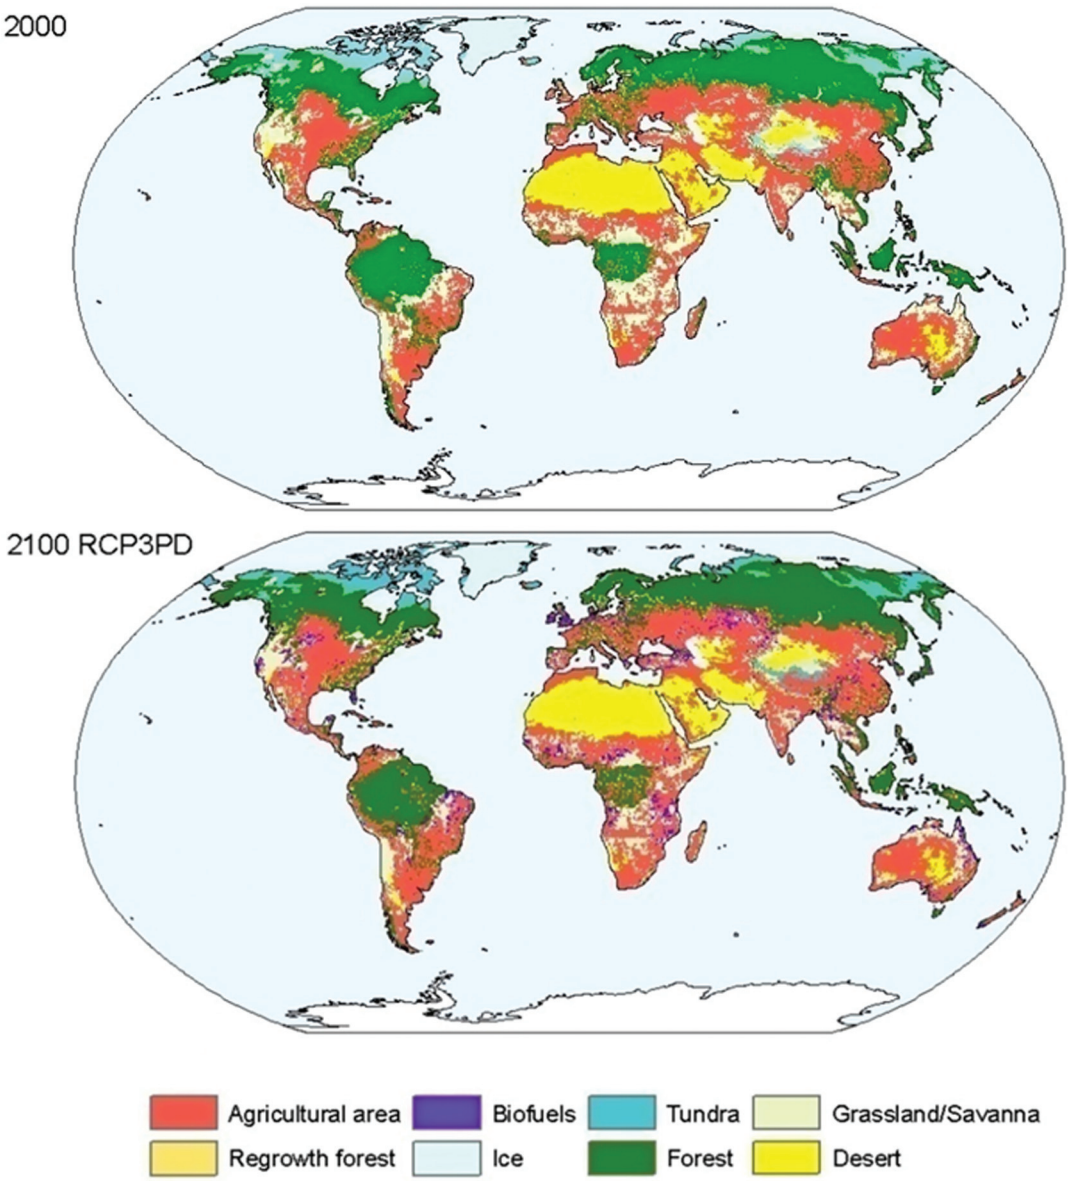

Figure 17.24 | Land uses in 2000 and in the illustrative GEA-Mix pathway in 2100.

30–60 years and sometimes longer. This longevity translates into high inertia in energy supply systems, which impedes rapid transformation. The energy investment decisions of the next several years are thus of central importance, since they will have long-lasting implications and will critically shape the direction of the energy transition path for many years to come.

17.3.5.1 Present Energy Investments

To put energy sector investment into context, it is helpful to first compare current worldwide energy investment with overall economic activity. Following a detailed, bottom-up cost calculation for the entire energy sector, from resource extraction (e.g., coal mining, oil wells) through development and production to delivery and transmission, as well as accounting for historical capacity extensions (and replacement schedules), the present study estimates total global supply-side investment in 2010 at about US$960 billion.[32] This corresponds to about 2% of global GDP that, while a relatively small share, varies greatly among countries at different stages of economic development. At 3.5% of GDP on average, energy investments are a much larger part of the economy in the developing world than in the industrialized world, where they average 1.3% of GDP.

Understanding the order of magnitude of demand-side investments is of critical importance, particularly because the lifetimes of end-use technologies can be considerably shorter than those on the supply side.

32 The calculations of present and future investments rely on estimates from the systems engineering MESSAGE model, which includes a detailed vintage structure and information on the development of historical capacities. All monetary values are given in 2005 US dollars at market exchange rates unless stated otherwise.

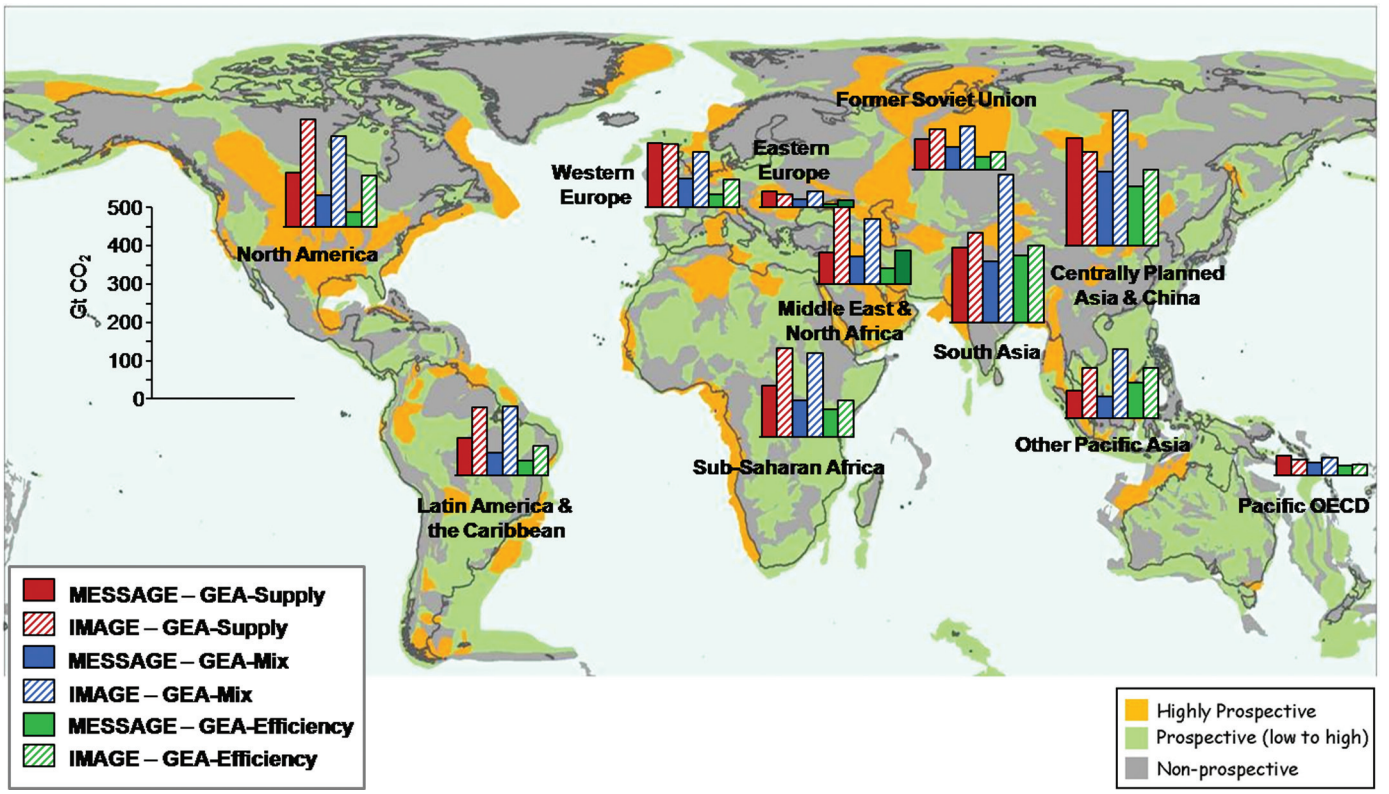

Figure 17.25 | Cumulative CO_2 storage by region until 2100 across the illustrative GEA pathways from MESSAGE and IMAGE. The figure also shows prospective areas in sedimentary basins where suitable saline formations, oil or gas fields, or coal beds may be found (prosperity map from Bradshaw and Dance, 2005).

Demand-side investments might thus play an important role in achieving pervasive and rapid improvements in the system. Following the analysis of Chapter 24, around US$300 billion is additionally invested in energy components at the service level, such as engines in cars, boilers in building heating systems, and compressors, fans, and heating elements in large household appliances. Demand-side investments are, however, subject to considerable uncertainty due to a lack of reliable statistics and difficulties in clearly defining what constitutes a purely energy-related investment. Chapter 24 thus reports a relatively wide range of energy component investments on the demand side of about US$100 billion to US$700 billion. In addition, accounting for the full cost of demand-side energy technologies (not only the energy components) would increase investment (but also uncertainty) by about an order of magnitude, to about US$1700 billion (with a range of US$1000 billion to US$3500 billion; see Chapter 24 for more details).

Uncertainties are considerably smaller for total supply-side investment. The estimates presented here are, for instance, similar to those of the International Energy Agency (IEA, 2009b).[33] There is nonetheless some uncertainty about investment in specific technologies, such as nuclear power. The estimates used for this study include about US$5 billion of investment into approximately 2 GW of new nuclear capacity additions worldwide. In addition, proportional investment in ongoing construction of about 43 GW capacity and investments in fuel processing and lifetime extensions are taken into account. These categories are subject to relatively more uncertainty, but they account for the bulk of total investment in nuclear by up to US$40 billion.

Figure 17.26 summarizes present investment for individual supply-side sectors. Investments are most capital intensive in the power sector, which includes generation, transmission, and distribution. This sector thus accounts for about 42% of total investment, with generation (US$270 billion) accounting for about the same share as transmission or distribution (US$260 billion). The remaining supply-side investment is dominated by the fossil fuels upstream sector: US$130 billion for natural gas, US$210 billion for oil, and US$33 billion for coal.[34] As mentioned above, the uncertainties are particularly large for demand-side investments, which account for at least 24% of total investment (if only energy components are considered).

33 Unfortunately, the IEA does not report all investment categories for the base year but focuses rather on cumulative numbers to 2030. The present analysis thus reconstructed the IEA base-year numbers for individual categories using activity numbers as proxies. Note also that the IEA investments are reported for 2008, whereas those reported here are for 2010. Hence, some of the difference might be due to the different base years.

34 Upstream investments include investment in extraction as well as transportation and distribution and upstream conversion facilities (such as LNG terminals and refineries). They exclude, however, investment for fossil fuel exploration (on the order of about US$50 billion).

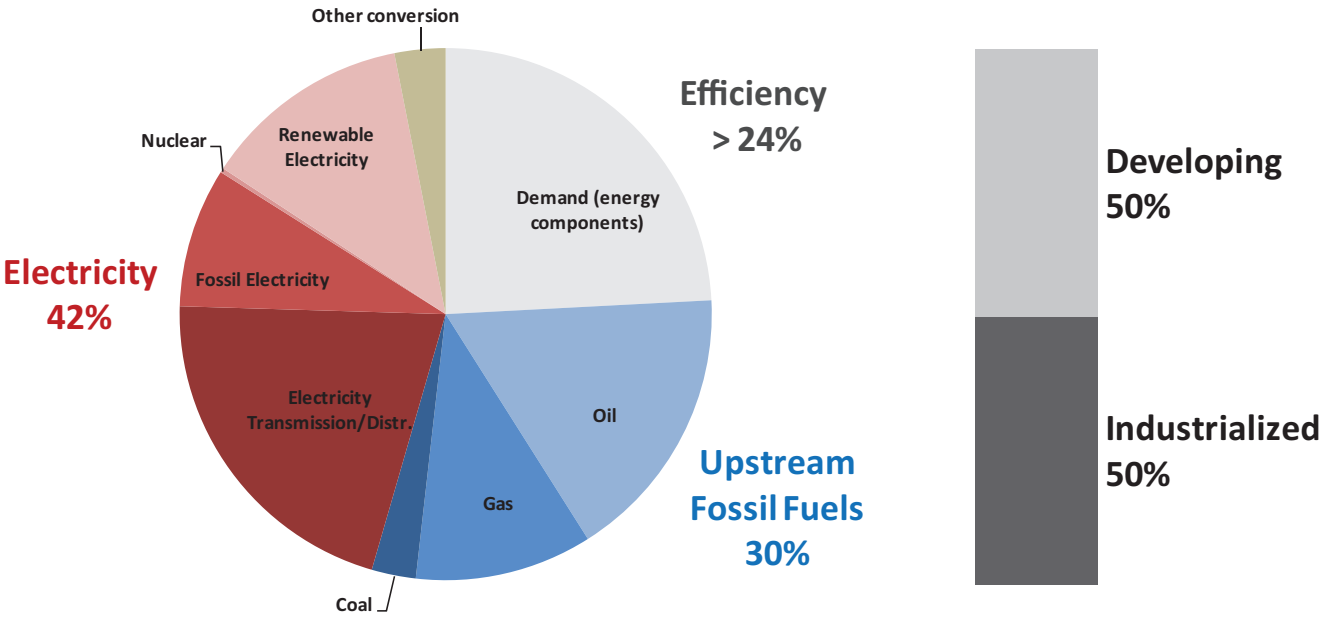

Figure 17.26 | Composition of energy investment in 2010. Total supply-side investment, excluding investment in fossil fuel exploration, is about US$960 billion. In addition >300 billion investments are made into energy components at the demand level.

The composition of investment has been especially dynamic in the past few years. Renewable energy investment, in particular, grew at an unprecedented rate of more than 50% annually between 2004 and 2008, reaching US$83 billion in the latter year, and is presently about US$190 billion (of which US$160 billion goes into power generation). By comparison, investment in fossil power generation in 2010 was about US$110 billion.

17.3.5.2 Future Investment Needs for Transformational Change

Investments in energy supply and demand will be critical for achieving virtually all energy objectives. Figure 17.27 shows the cumulative investment projection up to 2050 for each of the three illustrative GEA pathways. The figure indicates that achieving the GEA climate targets (Section 17.5.1) while also improving energy security (Section 17.6) and access and reducing pollution (Section 17.4) will require a scaling up of investment by almost a factor of 2 compared with today.[35] This corresponds to average annual investment globally of between US$1.7 trillion and US$2.2 trillion, or about 1.8–2.3% of global GDP.

In addition to the need to scale up investment, all the GEA transformational pathways depict significant changes in the structure of the investment portfolio. On the supply side, the transformation of the system is achieved through pronounced shifts of investment away from the upstream fossil fuel sector to downstream electricity generation and transmission. Consequently, the share of upstream fossil fuel-related supply-side investment in total investment decreases from 30% at present to about 12–23% by 2050. At the same time, electricity investment increases its share on average from about 55% to up to 68% by 2050.

Among all supply-side options, the largest increase in investment needs is for renewable power generation, ranging from US$160 billion/year in pathways with restricted renewables penetration to US$800 billion/year in pathways without CCS and nuclear power (compared with US$160 billion/year in 2010). Another priority for future investment is in building electricity transmission and distribution systems with sufficient operation and capacity reserves to increase reliability, as well as in power storage to allow the integration of intermittent renewables. Global average electricity grid investment (including storage) by 2050 thus increases to about US$310 billion to US$500 billion/year across the GEA pathways, compared with US$260 billion in 2010.

As discussed in the previous section, nuclear power and CCS play a prominent role in some of the GEA-Mix and GEA-Supply pathways, but the full portfolio also includes transformations excluding these options. The uncertainty ranges of these options are thus relatively wide. Investment in CCS ranges from zero to about US$65 billion/year, and investment in nuclear is between US$5 billion and US$210 billion/year. As Figure 17.28 indicates, the higher-bound estimates correspond to pathways in each GEA group that assume limited potential for other technologies.

Investment requirements for each pathway are the result of detailed, bottom-up cost calculations. Each technology of the energy system is characterized by a set of technical and economic parameters, one of which is investment cost measured in US dollars per kilowatt of installed capacity (US$/kW). In the long term, specific investment costs are not static. Innovation and technological learning tend to lower such costs,

35 Note that future demand-side investments of the pathways consider only efficiency-related investments at the margin. Comparable global investments into efficiency improvements for the year 2010 are not available. Hence, for 2010 investments for the demand-side consider the full investments into energy components. Future investment needs compared to the year 2010 might thus be an underestimate.

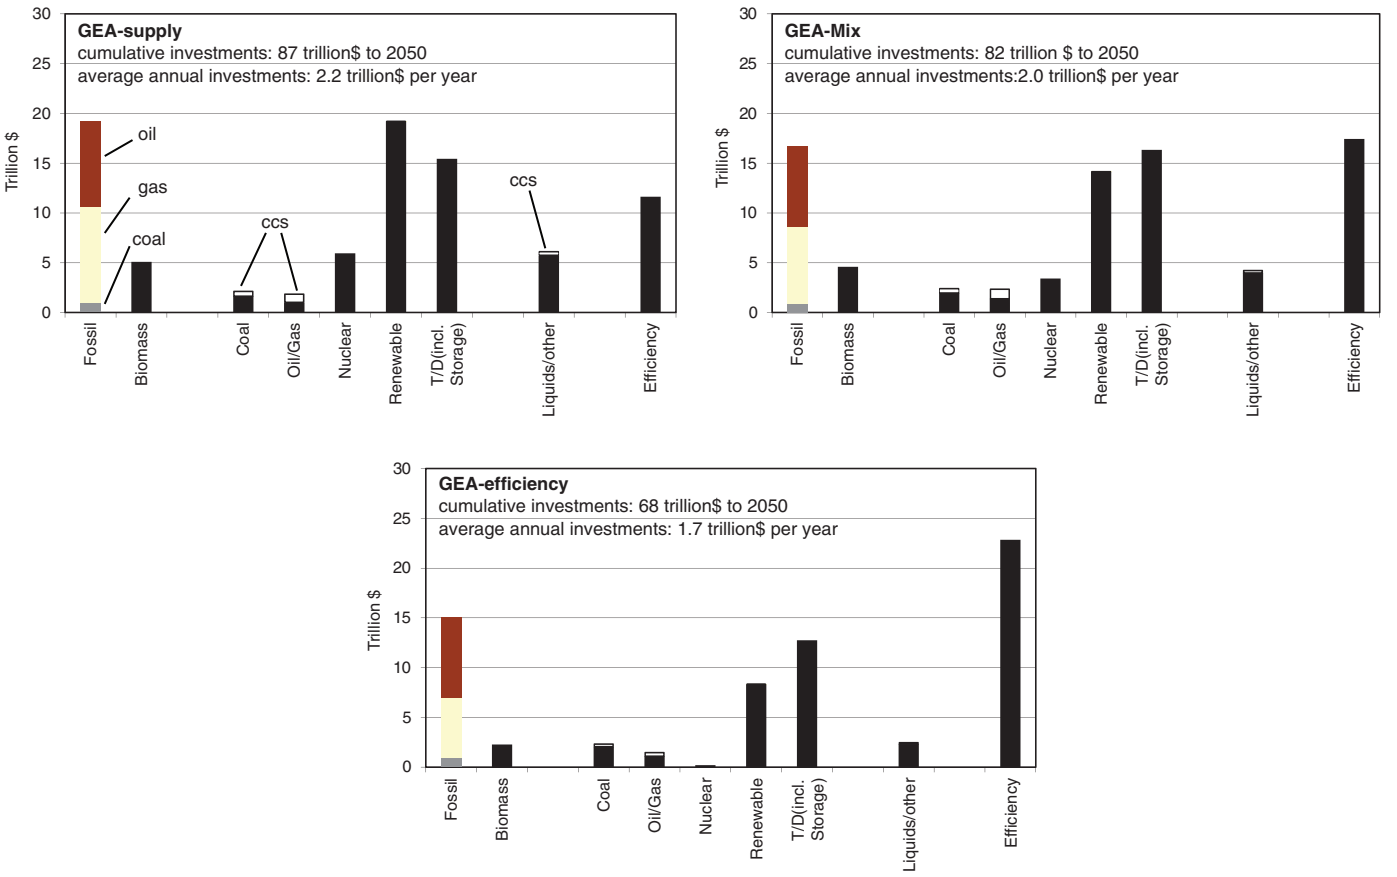

Figure 17.27 | Cumulative energy investment over 2010–2050 for the three illustrative GEA pathways. Within the "efficiency" category, only investments dedicated to improving efficiency are considered. Total demand-side investments for all energy components and appliances would be an order of magnitude larger.

and future energy sector investment requirements will depend greatly on the degree to which innovation and learning improve specific investment costs, efficiencies, emissions, and other performance characteristics (Nakicenovic et al., 1998; Roehrl and Riahi, 2000). Environmental regulation and resource depletion, on the other hand, tend to increase specific investment costs. In the past, innovation has more than compensated for depletion, and often for environmental regulation as well. The extent to which this trend continues in the future varies across pathways. The ranges of specific investment costs assumed for several key energy technologies are presented in the electronic appendix to this chapter, as well as in the GEA database at www.iiasa.ac.at/web-apps/ene/geadb/.

Generally, the present analysis suggests that the transition pathways that focus on energy efficiency achieve the targets at more modest cost and thus represent the lower bound of the investment range (Figures 17.27 and 17.28). One reason for this is the multiple benefits of efficiency measures (and behavioral and lifestyle changes) that limit energy demand and thus contribute to meeting virtually all energy objectives. By contrast, many supply-side measures, such as end-of-pipe pollution control, help improve the sustainability of the system with respect to one objective (local air pollution control) but do not necessarily contribute to others (e.g., climate change mitigation). The other reason why the efficiency pathways depict more modest costs has to do with the nonlinearity of the aggregate supply cost curve: the lower the demand, the less the need to deploy supply-side options with higher marginal costs.

Achieving high levels of efficiency enhancement is not, however, a free lunch. In the GEA-Efficiency pathways, about one-third of overall investment is efficiency related (Figures 17.27 and 17.28). Efficiency investment is calculated using a top-down methodology and thus includes investments on the margin only. In other words, only the efficiency-increasing part of an investment that directly contributes to improving energy intensity compared with a counterfactual (baseline) is accounted for. We thus do not consider the full demand-side investments in end-use devices.[36] Considering the latter would increase overall investment considerably (see the previous section and Chapter 24), but would not change the main conclusion with respect to the economic effectiveness of the efficiency measures.[37]

36 The baseline assumes the continuation of energy intensity improvement at historical rates.

37 Efficiency investments are calculated compared with a hypothetical case where the decline in the energy intensity of demand follows globally the historical trend of about 1%/year. For the accounting of macroeconomic feedbacks and price elasticity effects, the present analysis uses a macroeconomic equilibrium model (MACRO) linked to the systems engineering model MESSAGE from which are derived internally consistent energy intensity improvement rates for the alternative pathways (Messner and Schrattenholzer, 2000). Efficiency investments are then computed by assuming that, in equilibrium, the marginal investment to reduce demand would equal the marginal investment in supply. Efficiency investments thus include only investments that have been made to enhance the efficiency of demand in order to offset supply-side investments. Calculated efficiency investment thus does not represent all demand-side investments, including, for example, the component costs of appliances, which would be an order of magnitude larger (see Chapter 24).

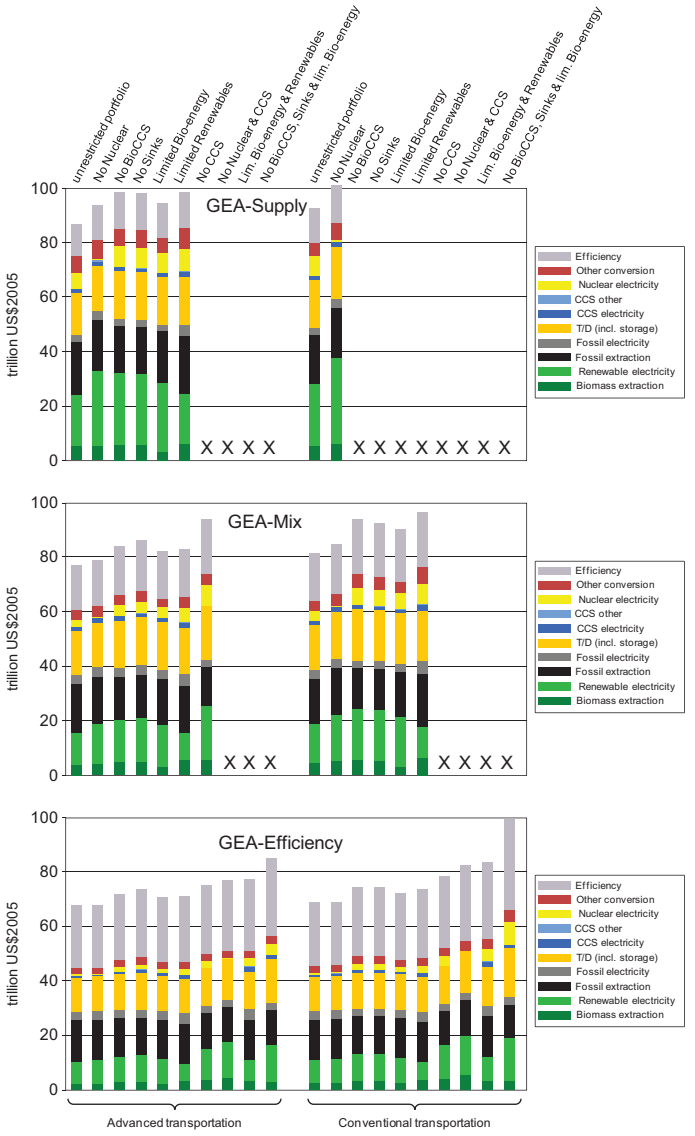

Figure 17.28 | Cumulative energy investment over 2010–2050 for all GEA pathways. Within the "efficiency" category, only dedicated investments to improve efficiency are considered. Total demand-side investments for all demand-side energy components and appliances would be an order of magnitude larger.

As in earlier analysis of stringent climate change mitigation scenarios (e.g., Fisher et al., 2007), the present study finds that the effect of the different investment patterns on the macroeconomy is relatively small. Compared to the counterfactual without policy interventions to achieve the GEA objectives, the projected loss to consumption by 2050 ranges from 0.6% for the GEA-Efficiency pathways to 1.4% for the GEA-Mix pathways and up to about 2.0% for the GEA-Supply pathways. This should be compared with 200% growth in overall consumption over the same period.[38]

38 Note that macroeconomic losses are indicative and do not, for example, include costs of overcoming policy barriers, effects of efficiency improvements, reduced losses from air pollution and climate change mitigation, and benefits of improved energy security.

17.3.5.3 Policies to Mobilize Financial Resources

Although the GEA pathways reveal considerable uncertainty about future needs for investment in specific technology options, they clearly illustrate that present investment in energy is neither sufficient nor compatible in structure with a sustainable investment portfolio. Mobilizing the required financial resources for the transformation will thus be a major challenge.

Increasing investment in the energy system as depicted by the GEA pathways requires the careful consideration of a wide portfolio of policies in order to create the necessary financial incentives. The portfolio needs to include regulations and technology standards in sectors with relatively low price elasticity, in combination with externality pricing, in order to avoid rebound effects, as well as targeted subsidies to promote specific "no-regrets" options while addressing affordability. In addition, attention must be given to building an enabling technical, institutional, legal, and financial environment to complement traditional deployment policies (particularly in the developing world).

Table 17.13 identifies effective combinations of policies for specific technology options (see also Chapters 22 and 26) and puts these in the context of the required future investment needs. In addition, the costs and policies for different technology options are compared with those for promoting energy access (see Section 17.4 for further details). Different types of technologies and objectives will require different combinations of policy mechanisms to attract the necessary investment. Table 17.13 thus distinguishes among various mechanisms: "essential" policy mechanisms are those that must be included for a specific option to achieve the rapid energy system transformation; "desired" policy mechanisms are those that would help but are not a necessary condition; "uncertain" policy mechanisms are those where the outcome will depend on the policy emphasis and thus might favor or disfavor a specific option; and "complement" policies are those that are inadequate on their own but could complement other essential policies.

As the table illustrates, future investment needs are comparatively modest for some objectives, such as access, but a variety of different policy mechanisms including subsidies, regulation, and capacity building need to be in place. Regulation and standards are also essential for almost all the other options; externality pricing (e.g., a carbon tax to promote the diffusion of renewables, CCS, or efficiency) might also be necessary for capital-intensive technologies to achieve rapid deployment. Capital requirements for energy infrastructure are among the highest of the options listed in Table 17.13. Thus, high priority needs to be given to future policies (including regulations) to address security and reliability aspects of the energy infrastructure. In addition, subsidies will need to ensure that customers can afford the reliability levels they value. For a more detailed discussion of implementation and policy issues, see Chapters 22 and 26.

Table 17.13 | Energy investments needed to achieve GEA sustainability objectives and illustrative policy mechanisms for mobilizing financial resources.

	Investment (billions of US$/year)		Policy mechanisms			
	2010	2010–2050	Regulation, standards	Externality pricing	Carefully designed subsidies	Capacity building
Efficiency	n.a.[1]	290–800[2]	*Essential* (elimination of less efficient technologies every few years)	*Essential* (cannot achieve dramatic efficiency gains without prices that reflect full costs)	*Complement* (ineffective without price regulation, multiple instruments possible)[3]	*Essential* (expertise needed for new technologies)
Nuclear	5–40[4]	15–210	*Essential* (waste disposal regulation and,of fuel cycle, to prevent proliferation)	*Uncertain* (GHG pricing helps nuclear but prices reflecting nuclear risks would hurt)	*Uncertain* (has been important in the past, but with GHG pricing perhaps not needed)	*Desired* (need to correct the loss of expertise of recent decades)[5]
Renewables	190	260–1010	*Complement* (renewable portfolio standards can complement GHG pricing)	*Essential* (GHG pricing is key to rapid development of renewables)	*Complement* (feed-in tariff and tax credits for R&D or production can complement GHG pricing)	*Essential* (expertise needed for new technologies)
CCS	<1	0–64	*Essential* (CCS requirement for all new coal plants and phase-in with existing)	*Essential* (GHG pricing is essential, but even this is unlikely to suffice in near term)	*Complement* (would help with first plants while GHG price is still low)	*Desired* (expertise needed for new technologies)[5]
Infrastructure[6]	260	310–500	*Essential* (security regulation critical for some aspects of reliability)	*Uncertain* (neutral effect)	*Essential* (customers must pay for reliability levels they value)	*Essential* (expertise needed for new technologies)
Access[7]	n.a.	36–41	*Essential* (ensure standardization but must not hinder development)	*Uncertain* (could reduce access by increasing costs of fossil fuel products)	*Essential* (grants for grid, microfinancing for appliances, subsidies for cooking fuels)	*Essential* (create enabling environment: technical, legal, institutional, financial)

1 Global investments into efficiency improvements for the year 2010 are not available. Note, however, that the best-guess estimate from Chapter 24 for investments into energy components of demand-side devices is by comparison about 300$ billion per year. This includes, for example, investments into the engines in cars, boilers in building heating systems, and compressors, fans, and heating elements in large household appliances. Uncertainty range is between US$100 billion and US$700 billion annually for investments in components. Accounting for the full investment costs of end-use devices would increase demand-side investments by about an order of magnitude (see Chapter 24 for details).

2 Estimate includes efficiency investments at the margin only and is thus an underestimate compared with demand-side investments into energy components given for 2010 (see note 1).

3 Efficiency improvements typically require a basket of financing tools in addition to subsidies, including, for example, low- or no-interest loans or, in general, access to capital and financing, guarantee funds, third-party financing, pay-as-you-save schemes, or feebates as well as information and educational instruments such as labeling, disclosure and certification mandates and programs, training and education, and information campaigns.

4 Lower-bound estimate includes only traditional deployment investments in about 2 GW capacity additions in 2010. Upper-bound estimate includes, in addition, investments for plants under construction, fuel reprocessing, and estimated costs for capacity lifetime extensions.

5 Note the large range of required investments for CCS and nuclear in 2010–2050. Depending on the social and political acceptability of these options, capacity building may become essential for achieving the high estimate of future investments.

6 Overall electricity grid investments, including investments for operations and capacity reserves, back-up capacity, and power storage.

7 Annual costs for almost universal access by 2030 (including electricity grid connections and fuel subsidies for clean cooking fuels).

17.3.6 Key Features of the Energy Transition

Fulfilling the GEA objectives is an extremely ambitious task, but it is technically possible. The full suite of GEA pathways, grouped according to the aggressiveness with which energy demand can be reduced, show the potential role for a range of energy conversion chains, from primary energy sources to conversion technologies to end-use technologies. Although there are a number of choices available to direct the energy system transformation, there is also a large number of givens – nonnegotiable, nondiscretionary components of an energy transition

Table 17.14 | Targets for the four main energy challenges and illustrative examples of policies and investments quantified by the GEA pathways.In addition to these targets, the GEA also adopted adequate energy services to support economic growth as a normative goal (see Chapter 6).

Objective/Goal	Target and timeline	Pathway characteristics	Examples of policies and investments	Further details
Improve energy access	Universal access to electricity and clean cooking by 2030	Diffusion of clean and efficient cooking appliances Extension of both high-voltage electricity grids and decentralized microgrids Increased financial assistance from industrialized countries to support clean energy infrastructure	Microcredits and grants for low-emission biomass and LPG stoves in combination with LPG and kerosene fuel subsidies for low-income populations *Estimated cost to provide clean cooking: US$17billion to US$22 billion per year to 2030* Grants for high-voltage grid extensions and decentralized microgrids *Estimated cost to provide rural grid connections: US$18.4 billion to US$19 billion per year to 2030*	Section 17.4
Reduce air pollution and improve human health	Achieve global compliance with WHO air quality guidelines (PM2.5 concentration < 10 μg/m^3) for the majority of the world population, and the remaining populations staying well within the WHO Tier I-III levels (15–35 μg/m^3) by 2030	Tightening of technology standards across transportation and industrial sectors (e.g., vehicles, shipping, power generation, industrial processes) Combined emissions pricing and quantity caps (with trading) Fuel switching from traditional biomass to modern energy forms for cooking in developing countries	Vehicles: Euro 3–4 standards for vehicles in developing countries by 2030 (e.g,, -60% NO_x, PM reductions by 2030) Shipping: Revised MARPOL Annex VI and NO_x Technical Code 2008 (-80% SO_x, NO_x reductions by 2030) Industry/power: rapid desulfurization, de-NO_x, and PM control around the world by 2030 *Estimated cost to meet air pollution targets: US$200 billion to US$350 billion/ year in 2030 (about 12% of energy costs); co-benefits of stringent climate mitigation policies reduce overall pollution control costs by about 50–65%*	Section 17.5.2 Section 17.7
Avoid dangerous climate change	Limit global average temperature change to 2°C above preindustrial levels with a likelihood >50% by 2100	Widespread diffusion of zero- and low-carbon energy supply technologies, with substantial reductions in energy intensity Energy-related CO_2emissions peak by 2020 and are reduced to 30–70% by 2050 from 2000 levels Globally comprehensive mitigation efforts covering all major emitters Financial transfers from industrialized countries to support decarbonization	Combination of cap-and-trade and carbon taxes (with initial carbon price >US$30/t$CO_2$, increasing over time) *Upscaling of investments into low-carbon technologies and efficiency measures to >US$600 billion/year to 2050* Additional financial transfers to developing countries of about 3–12% of total energy systems costs to 2050, depending on the domestic commitment of industrialized countries	Section 17.5.1
Improve energy security	Limit energy trade; increase diversity and resilience of energy supply (both by 2050)	Increase in domestic energy supply options (e.g., renewables to provide 30–75% of primary energy by 2050), and reduction of the share of oil in global energy trade. Increase in diversity of energy supply as well as end-use sectors and regions by 2050. Infrastructure expansion and upgrades to support interconnections and backup, including increased capacity reserves, stockpiles, and energy storage technologies.	Public procurement strategies and regulations to support local supplies (e.g., renewable obligations) Interconnection and back-up agreements between energy network operators Stockpiling of critical energy resources for coordinated release during acute market shortages *Estimated cost of infrastructure upgrades for the electricity grid: >US$310 billion/ year by 2050, co-benefits of stringent climate mitigation policies reduce overall security costs (import dependency and diversity) by more than 75%.*	Section 17.6 Section 17.7
Further details	Section 17.2.3	Section 17.3.4	Section17.3.5 (overview) and Sections 17.4–17.6 (details)	

that must begin immediately. These commonalities across all pathways (previously referred to as "musts" or necessities) are summarized here:

- improvements to at least the historical rate of energy intensity reduction (more rapid improvements in energy intensity, and thus aggressive efforts to improve end-use efficiency, would increase the flexibility of supply as well as the overall cost-effectiveness of the energy system transformation);
- a rapid shift from traditional biomass to widely accessible, clean, flexible energy forms;
- important regional constraints on availability of energy resources, although such constraints do not limit deployment on an aggregated global scale;
- a broad portfolio of supply-side options focusing on low-carbon energy from renewables, bioenergy, nuclear, and CCS and including:
  - strong growth in renewable energy beginning immediately, and a rising requirement for storage technologies to support the integration of intermittent wind and solar power into electrical grids;
  - strong bioenergy growth in the medium term, with extensive use of agricultural residues and nonagricultural feedstocks (second-generation bioenergy) to mitigate adverse impacts on land use and food production;
  - nuclear energy as an important part of the supply-side portfolio in many transition pathways, although it is also feasible to phase out nuclear energy completely; and
  - CCS as an optional bridging or transitional technology in the medium term unless energy demand is high, in which case CCS becomes necessary.
  - aggressive decarbonization in the electricity sector (especially in the high-demand case), a rapid phase-out of conventional (i.e., without CCS) coal power, and natural gas power as a bridging or transitional technology in the short to medium term;
- at least some electrification of the transportation sector, even in a conventional liquid fuels-based system;
- continued dominance of oil among liquid and gaseous fuels into and beyond the medium term, strong growth in liquid biofuels in the medium term, and thereafter the mix of liquid and gaseous fuels depends on transportation system choices and technological breakthroughs;
- substantial increases in investment on both the demand and the supply side (including energy infrastructure); and
- concerted and aggressive policies to support energy system transformation, including strong regulation and standards and externality pricing.

The storylines of the required energy system transformations that are quantified and elaborated on in the GEA pathways are far richer than these commonalities suggest. Nevertheless, this collation of all the required features of an energy system transformation describes the trunk off of which the many choices and possibilities branch.

Many of these choices are strongly influenced by one or more of the GEA objectives with respect to energy access, air pollution, climate change, and energy security. These are the subject of the second half of this chapter. Table 17.14 provides a link from Sections 2 and 3 on the GEA pathways to Sections 4–7 on the GEA objectives. Some of the main characteristics of the pathways are summarized in the context of each objective. More detailed policy and investment requirements are then given to illustrate how these pathways might be driven, and are explored at length in Sections 4–7.

17.4 Access to Modern Energy Carriers and Cleaner Cooking

This section builds on issues highlighted in Chapters 2 and 19 concerning the need for and benefits of providing universal access to clean cooking and electricity by 2030. This section discusses possible future scenarios for improving access to clean cooking and electricity to meet household energy needs in developing countries. All GEA scenarios are consistent with meeting a target of almost universal access by 2030.[39] The section starts with the GEA-Mix pathway and provides a detailed breakdown of specific access policies and their impacts toward reaching the target for the period 2005–2030. The detailed access modeling presented here focuses on three key regions where lack of access is currently the most acute – sub-Saharan Africa,[40] South Asia, and Pacific Asia – and for which disaggregate data are available on energy choices and use in the household sector. The detailed results from these regions are used to inform the estimation of costs and impacts of alternative policies to improve access to clean cooking and electricity. The section distinguishes between, on the one hand, access to clean fuels and stoves for cooking and, on the other, access to electricity for lighting and appliances. Electricity, even when available, is rarely used for cooking in most developing country households. Therefore, access to modern fuels is as important as access to electricity, if not more so, for meeting the thermal energy needs of most households.

39 The target is "almost universal access" because reaching the remotest rural populations is exceedingly expensive.

40 While Sudan is not included in the sub-Saharan Africa region in GEA, it is included in this region for the access analysis because Sudan has severe issues with energy access.

17.4.1 Access to Clean Cooking

There is enormous diversity in the types and amounts of fuels used for cooking in households in developing countries. The starting point for this analysis is data on existing energy choices and demands to meet cooking energy needs in each of the three regions considered. The estimates of energy choices and demand are based on bottom-up estimates using detailed household survey data for key nations in each of the regions (see Ekholm et al., 2010, and Pachauri et al., forthcoming, for details regarding data sources and methods). Most rural and low-income urban households in developing nations still depend predominantly on biomass to meet their cooking energy needs. For the base year 2005, the total quantity of final energy used for cooking in households for the three regions depicted in Figure 17.29 amounted to 15.8 EJ, of which 13.6 EJ was from biomass (including charcoal). This estimate differs substantially from that of the IEA for total residential sector biomass consumption: about 18.5 EJ for the same three regions in 2005. There are several reasons for this difference. Apart from the large uncertainties associated with biomass demand estimates globally, the IEA estimates are generally higher than most national estimates. This study bases its estimates of biomass demand on bottom-up estimates from national household surveys and corrects these for differences in biomass consumption patterns across nations within regions. The resulting estimates are then further compared with national estimates of biomass consumption, wherever available, and scaled up to derive the regional estimates of consumption. As can be seen from Figure 17.29, in rural sub-Saharan Africa and South Asia, the share of biomass (including charcoal) in total final cooking energy was as high as 97–98% in 2005. Among households in rural Pacific Asia, this share was about 60%. In urban centers of South and Pacific Asia, a larger share of kerosene and LPG is used for cooking. However, even in urban sub-Saharan Africa, about 87% of total final energy used for cooking is biomass (again including charcoal).

The GEA access scenarios also estimate the numbers of people dependent on biomass and other solid fuels. Since this study considers the total population dependent on these fuels and not only the share of the population that uses them as their primary source of cooking energy, our estimates tend to be slightly higher than other global estimates from the United Nations Development Programme, WHO, and the IEA (IEA, 2006; UNDP and WHO, 2009; IEA, 2010). This study finds that including only populations that report biomass or other solid fuels to be their primary source of cooking energy tends to underestimate the total population consuming solid fuels. Often populations that use solid fuels as a supplementary fuel actually consume a significant amount of these fuels and meet a large proportion of their total cooking energy needs from them.

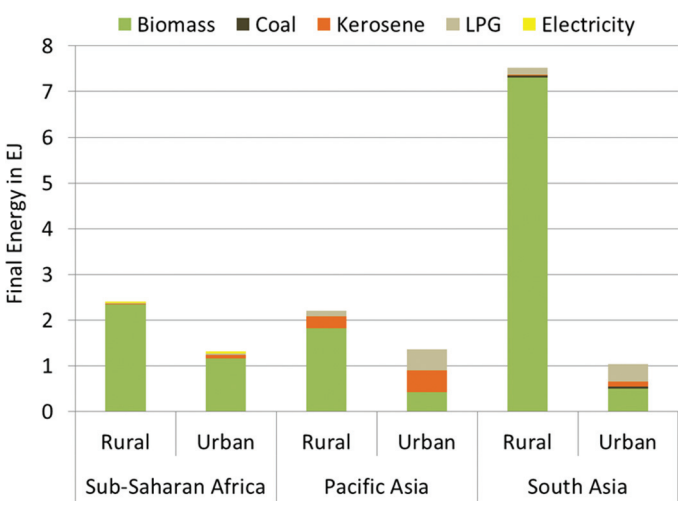

Figure 17.29 | Composition of final energy use for cooking in rural and urban households in three developing regions in 2005.

Past efforts to model residential sector energy demand for cooking have been limited, particularly in developing countries. The reason is that empirical data for the least developed countries and regions are sorely lacking. Even in emerging nations, finding reliable data for the household sector is a huge challenge. Given the heterogeneity of fuel choices and demand in the household sector, data at an aggregate scale is insufficient for such analysis. Besides the lack of data, uncertainties concerning socioeconomic and demographic trends in these countries add to the challenge of energy demand modeling. Other difficulties with modeling energy demand and choices in developing countries have to do with the special circumstances and conditions in these nations. These have been discussed in detail by Pandey (2002), Pachauri (2007), and van Ruijven et al. (2008).

The GEA access scenarios for residential cooking energy employ the MESSAGE-Access modeling framework (see Ekholm et al., 2010, and Pachauri et al., forthcoming, for details of the model). The model has several novel features that capture some of the special circumstances prevailing in developing countries. Demand is disaggregated both by rural and urban region and for heterogeneous income or expenditure groups. Data from detailed household surveys for key nations in each region are used to calibrate the model.

Various scenarios simulating different combinations of policy packages are modeled within the MESSAGE-Access framework to determine their impact on access to cooking fuels in these regions. Although the specific choice of fuels and cooking technologies will certainly need to be context specific, for the GEA access scenarios this study considers a final transition to LPG as the fuel of choice for cooking for those who have access to and can afford it. This should not in any way be interpreted as an endorsement of LPG as the best of the available choices. Clearly, other alternative cooking fuels, such as biogas, natural gas, and other emerging sources such as ethanol gel and dimethyl ether, in combination with different stove technologies, might be better suited to certain regions or nations. In some regions, there might even be a transition to electricity for cooking. However, in order to quantify the costs and impacts of alternative policies, this study uses LPG as a proxy for all clean cooking fuels.

The main policies considered to encourage a more rapid transition away from solid fuels for cooking include fuel subsidies, to reduce the cost of cleaner fuels, and grants or microlending, to make access to credit

easier and lower households' cost of borrowing. This makes it cheaper and easier for households to purchase both the fuel and the end-use equipment (cook stoves). Purchasing the stoves that use cleaner fuels often involves a capital outlay beyond the reach of poor and rural households, which often have irregular cash inflows. Policy packages that combine different levels of subsidies with microfinance options are also modeled.

17.4.1.1 Populations Dependent on Solid Fuels for Cooking

The GEA cooking fuel access scenarios project that the total population dependent on solid fuels for cooking will rise from 2.2 billion to 2.4 billion in South Asia, Pacific Asia, and sub-Saharan Africa between 2005 and 2030, in the absence of new policies to improve access. The population dependent on solid fuels is projected to decline marginally in South Asia and more significantly in Pacific Asia, whereas in sub-Saharan Africa the numbers rise during this period. In all regions the percentage of the population dependent on solid fuels decreases between 2005 and 2030. This decrease is significantly more rapid in urban centers than in rural regions (Figure 17.30). However, in urban sub-Saharan Africa, population growth is projected to outstrip the decrease in the percentage of population dependent on solid fuels, so that the total population dependent on these fuels continues to rise. These projections are based on outputs of the MESSAGE-Access model that account for changes in income level and distribution, urbanization, and population growth and for the consequent impact of these factors on the transition in cooking energy choices.

The impact of the alternative policy packages considered on the numbers of people dependent on solid fuels varies across the different regions from slight to dramatic. Figure 17.31 depicts the impact of the policies on the number of people dependent on solid fuels for each region and for the urban and rural sectors separately. A subsidy policy that reduces the price of clean fuels by 20% below existing prices in each region would reduce the number of people dependent on solid fuels in all three regions from 2.4 billion, in the case with no new policies, to 1.9 billion. A policy that provides cheaper microfinance options for upfront costs and the purchase of end-use equipment would also reduce that number to 1.9 billion. In estimating the effect of the microfinance policy, it is assumed that the interest charged on loans is 15%/year. This is at the low end of the range estimated by Robinson (1996) for interest rates on loans by microfinance institutions to the poor in developing countries, and much lower than the internal discount rate of poor households in these nations. The scenarios that combine a fuel subsidy with microfinance are more effective in all regions in accelerating a shift away from solid fuels than either a subsidy-only policy or providing microfinance alone, as Figure 17.31 also shows. However, even the policy scenario that combines a subsidy of 50% on the existing price with microfinance leaves about 500 million people, virtually all of them in sub-Saharan Africa, reliant on solid fuels in 2030.

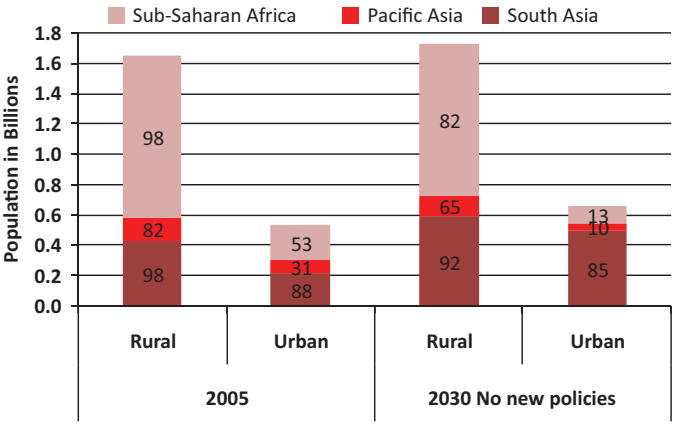

Figure 17.30 | Population relying on solid fuels in three developing regions in 2005 and in 2030 in the absence of new policies. Numbers on the bars are percentages of the total population in the indicated region and year.

17.4.1.2 Costs of Policies to Reduce Dependence on Solid Fuels

The GEA access scenarios quantify the costs of reducing dependence on solid fuels for several of the different policy packages considered. The net present value of the costs is estimated for each policy scenario and compared with the impact of the policy in reducing the number of people dependent on solid fuels to determine the relative effectiveness of each scheme. The cost of microfinance schemes is estimated to be zero for governments, as it is assumed that microfinance companies are able to cover the costs of their operations through the interest payments they receive. If however, the capital costs of new stoves are met through some form of public grants, these obviously represent a police cost. Although the objective of all access policies is to accelerate the transition away from the use of solid fuels to modern forms of liquid or gaseous cooking fuels, not all policies are able to achieve this equally. For those households that remain dependent on solid fuels, an estimate was made of what it would cost to provide them with improved cook stoves. Chapter 19 provides information on a range of improved cook stove technologies developed around the globe. These vary tremendously in design, sophistication, cost, emissions, and performance. However, it is assumed that, given the rapid improvements in stove technology, future deployment of such stoves will meet a minimum standard in terms of both efficiency and emissions as defined in Chapter 2. Table 17.15 provides a breakdown of costs by region and type cumulatively between 2010 and 2030. Figure 17.32 relates the cost per person gaining access per year to the number of people gaining access up until 2030, to provide an indication of the effectiveness of alternative policies in providing improved access to clean fuels.

The costs of policies aimed at encouraging a more rapid transition to the use of clean cooking fuels depend on the combination of the policy instruments deployed and the extent of subsidy, as shown in Table 17.15. Even a low-cost policy of providing easier access to credit through microfinance institutions is projected to substantially reduce

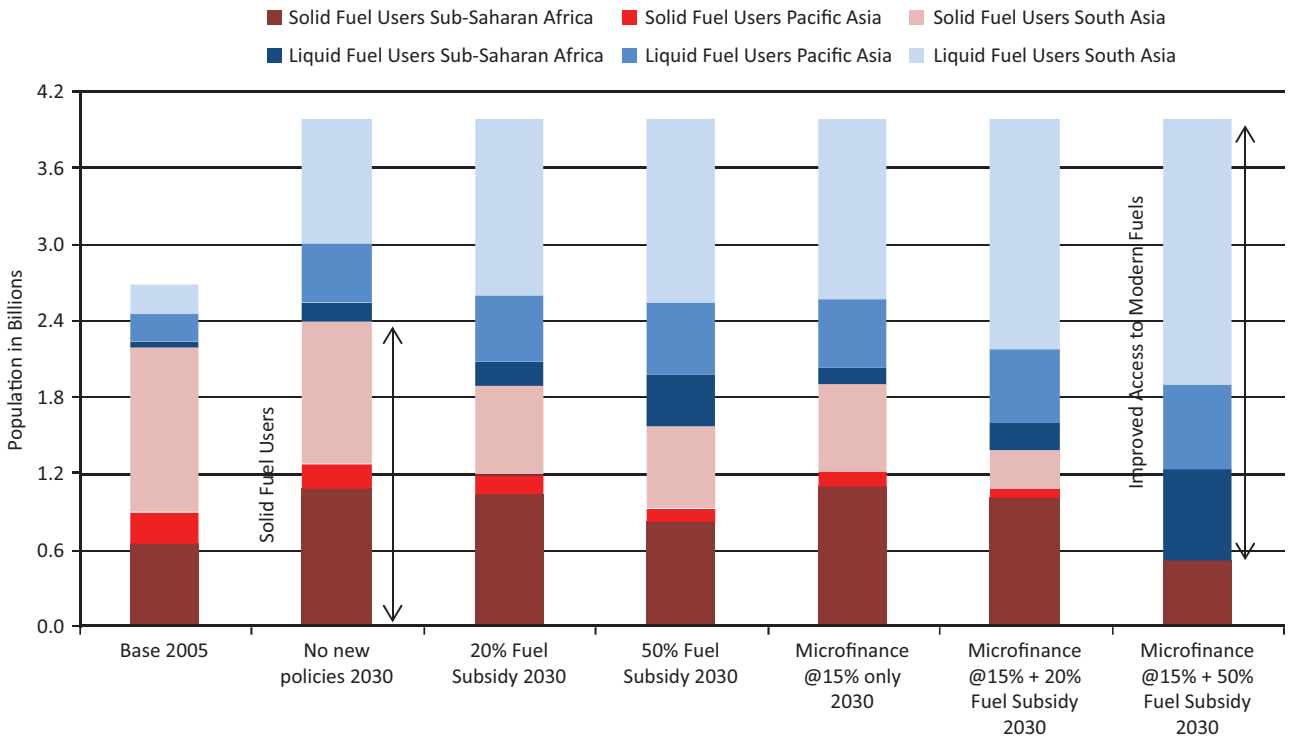

Figure 17.31 | Impact of alternative policy scenarios on access to clean cooking fuels in three developing regions. Subsidies are relative to consumer price levels and are additional to existing subsidies.

dependence on solid fuels among urban populations and the richer rural households in South Asia and Pacific Asia by 2030. However, a policy that promotes microfinance alone leaves about 1.4 billion people still dependent on solid fuels in 2030. Such a policy, if combined with a massive scale-up of improved cook stoves that are more efficient and less polluting than conventional stoves, along with better ventilation in cooking areas, might be a cost-effective interim solution for many rural households for whom a shift away from biomass may be out of reach in the short term. The financial requirements of such a policy are the lowest among the entire combination of policy scenarios assessed: on the order of US$1.1 billion to US$1.6 billion/year until 2030. A more stringent access target would require a combination of grants or microfinance for the purchase of stoves with a fuel subsidy and would cost considerably more, about US$15.8 billion to US$17.0 billion/year until 2030. The wide range of uncertainty in the cost estimates reflects the high capital costs associated with the use of cleaner fuels. The lower range of the cost estimates assumes that the entire cost of the stoves is met through cheap loans provided by microfinance institutions that are able to recover their costs. The total spending required to meet an access target for clean cooking fuels and stoves would be higher if stove costs have to be funded through public grants.

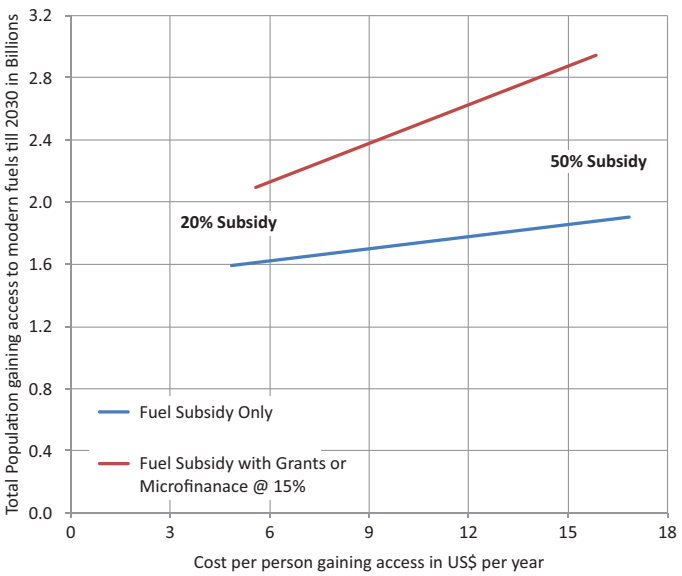

Figure 17.32 | Costs of alternative policy packages and their effectiveness in reducing dependence on solid fuels in three developing regions (sub-Saharan Africa, Pacific Asia, and South Asia) between 2010 and 2030.

Clearly, the choice of policies, the stringency of the targets, and the exact combination of clean fuels and end-use stove technologies promoted are likely to be specific to each country or region. However, the analysis presented here is indicative of the range of costs of different combinations of policies and their effectiveness in achieving different access targets. What is clear from this analysis is that, although fuel subsidies are necessary to increase access for the poorest households and regions, subsidies alone are likely to be less effective in accelerating a transition

Table 17.15 | Cumulative financing required to provide access to clean cooking fuels and devices in developing Africa and Asia, 2010–2030 (in billions of US$).

Policy intervention	Region	Fuel subsidy	New LPG stoves	Improved biomass cook stoves	Total, all three regions
20% fuel subsidy	Sub-Saharan Africa	7.54	0.43	8.98	59.6–67.2
	Pacific Asia	3.47	0.75	2.93	
	South Asia	27.56	6.41	9.11	
50% fuel subsidy	Sub-Saharan Africa	91.71	3.60	6.93	202.2–214.3
	Pacific Asia	10.42	0.95	3.01	
	South Asia	81.49	7.55	8.60	
Microfinance only[1]	Sub-Saharan Africa	0.00	2.19	9.66	21.6–31.2
	Pacific Asia	0.00	0.87	3.05	
	South Asia	0.00	6.54	8.92	
Microfinance + 20% fuel subsidy	Sub-Saharan Africa	9.04	0.89	8.72	85.0–100.0
	Pacific Asia	5.35	1.28	2.43	
	South Asia	50.87	12.88	8.56	
Microfinance + 50% fuel subsidy	Sub-Saharan Africa	130.67	6.52	5.20	315.2–339.4
	Pacific Asia	16.72	1.71	2.60	
	South Asia	152.65	15.97	7.36	

[1] It is assumed that no public costs are associated with microlending and that microfinance institutions are able to recover their full costs from the interest charged. However, these can be considered costs if purchase of the stoves is financed from public grants.

to the use of clean fuels for cooking than a policy that combines subsidies with improved access to credit through microfinance institutions. Such a policy would make it easier for households to cover the capital costs associated with a switch to cleaner fuels.

Fuel subsidies are considered controversial in many nations, and many developing countries already have generous subsidies on kerosene and LPG. Although such subsidies may be justified on social grounds, they have often resulted in market distortions, been appropriated largely by richer consumers, and led to poor economic returns for energy suppliers and distributors. Leakages to the black market from existing subsidies to households for kerosene in India have been estimated to be as high as 44% (Planning Commission, 2006). However, "smart" and targeted subsidy schemes and lifeline tariffs for poor customers can be designed and have proved successful, as in the case of the Bolsa Familia program in Brazil, which couples assistance to low-income families for the purchase of LPG fuel with mandatory child school attendance. Removing subsidies in a phased manner once incomes reach a level where households have the ability to pay can be challenging for governments, but this can be achieved if coupled with increased social spending in other areas. In other countries, such as many in sub-Saharan Africa, low-income consumers face prices for modern fuels that are at times even higher than the competitive market prices of these fuels in Europe. This difference in prices often arises from nonmarket factors such as weak institutions and safety and stability concerns, which urgently need to be addressed. For the design and implementation of more targeted subsidy schemes and removal of nonmarket barriers, additional enabling conditions will need to be created in these nations. This will require additional capacity building to strengthen the administration of governance systems and local institutions. Chapter 25, especially, addresses the issue of capacity building and concludes that good governance in the energy sector is especially critical for attracting investments in needed infrastructural development in the least developed and emerging nations, which face the greatest challenge to expanding energy access.

17.4.2 Access to Electricity

Improving access to electricity requires accelerating the pace of electrification in the least developed countries and regions. Decisions about setting targets for grid expansion are generally made by national governments or regional bodies. However, the literature shows that public or private utilities generally bear the financial responsibility for these programs as the executors of these decisions (Zomers, 2001; Kemmler, 2007; World Bank, 2008). In the best case, decisions about where to expand electrification are grounded in standards or criteria for electrification. In general, such criteria support electrification in places where it is cheapest. Thus, utilities often select projects that require the least infrastructure investment relative to demand. Villages or communities that are closest to existing grids, that have the highest population density, or where economic activity is greatest are generally connected to the grid first. Social criteria, including preferential selection of the poorest households or more remote rural regions, also influence the decision for grid expansion in some nations, but less so because these regions are not the logical choice from an economic perspective for electric utilities or developing country governments. In general, one can expect that electrification will proceed most rapidly where the costs are lowest.

In many countries, households also have to pay a connection fee and have to make their own decision about whether or not to get an electricity connection. Factors that influence whether households opt for grid connection are the amount of the connection fee, whether payments can be spread over time, and the household's understanding of the fees, tariffs, subsidies, and billing (Zomers, 2001; Gaunt, 2005; World Bank, 2008).

This section analyzes electrification using two separate model frameworks. Within the MESSAGE-Access and IMAGE models, rural electrification and grid infrastructure expansion are modeled in slightly different ways. As a starting point, both models take existing levels of electrification by nation, or by subpopulation within a nation, to calibrate the base year. For the purposes of quantification, two alternative levels of demand are assumed for household consumption within both models, corresponding to different electricity service levels:

- Low demand or minimal access: each household has one conventional light bulb (40W), and one out of three households has a television set (60W); on the assumption that these are used for three hours a day, this amounts to approximately 65 kWh/household/year.

- High demand or sustainable universal access: consumption is assumed to be 250W for four hours per day for lighting and other applications, as in the Tanzanian reference study of Modi et al. (2005), amounting to 420 kWh/household/year.

Electrification is defined differently in the two models. Within the IMAGE model, access is defined as connection to the grid. Thus, once the grid has been extended to reach a certain region, all households in that region are considered connected. The MESSAGE-Access model defines electrification in terms of whether a household's electricity demand exceeds an amount considered the basic minimum required to meet household needs: 65 kWh/year in the low-demand case and 420 kWh/year in the high-demand case.

Future rates of electrification in both models are driven by future income growth. However, within the IMAGE framework, in the base case a regression model is developed first by regressing national electrification levels on GDP per capita (in US dollars at purchasing power parity) in order to project what the future electrification level by region will be, based on future income (see the appendix for details of the methodology). Within the MESSAGE-Access model, future electrification in the base case is determined by income growth and distribution across rural and urban income groups. Thus, the MESSAGE-Access model incorporates a greater degree of heterogeneity on the demand side. By contrast, the IMAGE model takes into account a much finer degree of spatial resolution on the supply side, determining investment needs for rural electrification at the level of 0.5 × 0.5 degree grid cells. Each cell is considered to have either complete access to electricity or no access at all. Within a world region, grid cells are electrified over time, starting with those with the lowest levelized transmission and distribution costs.

17.4.2.1 Rural Populations with Access to Electricity

Figure 17.33 shows rates of access by region in the base year and projections to 2030 for both models in two separate cases: one with no additional new policies or resources for improving the rate of electrification, and another with universal access. Differences are observed across the two models both in base-year rural access and in progress with electrification across time for the two scenarios. Rural electrification levels differ in the base year across the two models in part because of differences in regional definitions in the IMAGE and MESSAGE models. For sub-Saharan Africa and South Asia, differences in regional composition across the two models are minor, and thus rural electrification levels are fairly similar. However, the regional definition for the Pacific Asia region differs significantly across the two models, as does the base-year electrification level. Differences in the sources of data used in the two models

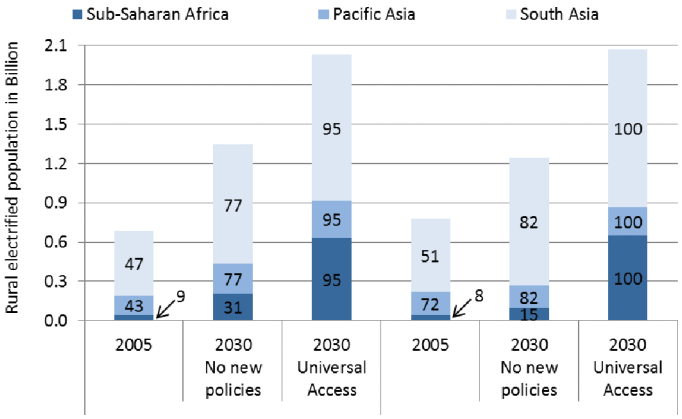

Figure 17.33 | Rural population with electricity in three developing regions in 2005 and in 2030 under business-as-usual and universal access scenarios. Numbers on the bars are percentages of the total rural population in the indicated region and year. Rural electrification level in the MESSAGE model refers to the 420 kW/household scenario.

also account for part of the variation in base-year electrification levels. Thus, for instance, in the MESSAGE-Access model, base-year electrification levels for Pacific Asia are based in large part on bottom-up estimates of access levels across rural income quintile groups in Indonesia. In contrast, in the IMAGE model, electrification levels in Pacific Asia are determined by estimates of rural electrification levels published in IEA (2006) and UNDP and WHO (2009). Progress with rural electrification in the two scenarios differs across the two models because of differences in base-year electrification levels and in methodology.

In sub-Saharan Africa, rural electrification in 2005 covers less than 10% of households in both models. Following a trend with increasing GDP per capita, in the no new policies scenario, this is projected to increase to 31% in 2030 according to the IMAGE model, but only to 15% according to the MESSAGE-Access model. In South Asia, the projected increase under the no new policies case is the largest, from 47% in 2005 to 77% in 2030 according to the IMAGE projections, and from 51% to 82% according to the MESSAGE-Access model. Thus, the shortfall with respect to universal access in 2030 is largest in sub-Saharan Africa. In other developing regions such as Latin America, rural electrification levels are already relatively high and are expected to reach over 90% by 2030 under the no new policies projections. For this reason, rural electrification is not modeled here for regions other than South Asia, Pacific Asia, and sub-Saharan Africa, which remain the regions where the gap between the no new policies scenario and the universal electrification scenario remains widest.

17.4.2.2 Investments for Improving Access to Electricity

The amount of investment required to increase electrification levels depends on the assumptions made about the costs of transmission and distribution, but also on population density. Costs rise as required capacity expands to meet rural household electricity demand. For example, regions with relatively high population density, such as South Asia, have lower costs per unit of capacity than less densely populated regions such

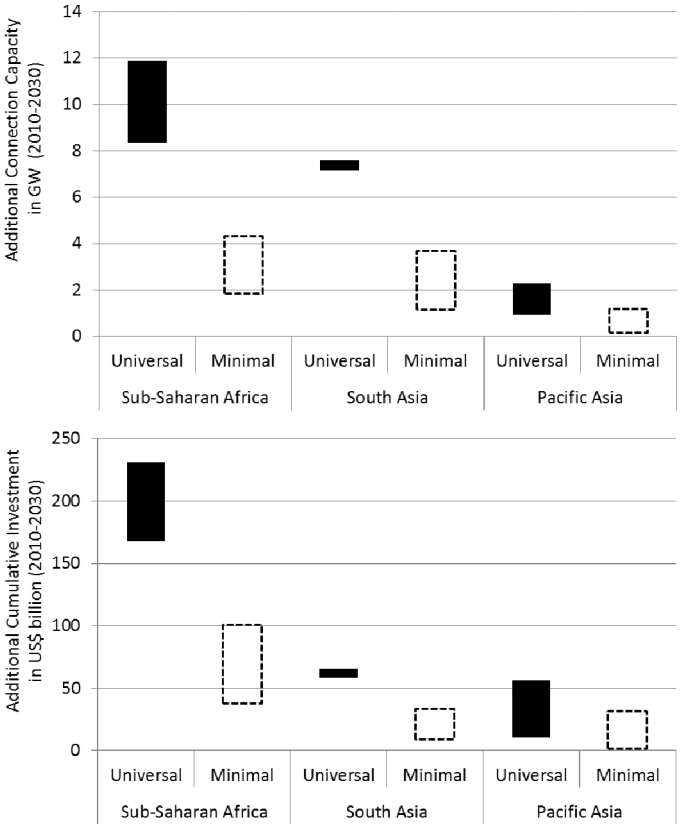

Figure 17.34 | Additional connection capacity and cumulative investment required to achieve almost universal rural electrification in three developing regions. Additional connection capacity equates to additional generation capacity of approximately 2 GW for the low case and 22 GW for the high case in the MESSAGE-Access model.

as sub-Saharan Africa. Levelized transmission and distribution costs for electrification within both models are determined in the following way. Within the IMAGE model, costs are based on the required increase in capacity and the distance over which transmission is required. Thus, costs are determined by spatial factors such as population density and distance from an existing electricity network at the grid cell level. In the MESSAGE-Access model, a simple three-step, region-specific technology cost curve differentiated by grid capacity is used to estimate costs. Given the least-cost optimization approach of the MESSAGE-Access model, the low-cost grid technology deploys first and the high-cost grid technology next as electricity demand increases. Both models estimate the costs of almost universal power supply in a given region through grid connection by estimating the total cost of extending transmission and distribution to all populated parts of the region. Decentralized technology alternatives such as mini-grids, off-grid, or stand-alone options might be more economic in some circumstances, but the present analysis does not include these.

Figure 17.34 shows, for each region, the additional connection capacity and total cumulative investment needed until 2030 to achieve rural electrification and compares results across the two models. The largest investment needs, not surprisingly, are in sub-Saharan Africa, where cumulative investment to achieve universal access amounts to an additional US$230 billion between 2010 and 2030. In the low demand scenario, where minimal access is assumed, the cost is significantly lower – about US$37 billion in the case of sub-Saharan Africa. However, this may not be considered sufficient and sustainable electricity access in the longer term. In general, the range in estimates depicted in the figure reflects the difference between the results from the two alternative models used. In Pacific Asia and South Asia, the majority of investment takes place in the no new policies case, so that the additional investment needed is relatively lower. This implies that additional investment for universal access in the three regions of sub-Saharan Africa, South Asia, and Pacific Asia is estimated at about US$300 billion cumulatively between 2010 and 2030.

17.4.3 Impacts of Access Policies on Energy Demand and Greenhouse Gas Emissions

The impacts of alternative policies for improving access to electricity and clean fuels for cooking are relatively modest in comparison with changes in demand in other sectors. As seen in Figure 17.35, compared with the base year 2005, energy demand in 2030 is projected to almost double in the case where no new access policies are implemented, from 17.7 EJ to 33.2 EJ, with most of this rise accounted for by additional LPG demand for cooking and kerosene and electricity for lighting and appliances. In an access scenario with no fuel subsidy but easier access to credit through microfinance and minimal electricity access, total energy demand in the low electricity demand case in 2030 is lower than in the no new policies case, but LPG and electricity demand are higher. In this scenario, in addition to improved microfinance, if it is assumed that all households dependent on solid fuels are provided with improved biomass stoves that double the efficiency of combustion, then biomass demand in this scenario could be cut in half, from 10 EJ, as shown in Figure 17.35, to about 5 EJ. Finally, in the case where a 50% fuel subsidy is combined with improved microfinance and high electricity demand with universal access, total energy demand actually drops to 16.8 EJ. This is explained by a rapid shift away from biomass to more efficient LPG for cooking and a substitution away from kerosene to electricity for lighting. Total LPG demand in this scenario is projected to rise from 1.1 EJ in the base year to 9.4 EJ in 2030; biomass demand declines from 13.4 EJ to 1.7 EJ over the same period. This increase in LPG demand over the entire projection period for the three developing regions amounts to less than half of energy use in 2005 in the Western European transportation sector alone. Electricity demand rises in this scenario from 1.7 EJ in 2005 to 5.7 EJ by 2030, displacing about 6.6 EJ of kerosene.

The changes in final energy demand due to various access policies also have implications for GHG emissions. Figure 17.35 presents the impacts of various access policies on total GHG emissions relative to the base year of 2005. The grey columns (scale on the right axis) depict total emissions, assuming that all biomass consumption is sustainably harvested, and the error bars indicate emissions in the case where 20% of biomass consumption is assumed to be harvested unsustainably. Without any access policy, total GHG emissions increase by 65%, to 4.7 gigatonnes

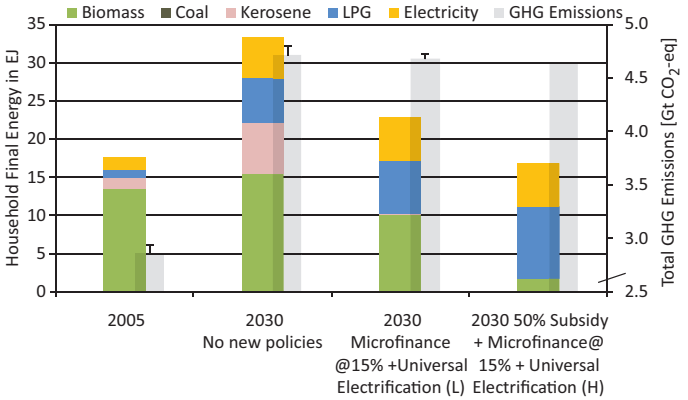

Figure 17.35 | Household final energy demand and total GHG emissions in three developing regions (sub-Saharan Africa, South Asia, and Pacific Asia) in 2005 and in 2030 under alternative access policy scenarios. GHG emissions include those on both the supply and the demand side. Error bars represent additional emissions on the assumption that 20% of biomass consumption in households is not sustainably harvested.

of carbon dioxide-equivalent ($GtCO_2$-eq.) in 2030 compared with 2.9 $GtCO_2$-eq. in 2005. As a consequence of implementing access polices, GHG emissions decline marginally, having a negligible impact overall.

17.4.4 Summary of the Costs and Impacts of Access Policies

The previous subsections have highlighted the level of existing access to both clean cooking and electricity in developing countries, the policies and measures required to accelerate access, and the relative costs and effectiveness of these policies and measures in achieving access goals and targets. Detailed assessments and scenarios were constructed for the three major regions of the world where the lack of access is most acute, namely, South Asia, Pacific Asia, and sub-Saharan Africa. These regions account for over 85% of the total global population without access to electricity and over 70% of the global population still dependent on solid fuels. Extrapolating the cost estimates for these three key regions to arrive at a global estimate of the costs of access policies suggests that between US$36 billion and US$41 billion will need to be spent annually until 2030 to ensure that almost universal access to clean cooking and electricity is achieved. For the high end of the estimate, about half of this amount will need to be spent on improving access to electricity and the rest on improving access to clean cooking. The largest share of this spending (more than a third of the total cost to achieve clean cooking access and two-thirds of the electrification bill) will need to occur in sub-Saharan Africa. The wide range in estimated costs is a consequence of whether the cost of stoves (LPG and improved biomass stoves) is included in the estimates or assumed to be provided through microfinance instruments that recover these costs. However, even the high end of this estimate is less than 5% of global energy sector investment today.

Spending on policies and measures to achieve access goals by 2030 will improve the welfare of those benefiting in several ways. Health impacts from improved household air quality are quantified in Section 17.5.2.3. Access policies will result in averting between 0.6 million and 1.8 million premature deaths, on average, every year until 2030, or a savings of over 24 million DALYs annually. Additional benefits that are likely to be substantial include time savings for women and children and the potential for improved livelihood opportunities.

17.5 Energy and the Environment

17.5.1 Climate Change

The ultimate goal of international climate change policy, as stated in Article 2 of the United Nations Framework Convention on Climate Change, is to "avoid dangerous anthropogenic interference with the climate system." This goal has motivated a wide array of analyses of potentially dangerous climate change impacts and of mitigation strategies that might limit GHG concentrations or global average temperature increases. (For an overview see, for example, Smith et al., 2009, or the report by IPCC AR4 Working Group II, IPCC, 2007). Political attention has increasingly focused on limiting global average warming to 2°C above preindustrial levels, as reflected most recently in the acknowledgment by the Copenhagen Accord of the scientific basis for such a limit (O'Neill et al, 2010b).

The 2°C limit on warming has also been adopted by the GEA as one of the main sustainability objectives. This target is one of the fundamental drivers of the demand- and supply-side transformations portrayed in Sections 17.3.2 and 17.3.3, respectively. The sequel of this section will focus on the consequences of the transformation for the required reductions of GHG emissions, the pace at which the energy system will need to decarbonize, associated costs, and finally, some potential implications with respect to the regional equity of the solutions.

17.5.1.1 Probability of Staying below 2°C Temperature Change

The relationship among future GHG emissions, resulting changes in GHG concentrations in the atmosphere, and the ultimate effect in terms of temperature change is subject to large uncertainty. Major reasons for this uncertainty include the limited present understanding of important carbon cycle feedbacks and, in particular, the uncertainty surrounding the so-called climate sensitivity, defined as the increase in global mean temperature resulting from a doubling of the GHG concentration in the atmosphere.

Implications of this uncertainty are manifold. First, climate change needs to be seen within the context of an adaptive risk management problem. That is, the risks of exceeding future thresholds for specific impacts need to be viewed in the context of measures undertaken today and in the future to reduce those risks, and the costs of those measures. Second, targets such as the 2°C limit need to be studied in a probabilistic context.

In other words, one has to define the likelihood with which a certain temperature target can be achieved to properly define the objective.

The GEA pathways aim at an ambitious target that maximizes the chances of keeping the global temperature increase below 2°C, while at the same time providing sufficient flexibility in the system to allow for multiple pathways to reach the target. Setting an ambitious target is important for limiting the risk of dangerous interference with the climate system with high likelihood. Flexibility of solutions is central for identifying decarbonization strategies that are robust against multiple uncertainties due, for example, to potential technological failure and the associated risks (see also the discussion about flexibility in Section 17.3.3). An extensive sensitivity analysis was therefore conducted to assess the "maximum" likelihoods under a range of assumptions for the stringency of emissions reductions. (For an illustration of likelihood estimates of different emissions pathways, see, for example, Figure 17.53.) Probabilistic assessment of the relationship between GHG emissions and global temperature change has been studied by den Elzen and van Vuuren, (2007), Keppo et al. (2007), Meinshausen (2006), Meinshausen et al. (2009) and O'Neill et al. (2010a). Like these earlier studies, the present analysis finds that under very stringent emissions reductions, the 2°C target can be achieved with a likelihood exceeding 50% (maximum likelihoods found in the analysis were around 67%).[41]

Exact numerical values for the likelihood of meeting the 2°C target differ slightly across the individual GEA pathways. In principle, however, all GEA-Efficiency, GEA-Mix, and GEA-Supply pathways stay below the 2°C target with a probability between 50% and 67%.

17.5.1.2 GEA Emissions Pathways

The target of limiting temperature change to 2°C with a probability above 50% translates into very stringent emissions reductions, comparable to the lowest emissions scenarios that have been developed so far with integrated assessment models. This section focuses on CO_2 emissions, as these make up the largest share of greenhouse gas emissions from energy and industry by far. For non-CO_2 emissions of the GEA pathways, see the online GEA database: www.iiasa.ac.at/web-apps/ene/geadb.

Figure 17.36 compares the total global CO_2 emissions pathways of the GEA with selected scenarios from the literature, including the most stringent climate change mitigation scenarios assessed by the IPCC AR4 (category I, Fisher et al., 2007) as well as high-emissions scenarios assuming no interventions or climate policies in the future (Nakicenovic and Swart, 2000). As the figure illustrates, total CO_2 emissions (from land use, energy, and industry) in the GEA pathways follow a trajectory comparable to those of the most stringent IPCC scenarios. In these low-emissions pathways, emissions may continue to increase for a very short period but have to peak and decline rapidly thereafter to reach zero to negative emissions in the long term.

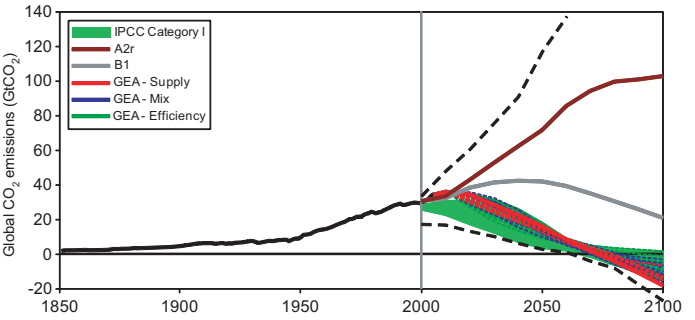

Figure 17.36 | Actual global CO_2 emissions, 1850–2000, and projections of the GEA pathways for 2000–2100. Solid lines in red, blue and green denote emissions under the three illustrative GEA pathways, and dashed lines those for individual pathways in the full set. Shaded area indicates the 90th percentile range of emissions under the most stringent mitigation scenarios of the IPCC AR4 (category I). Brown and grey lines of the A2r and B1 scenarios show the approximate range of nonintervention scenarios in the literature (Nakicenovic and Swart, 2000), assuming no implementation of climate policies.

The low-emissions pathways of the GEA and the IPCC category I scenarios are compatible with long-term atmospheric CO_2 concentrations below 400 parts per million (ppm). In fact, most of the GEA pathways reduce CO_2 concentrations to around today's concentration of about 390 ppm.[42] These low concentrations are the result of achieving globally negative emissions due to enhancements of the terrestrial sink potential (e.g., afforestation and reforestation) in combination with BioCCS in the late 21st century. Further details on emissions mitigation options are provided below. Accounting for the direct and indirect effects of non-CO_2 GHG emissions and other radiatively active substances results in long-term concentration levels under the GEA scenarios of 440–450 ppm CO_2-equivalent.

The CO_2 emissions of the GEA pathways are driven by stringent GHG mitigation policies to reduce emissions intensities across all sectors and sources (see Section 17.5.1.3). The magnitude of the challenge is huge, as Figure 17.36 illustrates by comparing the GEA emissions pathways with scenarios without any future climate change mitigation policies. Although, again, emissions in the absence of climate policies are subject to relatively large uncertainties, the GEA pathways depict reductions of about 70–85% by 2050 compared with scenarios without any policy interference.

Arguably, a more informative indicator of the necessary emissions reductions is obtained by comparing future emissions with today's levels. For this purpose, Figure 17.37 considers CO_2 emissions from energy and industrial sources only. The corresponding emissions profiles of the GEA pathways feature three major characteristics for the short, medium, and long term:

41 For the estimation of likelihoods of temperature outcomes, the probability distribution of the climate sensitivity of Forest et al. (2002) was used. The methodology is described in detail in O'Neill et al. (2010a) and Keppo et al. (2007).

42 As reported by the Mauna Loa observatory (www.esrl.noaa.gov/gmd/ccgg/trends/#mlo).

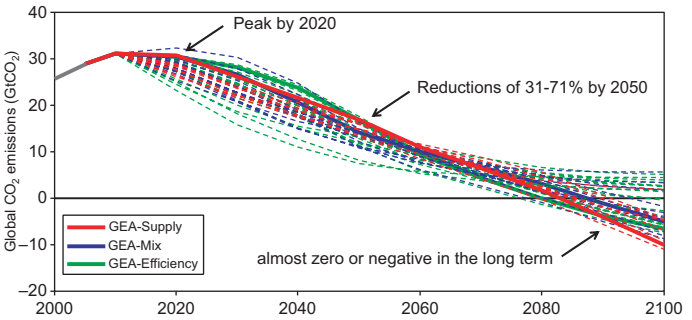

Figure 17.37 | Projected global CO_2 emissions from energy and industry in the GEA pathways. Solid lines denote emissions under the three illustrative GEA pathways, and dashed lines those for individual pathways in the full set.

- rapid introduction of climate change mitigation measures over the next decade to stop emissions growth, resulting in a peaking of emissions by about 2020;
- further strengthening of climate policies over the medium term to achieve CO_2 emissions reductions of about 30–70% by 2050 compared with 2000; and
- net negative emissions by the end of the century in the majority of pathways (particularly those that allow for BioCCS).

The relatively wide range of emissions reductions by 2050 reflects uncertainties with respect to emissions reduction potentials in the long and the short term. It is derived from the comprehensive sensitivity analysis across the transformation pathways and reflects choices as well as uncertainties with respect to policy implementation and technological development on both the demand and supply sides of the energy system (see Sections 17.3.2 and 17.3.3). Generally, pathways that have restricted supply-side portfolios (e.g., limited potential for renewables, or no CCS) require more rapid emissions reductions early in the century, to compensate for the loss of mitigation potential in the long term. For example, in the absence of bioenergy and CCS, emissions from the energy sector cannot become negative in the long term and thus need to be reduced comparatively more early in the century. A later subsection revisits the issue of how technology assumptions may influence the emissions profile.

The stringency of the emissions reductions becomes apparent when reviewing the cumulative emissions budgets of the GEA pathways. Given the cumulative nature of climate change, aggregate emissions over the full century represent one of the central boundary conditions for staying below the 2°C target. In the GEA pathways, the allowable emissions budget is on average around 1180 $GtCO_2$ between 2010 and 2100 (full range is 940–1460 $GtCO_2$). At today's rate of emissions, this "headroom" would be spent on average in about 38 years (full range between 30–45 years). With continuing growth in emissions in the absence of any new climate policies, the headroom would shrink further to about 27 years (full range between 22–32 years) before the overall objective for the full century would become out of reach.

Table 17.16 summarizes the characteristics of the GEA pathways and compares them with the lowest emissions scenarios assessed by the IPCC (category I). In addition to the IPCC scenarios, this analysis considers the three main recent studies that have looked into the relationship between short- and medium-term emissions characteristics of a wide set of scenarios. Van Vuuren and Riahi (2011) have conducted a survey of recent scenarios and updated the IPCC assessment with a wider set of new scenarios published since that assessment (collated from different sources). In addition, the results of studies by den Elzen and van Vuuren (2007) and O'Neill et al. (2010b) are shown, since they explicitly analyze short-term emissions reductions in the context of long-term temperature and GHG concentration targets.

The results across the studies are relatively similar, and all studies suggest the need for very ambitious short-term emissions reductions if CO_2 concentrations are to be kept below 400 ppm (corresponding to the 2°C target with a likelihood exceeding 50%). However, both the most recent studies and the GEA pathways indicate that there might be slightly greater flexibility for emissions reductions than indicated by the IPCC assessment. As noted by van Vuuren and Riahi (2011), a main reason for this difference is that a large number of new scenario studies have been published since the IPCC AR4 (IPCC, 2007), especially for very low long-term concentration levels. For instance, global emissions peak around 2020 in the GEA pathways as well as in the recent literature, which is around five years later than reported by the IPCC. Similarly, 2050 emission reductions in the least reduction scenarios are about 30% in the GEA pathways, compared to 50% at the time of the IPCC assessment. Studies that explicitly explored emissions thresholds that, if surpassed, would make the lowest long-term targets infeasible suggest even less stringent emissions reductions (O'Neill, 2010b). This latter conclusion depends, among other things, on assumptions about the future availability of technology and the feasibility of negative emissions in the second half of the century, which is reviewed next.

Impact of Technology Assumptions on Required Short-Term Emissions Reductions

As indicated earlier, the trajectory of emissions in the GEA pathways depends strongly on assumptions about technologies, the portfolio of abatement options considered, and their potentials. Crucial technological options include energy efficiency-enhancing technologies, renewables, CCS, and nuclear energy, as well as technologies that would allow for negative emissions later in the century, such as carbon plantations and BioCCS. For a discussion of the deployment of these options and how they shape the energy transformation, see Sections 17.3.2 and 17.3.3.

The full set of GEA pathways explores alternative combinations of the above options, including pathways with restricted supply-side portfolios (Section 17.3.3.5). These restrictions have significant implications for the short-term emissions pathway. Generally, pathways that assume limits on the potential of individual options in the long term require stronger short-term emissions reductions in order to stay within the cumulative emissions budget (dictated by the stringent climate change

Table 17.16 | Emissions trends in the GEA pathways and in the literature.

Study	Year of peak emissions	Emissions reduction in 2050 from 2000 level (%)	No. of scenarios	Cumulative emissions ($GtCO_2$)[4]	
				2000–2050	2000–2100
Van Vuuren and Riahi (2011)	Before 2020	-85 to -40	27	807–1357	807–1522
IPCC (2007, category I)[1]	2000–2015	-85 to -50	6	n/a	n/a
O'Neill et al. (2010b) [2]	Before 2030	-85 to -15	9	1393–1760	770–1503
Den Elzen and van Vuuren (2007)	Before 2020	-65 to -40	12	1144–1320	1364–1723
GEA (illustrative pathways)[3]	Before 2020	-45 to -35	3	1290–1350	1490–1520

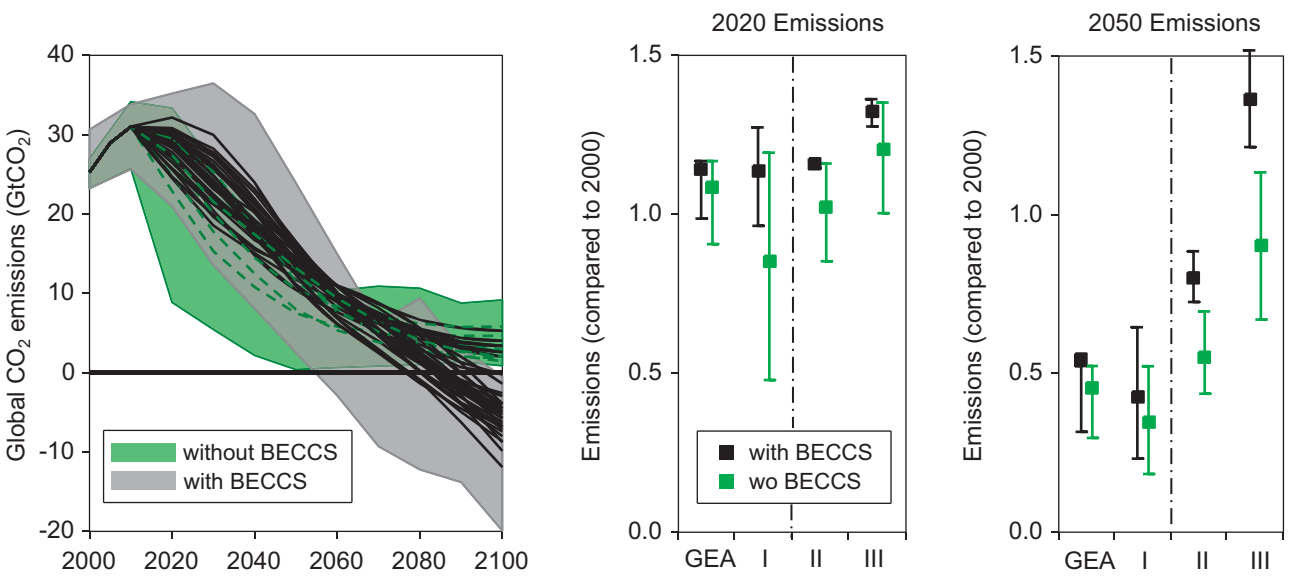

Figure 17.38 | Future CO_2 emissions with and without BioCCS. Left panel shows projected CO_2 emissions in the GEA pathways with and without BioCCS. Shaded areas show the corresponding ranges of the lowest (category I) mitigation scenarios in the literature. Middle and right panels compare average emissions in the GEA pathways by 2020 and 2050 with estimates from the scenario literature (van Vuuren and Riahi, 2011), with and without BioCCS. Error bands indicate 15–85% percentile range across the scenarios. "I" summarizes scenarios from the literature corresponding to similar targets as the GEA (category I of the IPCC, <400 ppm CO_2); "II" corresponds to scenarios of category II (400–440 ppm CO_2), and "III" corresponds to scenarios of category III (440–480 ppm CO_2).

objective). Although this is the case for all restricted pathways and technology combinations that were analyzed, Figure 17.38 shows the order of magnitude of this effect by using BioCCS as an illustrative example. The figure compares results of the scenario survey of van Vuuren and Riahi (2011) with the GEA pathways both for cases with BioCCS and for cases assuming that BioCCS does not become available in the future.

In general, pathways that include BioCCS allow for more modest emissions reductions in 2020 and 2050. Despite the fact that BioCCS is rather a long-term option (see Section 17.3.3.5), the differences across pathways with respect to emissions are already relatively large by 2020 (Figure 17.38). From a systems perspective, the results thus also illustrate the path dependency of the energy system and the importance of long-term planning for short-term decisions. In addition, this finding highlights the importance of the branching point concept and the restricted portfolio analysis of the GEA for deriving robust policy conclusions for the short term (see next section).

Comparison with Present Pledges

Having reviewed the emissions under the GEA pathways, this section turns to how they compare with present plans for GHG emissions reductions.

Various countries have made commitments to mitigation actions in the context of the Copenhagen Accord. The compound effect of these pledges on global GHG emissions is subject to uncertainty. Estimates differ between studies that have collated individual country pledges and translated them into global emissions levels due to different assumptions about, for example, the business-as-usual scenario, national actions, the use of offsets included in other countries' targets, particular emissions categories, and the role of land use change (UNEP, 2010). Rogelj et al. (2010), for example, estimate that the present pledges are likely to lead to global emissions of 47.9–53.6 $GtCO_2$-eq. by 2020, and UNEP (2010) estimates a range between 48.8–51.2 $GtCO_2$-eq. by that year.

Figure 17.39 compares the range of emissions expected to result from the pledges by 2020 with the emissions reductions under the GEA pathways. As the figure illustrates, even the most optimistic assumptions about future implementation of pledges lead to emissions levels at around the upper bound of the GEA pathways. Present commitments are therefore not sufficient and thus inconsistent with the vast majority of the GEA pathways, which aim at limiting global temperature increase to 2°C compared with preindustrial times (with a likelihood of above 50%).

The gap between the present pledges and the GEA pathways ranges between none (a slight overlap of around 2 $GtCO_2$-eq.) to as large as 11 $GtCO_2$-eq. The pathways with no gap combine the most optimistic assumptions about the emissions reductions resulting from present pledges with the highest emissions estimate from all 41 feasible GEA pathways in 2020. However, as discussed earlier, the GEA pathways with the highest emissions in the short term coincide with those cases that employ the most optimistic assumptions about the future availability of technology, and in which the full portfolio of all mitigation options can expand pervasively and successfully. Any restriction to the portfolio of mitigation options requires greater emissions reductions over the short term in order to compensate for the loss of emissions reduction potential in the long term. The gap between present pledges and the GEA pathways is therefore small only if one combines both the most optimistic assumptions about pledges with the most optimistic assumptions for the full portfolio of all mitigation options. The likelihood of the gap actually being small is thus rather low, especially if one considers the history of technology failure as well as the past performances of some countries in terms of emissions reductions.

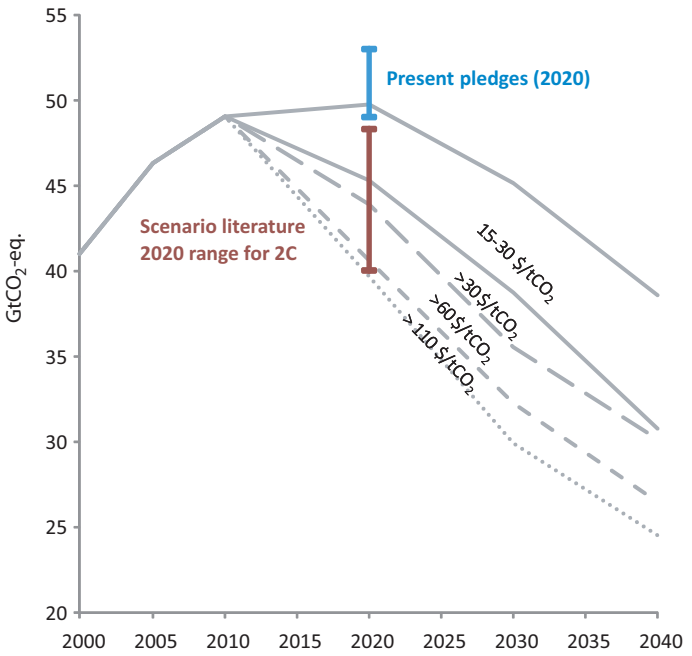

Figure 17.39 | Short-term GHG emissions in the GEA pathways compared with the range of emissions resulting from present pledges by 2020. The lower error bar gives the 90th percentile range of 2020 emissions from low-mitigation scenarios in the literature (van Vuuren and Riahi, 2011). The GEA pathways are grouped according to ranges of CO_2 prices by 2020.

The Price of CO_2

Figure 17.39 also shows, for each of several groups of GEA pathways, the CO_2 price that would need to be introduced globally to achieve the required reductions in emissions by 2020. According to this study's estimates, CO_2 prices would need to be on the order of US$15–45 per tonne of CO_2 to keep emissions in 2020 between 2005 and 2010 levels. As discussed in Section 17.3.5, however, higher carbon prices will need to be complemented by regulation and technology standards to mobilize the required investments and to act against, for example, rebound effects or barriers to implementation. In addition, the stringency of the mitigation policies needs to increase over time, leading to CO_2 prices increasing at about the pace of the discount rate (5%/year in the present analysis). In the most stringent emissions pathways, emissions need to drop to below the level of 2000 by 2020. The global CO_2 price corresponding to such stringent reductions is above US$110/tonne of CO_2, a value comparable with average gasoline taxes in Western Europe today.

17.5.1.3 Emissions Mitigation in the Energy Sector

As discussed earlier in this section, the objective to limit temperature change to below 2°C with a likelihood greater than 50% translates into stringent emissions reduction targets for virtually all GHG-emitting sectors.

The abatement of GHG emissions can be achieved through a wide portfolio of measures in the energy, industry, agriculture, and forestry sectors, which are the principal sources of emissions and thus of global warming. Measures to reduce CO_2 emissions range from structural changes to the energy system and the replacement of carbon-intensive fossil fuels with cleaner alternatives on the supply side (such as a switch from coal power generation to the enhanced use of nuclear and renewable energy) to demand-side measures geared toward energy conservation and efficiency improvements. In addition, CCS provides an "add-on" end-of-pipe

approach for the decarbonization of hydrocarbon fuels. Other important options for GHG emissions reductions encompass the enhancement of forest sinks through afforestation and reforestation activities, as well as non-CO_2 emissions reductions in the agricultural sector.

Section 17.3.2.2 provides a comprehensive discussion of specific measures to improve efficiency on the demand side. In addition, structural changes on the energy supply side of the GEA pathways are illustrated in detail in Section 17.3.3. This section primarily explores the GHG emissions implications of those transformations, with a specific focus on the resultant pace of the decarbonization of energy supply as well as on the demand-side sectors (industry, residential and commercial, and transport).

At present, roughly 50% (14 $GtCO_2$) of global CO_2 emissions from energy are due to supply-side conversion processes, including electricity and heat generation and refining, but also losses during the transmission and distribution of fuels (Figure 17.40). The other half of emissions come from the direct use of fossil fuels in the end-use sectors: industry (5.6 $GtCO_2$), transportation (6.1 $GtCO_2$), and residential and commercial (3.6 $GtCO_2$).[43] In addition, about 2.2 $GtCO_2$ are contained in industry feedstocks and about 2.7 $GtCO_2$-eq. of non-CO_2 GHGs are emitted by the energy and industrial sectors (for example, methane from coal extraction and long-lived gases such as sulfur hexafluoride and hydrofluorocarbons in industrial processes).

The stringent climate objective of the GEA pathways requires cutting CO_2 emissions from energy and industrial sources by about half in 2050 from 2000 levels (the full range across pathways is 30–70%). The bulk of these emissions reductions are achieved through decarbonization of supply, reducing its share of energy-related emissions from 50% today to between about 25–45% by 2050 (with exception of pathways assuming limited intermittent renewables assessed in Section 17.3). However, integration of supply and demand remains essential, since one of the main reasons for the comparatively rapid decarbonization of supply is the increasing quality and flexibility of fuels demanded by consumers (e.g., electricity). Higher fuel quality requires more elaborate conversion processes and thus permits decarbonization through both fuel switching (e.g., from coal power plants to renewable power) and end-of-pipe (CCS) solutions. The latter option is economic only in large centralized systems and is thus not applicable in the context of dispersed and heterogeneous demand-side sources (except for some industrial applications, such as CCS from cement production, which is considered in this analysis).

The enormous speed of supply-side decarbonization in the GEA pathways is also illustrated by the build-up rates of low-carbon power plants (nuclear, renewable, or fossil power plants with CCS), which reach a share of around 75–98% of global power generation by 2050. By comparison, the low-carbon share of primary energy increases to (still impressive but lower) shares of about 65–85% over the same period (see Section 17.3.4.3 for further details).

The decarbonization of the demand side is equally ambitious, although by mid-century significant amounts of fossil fuels continue to play a role in the final energy mix in most of the GEA pathways. Emissions reductions on the demand side are primarily due to fuel switching away from direct use of fossil fuels, as well as increased efficiency of end-use devices.[44] At the aggregate global level, emissions from the end-use sectors are reduced by about 45% in most of the GEA pathways by 2050 compared with 2000 (Figure 17.40). These reductions are achieved despite increases in energy services levels. The low-carbon share of final energy fuels for services thus needs to increase significantly, from about 30% today to 60–70% by 2050 (see Section 17.3.4.3 for further details). The GEA-Efficiency pathways, which aim at limiting demand as one of the principal measures to attain the GEA sustainability targets, show more flexibility with respect to the rate of decarbonization and structural changes and are thus obviously at the lower bound of the ranges for low-carbon shares (for final and primary energy as well as electricity shares). Efforts to reduce emissions differ significantly across regions and are generally higher in today's industrialized world than in the developing world (see Figure 17.40 and the GEA web database, at www.globalenergyassessment.org, for further regional detail).

17.5.1.4 Regional Perspectives and Equity Issues

Achieving emissions reductions, especially such drastic ones as those depicted by the GEA pathways, is a formidable task, considering that developing countries require increases in energy services and other activities that result in GHG emissions. The salient questions are how such reductions might be achieved and by whom, and what the effects (economic, distributive, etc.) might be. In other words, how is the burden of global emissions reduction going to be shared, and what might be the criteria for such burden sharing?

Of crucial importance in this context is the large disparity between industrialized and developing countries. The former are responsible for about 40% of global energy-related emissions but account for only 20% of the world population. The more industrialized countries are also responsible (some more than others) for the bulk of the historical increase in anthropogenic GHG concentrations. Conversely, developing countries will become more important contributors to GHG emissions in the future, almost independent of how high or low global GHG emissions actually turn out to be (Grubler and Nakicenovic, 1994; Riahi et al., 2007).

Regional disparities with respect to today's per capita emissions are illustrated in Figure 17.41. Differences between regions up to an order

43 Estimates from the industry sector include also process emissions (e.g., from cement production) and emissions related to nonenergy feedstocks (e.g., asphalt and lubricants).

44 The latter effect of reduced energy demand decreases emissions throughout the system and thus also contributes to the supply-side emissions reductions discussed above in this section.

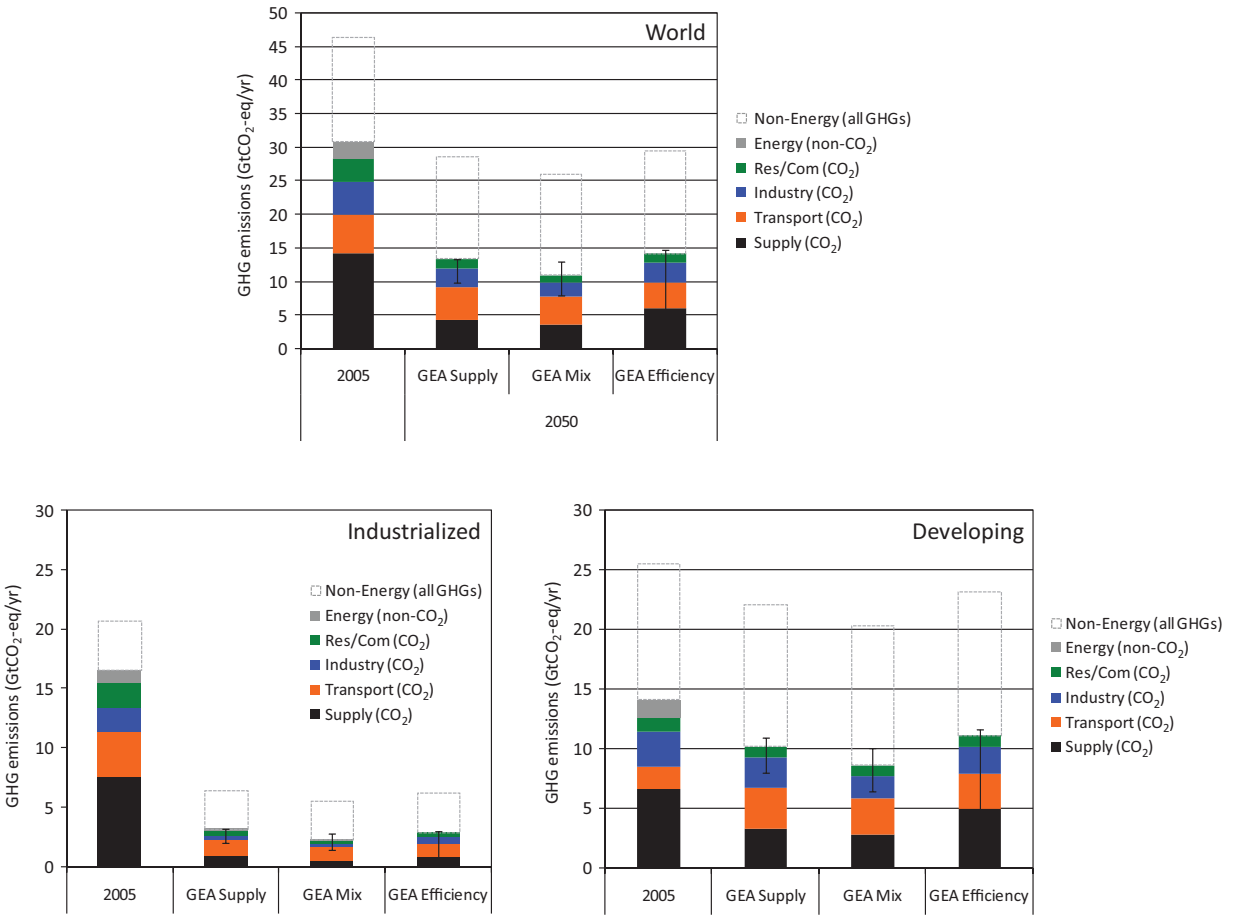

Figure 17.40 | GHG emissions from energy supply and from demand-side sectors in 2005 and in the three illustrative GEA pathways in 2050. Dashed lines indicate additional GHG emissions from the non-energy sector. Error bars show the range across all GEA pathways within each pathway group.

of magnitude are seen: all the high-income regions of the industrialized world are significantly above the world average, whereas most developing regions are considerably below the average.

The results of the GEA transition pathways clearly indicate the need for emissions reductions across virtually all regions in order to halve global per capita emissions by 2050 (Figure 17.41). Given the stringency of the GEA target and the implied magnitude of emissions reductions, today's industrialized countries must contribute proportionally greater reductions in per capita emissions. In the aggregate, this results in more equitable per capita emissions distributions in 2050 than today. Nevertheless, as Figure 17.41 illustrates, some of today's most emissions-intensive regions (e.g., North America and the former Soviet Union) continue to emit more than the world average in 2050, while the poorest regions (e.g., South Asia and sub-Saharan Africa) stay considerably below the world average.

It is important to emphasize that the vast majority of model-based mitigation analyses employ a cost-effectiveness approach. This means that emissions reductions are implemented globally when and where they are most cost-effective. The GEA scenarios are no exception in this respect. The GEA pathways address the question of when and how to spatially allocate, for

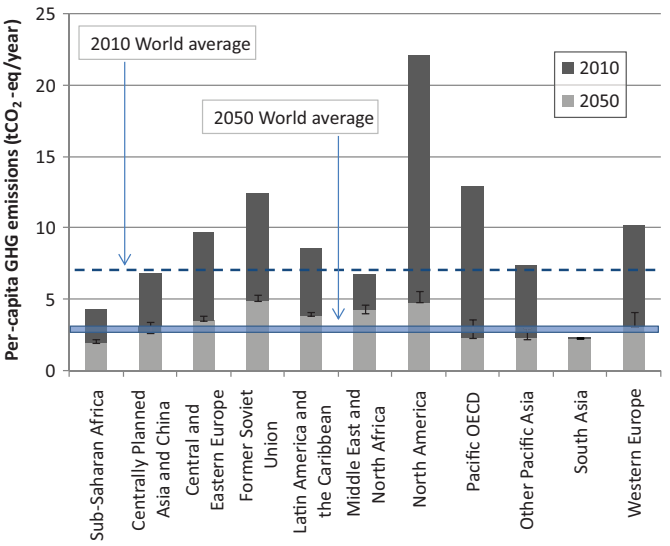

Figure 17.41 | Regional per capita GHG emissions. The full height of each bar represents per capita emissions in the indicated region in 2010, and the lower section per capita emissions in the illustrative GEA pathways by 2050. The upper section thus indicates per capita emissions reductions between 2010 and 2050. The dashed horizontal line denotes world average per capita emissions in 2010 and the solid line the range across the three illustrative GEA pathways in 2050.

example, scarce investments to meet the overall mitigation objective cost-effectively, but they do not explicitly quantify who pays for those reductions. That will depend specifically on international agreements about regional emissions entitlements and agreed-upon equity principles.

The regional allocation of future emissions reductions following equity principles may differ significantly under the cost-effectiveness approach. Generally, it is argued that given their historical responsibility and greater affluence, today's industrialized countries should take the lead in reducing emissions (Article 3.1 of the United Nations Framework Convention on Climate Change). Numerous studies have analyzed the regional emissions allocations or requirements for emissions reductions and time of participation in the international climate change regime. (For summaries see the IPCC AR4, Chapter 13, or Berk and den Elzen, 2001; Blanchard, 2002; Winkler et al., 2002; Criqui et al., 2003; Nakicenovic and Riahi, 2003;Bollen et al., 2004; Böhringer and Welsch, 2004; Groenenberg et al., 2004; Böhringer and Löschel, 2005; den Elzen and Meinshausen, 2005; den Elzen and Lucas, 2005; den Elzen et al., 2005;Höhne et al., 2005; Michaelowa et al., 2005; Höhne, 2006; and Persson et al., 2006). A large variety of system designs for allocating emissions allowances or permits has been analyzed, including contraction and convergence of per capita emissions, multistage approaches, and triptych (sectoral) and intensity targets.

A discussion of all the different proposals in the literature is beyond the scope of this chapter. Instead, this section addresses two central questions linked to the equity dimension of the GEA transition pathways. The first question is to what extent developing countries could delay their participation in emissions reduction, considering the stringency of the climate target of the GEA pathways. Here the analysis relies on findings from a recent modeling intercomparison project of the Energy Modeling Forum (EMF22), in which both modeling teams of the GEA (MESSAGE and IMAGE) were involved. The second question concerns the financial transfers that might be needed to create appropriate incentives in the developing world to join international climate agreements.

The Effect of Delayed Participation

A study by the Energy Modeling Forum (Clarke et al., 2009) investigated the effect of delayed participation of key regions in the developing world on the attainability and costs of a range of climate stabilization targets. Eleven of the leading integrated assessment modeling teams participated in the study. They jointly explored 10 alternative policy cases, assuming either full participation or a delay of the developing world and Russia in joining the international emissions mitigation regime.

Specifically, for the delayed participation scenarios, it was assumed that Brazil, Russia, India, and China do not start emissions reduction efforts until 2030, and other developing countries until 2050. The study also explored alternative emissions trajectories by differentiating between targets for CO_2-equivalent concentrations that may temporarily "overshoot" and targets that do not allow for overshoot. The summary of the EMF22 attainability analysis is presented and compared with the results of the GEA pathways in Figure 17.42.

The EMF22 results clearly indicate that whether delayed participation has any implications for the attainability of the target depends strongly on the ambitiousness, and thus the stringency, of the objective. The majority of the modeling frameworks, for example, found that although delayed participation by the developing world has significant implications for overall costs, targets above 550 ppm CO_2-eq. are still attainable. For more stringent target levels such as those adopted in the GEA (450 ppm CO_2-eq.), however, 12 out of 14 scenarios were rejected, since they were found to be infeasible under the assumption of delayed participation (see the category "Overshoot: Delay" in the right panel of Figure 17.42).

Delays by the major emitting countries of the developing world in joining a comprehensive international emissions mitigation regime would thus make attainment of the GEA objective, to limit temperature change to below 2°C with a probability greater than 50%, very unlikely. Full but differentiated participation in reduction efforts by the developing world, on the other hand, significantly increases the chance of success.

Transfers under Contraction-and-Convergence Assumptions

This section explores the implications of an illustrative burden-sharing scheme for the allocation of future emissions rights and applies it to the GEA pathways. This burden-sharing scheme is referred to in the literature as a "contraction and convergence" scheme (see, e.g., den Elzen and van Vuuren, 2007). In essence, under such a scheme, all regions need to converge to a common per capita emissions entitlement by a specified date (2050). For regions with per capita emissions above the world average, this implies reductions (hence the term "contraction") until the convergence criterion is fulfilled, but starting from very different initial conditions. For regions with per capita emissions below the world average, emissions can rise initially until they reach the world average. Thereafter, these regions also need to contract to the specified convergence level. The resulting emissions projections from the allocation scheme differ from the original GEA pathways, which assume that reductions take place where they are most cost-effective.

Figure 17.43 contrasts the difference between emissions entitlements and cost-effective emissions reductions of the original GEA pathways. In the aggregate, an equal allocation of per capita emissions by 2050 results in comparatively higher reduction needs in industrialized regions. This entails higher mitigation costs for these regions and creates an incentive to buy emissions permits on, for example, a global market. In addition to reducing total mitigation cost, trading emissions entitlements would have the co-benefit of generating revenue for developing regions. Developing countries with emissions below the world per capita average by 2050 therefore have an incentive to sell permits.

Figure 17.44 shows cumulative energy system expenditure for the original (cost-effectiveness based) GEA pathways, as well as the additional costs that would accrue for industrialized countries if the contraction-and-convergence target were achieved domestically. For developing countries this translates, of course, into lower energy system costs, due

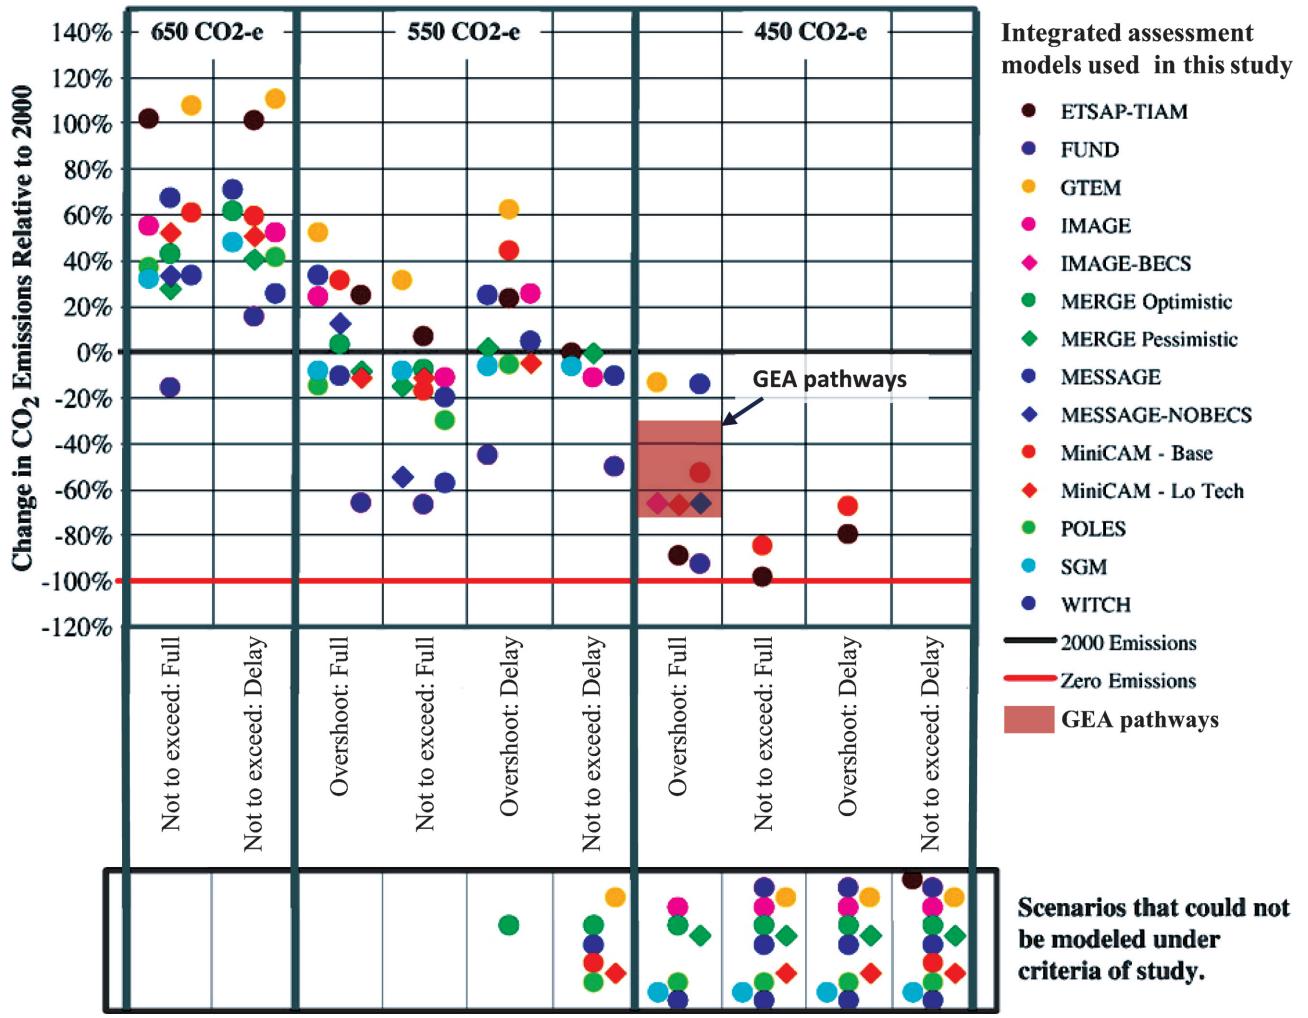

Figure 17.42 | Carbon emissions reductions from industrial and fossil sources in 2050 from 10 integrated assessment models. Dots outside the figure range indicate scenarios that were found to be infeasible under the specified criteria.

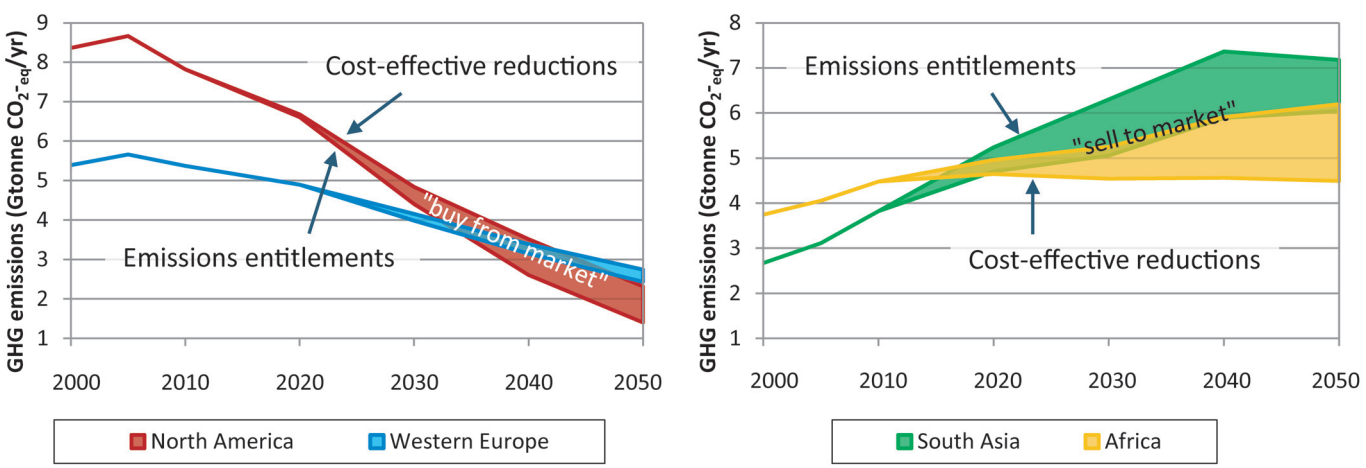

Figure 17.43 | Projected GHG emissions in the case of contraction-and-convergence allocation of emissions entitlements compared with cost-effective emissions reductions in the GEA-Mix illustrative pathway. Shaded areas in the left panel show the resulting demand for permit trade in North America and Western Europe. Shaded areas in the right panel show the resulting emissions surplus for permit sales in South Asia and sub-Saharan Africa.

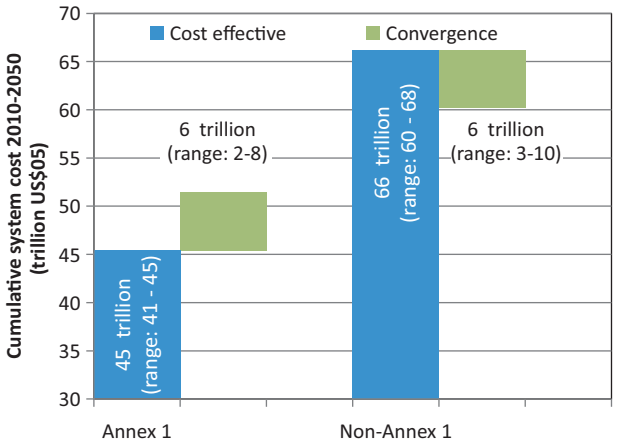

Figure 17.44 | Cumulative energy system costs of the GEA-Mix pathway in Annex 1 and non-Annex 1 regions (left bar in each pair). The right bar in each pair shows the effect on costs in the case where Annex 1 (industrialized) countries achieve the contraction-and-convergence pathway through domestic reductions only. Stated ranges are the corresponding values for the GEA-Efficiency and GEA-Supply pathways.

to their targets being relaxed, than if industrialized countries were to achieve all reductions domestically.

The increase in costs to industrialized countries to achieve the additional emissions reductions domestically approximates the region's willingness to buy permits outside the region (and thus to invest elsewhere to achieve the reductions at lower cost). This study estimates that this willingness to pay might be around US$2 trillion to US$8 trillion over the course of next 40 years, or about 3–12% of the total energy system costs of the developing world. This corresponds on average to between US$50 billion and US$210 billion/year. Although small in comparison with total energy system costs, this is a large sum compared, for example, with total official development assistance in 2000, which amounted to some US$53 billion (UNCTAD, 2003).

The estimates of financial transfers in this section are only illustrative, because they are derived from this particular contraction-and-convergence allocation scheme. Other allocation rules may yield different results. Science cannot answer the question of what particular ethical model should be used to determine the amount of international burden sharing appropriate to the challenges of mitigation and adaptation to a changing climate. Rather, this is a task for international negotiation and political decision making. Considering, however, the urgent need for rapid and globally comprehensive emissions reductions, as the GEA pathways make clear, decisions need to be made sooner rather than later, so that the 2°C target does not become out of reach.

17.5.2 Air Pollution

Pollution control is an essential component of sustainable development, as good air quality is a fundamental aspect of quality of life. Local air quality is directly linked to health, as discussed in detail in Chapter 3. As discussed in Section 17.4, household air pollution due to lack of access to modern cooking has serious health consequences; hence, improving the quality of fuels through policies on energy access is essential. Both ambient air quality in cities and air quality within rural and urban homes are major contributors to local health. In addition, a number of air pollutants have other environmental impacts, such as acidification and eutrophication as well as damage to vegetation, as discussed in Chapter 3. In this section, the focus is on the health implications of various policy packages that include increasingly stringent air quality control policies.

17.5.2.1 Air Quality Policies

Varying levels of stringency of air quality legislation are examined here in combination with a selection of other policies sampled from the GEA scenario space described in the earlier sections on energy efficiency (Section 17.3.2), energy access (Section 17.4), and climate change (Section 17.5.1). The objective is to cover a wide range of air pollution outcomes and to analyze in detail the implications of different policy packages in terms of their health benefits. This section thus explores both future pollutant levels in the absence of further improvements in air quality legislation and GEA pathways that address all challenges simultaneously.

The assessment builds upon the MESSAGE energy model as the primary tool for deriving detailed, sector-based estimates of various pollutant gases. In addition, MESSAGE is linked to the GAINS air quality model (Amann et al., 2008) to represent different levels of air quality legislation until 2030[45] (for further details see Rafaj et al., 2010, and Rao et al., forthcoming). Regional emissions estimates for 2005 are based on historical and current inventories as described in Granier et al. (2010) and Lamarque et al. (2010). A number of air pollutants and GHGs have been downscaled to spatially explicit levels for 0.5-degree resolution (see Riahi et al., 2011 for methodology). To estimate the impacts of the spatially explicit emissions, atmospheric concentrations of particulate matter, aerosols, and ozone were derived using the TM5 model (Dentener et al., 2006; Stevenson, 2006; Kinne et al., 2006; Textor et al., 2007; Bergamaschi et al., 2007). TM5 includes contributions from (i) primary PM2.5 (particulate matter <2.5 μm in diameter) released from anthropogenic sources, (ii) secondary inorganic aerosols formed from anthropogenic emissions of sulfur dioxide, nitrogen oxides, and ammonia, and (iii) particulate matter from natural sources (soil dust, sea salt, biogenic sources). Table 17.17 describes in detail the background of the chosen policy packages and the types of air pollutants, sectors, and spatial scales covered by them.

The policies driving each of these scenarios and their relevance for air pollution outcomes are discussed in more detail below:

45 Although the focus of this section is on the shorter-term pollution estimates until 2030, emissions pathways are represented until 2100 based on assumptions of future improvements in emissions factors as described in Rafaj et al. (2010) and Rao et al. (2012).

Table 17.17 | Policy matrix and coverage.

Policy package	Policies			
	Air pollution	Climate change	Energy efficiency	Energy access
FLE	No improvement in air quality legislations beyond 2005	No climate change policy	Annual energy intensity reduction of 1.5% until 2050	No specific energy access policy; slow improvement in quality of cooking fuels
CLE1	All current and planned air quality legislations until 2030	No climate change policy	Annual energy intensity reduction of 1.5% until 2050	No energy access policy; medium improvement in quality of cooking fuels
CLE2	All current and planned air quality legislations until 2030	Limit on temperature change to 2°C in 2100	Annual energy intensity reduction of 2.6% until 2050	Moderate energy access policy
SLE1	Stringent air quality legislations globally	Limit on temperature change to 2°C in 2100	Annual energy intensity reduction of 2.6% until 2050	Moderate energy access policy
SLE2	Stringent air quality legislations globally	Limit on temperature change to 2°C in 2100	Annual energy intensity reduction of 2.6% until 2050	Policies to ensure global access to clean energy by 2030

Note: Sectors included in all policy packages are power plants, industry (combustion and process), road transport, international shipping and aviation, agricultural waste burning, biomass burning (deforestation, savannah burning, and vegetation fires). GHGs and air pollutants gridded include methane, sulfur dioxide, nitrogen oxides, carbon monoxide,volatile organic compounds, black carbon, organic carbon, and PM2.5; gridding is based on spatial allocation maps (using the dataset described in Lamarque et al. (2010) and methods from Riahi et al. (2011)).

- *No sustainability policies (FLE)*: This policy package assumes that no specific policies on sustainability are implemented. There is no change in future air pollution policies relative to 2005. Energy demand in this scenario is higher than in the GEA-Supply illustrative scenario, as no climate change policies are implemented, and therefore no feedback on energy demand from such policies is assumed. There is also no implementation of policies on improving energy access, although increasing economic growth leads to a slow decline in the use of solid fuels for cooking and heating in developing regions. As a result of the "frozen legislation" (FLE) assumptions, pollution levels in this scenario are the highest among the scenarios described.

- *Moderate air pollution policies (CLE1)*: This scenario is identical to the FLE case in terms of energy structure and lack of specific policies on climate change and energy access. However, it assumes full implementation of all current and planned air pollution legislation (CLE) worldwide until 2030. (See Table 17.18 for details of the types of measures undertaken.) Thus, this scenario provides a measure of the impact of current and planned air pollution policies in the absence of any specific climate or energy access policy.

- *Moderate air pollution, stringent climate, and moderate energy access policies (CLE2)*: This scenario is based on the illustrative scenario of the GEA-Efficiency pathways group described earlier in this chapter in terms of energy demand and use and the implementation of a stringent climate policy corresponding to a global temperature target of 2°C maximum warming. In addition, it assumes a moderate energy access policy, corresponding to availability of microfinance and a 20% fuel subsidy (as described in Section 17.4.1.2), as well as full implementation of all current and planned air quality legislation until 2030 as in the previous scenario. Thus, this scenario explicitly provides an indication of the multiple benefits of combining moderate policies on climate change, energy access, and air pollution.

- *Stringent air pollution, stringent climate, and moderate energy access policies (SLE1)*: This scenario differs from the previous one in that it assumes global implementation of extremely stringent pollution policies until 2030 (see Table 17.18 for details). These policies are much more aggressive than the currently planned legislation assumed in the previous two cases, but are less aggressive than the so-called maximum feasible reduction (MFR) level, which describes the technological frontier in terms of possible air quality control strategies by 2030 (for further details on CLE and MFR, see Amann et al., 2004).

- *Stringent air pollution, stringent climate, and universal energy access policies (SLE2)*: This is a variant of the previous scenario that includes in addition the universal access policy described in Section 17.4, and investigates specifically how stringent policies on energy access in developing regions, combined with stringent air pollution legislation, can affect emissions levels and associated health impacts.

Table 17.18 describes in detail the types of air pollution control technologies and policies adopted in the CLE and SLE cases. The information is derived and summarized from a number of GAINS-related publications including Cofala et al. (2007) and Kupiainen and Klimont (2004).

Policy Impacts on Pollutant Emissions

Anthropogenic sources are major contributors to outdoor air pollution, with the energy system alone contributing around 60% of PM2.5 emissions in 2005. A number of policies to control air pollution have been implemented, especially in the industrialized countries, in the past two decades: global air pollution control costs in 2005 are estimated at US$195 billion. However, more than 80% of the world's population is estimated to be exposed to PM2.5 concentrations exceeding WHO air quality standards (annual mean) of 10 μg/m^3 in 2005 (see Rao et al., 2012, for details). Future air pollution levels will depend on the future development of the energy system and the types of policies that are

Table 17.18 | Policies and measures for air pollution control.

	Transport	Industry and power plants	International shipping	Other
Current legislation (CLE)				
Sulfur dioxide (SO_2)	OECD: Directives on the sulfur content in liquid fuels; Non-OECD: National legislation on the sulfur content in liquid fuels	OECD: Emission standards for new plants from the Large Combustion Plant Directive (LCPD) (OJ 1988) Non-OECD: increased use of low-sulfur coal, increasing penetration of flue gas desulfurization (FGD) after 2005 in new and existing plants	MARPOL Annex VI regulations	Reduction in gas flaring, reduction in agricultural waste burning
Nitrogen oxides (NO_x)	OECD: Emission controls for vehicles and off-road sources up to the EURO-IV/ EURO-V standard Non-OECD: National emission standards equivalent to approximately EURO III-IV standards (vary by region)	OECD: Emission standards for new plants and emission ceilings for existing plants from the LCPD (OJ 1988). National emission standards on stationary sources– if stricter than in the LCPD Non-OECD: Primary measures for controlling of NO_x	Revised MARPOL Annex VI regulations	Reduction in gas flaring, reduction in agricultural waste burning
Carbon monoxide (CO)	As above for NO_x			Reduction in gas flaring, reduction in agricultural waste burning
Volatile organic compounds (VOC)	End-of-pipe measures as described above for NO_x	Solvent Directive of the EU (COM(96)538, 1997); 1999 UNECE Gothenburg Protocol to Abate Acidification, Eutrophication and Ground-level Ozone		Reduction in gas flaring, reduction in agricultural waste burning
Ammonia (NH_3)		End-of-pipe controls in industry (fertilizer manufacturing)		Substitution of urea fertilizers
PM2.5[1]		EU and national legislation on power plants and industrial sources limiting stack concentrations of PM		Reduction in gas flaring, reduction in agricultural waste burning
Stringent legislation (SLE)				
SO_2	As in CLE	High-efficiency flue gases desulfurization (FGD) on existing and new large boilers Use of low-sulfur fuels and simple FGD techniques for smaller combustion sectors High-efficiency controls on process emission sources	Revised MARPOL Annex VI and NO_x Technical Code 2008	Cessation of gas flaring, reduction in agricultural waste burning
NO_x	As in CLE	Selective catalytic reduction at large plants in industry and in the power sector Combustion modifications for smaller sources in industry and in the residential and commercial sectors High-efficiency controls on process emission sources	Revised MARPOL Annex VI and NO_x Technical Code 2008	Cessation of gas flaring, reduction in agricultural waste burning
CO	As in CLE			Cessation of gas flaring, reduction in agricultural waste burning
VOC	As in CLE	Regular monitoring, flaring, as well as control of the evaporative loses from storage Solvent use: full use of potential for substitution with low-solvent products in both "do it yourself" and industrial applications, modification of application methods and introduction of solvent management plans		Cessation of gas flaring, reduction in agricultural waste burning
NH_3		End-of-pipe controls in industry (fertilizer manufacturing)		Substitution of urea fertilizers, rapid incorporation of solid manure, low nitrogen feed and biofiltration
PM2.5 (including BC and OC)		High-efficiency electrostatic precipitators, fabric filters, new boiler types, filters, good practices	Revised MARPOL Annex VI regulations	Good practices in agriculture production, ban on agricultural waste burning

1 Legislation is for PM2.5 only, but black carbon and organic carbon emissions can be expected also to decline as a result.

implemented. The impacts of specific policies described in Table 17.17 on pollutant emissions in 2030 are examined below.

The absence of significant future legislation on air quality, combined with a lack of policies on energy efficiency and energy access (the FLE scenario), is seen to lead to a significant increase in all categories of emissions to more than 30% above 2005 levels and added deterioration in air quality, with 90% of the world's population exposed to PM2.5 concentration levels above WHO air quality standards – an increase of 10 percentage points compared with 2005.

Currently planned air quality legislation (the CLE1 scenario) is seen to curb the growth of emissions, especially in OECD countries. However, emissions continue to increase in non-OECD countries because of the overall high energy demand and very little or nonexistent air quality legislation in many countries (e.g., in Africa). Sulfur dioxide emissions decrease globally by only 2% in 2030 compared with 2005, in spite of a 30% decrease in OECD countries. Nitrogen oxide emissions increase globally to 115 Mt, a 15% increase over 2005 levels, again mainly due to increasing emissions – in particular, from the transportation and power sectors – in non-OECD countries, particularly in Asia. Globally, PM2.5 emissions decrease by around 2–3%, mainly from shifts in cooking fuels in the residential sector, currently the largest source of emissions (around 50% of the total, almost 90% of which is in non-OECD countries), as well as assumed legislation that establishes stronger controls on power plants, industry, and road transport. More than 80% of the world's population continues to be exposed to levels above the mandated WHO standards, the same as in 2005. This clearly indicates that, even if currently legislated air pollution control policies were globally implemented, only modest declines in pollutants would be expected. This occurs mainly because of increasing growth in emissions in developing countries in spite of the significant technological shifts that can be expected in many parts of the world in the next two decades.[46]

Emissions decline when air pollution policies are combined with additional policies on climate change, energy access, and energy efficiency. The effects of such combined policies are determined by the stringency of the individual policies assumed. A policy package of currently legislated air quality controls, together with policies on climate change, energy access, and energy efficiency (the CLE2 scenario), results in emissions reductions on the order of 50% for sulfur dioxide (SO_2), 35% for nitrogen oxides (NO_x), and 30% for PM2.5. Most of these reductions (up to 80%) occur in non-OECD countries, thus indicating that the co-benefits of combined policies are the highest there. Comparing the panels of Figure 17.45, transport and industrial sectors in particular are seen to be the most important sources of

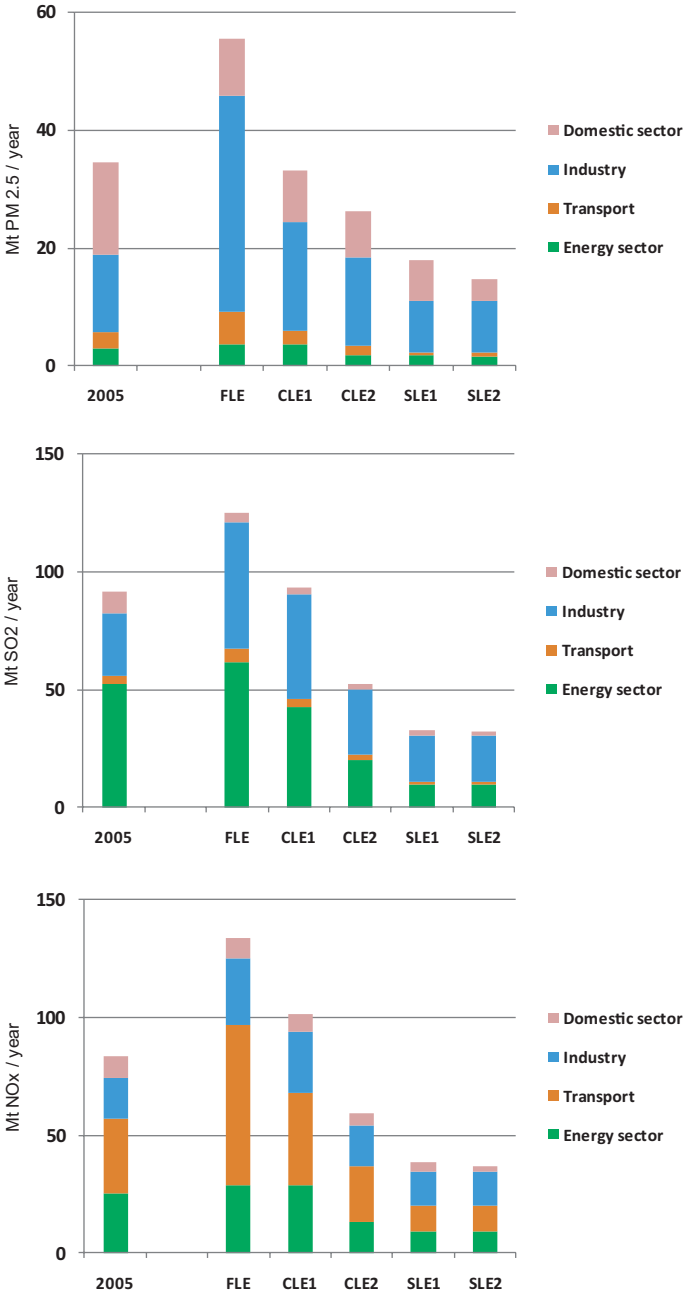

Figure 17.45 | Global energy-related pollutant emissions by sector in 2005 and under alternative policy packages in 2030.

reductions (a 28% reduction in NO_x and a 35% reduction in PM2.5), as these sectors offer significant opportunities for combined policies that can tap the co-benefits of GHG mitigation and air pollution control.[47] In the residential sector, moderately stringent policies on access to modern energy forms in developing countries have a significant impact on pollutant emissions (a 60% reduction in SO_2 and 30–40%

46 Emissions from international shipping, however, show a significant decline (80% reduction in SO_2 and 20% reduction in NO_x) despite increasing fuel use in this sector. This is because of the stringent international policies that are expected to govern this sector.

47 NO_x emissions from the power sector, although decreasing in the short term, may increase in the longer term because of the increase of overall electricity demand.

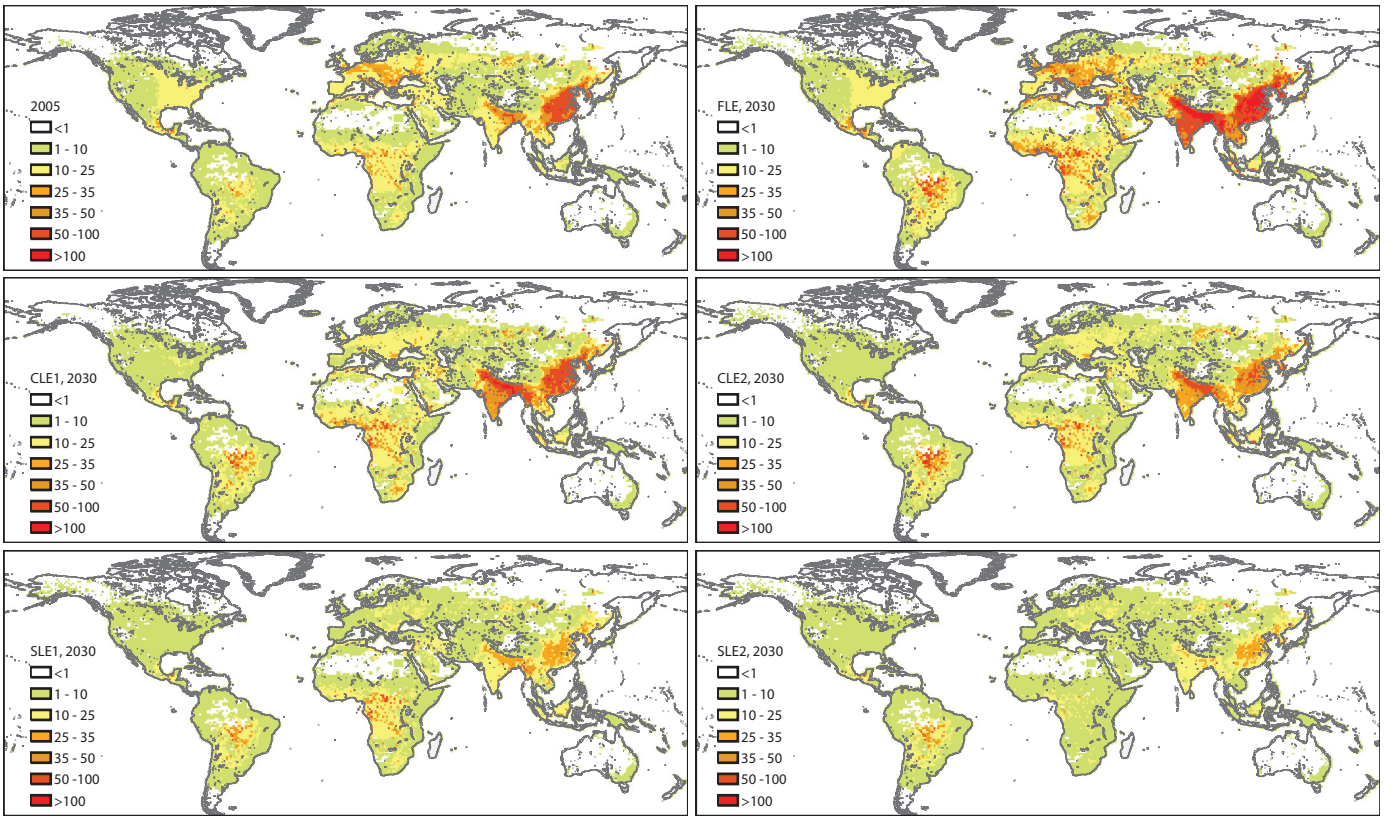

Figure 17.46 | Geographic distribution of anthropogenic PM2.5 concentrations in 2005 and under alternative policy packages in 2030 in μg/m³.

reductions in NOx and PM2.5). The pollution control costs of CLE2 are around 12% lower than those of CLE1. However, a CLE2 policy package still results in 70% of the world's population at levels beyond WHO's air quality guidelines in 2030, indicating that more stringent policies will be needed if further improvements are required.

Increasing the stringency of air quality legislation (the SLE1 scenario) leads to significant reductions across air pollutants by more than 50% (see Table 17.18 for details on controls), especially in sectors such as transport, where stricter controls yield large benefits. The annual air pollution control costs of such a scenario in 2030 are estimated at 50% lower than for the CLE1 policy package, thus implying significant co-benefits of combined policies. Around 60% of the world's population is still exposed to levels beyond WHO's air quality guidelines in 2030, but fewer than 5% are above the WHO-mandated tier I levels of 35 μg/m³ PM2.5 concentrations (Figure 17.47). Maximum benefits accrue when, in addition to stringent air quality controls, there is also a universal energy access policy that ensures clean energy globally by 2030 (the SLE2 scenario). This highlights that compliance with stringent air quality standards in developing countries cannot be achieved with only increasing the stringency of outdoor air pollution controls but will require in addition, controlling for household air pollution through access to modern cooking. This results in an overall emissions reduction of 50% in 2030 compared with 2005 levels, 100% of the world's population below WHO-mandated tier I levels, and more than 50% of the population at levels below WHO air quality guidelines of 10 μg/m³ PM2.5 concentrations. In addition to PM2.5, there are also significant differences across the scenarios for SO_2 and other pollutant emissions. The resulting spatial emissions patterns of PM2.5 across the different scenarios are illustrated in Figure 17.46.

17.5.2.2 Health-Related Impacts

Outdoor Air Pollution

This section presents estimates of global health impacts attributable to outdoor air pollution based on implementing the various policy packages discussed in earlier sub-sections. Results presented are based on combining estimated PM2.5 concentrations with WHO (2008) data on mortality and DALYs and risk rates (RRs) detailed in Cohen et al. (2004)[48] (see Box 17.4 and Table 17.19 for comparison with alternative health impact methodology used in this study). In 2005, outdoor air pollution is estimated to result in 2.75 million deaths or 23 million DALYs lost globally, which

48 Both urban and rural populations are considered here.

Box 17.4 | Alternative Methodology for Calculating Health Impacts

In addition to the standard approach for calculating DALYs, an alternative methodology is also applied in the outdoor air pollution related health impact estimations. This methodology, which is based on Mechler et al. (2002) and used in World Energy Outlook 2009 (IEA, 2009a), calculates absolute changes in life expectancy based on modification of survival functions for population over 30 years of age. The end point is the statistical years of life lost (YOLLs) over the remaining lifetime of the entire population. The main features in this approach include:

Risk rates are assumed to be linear from 5 μg/m³ until 200 μg/m³; all cause risk rates are used as opposed to a cause specific one (RR of 1.04 is used for developing countries and RR of 1.06 for developed countries); and baseline mortality data are derived from UN Department of Economic and Social Affairs (UN DESA, 2009) and include all non-accidental mortality, i.e., not distinguished by cause of death. Country-specific life tables were used to reflect different mortality levels.

The YOLLs calculated from this approach are available in Table 17.19 (and Table 17.25 in Section 7).

Table 17.19 | Health impacts of outdoor air pollution in millions of DALYs (millions of population integrated YOLLs).

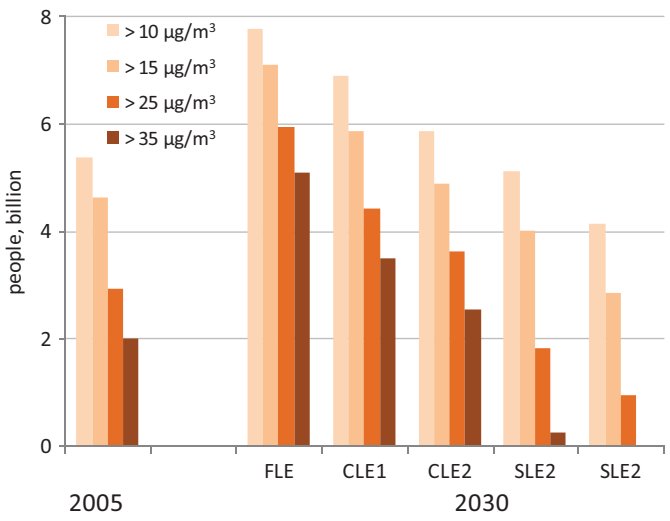

Figure 17.47 | Global population exposed to fine particulate matter concentrations exceeding WHO air quality targets in 2005 and under alternative policy packages in 2030. The rightmost bar indicates the compliance with WHO Tier 1 level of 35 μg/m³ PM2.5, representing the global target of the GEA pathways for the environmental and health objective by 2030. Bars to the left indicate a comparison to lower (more stringent) WHO Tier levels with the leftmost bar corresponding to the lowest WHO AQG of 10 μg/m³.

represents around 5% of all deaths, 2% of all DALYs and around 12% of the total burden that can be attributed to cardiovascular, respiratory, and lung cancer (for further discussion see Rao et al., 2012). More than 70% of this burden is felt in Asia alone.

Failure to implement further air pollution control policies beyond 2005 levels (the FLE scenario) is seen to result in a global increase of close to 50% in DALYs (and deaths) in 2030 as compared to 2005 (shown in Table 17.19), indicating that the implementation of air pollution policies is an absolute must for controlling the health-related impacts of air pollution in the future. However, an air pollution control-only policy, as in the CLE1 scenario, still leads to an increase in health impacts by more than 30% between 2005 and 2030[49] with the share of the outdoor air pollution related in the total burden increasing slightly from 2005 levels. This is mainly due to the large increases in emissions in many developing regions, particularly South Asia and Africa, where currently legislated policies do not lead to emissions declines in the future, as discussed earlier. In addition, a growing population in these regions means that the future population over 30 years of age at risk for air pollution

49 This is comparable to findings in the *World Energy Outlook 2009* of the IEA (2009a), which estimates a 70% growth of emissions in selected regions for the baseline scenario in spite of current air quality legislation.

Table 17.20 | Outdoor and household health impacts in 2005 and in 2030 for the CLE1 and SLE2 scenarios (in millions of DALYs).

* Indicated in parenthesis are estimated outdoorhealth impacts attributable to use of solid fuels (biomass and coal)in households. Note that these estimates are based on interpolations between scenarios and are only indicative. Range represents the inherent uncertainty in calculating these impacts.

1 Explicit energy access scenarios for these regions have not been constructed. The numbers of DALYs lost for these regions for the CLE1 scenario are therefore estimated by extrapolating trends from the other regions.

will also be larger than today's, leading to increases in health impacts in most developing countries.

The combination of currently legislated air quality policies with other policies, as in the CLE2 scenario, helps to slow the health-related impacts, with 1.2 million avoided deaths in 2030 and a reduction of more than 7 million DALYs compared with the air pollution-only CLE1 scenario. While more stringent air pollution policies (as in the SLE1 scenario) yield further reductions in deaths and DALYs, including universal energy access policies for 2030 that directly affect outdoor air pollution through cleaner fuels, the SLE2 policy case yields maximum health benefits by 2030, corresponding to 2.6 million avoided deaths or a reduction of 20 million DALYs compared to the CLE1 policy case. The air pollution-related burden in 2030 (1.2 million deaths and 13 million DALYs) reduces to less than 2% of total deaths, 1% of total DALYs and around 5% of deaths and DALYs that can be attributed to cardiovascular, respiratory, and lung cancer. Thus, maximum benefits in terms of meeting environmental aims and reducing the health-related impacts of outdoor air pollution will require not only an increase in the stringency of air quality controls globally, but also an integration of a wider spectrum of policy concerns.

Comparison with Household Air Pollution

This section compares the impacts of policies to control outdoor air pollution that were explained earlier with specific policy scenarios, such as fuel subsidies and microfinance options, that facilitate access to cleaner cooking fuels (LPG) and thereby limit household air pollution (see Section 17.4.1).

Estimates of the current health impacts of household pollution are based on the effects of solid fuel dependence today, whereas future estimates are based on the detailed access scenarios described in Section 17.4.1.2 and account for forecasted demographic change and trends in background disease and mortality levels as estimated by the WHO. The methodology is described in detail in Rao et al., (forthcoming).[50] In 2005, total deaths attributed to solid fuel combustion in traditional stoves were about 2.2 million,[51] and more than 41.6 million DALYs were lost, with the impacts felt mainly by women and children. Although substantial uncertainty is associated with these estimates, policies that improve access to modern cooking have the potential to avert between 0.6 million and 1.8 million premature deaths, on average, every year until 2030, in the three regions of sub-Saharan Africa, South Asia, and Pacific Asia. These include between 0.4 million and 0.6 million deaths per year of children below the age of five. Deaths attributable to acute lower respiratory infection (ALRI) among children under five are seen to decline between 2005 and 2030 even in the absence of any access policies, but deaths due to chronic obstructive pulmonary disease (COPD) and ischemic heart disease (IHD) in adults

50 In contrast to outdoor effects, which are quantified only for the population older than 30 years, estimates of health impacts from household pollution include the effects on children. The present study includes impacts due to acute lower respiratory infections (ALRI) in young children, chronic obstructive pulmonary disease (COPD) in adults and ischemic heart disease (IHD) in adults. In addition, we also estimate the incidence of lung disease in adults due to the combustion of coal in homes.

51 About 1.6 million deaths were in South and Pacific Asia and sub-Saharan Africa, regions where the lack of access to modern energy carriers is the most acute and for which explicit energy access scenarios have been assessed in Section 17.4.

are expected to increase during the same period. These trends are in line with those reported by Bailis et al. (2005), who find that the observed decline in childhood ALRI mortality over time is a result of additional factors,[52] whereas the upward trend in adult incidence of COPD is mainly due to population aging. Alternatively, in the absence of any new policies to enhance access to modern cooking fuels or devices, it is estimated that in 2030 there could still be over 24 million DALYs lost due to household air pollution. See Rao et al., (forthcoming) for details on disease-specific impacts.

Table 17.20 lists the health impacts in DALYs from outdoor and household air pollution for 2005 and for an air pollution-only policy (CLE1) compared with a combined policy (SLE2). There are significant health benefits from a combination of stringent outdoor air pollution policies and a policy that ensures universal access to clean cooking by 2030. These are especially effective in developing countries that face the dual problems of outdoor air pollution due to a growing motorized fleet combined with household pollution from poor quality cooking fuels and devices. Thus, such policies can have multiple benefits both for human well-being and for the environment (as highlighted in Chapter 19 and Section 17.4), including major health gains.

17.6 Energy Security

17.6.1 Introduction

Energy security has been a major concern for energy systems for decades, and therefore needs to be addressed in the transition pathways presented in this chapter. As reviewed in detail in Chapter 5, energy security has multiple dimensions, which are not easily combined into a holistic concept or single indicator. Therefore, the concept of energy security is not used as a quantitative target or a technical modeling constraint in the GEA pathway scenarios described here. Instead, this section draws on the conceptual and quantitative framework developed in Chapter 5 to illustrate the implications of the GEA transition pathways for energy security. Section 17.7 then extends the discussion to the multiple benefits of the transition pathways, considering especially the synergistic effects between other energy development objectives and energy trade.[53]

Chapter 5 summarized the present main energy security concerns as follows:

- *Oil and transport:* volatility in the global oil market coupled with the geographic concentration of oil production; rapidly increasing demand under potentially constrained production capacities; growing dependence of an increasing number of countries on imported oil from ever fewer producing countries, with low-income countries often facing unaffordable costs of imports; and the dominance of oil in the transportation sector, where easily-available substitutes are lacking.

- *Natural gas:* dependence of a number of countries on imported natural gas, often procured from a single supplier and delivered through a limited number of potentially vulnerable routes and infrastructure.

- *Electricity:* vulnerability of electricity systems associated with low diversity of power generation options, aging infrastructure, inadequate generation capacity, and rapid demand growth.

- *Energy export revenue:* volatility and uncertain sustainability of energy export revenue ("energy demand" security) in countries where energy is a vital economic sector.

- *Total primary energy supply vulnerabilities:* overall energy vulnerability of a number of individual countries that face several of the above concerns simultaneously.

Chapter 5 established a framework for analyzing the energy security-related vulnerabilities of energy systems associated with fuels, end-use sectors (including electricity as a carrier), and individual countries. For each of these three subsystems, that chapter identified three dimensions of energy security concerns: sovereignty (the degree of control that national governments have over energy systems), resilience (the ability of energy systems to respond to disruptions), and robustness (the risks related to the physical state of energy resources and infrastructure). This section adopts the same framework, but considers different energy subsystems to reflect game-changing developments in the transition pathways. The section analyzes not only the globally traded fuels that dominate today (oil, gas, and coal) but also those of the future (biofuels and hydrogen). The main energy end-use sectors (transportation, industry, residential and commercial) and electricity generation are also analyzed. Finally, since the modeling frameworks do not provide detail on individual countries, the analysis is applied at the world and regional level.

Table 17.21 summarizes the energy security perspectives and indicators analyzed in this section. The analysis relates to sovereignty and resilience concerns. The robustness concerns could not be addressed at this aggregated level.

This analytical framework is applied to the three illustrative GEA transition pathways (GEA-Supply, GEA-Mix, and GEA-Efficiency) but considers both of the transportation cases for each, because the transportation sector is a key policy concern, given the limited alternatives to the use

52 These include increased coverage and efficacy of pneumonia case management using antibiotics; increased awareness and practice of breastfeeding, which increases child immunity and survival; and other economic and technological factors.

53 The energy security analysis of the GEA pathways relies on the MESSAGE interpretations of the GEA pahtways, including the alternative transportation sector setups and reduced supply-side portfolios.

Table 17.21 | Indicators for analyzingenergy security across subsystems and security perspectives.

Subsystems	Security perspectives	
	Sovereignty	Resilience
Upstream		
Fuels (total fuel supply and globally traded fuels)	Volume and intensity of trade (by fuel and total)	Global diversity of the primary energy system; dominance of a single fuel
Downstream		
Carriers (electricity) and end uses (transport, residential and commercial, industry)	Reliance of carrier or end-use sector on insecure fuels	Diversity of fuels used in the carrier or end-use sector
Regional	Import dependency (and export flows)	Diversity of primary energy supply in the region

of oil in internal combustion vehicles. The analysis focuses on changes between now and 2050, because this is the longest time horizon under which energy security concerns are considered in present policies. The analysis first considers the energy security concerns associated with fuels, then examines the future vulnerabilities of end-use sectors, and concludes with an examination of the energy security of individual GEA regions.

17.6.2 Fuels

Under the GEA transition pathways, the vulnerabilities of globally traded fuels in the aggregate as well as of individual fuels decrease over time in terms of both sovereignty and resilience.

A proxy measure of the sovereignty aspects of energy security is global trade in energy. Absolute volumes of traded energy and the share of traded energy in overall energy use (the latter referred to here as "trade intensity") indicate the extent to which regions rely on fuels produced in other regions, raising sovereignty concerns.

Figure 17.48 shows both trade volumes and trade intensity under the six GEA pathways considered here. The global aggregate energy trade volumes among the 11 GEA regions (estimated at some 104 EJ in 2005) peak in 2030 or 2040, and trade intensities peak in 2020 or 2030. Thereafter both indicators decline, so that by 2050 the intensity of trade is lower than at present but the absolute amount of trade remains higher than present values under the GEA-Supply scenarios. The decline in absolute trade volumes after 2030 is most pronounced in the Advanced Transport GEA-Mix and -Efficiency pathways and least pronounced in the high-demand, supply-dominated GEA transition pathways.

Concerning individual fuels, the analysis shows the following trends. In all the GEA pathways considered, oil is phased out in the long term. It accounts for between 9% and 15% of global primary energy supply by 2050 and declines to less than 1% by the end of the century

Table 17.22 | Characteristics of globally traded fuels in 2050 compared with oil in 2005.

Characteristic	Oil, 2005	Gas, 2050	Coal, 2050	Biofuels, 2050
Predominance (% of primary energy supply)	34	19–22	8–10	6–8
Trade volume (EJ/year)	83	35–54	10–20	7–14
Geographic concentration of production (diversity index)[1]	1.0	0.9–1.0	1.3–1.4	1.2–1.5

1 See text for definition of the diversity index.

(Table 17.22). As a result, trade volumes of oil for all pathways peak at about 100 EJ (compared with approximately 83 EJ today[54]) between 2020 and 2030 and decline thereafter.

Present energy security concerns associated with oil drastically diminish in the GEA pathways because of their comparatively modest demand growth, which is due to efficiency improvements and a more diversified supply mix. No other fuel assumes a dominant role similar to that which oil plays today, accounting for 36% of primary energy supply worldwide.[55] Moreover, no "new oil" emerges in the global energy arena. Table 17.22 summarizes the characteristics of the globally traded fuels in 2050 as compared with oil today. Figure 17.49 shows the shares of different fuels in global primary energy supply, indicating a more diversified supply portfolio. Figure 17.50 illustrates how trade volumes and the geographic concentration of production of oil, gas, and coal change across the GEA pathways.[56] Biofuels, hydrogen, and electricity are traded in much smaller volumes (a maximum of 50 EJ for hydrogen in the GEA-Supply pathway with Advanced Transportation) and with greater geographic diversity of producers than is the case with oil today.

At the same time, by 2050 natural gas trade exhibits some of the characteristics of oil trade today under certain pathways. By 2050 gas accounts for about 20% of primary energy and 36–51 EJ of trade per year (compared with oil's current 83 EJ). Additionally, gas production stays at its current level of geographic concentration until about 2050, which is comparable to the geographic concentration of oil production, and becomes even more concentrated than current oil production under most pathways thereafter, as shown by its decreasing Shannon-Wiener diversity index in Figure 17.50. Although natural gas is a potentially more risky fuel, the overall resilience of energy systems, as measured

54 BP (2009) estimates a total volume of country-to-country oil trade of some 110 EJ in 2005. Thus, the GEA interregional model representation covers some 75% of actual oil trade flows at the country level.

55 Although electricity comes to dominate final energy use, it is not, strictly speaking, a "fuel," as it is produced from a variety of sources. Moreover, global trade in electricity is minimal in all pathways, never accounting for more than 2% of total electricity supply.

56 The geographic concentration of production is measured by the Shannon-Wiener Diversity Index (SWDI), described below.

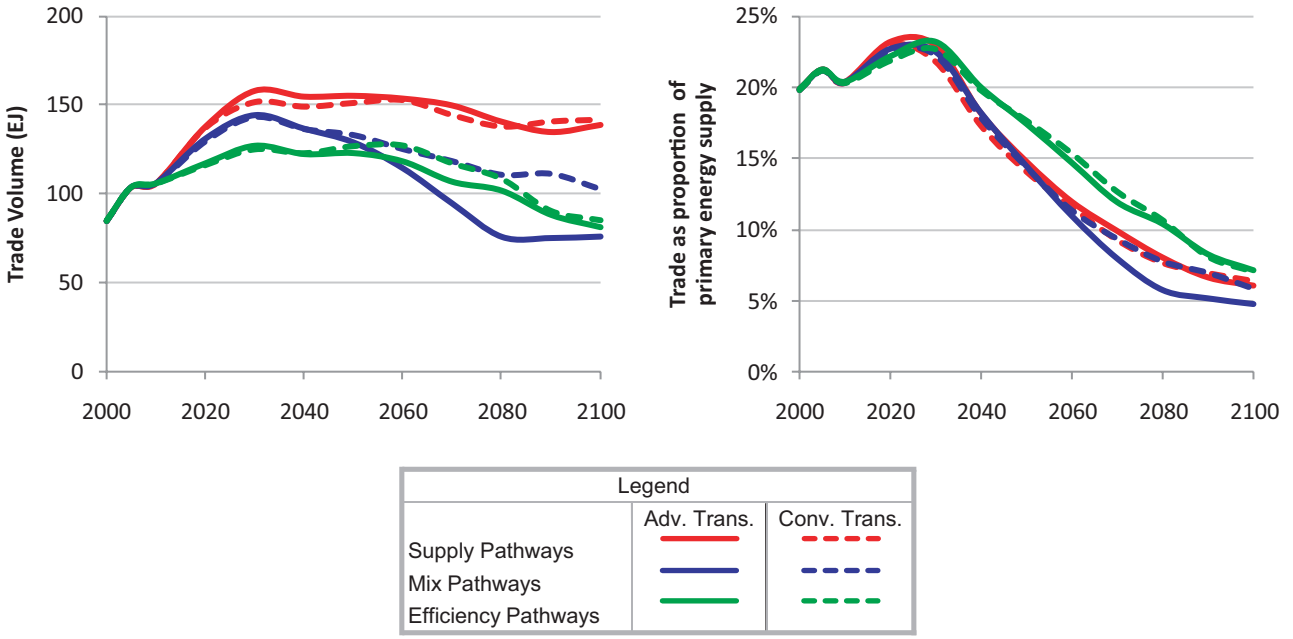

Figure 17.48 | Volume of energy trade and trade intensity in the illustrative GEA pathways. Each of the transportation variants of the three GEA transition pathways is represented.

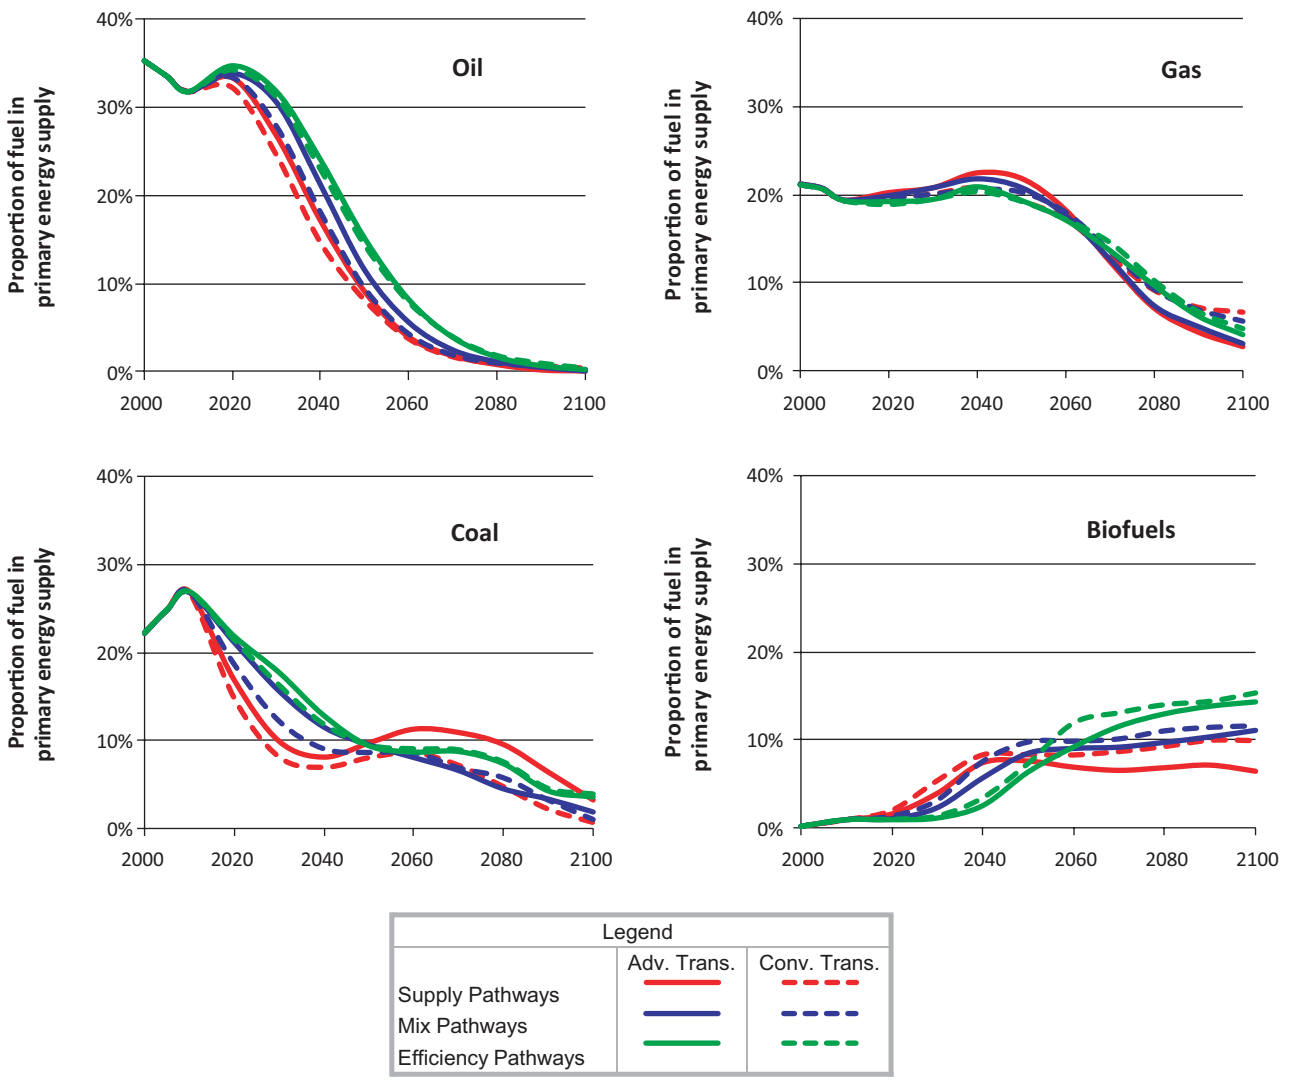

Figure 17.49 | Contributions of fossil fuels and biofuels to global primary energy supply in the GEA pathways (unrestricted portfolios for advanced and conventional transport).

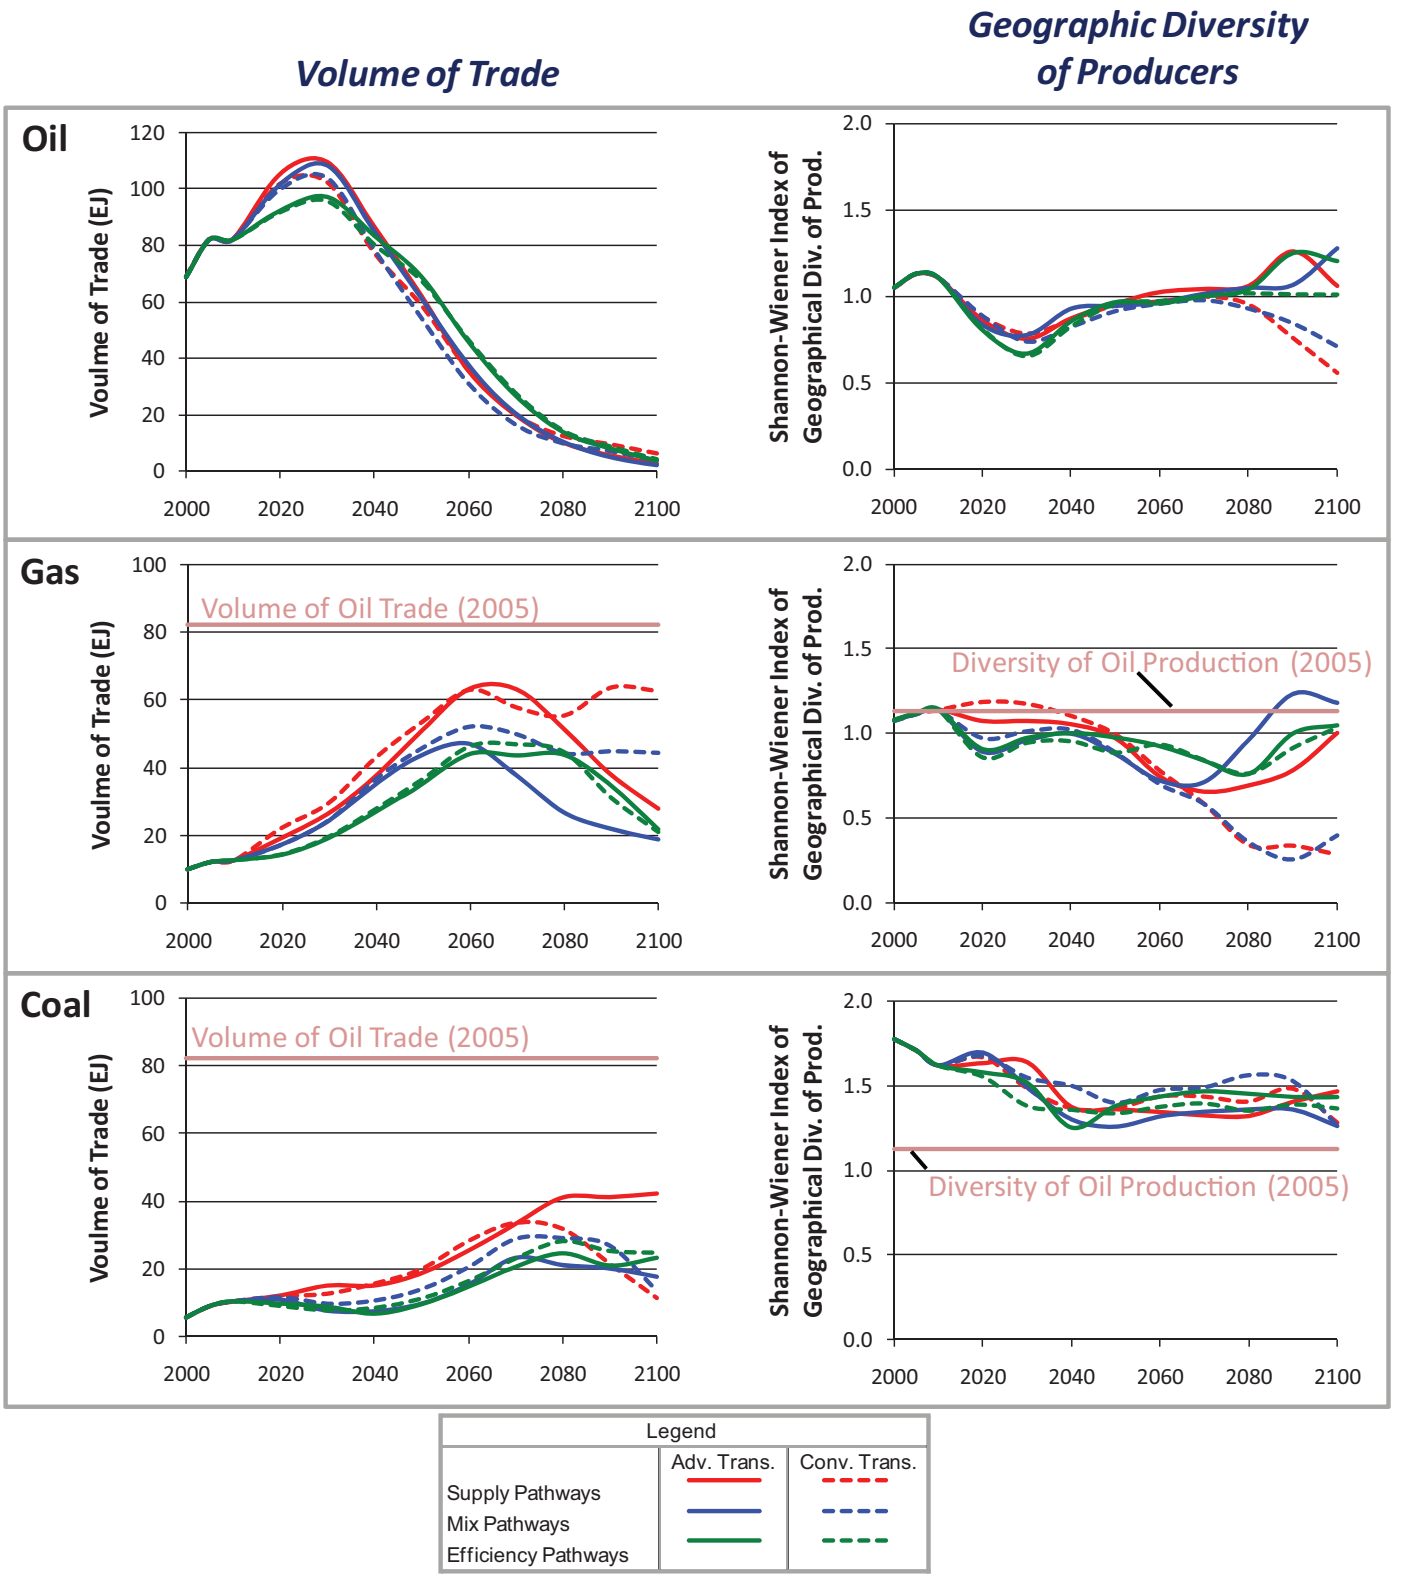

Figure 17.50 | Volume of trade and geographic diversity of production of globally traded fuels in the GEA pathways (unrestricted portfolios for advanced and conventional transport).

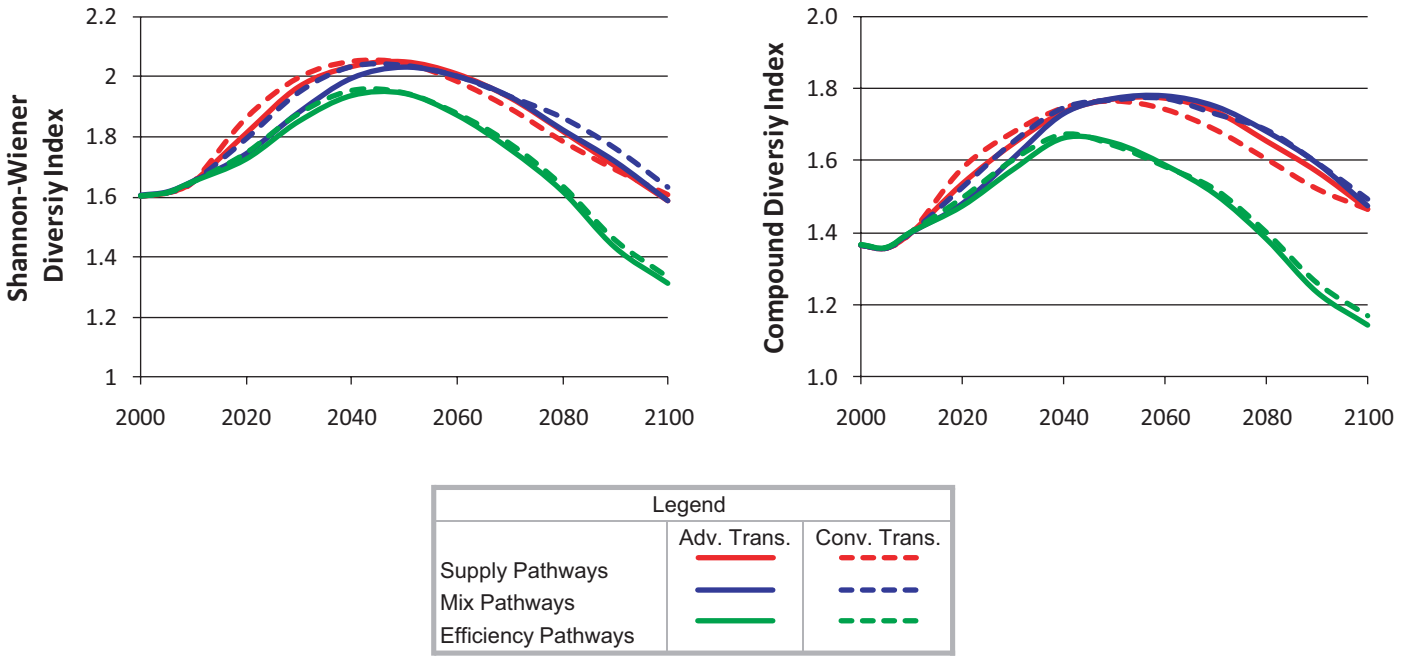

Figure 17.51 | Primary energy supply diversification in the GEA pathways (unrestricted portfolios for advanced and conventional transport). See text for definitions of the indexes.

by the diversity of primary energy supply, increases under all transition pathways.

The Shannon-Wiener diversity index (SWDI; see Shannon and Weaver, 1963) is frequently applied as a measure of energy security of supply (see, e.g., Jansen et al., 2004; APERC, 2007) and electricity generation (Stirling, 1994). The index is calculated as follows:

$$SWDI = -\sum_i (p_i * \ln(p_i)) \quad (1)$$

where p_i is the share of primary energy i in total primary energy supply. In the GEA pathways, the global SWDI rises (supply diversification increases) from the current level of 1.6 to 2.0 by 2050, before falling to between 1.3 and 1.6 in the latter half of the century.[57]

Measures of global energy trade (reflecting sovereignty concerns) and diversity (reflecting resilience concerns) can be aggregated into a single index called a compound SWDI. This compound indicator differs from the simple SWDI in that it does not count globally traded fuels as contributing to the overall diversity of primary energy supply.[58] It is calculated by excluding the imported energy in a nation's or region's diversity index:

$$Compound\ SWDI = -\sum_i (1 - m_i) * (p_i \ln(p_i)) \quad (2)$$

where p_i is again the share of primary energy resource i in total primary energy supply, and m_i is the share of primary energy resource i that is supplied by net imports.

This indicator shows a trend similar to that of the simple SWDI (Figure 17.51), increasing from 1.4 in 2000 to about 1.7 in 2050 before falling slightly to about 1.5 in the second half of the century.[59]

17.6.3 End-Use Sectors

The diversity of fuels used in a sector is generally considered an indicator of the resilience of energy supply for the sector. Sectoral diversity indexes are shown in Figure 17.52. The increase in diversity in the transportation sector is particularly pronounced in the GEA pathways, whereas the improvement is more gradual in the other end-use sectors and in electricity generation.

Although this pattern of increasing diversity of the energy mix in individual end-use sectors is relatively homogeneous across regions, there is some regional variation. In some regions, the rise in diversity is more rapid and pronounced, whereas in others, individual fuels (particularly gas) come to dominate certain sectors in certain periods. These regional deviations are discussed in the next section.

57 It is important to note that the diversity index strongly depends on the primary energy accounting convention used. In GEA, a consistent substitution-equivalent accounting of primary energy is applied across all chapters to ensure comparability. Under this accounting convention, diversity indicators drop in the latter half of the century with the strong decarbonization of the energy system. Thus, it is also important to consider the sectoral or end-use diversity indices, discussed below.

58 This index was first used in Jansen et al. (2004) as a measure of long-term energy security.

59 See also the electronic appendix to this chapter for further illustrative examples of diversity indicators for specific regions.

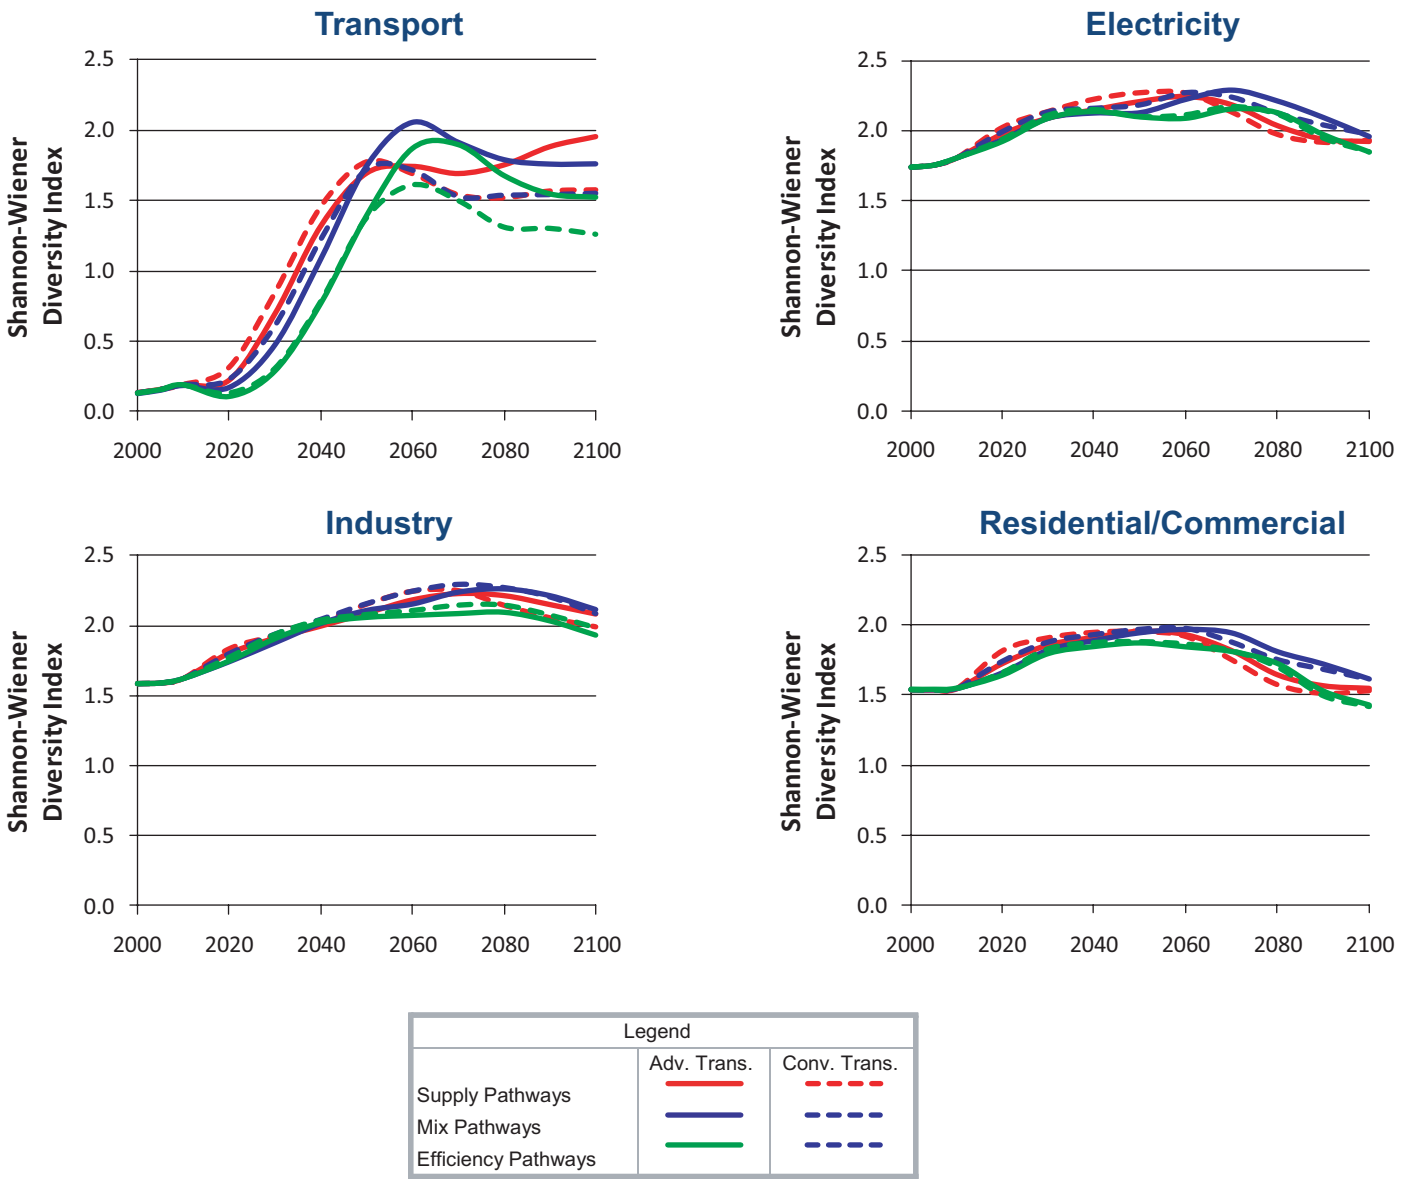

Figure 17.52 | Diversification of end-use sectors and of electricity generation in the GEA pathways (unrestricted portfolios for advanced and conventional transport).

17.6.4 Regions

At present, energy security concerns vary across countries. In the GEA pathways, different regions also face different energy security trends and challenges.

17.6.4.1 Regional Import Dependency and Energy Export Volume

Different regions fare differently in terms of sovereignty concerns related to energy trade. Fewer regions are net energy importers under the GEA pathways than today; across all pathways, the number of regions with low import dependency rises from five in 2000 to between seven and eight in 2050 and between nine and 11 in 2100 (Table 17.23).

The flip side of the decrease in energy imports is a fall in energy exports for certain regions. Energy exports provide vital revenue for a number of countries, and rapid and profound declines in such revenue could adversely affect energy-exporting regions. (Chapter 5 conceptualizes energy exports as a "vital energy service.") This drop in export volumes may be partly mitigated, however, by rising energy prices.

The most important energy-exporting region today is the Middle East and North Africa (MEA), with net energy exports of over 52 EJ in 2005, followed by the Former Soviet Union (FSU), which exported about 24 EJ in that year; Latin America and the Caribbean (LAC) and sub-Saharan Africa (AFR) each exported some 11–13 EJ.

Because of the declining share of oil in the global energy mix, MEA experiences the largest decline in energy export volumes. The region's

Table 17.23 | Import dependency of GEA regions in the GEA pathways.

Imports as share of primary energy supply	No. of regions		
	2005	2050	2100
Low[1] (<16%)	**5** (AFR, CPA, FSU, LAC, MEA)	**7–8** (AFR, CPA, FSU, LAC, MEA, NAM, PAO, PAS[2])	**9–11** (AFR, CPA, FSU, EEU, LAC, MEA, NAM, PAO, PAS,[3] SAS,[4] WEU)
Medium (16–34%)	**3** (NAM, PAS, SAS)	**1–3** (EEU, PAS,[2], SAS, WEU[5])	**0–2** (PAS,[3] SAS,[4])
High (>34%)	**3** (EEU, PAO, WEU)	**0–1** (WEU[5])	**0**

Note: AFR (Africa); CPA (Centrally Planned Asia); FSU (Former Soviet Union); EEU (Eastern Europe); LAC (Latin America and the Caribbean); MEA (Middle East and North Africa); NAM (North America); PAO (Pacific OECD); PAS (Pacific Asia); SAS (South Asia); WEU (Western Europe).

1 Includes net energy exporters.

2 Has medium import dependency (~25%) under the GEA-Efficiency pathways.

3 Has medium import dependency (~32%) under the GEA-Efficiency pathways.

4 Has medium import dependency (17–20%) under the GEA-Mix and GEA-Efficiency pathways with Conventional Transportation.

5 Has medium import dependency (17–30%) under the GEA-Mix pathways and GEA-Supply pathways with Advanced Transportation.

exports peak at between 80 and 90 EJ/year in 2030 before falling to 43–55 EJ/year in 2050 (slightly higher for the GEA-Efficiency pathways) and to less than 15 EJ/year in the second half of the century. Similarly, LAC's exports approximately double to about 20 EJ/year between now and 2030 or 2040 before dropping to between 7 and 10 EJ/year by the end of the century. Exports from AFR also drop, although not as profoundly, stabilizing in some pathways at approximately the present levels in the second half of the century.

The major export "winner" under all the pathways is FSU, which experiences a dramatic rise in its energy exports due to the increasing demand for gas. The region's energy exports rise from the 2005 level of some 24 EJ/year to between 47 and 52 EJ/year in 2050, and then experience a continued rise through 2070 or 2080 to between 50 and 65 EJ/year. Three other regions –Centrally Planned Asia (dominated by China), North America, and Pacific OECD – also see a rise in export volumes over all the GEA pathway analysed, although their increases are not as pronounced and differ across pathways and time horizons.

17.6.4.2 Regional Resilience and Diversity

As noted above, global energy supply becomes more diverse in the GEA pathways both as a whole and within individual end-use sectors, especially the transport sector. This increase in diversity is also observed across all GEA regions (Table 17.24), with a generally smaller rise in MEA (a consequence of the region's exceptional oil and gas resource endowment).

The fuel diversity of electricity generation increases in all pathways in five out of the 11 GEA regions. In five other regions, diversity increases in at least some pathways. Only in Western Europe does electricity production diversity decrease compared with the current (relatively high) level.

In general, the GEA regions may be divided into three broad groups. The first group includes such industrialized regions as the Pacific OECD, Latin America and the Caribbean, North America, and Western Europe, which generally follow the global trends with respect to fuels and end-use sectors. Transitions in their energy systems are primarily driven by global factors, including the switch away from fossil fuels, increases in efficiency, and the diversification of transport technologies. Since all these transitions generally improve energy security by increasing resilience and sovereignty, energy security in these regions also improves significantly.

The second group includes Sub-Saharan Africa and Centrally Planned Asia, in which the global energy transitions provide a context for massive growth in regional energy systems. The expansion of energy systems in Sub-Saharan Africa to extend energy access to all, and in Centrally Planned Asia (dominated by China) to keep up with rapidly growing economies, results in dramatically altered configurations of energy systems, leapfrogging the inherited energy systems inertia of the industrialized world. As a result, many energy security indicators in these regions improve much more rapidly and dramatically than in the rest of the world, as their energy systems become more diverse and more reliant on regional rather than global resources.

The third group includes those regions that, because of their geography and either fossil fuel resource endowments (the Former Soviet Union, the Middle East and North Africa) or resource scarcity (Eastern Europe and South Asia), have more limited options for radical systemic change. The diversity of energy supply, especially in specific sectors in these regions, may be below the global average. For example, their transportation and electricity sectors may become dominated by natural gas, a fuel of choice in the middle of the century.

17.6.5 Conclusions on Energy Security

Under the GEA pathways, energy security improves in the world as a whole and in the majority of regions. The diversity of energy sources increases, whereas the volume and the intensity of trade decline in most pathways. No individual fuel is likely to cause energy security concerns similar to those caused by oil at present. The one exception is natural gas, which, as a transition fuel, experiences growth to some 30% of global primary energy supply (compared with oil's 36% share today) in 2050, with increasing trade flows and a decrease in the diversity of production.

Table 17.24 | Regional trends in diversity and import dependency, 2005 and 2050.

Import Dependency*			Diversity						Compound diversity index	
			Electricity		Transport		Primay Energy Supply

* Import dependency values are reported as negative if a region is a net energy exporter. World import dependency is the proportion of primary energy that is traded.

In the GEA pathways, individual end-use sectors generally use a more diverse mix of energy sources than today. The transportation sector, presently associated with major energy security concerns, achieves diversity similar to that in other end-use sectors. No end-use sector relies on a single fuel to the extent that transport relies on oil today.

Each of the 11 world regions generally follows the global trend toward improved energy security. Some experience a more rapid and pronounced increase in diversity and self-sufficiency of their energy systems. At the same time, some regions with more limited energy options may experience continued reliance on particular fuels (primarily natural gas) in specific sectors (transportation and electricity generation) under certain pathways.

The next section examines, among other issues, the impact of the other energy objectives for energy security, including global energy trade and primary energy source diversity.

17.7 Synergies and Multiple Benefits of Achieving Different Energy Objectives Simultaneously

The previous sections have illustrated a variety of energy futures in which the objectives of climate change mitigation, air quality, health, access, and security could be achieved simultaneously. These pathways show that a dramatic transformation of the energy system is technically possible, and that if society truly values sustainability across all dimensions, such a transformation is indeed necessary. Transitions of this kind would likely lead to enormous synergies between objectives – synergies that are, at the moment, not fully understood by decisionmakers, or often overlooked, because the analysis is complex and requires an integrated, holistic perspective.

This section builds upon the main findings of an analysis conducted at IIASA in support of the GEA (McCollum et al., 2011), which attempts to illuminate the major synergies and, to a lesser extent, the trade-offs among the various energy objectives and the requisite policy choices and outcomes. In so doing, the analysis takes a slightly different approach from the core illustrative GEA pathways described so far in the chapter. Here the GEA-Mix scenario is used as a starting point for generating a wide array of scenarios that attempt to cover a large portion of the full scenario space across several different dimensions. Within this space, many of the scenarios are unsustainable by GEA standards, as each meets (or fails to meet) the different energy objectives to varying degrees. The analysis uses these less stringent scenarios as counterfactuals and for comparison purposes, in order to show how certain objectives and policy choices push in the same direction, while others are in conflict.

Table 17.25 | Indicators for climate change, pollution and health, and energy security and levels of satisfaction within the weak-intermediate-stringent framework.

Fulfillment	Climate Change [probability of staying within 2°C warming limit]	Pollution and Health [million DALYs (YOLLs), 2030]	Energy security [compound diversity indicator, 2030]
Weak	<20%	>33 (7300)	<1.40
Intermediate	20–50%	15–33 (2700 – 7300)	1.40–1.50
Stringent	>50%	<15 (2700)	>1.50

17.7.1 Characterization of the Full Scenario Space

In this section, the feasible scenario space is represented by several hundred distinct scenario pathways. These scenarios stretch the potential development of the energy system in several dimensions, each fulfilling the individual GEA objectives with respect to climate change, air pollution and health, and energy security to varying levels of satisfaction. For instance, some scenarios push climate change mitigation while ignoring security and air pollution, whereas other scenarios prioritize security only while ignoring the climate objective. Notably, the access objective is taken as a given in this analysis, as all scenarios have been developed to meet the access targets of the GEA, including even the corresponding counterfactual (baseline) scenario.[60] This simplification was made because energy access, compared with other objectives, has the lowest impact on energy use and GHG emissions (see Section 17.4). For further methodological details on how the full scenario ensemble was developed, see the electronic appendix.

As discussed earlier in this chapter, satisfaction of each of the individual GEA objectives can be measured in their own unique way: climate change in terms of the probability of limiting global temperature rise to 2°C (Section 17.5.1), pollution and health impacts in terms of DALYs (Section 17.5.2), and energy security in terms of a compound diversity indicator (Section 17.6). The use of such different metrics, although necessary given the far-ranging impacts of the energy system, tends to complicate the comparison of scenarios that meet certain objectives but not others. For this reason, this section adopts a simple framework to describe the scenario space across all three objectives; at the same time, it allows for ready comparison with the previous discussions in this chapter. The framework, summarized in Table 17.25, defines three levels of satisfaction – Weak, Intermediate, and Stringent – for each of the three energy objectives. Specific numerical ranges are given for what constitutes each of these levels in terms of the relevant indicators. (Note that health impacts are also presented in terms of YOLLs, the methodology for which is described in Section 17.5.2.) Importantly, within a given scenario, the fulfillment of each objective is independent of the fulfillment of another (except for some important synergies, discussed later in this section). Therefore, a given scenario could, for example, fulfill the climate objective at the Weak level while at the same time satisfy the pollution and health objective and the energy security objective at the Intermediate level. By sharp contrast, all of the core GEA pathways described up to this point in the chapter (GEA-Efficiency, GEA-Mix, and GEA-Supply, along with their variants) have been designed to fulfill all of the objectives simultaneously at the Stringent level. In fact, the minimum allowable indicator values corresponding to the Stringent level are derived from the originally stated targets of the GEA (see Cluster I of the report and Section 17.2.3).

Figure 17.53 illustrates the full scenario space across all three dimensions: climate, pollution and health, and energy security. The degree to which each scenario (or rather, class of scenarios) fulfills the individual objectives is indicated in the figure by the shaded Weak, Intermediate, and Stringent regions. For instance, the top panel illustrates ranges of GHG emissions trajectories for all scenarios in the large ensemble that correspond to probabilities of reaching the 2°C target. The baseline scenario, which assumes no new climate, pollution and health, or energy security policies, sees the largest growth in emissions throughout the century and is therefore at the upper bound of the Weak region. Annual emissions in the baseline scenario climb from 49 $GtCO_2$-eq. in 2010 to 84 $GtCO_2$-eq. in 2050.[61] Emissions then peak near 100 Gt in the later part of the century. All other scenarios achieve emissions reductions compared with the baseline, and hence have comparatively higher probabilities of meeting the 2°C target. In the most stringent climate scenarios (lower bound on the Stringent region), emissions in 2050 are just 18.6 Gt. As discussed more fully in Section 17.5.1, reaching the 2°C target with greater than 50% probability (Stringent region) requires that emissions peak in 2020 at levels only marginally higher than today and then be reduced significantly in the decades that follow. If, however, the climate objective is of lower priority (i.e., if probabilities of meeting the 2°C target at less than 50% are acceptable), the permissible peak in emissions could certainly be greater and could even be delayed far beyond 2020. In the case of such weak and intermediate fulfillment of the climate objective, emissions reductions in the middle to late part of the century would not need to be nearly as drastic. For example, annual GHG emissions in 2050 for the Intermediate region (corresponding to a 20–50% probability of meeting the target) range from levels approximately the same as today to levels up to 45% lower. Comparing the latter case with the former, the emissions peak must occur almost two

60 Importantly, the baseline scenario referred to here differs from that discussed elsewhere in the chapter. Here, the baseline corresponds to a variation of the GEA-Mix pathway (thus including intermediate efficiency focus to limit energy demand), in which the policy constraints are relaxed to business-as-usual conditions. The counterfactual referred to in other sections builds upon the GEA-Supply storyline, and a corresponding baseline depicting future developments in the absence of any of GEA sustainability policies at levels of relatively higher demand.

61 Note that these GHG estimates include all well-mixed Kyoto greenhouse gases (CO_2, methane, nitrous oxide, sulfur hexafluoride, tetrafluoromethane, and halocarbons).

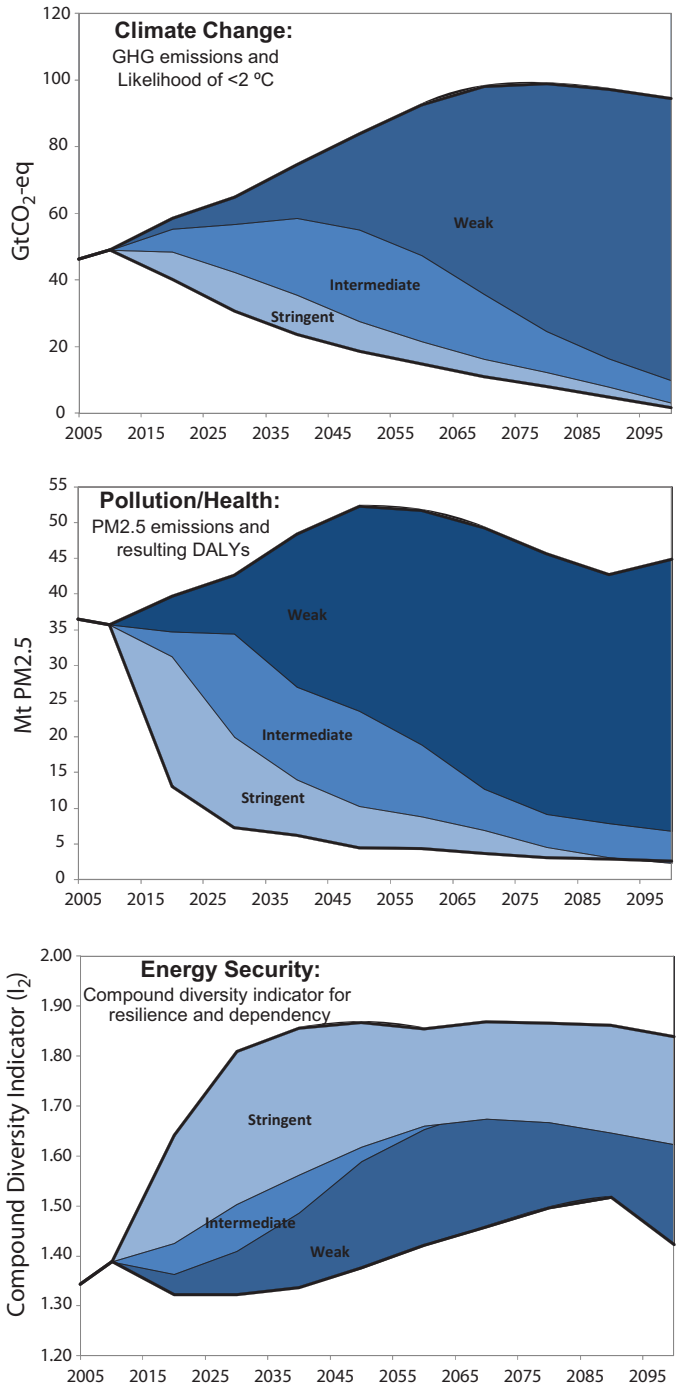

Figure 17.53 | Trajectories for global GHG emissions, PM2.5 emissions, and the compound energy diversity indicator for the full scenario ensemble. See Table 17.25 for definitions of Weak, Intermediate, and Stringent fulfillment of objectives.

decades earlier in order to preserve the feasibility of achieving the 2°C target with near 50% probability.

The middle panel of Figure 17.53 illustrates the full space of the scenario ensemble in the combined air pollution and health dimension by showing PM2.5 emissions trajectories and resulting DALYs. Particulate matter is chosen as a representative pollutant for this discussion because, as discussed in Section 17.5.2 and Chapter 4, of all types of air pollutant emissions, PM2.5 causes some of the most serious impacts on human health.[62] The emissions trajectories shown in the figure correspond to multiple pathways for energy system development under different portfolios of air pollution control policies. These policy packages are described more fully in Section 17.5.2, where further details on the assumed types of controls are provided. Moreover, whereas that section focuses in detail on the impacts of the different air pollution policies in terms of health and other environmental benefits, this section specifically examines the economic implications of combined policies. In Figure 17.53, the shaded Weak, Intermediate, and Stringent regions correspond to DALYs at the global level (the aggregate of all world regions) that would be expected in 2030 by following the ranges of PM2.5 emissions trajectories shown. The important point here is that by making a more concerted effort to control air pollution throughout the world over the next two decades, especially in the densely populated urban centers of rapidly developing countries, the collective health of the global population can be significantly improved and DALYs can be reduced quite substantially. And although these reductions might be achieved by more stringent pollution control policies and measures (i.e., end-of-pipe technologies), they may also be achieved, to some extent, through decarbonization of the energy system in response to strong climate policy. The latter point touches upon an important synergy between the climate objective and the air pollution and health objective that, although not immediately evident in Figure 17.53, is discussed in more detail later in this section. In short, by driving the energy system toward zero-carbon, emissions-free technologies, stringent climate (and indeed energy security) policies can play an important role in reducing air pollutant emissions, even under an otherwise weak pollution policy regime. In other words, fulfillment of the pollution and health objective at the Weak, Intermediate, or Stringent level depends on measures for both pollution and climate control.

The scenarios also cover a broad space in the energy security dimension, as illustrated by the bottom panel of Figure 17.53. This analysis measures energy security using the compound diversity indicator introduced in Section 17.6 (see also Chapter 5). This indicator takes into account the diversity of primary energy resources at the global level, as well as where those resources are sourced – that is, whether from imports or domestic production. The diversity indicator rises with increasing diversity of the energy system but falls at higher levels of import dependency (see further details in Section 17.6 and the electronic appendix). In this sense, the higher the diversity indicator for a given country or region, the more secure its energy system. Figure 17.53 shows how global energy system diversity develops over time in all of the scenarios of the full ensemble, with the Weak, Intermediate, and Stringent regions grouping together scenarios that fulfill the security objective to a similar degree, as outlined in Table 17.25. The lower bound of the Weak region

62 Note that in addition to PM 2.5, each scenario of the large ensemble possesses unique emissions trajectories for sulfur dioxide, nitrogen oxides, volatile organic compounds, carbon monoxide, black carbon, organic carbon, and ammonia.

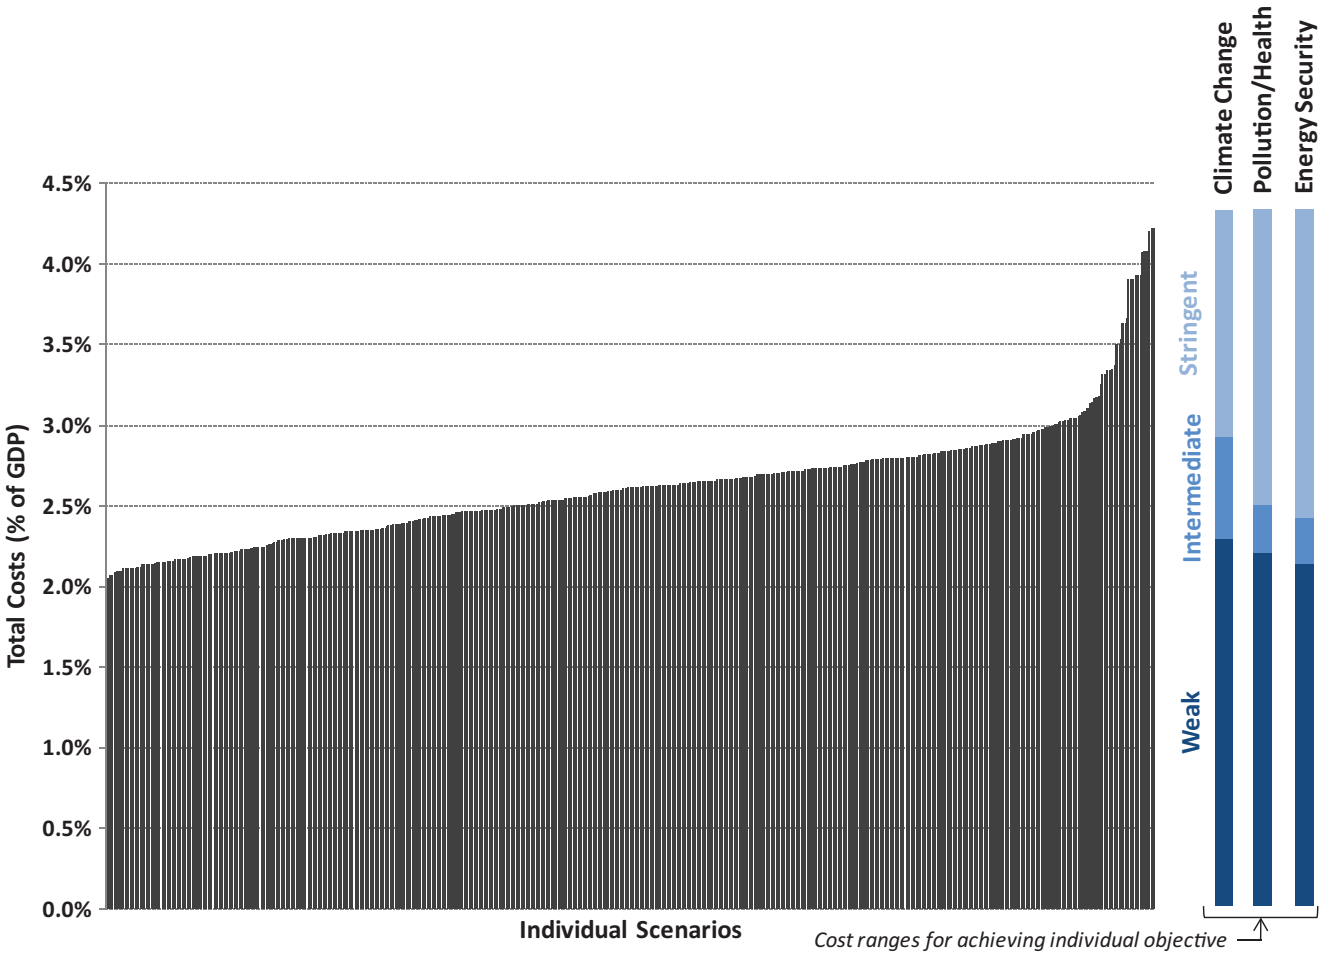

Figure 17.54 | Cumulative discounted total energy system costs for all scenarios in the full ensemble (2010–2050). Bars at right illustrate the ranges of total cost that correspond to Weak, Intermediate, and Stringent fulfillment of the climate, pollution and health, and energy security objectives.

is represented by the baseline scenario, which is obviously one of the least desirable in terms of diversity. (Nor does the baseline meet any of the other sustainability targets of the GEA, lying within the Weak region in all cases.) Compared with the baseline, virtually every other scenario, whether motivated by security or by climate policy, achieves a greater diversification of the global energy mix over time. As discussed more fully in Section 17.6, fulfilling the GEA targets for near-term energy security (the Stringent region in the figure) necessitates a global energy system that transitions to a broader portfolio of energy sources over the coming decades, while at the same time individual countries and regions (e.g., North America) come to rely less on imported energy commodities and more on domestic supplies. However, given the combination of the dominance of fossil energy in today's energy mix and the uneven distribution of fossil resource deposits around the globe, increasing energy diversity, and thus security, essentially requires that countries and regions move away from fossil energy and instead toward renewable energy sources such as biomass, wind, solar, and geothermal. Indeed, this is what emerges from the illustrative GEA pathways described previously in this chapter, as well as from the scenarios represented by the Stringent and Intermediate regions in Figure 17.53. Section 17.7.2.2 discusses this point further.

Because the individual scenarios in the ensemble vary so greatly along the dimensions of climate change, pollution and health, and energy security, total energy system costs naturally span a fairly wide range as well. This is illustrated in Figure 17.54, where each bar represents the costs of a single scenario, and the scenarios are sorted in order of increasing costs. Included in these costs is the cumulative sum between 2010 and 2050 (discounted at 5% annually) of energy system investments (including supply and demand as well as climate change mitigation, energy security, and pollution control investments), operation and maintenance, fuel, and nonenergy mitigation costs.[63] Total system costs for each scenario are then related to the cumulative discounted sum of global GDP over the same time period. The least costly scenario in the ensemble is the baseline, since it assumes no climate change mitigation, pollution control, or energy security policies other than what is already planned over the next

63 For the investment intensity of GDP, see also Section 17.3.5.

few years. Fulfillment of the GEA objectives (to any level of satisfaction) then adds to energy system costs to a certain degree. If one thinks of the multiple objectives as societal targets that the energy system should attempt to satisfy (i.e., scenario inputs), then total costs are an embodiment (i.e., scenario outputs) of the system-wide transformations that must take place in order to meet those objectives (e.g., increased utilization of advanced technologies and alternative fuels). The resulting total cost of a given scenario depends entirely on how far it goes toward satisfying each individual objective, as shown by the bars on the right side of Figure 17.54, which illustrate the ranges of scenarios, from a cost perspective, that correspond to Weak, Intermediate, and Stringent fulfillment of the climate, pollution and health, and energy security objectives. The least costly scenarios – those yielding little or no improvement in the objectives, such as the baseline – lie within the Weak region, whereas scenarios that achieve one or all of the objectives at the Intermediate or the Stringent level obviously incur costs in the middle or the upper end of the range, respectively. Notably, total costs range from 3.1–4.2% of GDP for the class of scenarios that achieves stringent fulfillment of all three objectives simultaneously. By comparison, energy system costs in the counterfactual baseline are about 2.1% of GDP over the same time period.

An important caveat to the cost analysis shown here is that it performs only a partial economic accounting. The analysis attempts to capture multiple benefits in terms of avoided or reduced costs for climate change mitigation, energy security, and pollution control. However, given the inherent difficulties in valuing human life in the economic sense, and given the vast uncertainties with respect to the economic valuation of, for example, climate-related damages, the analysis does not attempt to value other benefits of pursuing these three objectives (for a discussion of other benefits see Chapters 3, 4, and 5). For instance, the analysis does not consider the avoided costs of climate change (e.g., more frequent extreme weather events, impacts on global agriculture and food production), nor does it capture the avoided costs of adaptation to climate change (e.g., construction of sea walls, relocation of coastal populations). Similarly, the benefits accruing from reduced health expenditure and increased life expectancies have not been quantified here. Hence, the conclusions on multiple economic benefits presented in this section relate to "mitigation" costs only; they would become larger if other benefits were assigned an economic value as well.

17.7.2 Synergies between Objectives

The discussions above have already begun to show the inherent synergies, and to a lesser extent the trade-offs, among the various energy objectives and how these complex interdependencies can be illuminated through analysis of a large ensemble of possible energy futures. Among energy planners and decision makers, however, these relationships are not well enough understood. Cost trade-offs are obviously the more familiar: the greater society's aspiration for achieving the energy objectives, the larger the costs for the energy system. However, for such questions as, "How much extra might it cost to achieve each additional objective?" and "How can costs be reduced by pursuing multiple objectives?" the answers are much less clear. The discussion that follows highlights the main findings of one of the few attempts in the scenario literature to explore the important relationships among climate change mitigation, energy security, and reduced air pollution and health impacts (for further reading, see van Vuuren et al., 2006; Cofala et al., 2009; Cofala et al., 2010; Bollen et al., 2010; McCollum et al., 2011).[64]

17.7.2.1 Climate Change Mitigation and Pollution and Health

Section 17.5.1 discussed in detail how decarbonization of the global energy system, combined with energy and conservation efforts, may be instrumental in limiting climate change to safer levels. This section takes the analysis a step further, showing that climate change mitigation can also help to reduce air pollutant emissions and their corresponding impacts on human health. Put more directly, climate change mitigation can be an important entry point for achieving society's pollution- and health-related goals. This is illustrated clearly in Figure 17.55, which relates global PM2.5 emissions in the near term (to 2030) to the probability of staying below a 2°C maximum temperature rise over the course of the century. Each data point in the figure represents values for a single scenario in the ensemble. The specific combination of pollution and climate policy stringency is what distinguishes the scenarios from one another. In particular, the different levels of air pollution control policy, indicated by the varying shapes of the data points, correspond to the scenario assumptions discussed previously in the pollution section (FLE, CLE, and SLE; see Section 17.5.2).

What one first notices in Figure 17.55 is that as the energy system is decarbonized and increasing shares of zero-carbon, pollution-free technologies are utilized, the probability of meeting the 2°C target increases, and pollutant emissions are significantly reduced. Moreover, the spread between the pollution control levels narrows as climate change mitigation becomes more of a priority. (The shaded areas in the figure help to illuminate this effect.) This last point is important, as it shows how the impacts of pollution control policy are much less variable as zero-carbon technologies penetrate the market and fossil technologies are forced out. This result stems from pollution control being applicable to fewer technologies (e.g., power plants, factories, vehicles) when there is less fossil energy in the system. A final observation is that climate change mitigation measures alone can yield pollutant emissions reductions on the order of currently planned legislation for pollution control.

Figure 17.55 also illustrates the extent to which each scenario fulfills the climate and pollution and health objectives, utilizing the Weak-Intermediate-Stringent framework discussed in Section 17.7.1.

64 As a supplement to the GEA, an interactive web-based scenario development tool has been developed at IIASA, which allows members of the public to improve their understanding of how different policy choices (i.e., prioritization of certain objectives above or below others) could potentially impact the development of the global energy system over the next several decades, in terms of resources, technologies, fuels, investments and the corresponding impacts on human health and the environment. To experiment with the Multi-criteria Analysis tool, see www.iiasa.ac.at/web-apps/ene/GeaMCA.

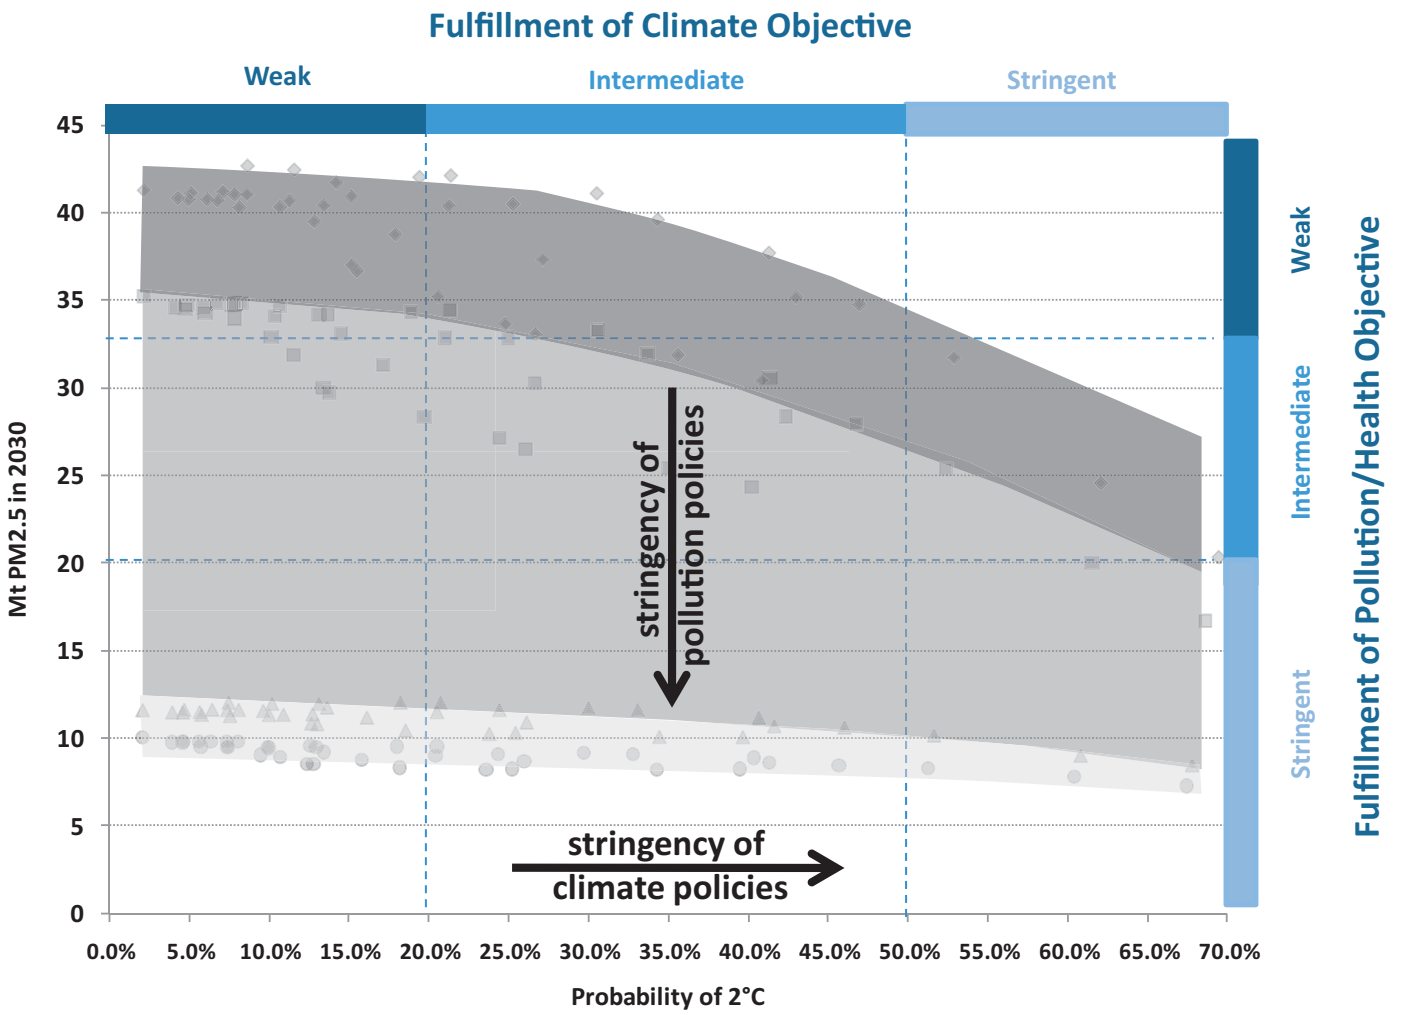

Figure 17.55 | Synergies between climate change mitigation and near-term reduction of PM2.5 emissions.

Because the core illustrative GEA pathways are designed to simultaneously satisfy all objectives at the Stringent level, they would be found in the lower-right corner of Figure 17.55. All other scenarios shown in the figure are unsustainable from the perspective of the GEA, as they satisfy the climate objective and the pollution and health objective at some other combination of levels (e.g., Weak on climate, Intermediate on pollution and health). Interestingly, the upper-right corner of the figure (corresponding to scenarios that would be Stringent on climate but Weak on pollution and health) contains not a single scenario, a result that again highlights how climate change mitigation can be an important entry point for achieving society's pollution- and health-related goals. In other words, strong climate change mitigation measures alone can yield pollutant emissions reductions that are as great as, or even greater than, currently planned pollution control legislation would likely yield in the absence of climate policy (i.e., through end-of-pipe pollution control technologies only), thereby allowing the pollution and health objective to be satisfied at the Intermediate level at a minimum. The opposite case (i.e., Weak on climate, Stringent on pollution and health) does not necessarily lead to the same conclusion, however; pollution control on its own is not likely to lead to dramatic reductions in GHG emissions. That being said, reducing key air pollutant emissions, namely, those that cause warming (black carbon and the ozone precursors methane, nitrogen oxides, carbon monoxide, and volatile organic compounds), may be able to play a modest role in mitigating climate change. The climate feedbacks of air pollution are rather complex, and although the scenarios in the large ensemble shown here assume across-the-board reductions in all pollutants, one could certainly envision control strategies in which some specific pollutants are reduced proportionally more than others (e.g., warming components are reduced more than cooling components, namely, sulfur dioxide and organic carbon), in an effort to preserve the overall cooling effect of aerosols and, thus, to produce a net gain for the climate, or to at least remain radiant energy-neutral (Cofala et al., 2009; Ramanathan and Xu, 2010).

Reducing global air pollution levels, whether through pollution control or climate policy, or both, will necessarily lead to additional energy system costs – an important trade-off that relates to policy choices and the resulting direction of the energy system. However, given the enormous co-benefits between pollution and climate policy, achieving society's pollution and health objectives through climate change mitigation as an entry point has the potential to significantly reduce the added costs of pollution control. This is illustrated in Figure 17.56, which plots pollution

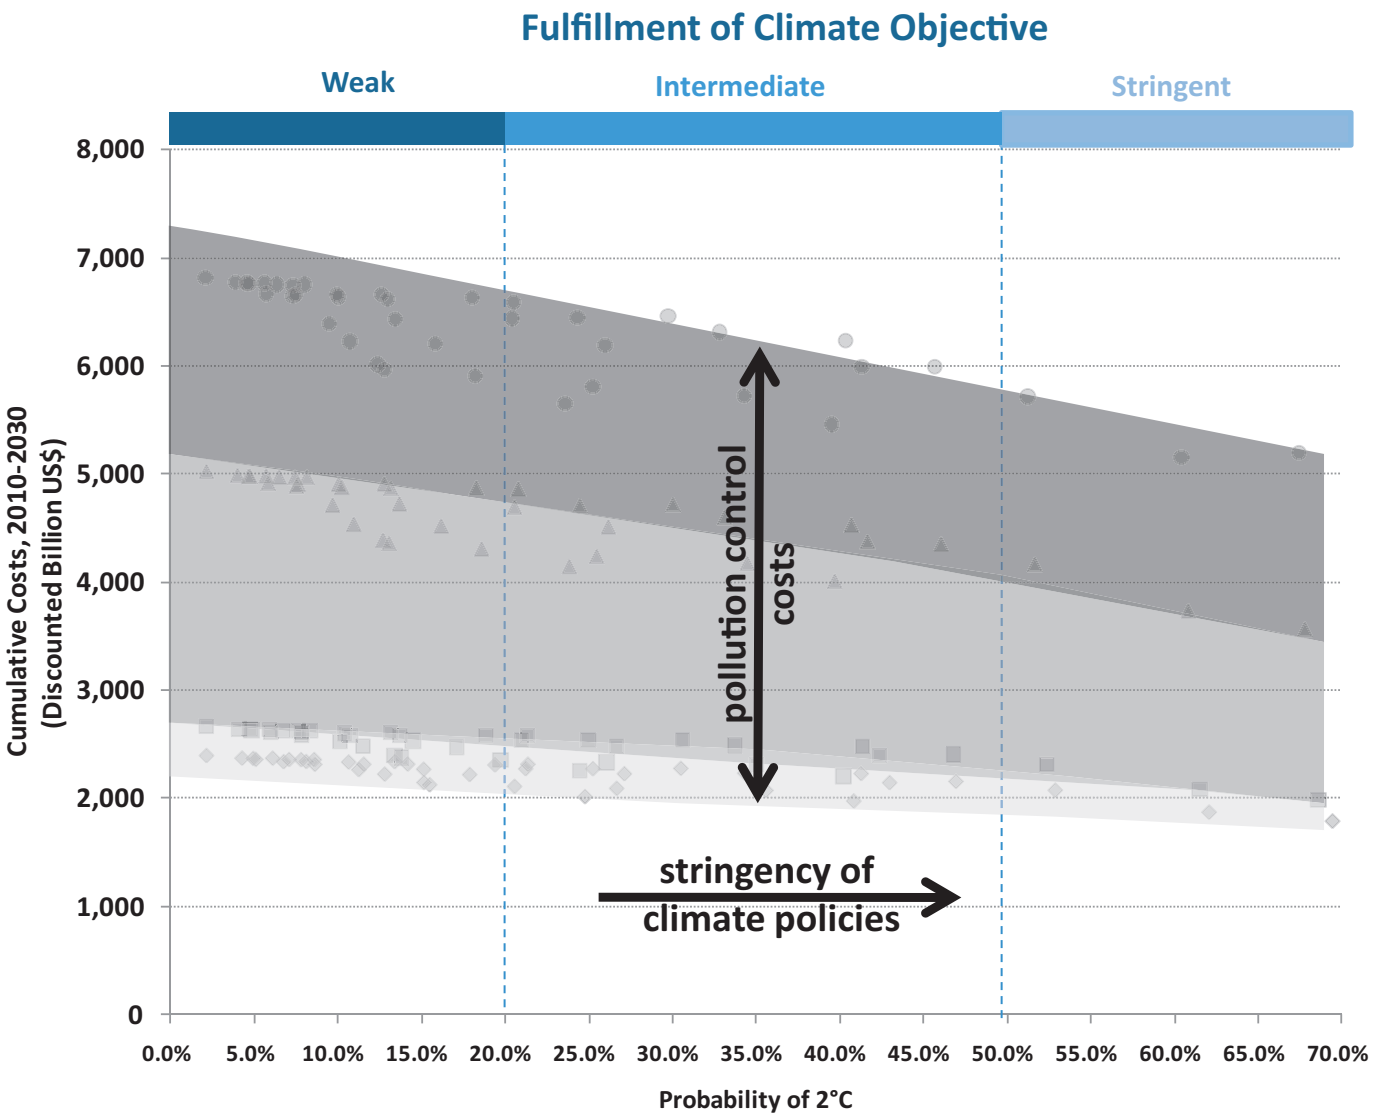

Figure 17.56 | Synergies between pollution control costs and climate change mitigation. The vertical axis represents the added costs of pollution control for each scenario in the ensemble.

control costs (relative to all other energy system costs) for each scenario in the ensemble. The data points toward the right side of the figure, particularly in the middle-right portion, are some of the most interesting, as these represent scenarios that fulfill both the climate objective and the pollution and health objective (see Figure 17.55) at the Stringent level, yet their added costs of pollution control are not much higher than in the baseline scenario (lower-left corner of the figure).

A closer look at three select scenarios of the ensemble provides a more detailed understanding of the climate-pollution-cost relationship. These three scenarios, shown in Figure 17.57, each fulfill the pollution and health objective at the Stringent level (consistent with the three illustrative sustainable GEA pathways); however, they do this by pursuing the climate objective to a greater or lesser degree (Weak, Intermediate, or Stringent fulfillment). The Weak Climate scenario represents baseline energy system development under a more stringent air pollution policy framework than would likely be realized in a typical business-as-usual future. Such a policy adds a significant US$830 billion to total annual costs in 2030, compared with US$1630 billion for all other energy system costs (including both investments and operation and maintenance) in the same year.[65] Then, as the stringency of climate policy increases, the added costs of pollution control decrease substantially, especially in the Stringent Climate scenario, where control costs are US$470 billion less than in the Weak Climate scenario, a 57% reduction.[66] This striking result, which corroborates findings from other studies (e.g., Amann et al., 2009 for Europe), shows that a significant portion of climate change mitigation costs

65 Note the uncertainties of pollution control costs in absence of climate policies. For instance, pollution control costs in the so-called CLE1 scenario in Section 17.5.2 amount to about US$600 billion in 2030. Differences are due to alternative baselines used in the two sections.

66 Generally, pollution control costs of scenarios reaching the Stringent fulfillment level are on the order of US$200 billion to US$350 billion in 2030.

can be compensated for by reduced pollution control requirements, while at the same time still allowing for the stringent fulfillment of society's pollution- and health-related targets. Furthermore, the multiple benefits of climate change mitigation also show up as avoided damage costs for the impacts of air pollutant emissions on human health, though it should be clearly stated that the synergies analysis described in this section has not attempted such an estimation.

Another noteworthy observation from Figure 17.57 relates to which sectors contribute most to the added costs of pollution control. In the Weak Climate scenario, all sectors require significant amounts of investment, with the energy conversion sector and the residential and commercial end-use sectors being responsible for the bulk of the costs. In the Stringent Climate scenario, however, end-of-pipe pollution control requirements decrease substantially in all sectors.

In sum, when viewed from a holistic and integrated perspective, the combined costs of climate change mitigation and pollution control come at a significantly reduced total energy bill if the benefits of pollution reduction are properly figured into the calculation of GHG abatement strategies (see also Nemet et al., 2010). The design of cost-effective future policies, therefore, would benefit by integrating holistic portfolios of measures that address both pollution and climate objectives simultaneously. This is, of course, no simple task, given that in many countries air pollution and climate change are dealt with by separate policy institutions. For this reason the enormous co-benefits of the two objectives are often overlooked, and the costs of reaching each objective individually are often overstated (Amann, 2009). In terms of the technology mix, a robust finding of the analyses summarized in this chapter is that a key strategy for meeting both climate and pollution and health objectives is to increase the utilization of efficiency measures as well as zero-carbon, pollution-free energy technologies, such as nuclear and renewable energy.

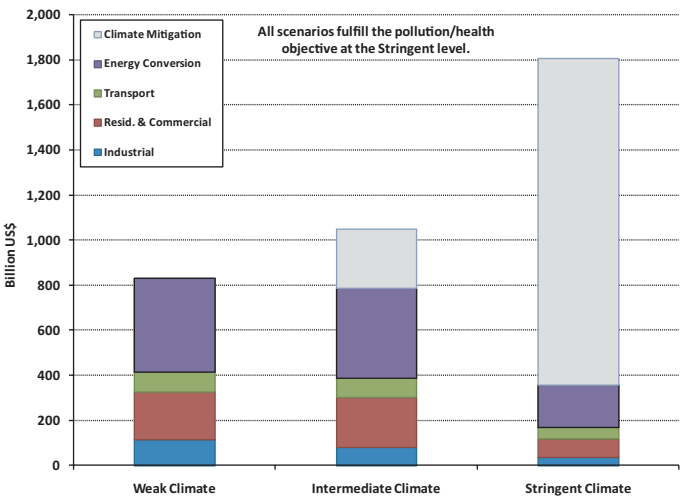

Figure 17.57 | Global annual pollution control and climate change mitigation costs for Weak, Intermediate, and Stringent climate policy scenarios in 2030. The Stringent Climate scenario achieves the 2°C target with a comparatively high probability of >60% and thus represents an upper-bound estimate for climate change mitigation costs and pollution control co-benefits across the GEA pathways.

17.7.2.2 Climate Change Mitigation and Energy Security

The previous discussion has shown that early deployment of zero-carbon technologies can help to achieve both near-term pollution and long-term climate targets. In addition, this analysis finds that there are important synergies between decarbonization and energy security, yet another key near-term objective. In short, as countries and regions invest more heavily in renewables in an effort to decarbonize their economies, they will by extension reduce their need to import globally traded fossil energy commodities such as coal, oil, and natural gas. Because renewables (biomass, hydro, wind, solar, and geothermal) can potentially be produced almost entirely domestically (or at least regionally within a cluster of like-minded countries), they are from a dependency perspective inherently secure resources. Moreover, increased utilization of renewables and nuclear energy tends to diversify the energy resource mix away from one that relies so heavily on fossil energy. Thus, decarbonization of the energy system can simultaneously reduce import dependence and increase energy diversity, both of which are key indicators of a more secure energy supply (see Chapter 5 on energy security). In fact, the results of this analysis indicate that the most "secure" scenario, from the perspective of both diversity and trade, is one in which all regions pursue very stringent policies that promote both climate change mitigation *and* reduced import dependence.

Figure 17.58 illustrates the relationship between the climate and security objectives by showing global primary energy diversity and dependence in 2030 (measured in terms of the compound SWDI, introduced in Section 17.6.2) as a function of the probability of staying below the 2°C warming target. The third dimension captures several alternative policy levels representing the varying stringency of efforts to limit import dependency by individual world regions; these levels are grouped together by the shaded areas. Note that all the scenarios are identical with respect to the stringency of air pollution legislation that is assumed. Figure 17.59 focuses on costs, plotting the probability of meeting the 2°C target against cumulative total global policy costs as a share of global GDP between 2010 and 2030. Total policy costs, calculated relative to the baseline scenario, attempt to capture the added costs of energy security, climate change mitigation, and air pollution control policies.[67]

The double effects of decarbonization and reduced import dependence are quite clear from Figures 17.58 and 17.59. As regions pursue strategies to mitigate climate change or enact policies and procurement strategies that prioritize domestic supplies over imports, the diversity of

67 Costs include energy system investments, pollution control investments, operation and maintenance, fuel, nonenergy mitigation, and demand reduction (i.e., the macroeconomic response).

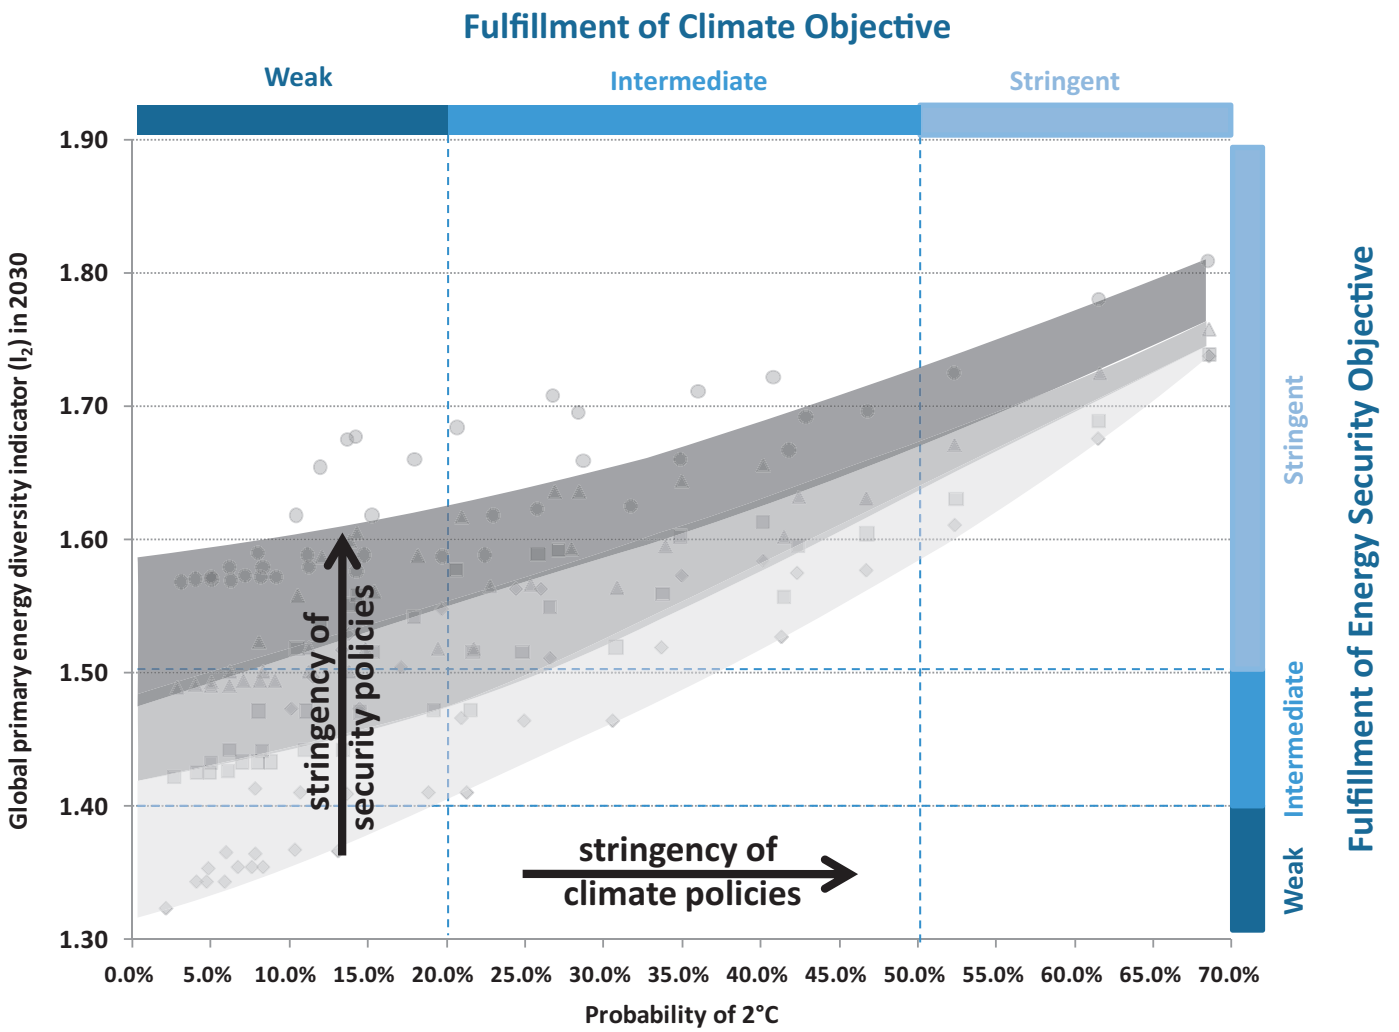

Figure 17.58 | Synergies between near-term energy security policies and climate change mitigation.

their energy resource mix is likely to increase. Naturally, pushing both the climate and security objectives adds to total energy system costs; yet, as in the relationship between climate change mitigation and pollution control, at higher levels of decarbonization, the costs of security are significantly reduced, highlighting the synergies and multiple benefits of the two objectives. As Figure 17.59 illustrates, when climate change is of relatively low priority (the Weak climate region), security costs can increase total system costs by as much as 0.2 percentage points. Conversely, under Stringent climate policies, the added costs of security approach zero.

Figure 17.60 takes a deeper look into the climate-security-cost relationship by summarizing energy security costs for three alternative pairs of scenarios.[68] The scenarios in each pair fulfill the climate objective to the same degree (Weak, Intermediate, or Stringent). What distinguishes them is the level at which the two scenarios in a given pair satisfy the energy security objective; hence, the difference in their costs represents the added costs of security. For instance, under a Weak Climate regime, as envisioned in a business-as-usual future, this cost premium, in terms of globally aggregated annual energy system investments, is approximately US$160 billion in 2030. By comparison, under an Intermediate or a Stringent Climate regime, the added costs of security decline significantly, to just US$64 billion and US$28 billion/year, respectively (reductions of 61% and 84% compared with the Weak Climate case). As evidenced by Figure 17.60, security policy, applied at the level of individual countries and groups of countries, primarily spurs additional investments in end-use efficiency and electricity generation, while at the same time lower the global investment requirements for upstream energy extraction (coal mining and oil production). The security co-benefits that stem from climate change mitigation are then largely attributed to the reduced need for extra "security investments", since climate policy promotes energy efficiency and conservation and the increased utilization of domestically produced, low-carbon energy sources. Of course, climate policy itself also adds to the total energy bill, as is shown separately in Figure 17.60 for comparison. Climate change mitigation costs are clearly quite substantial, although it is important to note that the cost accounting for climate policy is more comprehensive than that shown for security, which captures

68 Each scenario incorporates the same assumptions for the stringency of air pollution legislation (CLE level). See the pollution section for more information.

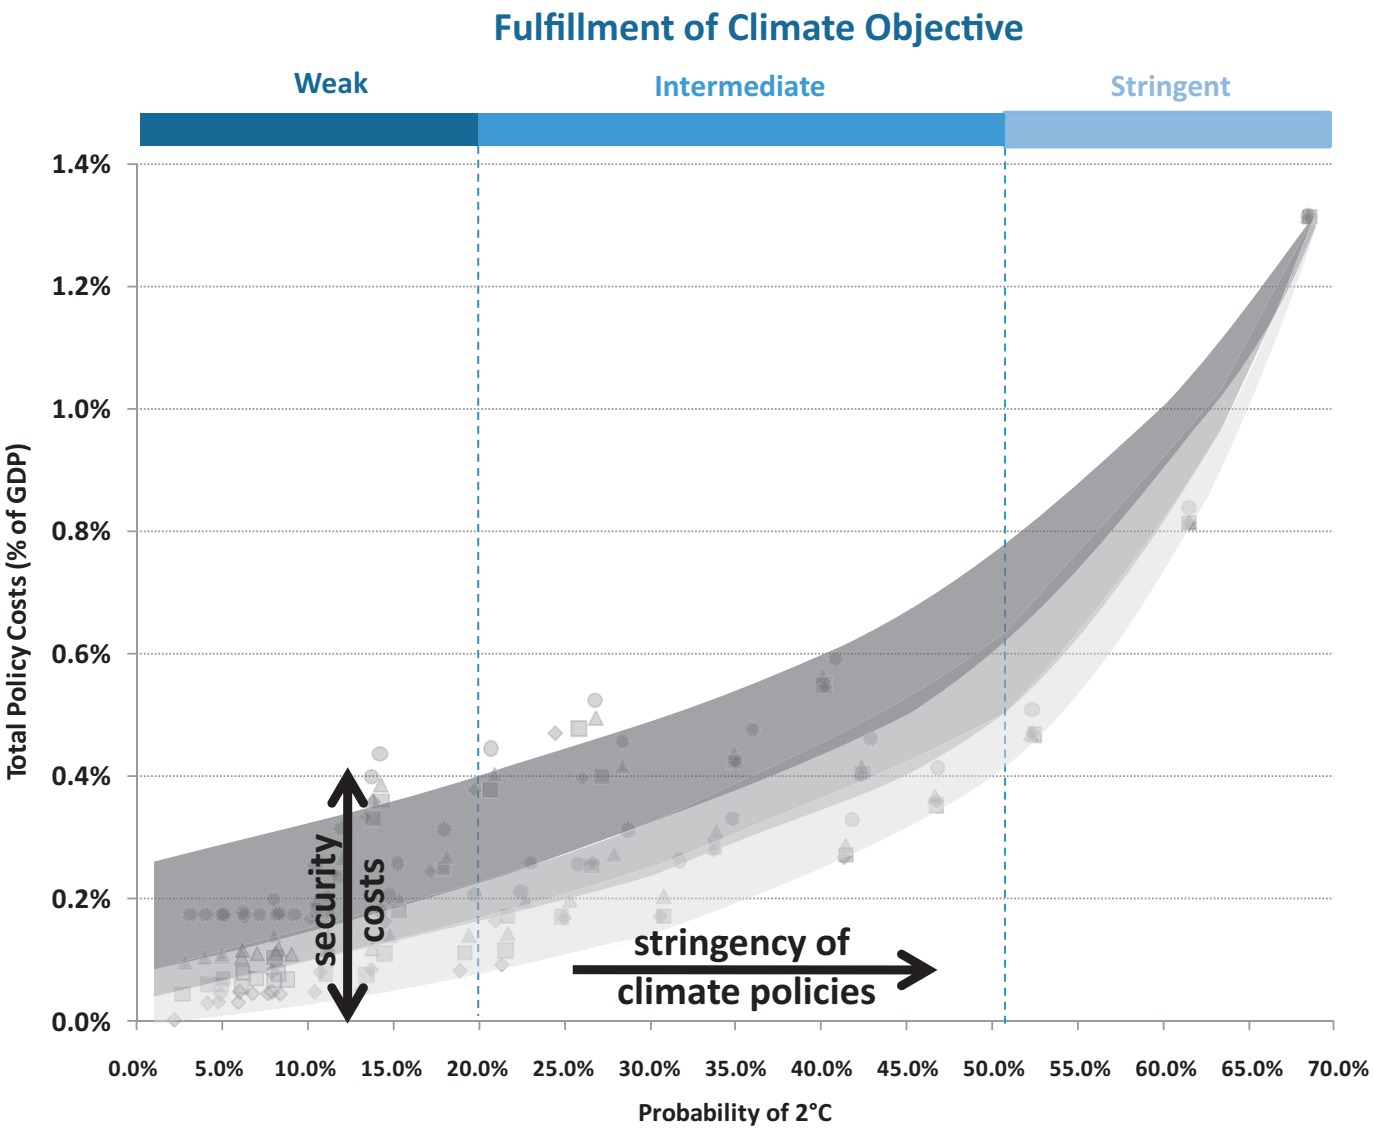

Figure 17.59 | Total global policy costs of simultaneously achieving energy security and climate objectives to varying degrees. Cumulative discounted costs from 2010 to 2030, relative to baseline.

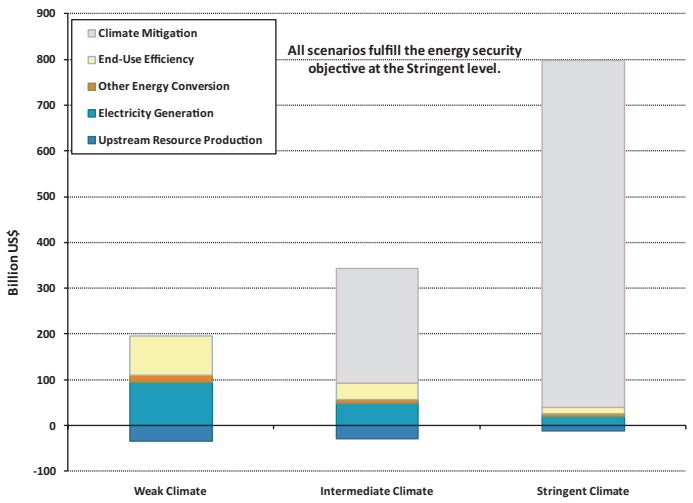

Figure 17.60 | Global annual energy security investment and climate change mitigation costs for Weak, Intermediate, and Stringent climate policy scenarios in 2030.

only investments. In the figure, climate change mitigation costs refer to all costs beyond those motivated by security policy, including investments in low-carbon technologies and their associated variable costs, as well as the costs associated with demand reduction (energy efficiency investments and conservation efforts) and nonenergy GHG mitigation measures. The bottom line is that, as with the climate-pollution-cost relationship, when viewed from a holistic and integrated perspective, the combined costs of climate change mitigation and energy security come at a significantly reduced total energy bill when the benefits of security are properly figured into the calculation of GHG abatement strategies.

17.7.3 Conclusion

The energy system of the future could potentially develop in a number of different directions, depending on how society and its decision makers prioritize various worthwhile energy objectives, including, but not

limited to, climate change mitigation, energy security, and air pollution and human health. These objectives are generally discussed in the context of different time frames (security and pollution and health in the near term, climate in the medium to long term). For this reason, they frequently compete for attention in the policy world. An added challenge is that in many countries, separate policy institutions are responsible for dealing with each of the multiple objectives. As a result, the important synergies between them are not well enough understood, or are simply overlooked, and the costs of reaching each objective individually are often overstated.

In short, by adopting a holistic and integrated perspective that addresses all of the objectives simultaneously, the analysis described in this section clearly indicates that cost-effective climate-pollution-security policies are likely to lead to substantial co-benefits, in terms of costs avoided and the achievement of societal objectives for sustainability. First, fulfillment of near-term pollution and health goals at the Stringent level is greatly furthered by climate change mitigation. Under stringent climate policy scenarios, for instance, globally aggregated DALYs can be reduced by up to 22 million in 2030. At the same time, stringent climate policy can help to further the energy security goals of individual countries and regions by promoting the increased utilization of domestically available renewable energy sources that are both more dependable and more resilient than imports of fossil energy commodities. Such a strategy would lead to the diversification of a given region's supply mix, a widely acknowledged approach for achieving security. Both of these findings illustrate how climate change mitigation can be an important entry point for achieving society's pollution- and health-related goals. Moreover, the combined costs of climate change mitigation, energy security, and air pollution control come at a significantly reduced total energy bill if the multiple benefits of each are properly accounted for in the calculation of total energy system costs. For instance, the total added costs of pollution control at the global level are cut significantly (by up to US$500 billion annually in 2030 compared to a baseline scenario) as the stringency of climate policy increases and the utilization of zero-carbon, pollution-free (thus, pollution control-free) technologies rises. Similarly, security costs also decrease substantially under increasingly aggressive levels of decarbonization, and in scenarios with very stringent climate policies, the added costs of security actually approach zero (translating to an annual cost savings of more than US$130 billion in 2030). Although steps taken to mitigate climate change will themselves add to total energy system costs compared with a baseline scenario (a key trade-off), these climate costs will be substantially compensated for by the corresponding cost reductions for pollution control and energy security (key synergies).

Other economic benefits of rapidly decarbonizing the energy system are the reduced need for subsidies into carbon-intensive petroleum products and coal. Following the IEA (2009b) and Coady et al. (2010) subsidies from these fuels amount at present to about US$132 billion to US$240 billion/year. Just 15% of this total is spent directly for the poor who have limited access to clean energy. As noted in Section 17.4, subsidies for the poor must be increased in order to achieve universal access. GHG mitigation in the GEA pathways would, however, at the same time reduce consumption of carbon-intensive fossil fuels by the rest of the population, leading to a reduction in the need for subsidies for oil products and coal on the order of US$70 billion to US$130 billion/year by 2050 compared with today.

Many other benefits of the energy transformation have not been assigned economic values in detail here but are important to account for as well. As illustrated in this section and earlier, in Section 17.5.2, the health benefits of the transformation can be significant. In addition, pollution control reduces damages to vegetation and may result in significant benefits for land productivity by avoiding eutrophication and acidification (see Chapter 3). As discussed in Chapter 19 and in Section 17.4, universal access to electricity and clean cooking not only leads to significant health benefits, but also increases the productivity of the poorest, thus contributing to well-being and more equitable economic growth. In addition, limiting the global temperature rise to less than 2°C compared with preindustrial times reduces the risks for a number of different types of climate impacts, summarized by five main reasons for concern (Smith et al., 2009; see also Chapter 3): (i) the risk to unique or threatened systems; (ii) the risk of increases in extreme weather; (iii) the distribution of impacts (and the disparities of those impacts, given that some regions, countries, and populations may face greater harm from climate change); (iv) aggregate damages (assessing comprehensive measures of impacts through efforts to aggregate into a single metric, e.g., monetary damages); and (v) the risk of large-scale discontinuities (e.g., possible tipping points associated with very large impacts such as deglaciation of the West Antarctic or the Greenland ice sheet). Finally, rapid decarbonization, which leads to a stronger reliance on efficiency and zero-carbon energy (e.g., renewables), may create new job opportunities and thus provide additional economic benefits.

Realizing the multiple benefits of the energy transformation requires, however, a holistic and integrated approach that addresses a diverse set of objectives simultaneously. Although the GEA pathways have shown that such a transformation is in principle technically possible, the task remains extremely ambitious and will require rapid introduction of policies and fundamental political changes that lead to concerted and coordinated efforts to integrate global concerns, such as climate change, into local and national policy priorities such as health and pollution, access to clean energy, and energy security.

Executive Summary

More than 50% of the global population already lives in urban settlements and urban areas are projected to absorb almost all the global population growth to 2050, amounting to some additional three billion people. Over the next decades the increase in rural population in many developing countries will be overshadowed by population flows to cities. Rural populations globally are expected to peak at a level of 3.5 billion people by around 2020 and decline thereafter, albeit with heterogeneous regional trends. This adds urgency in addressing rural energy access, but our common future will be predominantly urban. Most of urban growth will continue to occur in small- to medium-sized urban centers. Growth in these smaller cities poses serious policy challenges, especially in the developing world. In small cities, data and information to guide policy are largely absent, local resources to tackle development challenges are limited, and governance and institutional capacities are weak, requiring serious efforts in capacity building, novel applications of remote sensing, information, and decision support techniques, and new institutional partnerships. While 'megacities' with more than 10 million inhabitants have distinctive challenges, their contribution to global urban growth will remain comparatively small.

Energy-wise, the world is already predominantly urban. This assessment estimates that between 60–80% of final energy use globally is urban, with a central estimate of 75%. Applying national energy (or GHG inventory) reporting formats to the urban scale and to urban administrative boundaries is often referred to as a 'production' accounting approach and underlies the above GEA estimate. This contrasts to a 'consumption' accounting approach that pro-rates associated energy uses per unit of urban consumer expenditures, thus allocating energy uses to urban consumers irrespective of the form energy is used (direct or embodied energy) or its location (within or outside a city's administrative boundary). Available consumption-based energy accounts for cities are too limited (estimates exist for only a handful of megacities) to allow generalization but it is highly likely that urban energy use under a consumption accounting approach approximates the urban share in the world GDP, estimated by this assessment to be some 80%. There is great heterogeneity in urban energy-use patterns as revealed by this assessment drawing together a novel urban energy use data set. In many developing countries, urban dwellers use substantially *more* final energy per capita than their rural compatriots. This primarily reflects their much higher average urban incomes. Conversely, in many industrialized countries per capita final energy use of city dwellers is often *lower* than the national average, which reflects the effects of compact urban form, settlement types (multi- versus single-family dwellings) and availability and/or practicability of public transport infrastructure systems compared with those in the suburban or rural sprawl. The few available data, however, suggest that urban energy use in high-income countries is not substantially different from the national average when using a consumption-based accounting approach, whereas in low-income countries the urban-rural energy difference is likely to be even larger under this alternative energy accounting method. This Assessment concludes that both accounting methodologies provide complementary, valuable information to inform urban policy decisions. However, because of complexities in systems boundaries and accounting, urban studies need to adhere to high standards in terms of clarity and documentation of the terminology, methodology, and documentation of underlying energy data used.

Addressing Urban Challenges

Rapid migration rates and natural population growth in cities can overwhelm the provision of basic urban services, particularly for the poorest urban dwellers. Several hundred million urbanites in low- and middle-income nations lack access to electricity and are unable to afford cleaner, safer fuels which results in significant adverse consequences for human health and local air quality. Most are in low-income nations in Southeast Asia and sub-Saharan Africa. Innovations have reduced access costs – for instance, rising tariffs with low prices for 'lifeline' consumption, pay-as-you-use meters, and standard 'boards' that remove the need for individualized household wiring—but urban energy access also faces political and institutional obstacles. A large part of the urban population that lack clean energy and electricity (and other basic services like water, sanitation, and transport) live in informal settlements. It is mostly in situations where the often antagonistic relationship between local government and the inhabitants of informal

settlements has changed, through widespread public support to upgrade 'slums' and squatters, that clean energy and electricity and other public services have reached the urban poor.

Housing, water supply and sanitation infrastructure, energy, and transport services are the key sustainability challenges to accommodate some three billion additional urban dwellers in the decades to come, especially in low-income countries. Informal settlements will often be one of the transitional forms of settlement for many of these new urban dwellers and will require a much more proactive, anticipatory policy approach, especially with respect to the location of informal settlements and subsequent infrastructure connections and upgrading programs. Energy-wise, low-cost and fast implementation options will take precedence over 'grand' new urban designs that require unrealistically large sustained capital provision over long periods. In low-income countries access to clean cooking fuels and electricity, as well as pro-poor transport policies, which include safer use of roads by non-motorized modes (walking and bicycling) and making public transport choices available need to be ranked high on the urban policy agenda.

From all the major determinants of urban energy use – climate, position in the global economy, consumption patterns, quality of built environment, urban form and density (including transport systems), and urban energy systems and their integration – only the final three are amenable to policymaking by city administrations, at least partially. Therefore, both in terms of leverage and potentials, energy policy at the urban scale needs to focus above all on *demand management* with a focus on energy efficient buildings, structuring urban form and density conductive to energy efficient housing forms, high-quality public transport services, and to urban energy systems integration. This demand-side focus at the urban scale represents a paradigm shift compared to the traditional, more supply-side energy policy focus at the national scale.

Systemic characteristics of urban energy use are generally more important determinants of the efficiency of urban energy use than those of individual consumers or of technological artifacts. For instance, the share of high occupancy public and/or non-motorized transport modes in urban mobility is a more important determinant of urban transport energy use than the efficiency of the urban vehicle fleet (be it buses or hybrid automobiles). Denser, multifamily dwellings in compact settlement forms with a corresponding higher share of non-automobile mobility (even without thermal retrofit) can use less *total energy* than low-density, single-family 'Passivhaus'-standard (or even 'active,' net energy generating) homes in dispersed suburbs deploying two hybrid automobiles for work commutes and daily family chores. Evidently, urban policies need to address both systemic and individual characteristics in urban energy use, but their different long-term leverage effects should structure policy attention and perseverance. In terms of urban energy-demand management, the quality of the built environment (buildings efficiency) and urban form and density that, to a large degree, structure urban transport energy use are roughly of equal importance. Also, energy-systems integration (cogeneration, waste heat cascading) can give substantial efficiency gains, but ranks second after buildings efficiency and urban form and density, and associated transport efficiency measures, as shown both by empirical cross-city comparisons and modeling studies commissioned by this assessment. The potential for energy-efficiency improvements in urban areas remains enormous, as indicated by corresponding urban exergy analyses reviewed in this Assessment and that suggest urban energy-use efficiency is generally less than 20% of the thermodynamic efficiency frontier; representing an improvement potential of more than a factor five. Conversely, the potential of supply-side measures within the immediate spatial and functional confines of urban systems is very limited, especially for renewable energies. *Locally harvested* renewables can, at best, provide 1% of the energy needs of a megacity and a few percentage points in smaller, low-density cities because of the mismatch between (high) urban energy demand density and (low) renewable energy supply densities at the local level.

Urban Policy Choices and Priorities

The historical evolutionary processes that govern urban growth have largely been *path dependent* with variation that played out differently over time and space. Cities that evolved along alternative pathways have alternative

density levels from high-density 'Asian' (e.g., Tokyo, Shanghai, Mumbai) and 'old European' (e.g., London, Madrid, Warsaw) to low density 'new frontier' (e.g., Los Angeles, Brasilia, Melbourne) pathways, each of which have different structural options available to improve energy efficiency and optimize urban energy and transport systems in terms of sustainability criteria. Despite this diversity, two important generalizations can be drawn.

First, the implications of urban density on the requirements of urban energy systems are that they need to be basically *pollution free*, as otherwise even relatively clean energy forms can quickly overwhelm the assimilative capacity of urban environments. This especially applies to the million, decentralized energy end-use combustion devices (stoves, heating systems, vehicles) for which end-of-pipe pollution control is often not an option. Thus, in the long-term all end-use energy fuels burnt in urban areas need to be of zero-emission quality. This requires energy vectors from remote 'clean' plants, as exemplified by electricity or (possibly) hydrogen. Natural gas plays the role of the transitional fuel of choice in many urban areas. This 'zero-emission' requirement for urban energy transcends the customary sustainability divide between fossil and renewable energies, as even 'carbon-neutral' biofuels when used by millions of automobiles in an urban environment will produce unacceptable levels of NO_x or O_3 pollution. The observed significant improvements in urban air quality caused by the elimination of traditional air pollutants, such as soot, particles, and SO_2, in cities of high-income countries are a powerful illustration that cities act as innovation centers and hubs for environmental improvements that can lead to a sustainability transition path. First signs of progress in traditional air pollutants are evident in low-income countries as well, as illustrated by the recent decline in the emissions of some traditional pollutants in Asian megacities discussed in this assessment. Nonetheless, an exceedingly high fraction of urban dwellers worldwide are still exposed to high levels of urban air pollution, especially total suspended particles (TSPs), with fine particle emissions (PM-10s) continuing their upward trend. A wide portfolio of policy options is available, ranging from regulatory instruments such as mandated fuel choice ('smokeless zone' regulations), air-pollution standards, regulation of large point-source emissions and vehicle exhaust standards, to market-based instruments (or hybrid) approaches that incentivize technological change. An important feature of these regulatory approaches is *dynamic target setting* to reflect changing technology options and to counter the consequences of urban growth and potential consumer 'take-back' effects. Air pollution is also the area of urban environmental policymaking where the most significant co-benefits of policies can be realized: improving access to clean cooking fuels, for example, improves human health and lowers traditional pollutant emissions, and also has (through reduced black carbon emissions) significant net global warming co-benefits.

Second, the literature repeatedly identifies important size and density thresholds as useful guides for urban planning. The importance of these urban thresholds extends to specialized urban infrastructures, such as underground (metro) transport networks that are, as a rule, economically (in terms of potential customers and users) not feasible below a threshold population size of less than one million. It also extends to energy (e.g., cogeneration-based district heating and cooling) and public transport networks, whose feasibility are framed by a gross[1] population density threshold between 50 and 150 inhabitants/hectare (ha) (5000–15,000 people/km^2). Such density levels of 50–150 inhabitants/ha certainly do *not* imply the need for high-rise buildings, as they can be achieved by compact building structures and designs, both traditional and new, including town or terraced houses, while still allowing for open public (parks) or private (courtyard) spaces – but they do not allow for unlimited (aboveground parking) spaces for private vehicles. Zoning and parking regulation, combined with public transport policies and policies that promote non-motorized transport modes and walkability thus constitute the essential 'building blocks' of urban energy efficiency and sustainability 'policy packages.'

1 i.e., a minimum density level over the entire settlement area that comprises residential zones of higher density with low density green spaces.

The wide variation in urban transport choices observed in the modal split in different cities illustrates that urban mobility patterns are not *ex ante* given, but rather result from specific choices of individuals and decision makers. Urban transport choices can be modified, if both a strong determination for a sustainable urban transport policy *and* a corresponding wide public acceptance of the overall goals of such a policy exist. Restrictive measures that limit individual mobility by automobiles need to be complemented by proactive policies that enhance the attractiveness of non-motorized and public transport choices, and 'soft' policy measures (e.g., fees, tariffs) also need to be complemented by 'hard' (i.e., infrastructural investment) measures. Investments in public transport systems need to find an appropriate balance between improvements that are less capital intensive and faster to implement, and radical solutions. Bus-based Rapid Transit systems (BRT) with own dedicated lanes are, therefore, a much more attractive option for many cities in low-income countries than are capital-intensive subway or light-rail systems, even though, in the long term, the latter offer the possibility of higher passenger fluxes and greater energy efficiency. Often there is no contradiction between incremental versus radical public transport policy options: for instance, BRT can also be considered as a transitional infrastructure strategy to secure public transport 'rights of way,' which offer subsequent possibilities for infrastructure upgrades, for example in putting light rail systems in BRT lanes. Many of the new urban settlements being formed meet the required density targets for attractive and efficient public transport systems. The policy issue is to exploit the available advantages before a 'lock-in' into a private automobile-dependent 'vicious' development cycle becomes entrenched.

A common characteristic of sustainable urban energy system options and policies is that they are usually systemic: for example, the integration of land-use and urban transport planning that extends beyond traditional administrative boundaries; the increasing integration of urban resource streams, including water, wastes, and energy, that can further both resource (e.g., heat) recovery and improve environmental performance. This view of a more integrated (and often also more decentralized) urban infrastructures also offers possibilities to improve the resilience and security of urban energy systems. And yet, this systemic perspective reveals a new kind of 'governance paradox.' Whereas the largest policy leverages are from systemic approaches and policy integration, these policies are also the most difficult to implement and require that policy fragmentation and uncoordinated, dispersed decision making be overcome. The urban governance paradox is compounded by weak institutional capacities, especially in small- to medium-sized cities that are the focus of projected urban growth, as well as from the legacies of market deregulation and privatization that have made integrated urban planning and coordinated energy, transport, and other infrastructural policy approaches more difficult to design and yet more difficult to implement. However, there are good reasons for (cautionary) optimism. Urban areas will continue to act as innovation centers for experimentation and as diffusion nodes for the introduction of new systems and individual technological options by providing critical niche market sizes in the needed transition toward more sustainable urban energy systems.

18.1 Introduction

18.1.1 Preamble

Towns and cities and their increasing coalescence into urban agglomerations are now the dominant form of spatial organization in which people live, economies operate, technologies are generated and used, corresponding demands for *energy services* arise and environmental sustainability is critically defined. The decade 2000–2010 marked an important watershed in human history: for the first time more than 50% of the global population are urban dwellers and estimates indicate that already some three-quarters of global (direct) final energy use is urban, with corresponding primary energy and carbon dioxide (CO_2) emissions probably being comparable.

Given the robust trends toward a convergence of much of the developing world to levels of urbanization already found in the developed world, the energy and sustainability challenges of equitable access to clean-energy services, of energy security, and of environmental compatibility at local through global scales cannot be addressed without explicit consideration of urban energy systems and their specific sustainability challenges and opportunities. The future development of the demand side for energy cannot be described without understanding changes at the level of the urban settlements. Research shows how the properties of urban areas across the world are scalable, revealing distinct patterns. Just as it is possible 'to fail to see the forest for the trees,' it is possible 'to fail to see the city for the buildings.' Hence the GEA includes a specific chapter on urbanization and urban energy use.

Paradoxes in conventional analysis abound. A single urban agglomeration, such as greater Tokyo, generates more gross domestic product (GDP) than the venerable pioneer country of the Industrial Revolution – the current United Kingdom. And yet, our statistical reporting systems almost exclusively focus on nation states, as represented by Systems of National Accounts, Energy Balances, or similar reporting standards. In fact, as detailed throughout this chapter, the difficulty of finding data at the urban level starts with the very definition of urban areas and urban populations. The study of urban energy must take this diversity and uncertainty into account. Accordingly, this chapter draws attention to the limits of comparability and policy guidance of existing studies that suffer from inconsistent or unclear system boundaries and accounting methodologies, and concludes with the need to develop clear methods and guidelines for a range of complementary urban energy accounting tools to guide policy. The energy-accounting system boundary issue thus adds to the conundrum of different territorial and administrative boundaries that range from core cities through metropolitan agglomerations to transnational urban corridors.

In this chapter the terminology used is of an 'urban system' when describing the urban phenomenon from a *functional* perspective in addition to the traditional territorial or administrative perspective. Thus, an *urban energy system* comprises all components related to the use and provision of energy services associated with a functional urban system, irrespective where the associated energy use and conversion are located in space, such as power plants and transport fuel requirements both locally and internationally (airports, ports). The full urban energy system entails both energy flows proper (fuels, 'direct' energy flows) and 'embodied' energy (energy used in the production of goods and provision of services *imported* into but also *exported* from an urban system). The functional perspective of urban energy systems highlights that urban locations and their growth (urbanization) are not only the locations of people and economic activities in space, but also include the types of activities they pursue and the infrastructural and functional framing conditions (service functions) urban agglomerations provide. Functional characteristics increasingly define urban areas and need to be reflected in urban energy systems analysis, and thus need to combine both 'production' and 'consumption' perspectives. From a spatial perspective, this chapter also extends – within the limits of available data – the traditional discussion of cities as defined by political and/or administrative boundaries toward urban agglomerations, including 'periurban' and larger metropolitan areas, through urban 'clusters' or 'corridors' to Doxiadis' (Doxiadis and Papaioannou, 1974) 'ecumenopolis.'

The future development of urban energy systems is characterized by specific challenges and opportunities. The high density of population, economic activities, and resulting energy use severely limit an obvious sustainable energy choice: In many larger cities locally harnessed renewables can provide for only some *one per cent* of urban energy use which implies large-scale *imports* of renewable energies generated elsewhere, much like in the currently dominating fossil energy systems. The diversity of activities and energy uses characteristic of urban systems opens numerous opportunities for intelligent energy management and 'recycling' (e.g., electricity-heat cogeneration and 'heat cascading', in which different energy end uses can 'feed' on waste energy flows from energy conversion and industrial applications). Both *diversity and density* (at least above a critical threshold value of some 50–150 inhabitants/ha) can be considered as key *strategic assets* of urban areas that help to use energy more efficiently by energy-systems integration, compact energy-efficient housing, and co-location of activities that can help to minimize transport distances and automobile dependence. The provision of transport services via environmentally friendly, high-quality urban public transport systems is a unique option for cities, generally not available in low-density sub-urban or rural contexts.

The vital urban infrastructures all depend on energy: water supply, treatment and waste water disposal, transport and communication systems, complex webs of food and material supplies, the resulting disposal of wastes, and, of course, energy supply itself. Many urban infrastructures have shown great adaptability, but catastrophes like hurricane Katrina, or the 9/11 attacks on New York, show that urban systems and, by extension, their populations are vulnerable. Urban infrastructures are almost always considered in isolation, but this ignores their interdependence, and common vulnerabilities, as well as their potential synergies and efficiency gains. This highlights the importance of improved planning, but

this will require new institutional frameworks and the inclusion of different stakeholders to address the complex coordination issues across sectors and across spatial scales.

Urban agglomerations are dominant in terms of production, consumption, and associated energy use (irrespective of where these take place physically). But they are also unique centers of human capital, ingenuity and innovation, financial resources, and local decision-making processes, which are all 'human' resources that can be harnessed for a sustainability transition. While global and national policy frameworks are clearly needed, ultimately all implementation is *place-based* and requires local formal and informal supportive frameworks. To promote more sustainable development, cities may thus be the right scale for an 'intermediate' (even mediating) actor level between the individual and national and transnational initiatives. The urban scale is also the appropriate one to identify and realize many options in promoting energy efficiency that may not always be apparent at higher levels of policymaking.

Cities thus could become *the* innovation centers in developing and implementing solutions in the sustainability transition, a perspective that well merits their explicit consideration in an assessment like GEA.

18.1.1 Objectives and Approach

Given the above, the broad objective is to address urban energy issues in an increasingly urbanizing world from a *systemic* perspective that focuses on the specific energy challenges and opportunities represented by urban settlements.

The specific objectives of this chapter are to perform first a global assessment to establish the order of magnitude of urban energy systems and their drivers, then develop some generalized hypotheses to understand urban energy use, its differences and dynamics, and finally test these hypotheses through case studies at the local and regional levels, drawing on specific examples of individual cities.

This chapter addresses the systemic and structural interlinkages of urban systems and how these interact within and outside traditional territorial urban system boundaries. It adds to the information and knowledge of the sectorial GEA chapters (buildings, industry, transport) by addressing the *integrated* issues specific and unique to urban systems. Sectoral perspectives are therefore addressed here only to the extent that they contain an explicit urban specificity, e.g., (public) urban transport systems, or urban energy cogeneration systems.

Urbanization is a multidimensional phenomenon that can be described from demographic, land use, or economics perspectives. Empirical data are well developed for demographics (through regular population censuses) and for land-use perspectives (through remote sensing data). Conversely, there is a paucity of widely available and comparable economic data at the urban scale. Systems of National Accounts that underlie much of the available economic data were developed and continue to be used predominantly at the national scale, with comparatively few applications at the urban scale, which explains the significant gap between urban economic data[2] and the largely theoretical discussion of urbanization in the economics literature. The literature on urban land use and urban land-cover changes, while most valuable for describing a physical dimension of urbanization, is of limited use in an energy assessment despite the richness of quantitative data available. After all, it is not the square kilometers of urban extent that can explain urban energy use, but only the linkage of urban land use with demographic and economic data and characteristics as reflected through urban form and population density, infrastructure endowments, level and structure of economic activities, lifestyles of city dwellers, among other factors. Therefore, *demographics* (population) is adopted quite naturally as a fundamental driver and core metric to discuss urbanization and urban energy use, drawing on the urban land-use change and economics literature only to the degree necessary to understand urban energy use and its variation through derived metrics centered on population, like population density, or per capita incomes and expenditures, in addition to more narrow disciplinary land-use and economic metrics, such as urban extents/form or economic structure.

As comprehensive energy information and accounts at the urban scale are extremely limited, developing a robust assessment storyline from the bottom-up alone is challenging. Therefore in this analyses a mixed approach of both top-down and bottom-up perspectives is utilized, combining estimates derived from 'downscaling' or remote sensing approaches with bottom-up statistical information where available.

18.1.2 Roadmap

After the introductory section (18.1), Section 18.2 gives an overview of the urbanization phenomenon and the contexts for understanding urban energy use. Its focus is on the demographic dimension of urbanization, both from historical and futures (scenarios) perspectives, and on the drivers and patterns of urbanization dynamics. It also addresses the specifics of urban energy systems and elaborates on the importance of system boundaries.
