for resources located within the Arctic Circle (USGS, 2008). The table compiles reserves estimates from BP, BGR, and the USGS – the three organizations that regularly assess global oil reserves or resources. While reserve estimates exhibit only slight variance, less than 15% between the highest (7615 EJ by BP) and lowest estimates (6635 EJ by BGR), resource estimates show almost a 50% difference (4170 EJ by BGR and 6150 EJ by USGS).

The discrepancies arise because of different definitions, boundaries, and classifications of different oil types. While reserves estimation is somewhat better defined, resource estimation has very few guidelines and is thus subject to greater institutional subjectivity. For example, the USGS resource estimate includes oil occurrences in the Arctic (768 EJ). Furthermore, estimates of resources in undiscovered fields, despite their inherent ambiguity, have also grown over time. This is mainly because technology changes that have either shifted resources from the unconventional to conventional category, or have opened new territories to exploration (e.g., deep-water areas).

Figure 7.6 displays the regional distribution of conventional oil reserves and resources. Almost two-thirds of global conventional oil is shared between the Middle Eastern countries (48.6%) and the Former Soviet Union (FSU) (16.7%), while the remaining regions, except Latin America (9.0%) and the United States (5.7%) hold less than 5% (BGR, 2009).

The regional distribution of oil resources has significant implications for rapidly developing economies such as China and India. China's ability to provide for its own needs is limited because its proven oil reserves are small compared to its consumption. Despite recent attempts at diversifying its oil supply, China will inevitably become more dependent on Middle Eastern oil to fuel its economic development.

7.2.3 Types of Unconventional Oil

7.2.3.1 Viscous Oil

Anaerobic biodegradation of light oil is recognized as the main process responsible for the large viscous oil deposits around the world (Atlas and Bartha, 1992; Head et al., 2003). Aitken et al. (2004) investigated the hydrocarbon degradation of 77 oil samples from around the world, including Canadian tar sands deposits, and concluded that the hydrocarbon biodegradation must have been an anaerobic process, at least at some point, and this is certainly the case for viscous oil deposits at depths where aerobic biodegradation was unlikely. Thus, light oil generated deep in megasynclinal structures migrated up-dip because of density differences and hydrodynamic forces until geochemical conditions suitable for biodegradation were encountered. Archaeobacteria then fed on the light oil, generating viscous oil and CH_4. Furthermore, at shallow depths, some aerobic effects may occur, and light-oil fractions can also be removed by hydrodynamic washing and diffusion, further increasing the viscosity. As a result of increasing temperature and the biodegradation origins of viscous oil, it is rarely found below depths of ~2000 m; probably greater than 85% of the resource base is shallower than 1000 m (Figure 7.7).

Many of the molecules of high molecular weight, such as asphaltenes, that give the oil its high viscosity are the remnants of the cell walls (lipids) of the bioorganisms. The oil contains sulfur, as well as heavy

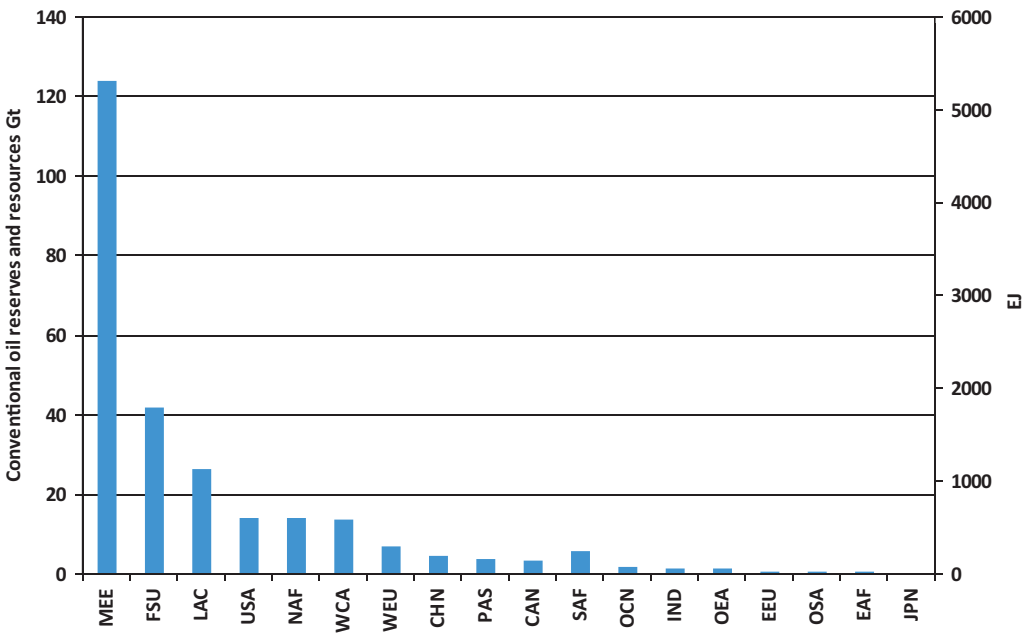

Figure 7.6 | Regional distribution of conventional oil reserves and resources. Source: BGR, 2010.

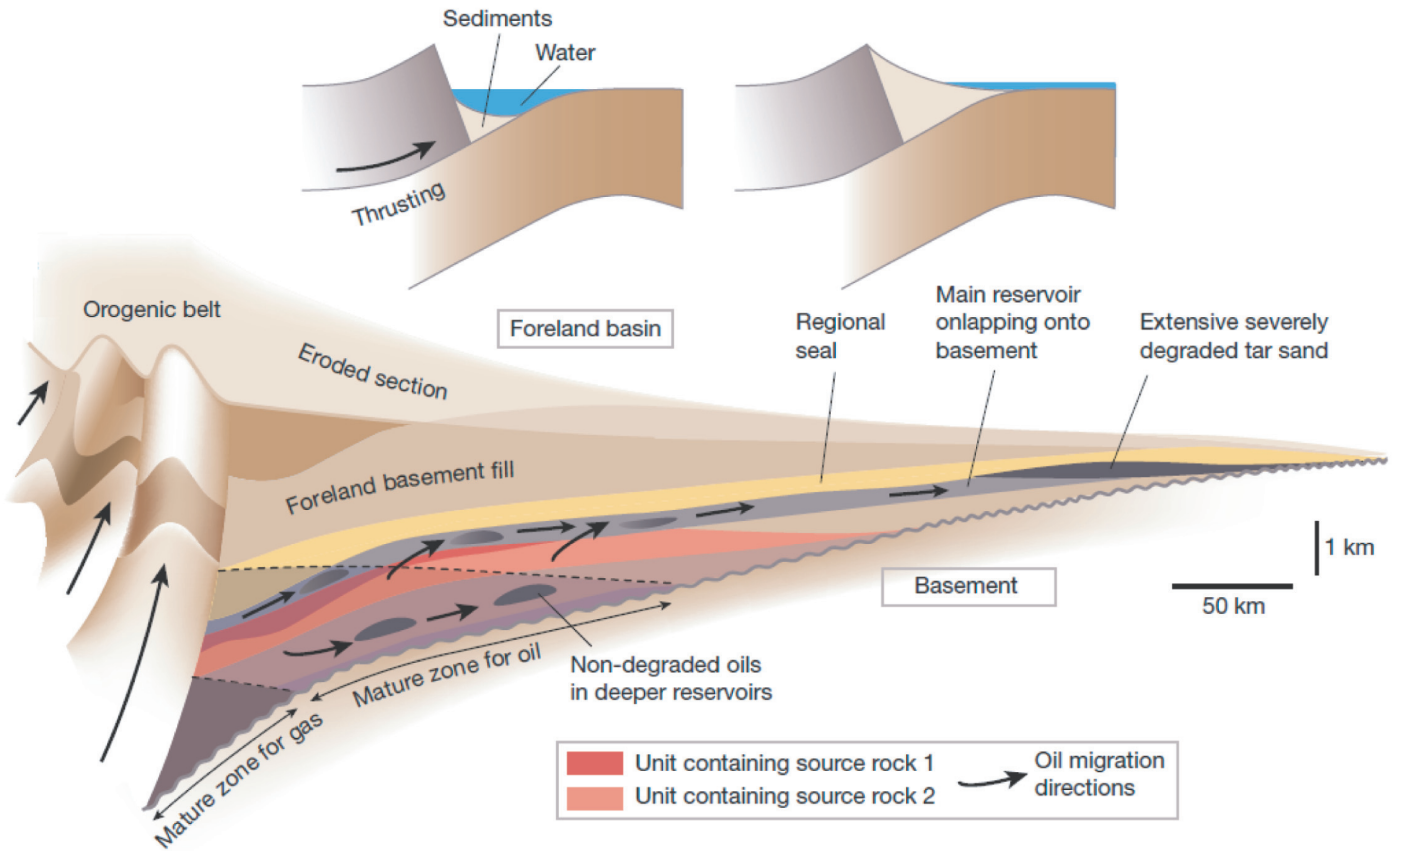

Figure 7.7 | The 'standard' model for viscous oil formation. Source: Head et al., 2003.

metals such as vanadium and nickel. The concentration of these elements in viscous oil is a function of density: oils of ρ>1.0 can have sulfur concentrations greater than 4% and heavy metal contents as high as 500 parts per million (ppm). Viscous oils with ρ<0.92–0.93, by contrast, typically have less than 25% of such concentrations. In the production of these resources, the elements S, V, Ni, Fe, and the high oil viscosity lead to problems in processing and environmental management (Head et al., 2003).

Bitumen is the heaviest, thickest form of petroleum. The bitumen contained in shallow oil (tar) sands can be recovered using surface mining techniques. However, it takes about two tonnes of oil sands mined (0.9 m^3) and processed to obtain one barrel of synthetic crude oil. About 90% of mined bitumen can be recovered by way of hot water and surfactant mixing and separation from the sand in special agitation-flotation tanks. After oil extraction, solids and water are returned to the mine, which is eventually reclaimed. Separated bitumen is then shipped or upgraded to synthetic crude oil.

Deposits with overburdens of more than perhaps 60 m must be exploited by in situ methods, e.g., injecting steam into the deposits to reduce the bitumen's viscosity and increase reservoir pressure (which also induces fracturing), and thereby enable bitumen to flow (Dusseault, 2002). The advantage of in situ extraction is avoidance of the massive movement of the oil's host material and attendant surface disruption. The disadvantage is its water and energy intensity (about 3–4 barrels of steam per barrel of oil produced). Two processes are currently applied: cyclic steam simulation (CSS) (Nasr and Ayodele, 2005) and steam-assisted gravity drainage (SAGD) (Butler and Stephens, 1980; 1981). CSS involves the injection of a charge of high-pressure steam into a well over some time, and during the production cycle the heat and pressure mobilize bitumen flow to the same well, along with hot water. The cycle is repeated when the rate of production flow declines and a well may have a lifespan of 8–12 years. SAGD involves twin parallel horizontal wells separated vertically by about 4–5 m. Steam is injected into the top well, the mobilized bitumen drains into the bottom well and is lifted to the surface. Other in situ extraction processes being tested include the use of chemical solvents, electric heating, and partial combustion, none of which are currently considered commercially viable.

In situ production of heavy and extra-heavy oils utilizes methods similar to those for the production of oil sands, except that if the viscosity is modest and the permeability high, conventional pumping and water flooding may result in modest recovery factors (5–20%) without steam stimulation. If the sand is unconsolidated and has good solution-gas content, in many cases encouraging sand influx has proven to be a viable and economic production process.

Not only are viscous oils difficult to extract, they are difficult to process and transport. These oils may be viewed as deficient in hydrogen (carbon rich) and must be upgraded to produce useful products. Hydrogenation and carbon rejection (coking) are used to improve the hydrogen-to-carbon ratio, with CH_4 used as the source of hydrogen during upgrading. The heavy metals lead to difficulties in processing because they rapidly poison catalyst beds. Large volumes of sulfur and coke are by-products of typical upgrading operations. Once upgraded, the synthetic crude oil is sent to conventional refineries for further beneficiation to create marketable products. If local upgrading is not used, pipelining viscous oil requires blending with diluents, light oil, or synthetic crude oil.

At the present time (2010), only nine countries in the world produce more than 250,000 bbl/day or 12.5 Mt/yr of non-conventional (viscous) oil: Canada (~90 Mt/yr), Venezuela (~50 Mt/yr), the United States (~20 Mt/yr), Mexico (~18 Mt/yr), and each of Russia, China, Oman, Iran, and Brazil at about 15 Mt/yr.

7.2.3.2 Oil Shales (Kerogen)

Kerogen is a semisolid organic compound formed from algal residues. It is found in shales – sedimentary rocks that were buried rapidly, which led to low oxygen conditions that preserved the lipids and other similar cellular debris from the algae. Over geological time, kerogen buried to depths greater than 3 km and at temperatures greater than 80–90°C is broken down and converted into light oil. Economically interesting kerogen deposits are found at relatively shallow depths, less than 1500–2000 m. Kerogen in oil shales is viewed as 'immature oil' and, like viscous oil, is deficient in hydrogen (Dyni, 2006; Altun et al., 2006; WEC, 2007).

Near-surface deposits can be produced with standard surface and underground mining techniques using surface retorting (pyrolysis), and the shale-oil product (a mixture of gases and liquids) used directly as boiler fuel or as hydrocarbon products. The generation of synthetic crude oil from kerogen requires pyrolytic retorting with collection and treatment of the product. In contrast to most viscous oil, kerogen in deeper reservoirs cannot be mobilized, but must be converted physically through pyrolytic approaches. For example, kerogenous shale can be exposed to a combustion process (oxypyrolysis) that literally cooks the shale by partial combustion, generating valuable lighter products.

In situ or surface anoxic pyrolysis requires temperatures greater than 325°C to decompose the complex molecules into liquid and gaseous products that can be recovered, leaving behind perhaps 30% of the organic matter as elemental carbon. Anoxic in situ extraction technologies are based on conductive heating of shale beds using thermal energy (electrical heating or hot fluid circulation), with separate wells to collect generated fluids (e.g., Biglarbigi et al., 2009; Crawford et al., 2008, 2009).

Unlike heavy oil, kerogen does not contain sulfur and heavy metals. Thus, the products from pyrolysis are light 'sweet' gases and liquids that are processed relatively easily.

7.2.4 Estimates of Unconventional Oil

There are about 1780 Gt (74.8 ZJ) of liquid petroleum (shale oil, heavy oil, extra-heavy oil, and bitumen) trapped in sedimentary rocks in several thousand basins around the world (Table 7.7). Oil-shale resources are estimated at about 382–450 Gt (16–18.9 ZJ) (Dyni, 2006; WEC, 2007). However, these figures, particularly for oil shale, are somewhat conservative because of the lack of detailed exploration for these resources, particularly in countries with large conventional oil resources. For example, Libya, Iraq, Saudi Arabia, Iran, Oman, Kuwait, the United Arab Emirates, and other countries

Note: Viscous oil production from oil sands mining, Canada only, for the period of 1967–2009 is about 4 Gbbl (CAPP, 2009). The shale oil production for the period of 1880–2009 is estimated at 1.5 Gbbl assuming an average shale oil content of 100 l/t (WEC, 2007).

Sources: Authors' estimates; IEA, 2008a; USGS (i.e., see Meyer and Dietzman, 1981; Meyer and Duford, 1989; Meyer and Attanasi, 2004; Meyer et al., 2007; Schenk et al., 2009); Laherrère, 2005; CAPP, 2009; BGR, 2009; WEC, 2010; Dusseault and Shafiei, 2011.

have extensive deposits of viscous oil, but the volumes are not well delineated largely because of lack of interest. As conventional oil becomes more difficult to exploit, greater interest in unconventional oil will result in better delineation of the world resource base.

The definition of what constitutes a resource remains contentious. A 3 m thick conventional oil zone with good permeability is exploitable under many conditions, but not a 3 m thick bitumen bed, or a deeply buried 10 m thick oil shale, or oil shale with less than 7–8% organic content by mass. Viscous oil in thinly bedded, low-permeability strata at depth is not likely to be included in a resource survey.

Tables 7.8 and 7.9 contain estimates of unconventional oil resources for the 18 GEA regions. The figures are approximate because the category of technically recoverable reserves is a moving target as prices change, costs rise, and technologies are developed. Technically 'recoverable oil' implies the use of currently commercialized methods, whereas 'ultimately recoverable oil' assumes that currently known but non-commercial methods achieve commercial status. Additional oil will also become accessible with innovative, but presently unknown, extraction technology.

7.2.5 Oil Supply Cost Curves

As seen in Table 7.6, conventional oil reserves and resources, more than half of which are in the Middle East and North Africa, amount to about 11,000 EJ (~2 Tbbl). To put this amount of oil into perspective, cumulative past oil production amounts to around 6500 EJ.

Figure 7.8 shows an aggregate (of the 18 GEA regions) global oil supply cost curve. The curve plots the potential long-term contributions from conventional resources (Table 7.6) and non-conventional resources (Table 7.8) against their 2007 and projected 2050 production costs. The costs do not include taxes or royalties. The projected productivity gains in upstream oil operations vary between 0.25% and 0.75% per year. While the 2050 supply cost curve accounts for a constant oil production rate of 4000 Mtoe/yr until 2050, it does not reflect the added knowledge brought about by geological work between now and 2050, and the volumes underlying the 2050 curve are very much on the conservative side.

The supply curve suggests some 4000 EJ of conventional oil can be produced for 2 $/GJ (~12 $/bbl) or less at 2007 prices and exchange

rates (these supply costs are not the actual prices of the fuel in the market place).

The total long-term potential oil resource base assessed here amounts to some 34,000 EJ (810 Gt). This includes 11,600 EJ of conventional oil reserves and resources (USGS, 2000, 2008), 3700 EJ of unconventional oil reserves, and 33% or 18,700 EJ of unconventional oil resources (Table 7.8).

The cost of producing conventional resources typically ranges from less than 5 $/bbl in the Middle East up to 40 $/bbl. Deep-water and Arctic production could drive costs to 70 $/bbl.

The production costs of heavy oils and oil sands range from 15–80 $/bbl. A lack of major commercial production experience means the costs of shale-oil recovery are uncertain and estimated to range between 60–140 $/bbl. Continued demand for oil-based energy services throughout the 21st century is expected to induce technology change, and production cost levels could be 25% lower by 2050.

Environmental considerations could adversely affect oil-production costs, especially for unconventional resources that leave a large environmental footprint, including through the GHGs emitted during the extraction and upgrading processes. GHG-emission penalties would change the shape of the cost curve, as unconventional oil would become relatively more expensive, and enhanced oil recovery based on CO_2 injection potentially cheaper (IEA, 2008a).

Figure 7.9 presents the uncertainties regarding future liquid-fuel availability and associated production costs (Farrell, 2008).

7.2.6 Environmental and Social Implications

The upstream oil industry has a blemished reputation in environmental protection. There are four major factors behind this. First, spending on waste management has been viewed as a direct revenue loss. For example, rehabilitation of drill sites prevents erosion and long-term soil and water degradation, but brings no financial returns and is thus often avoided or poorly managed.

Second, in exploration and production activity, there has been little commitment to local communities. Company employees are usually from

distant communities, spending a limited time in the area. Again, drill-site rehabilitation serves as a useful example. In Wytch Farm (UK), only a few kilometers from expensive beach properties, drill sites are fully rehabilitated, reforested, and invisible from all recreational sites. However, in southeastern Ecuador, 30-year-old drill sites in the jungle, including drilling waste pits and oil spills, continue to erode and cause silting and local contamination (San Sebastian et al., 2001).

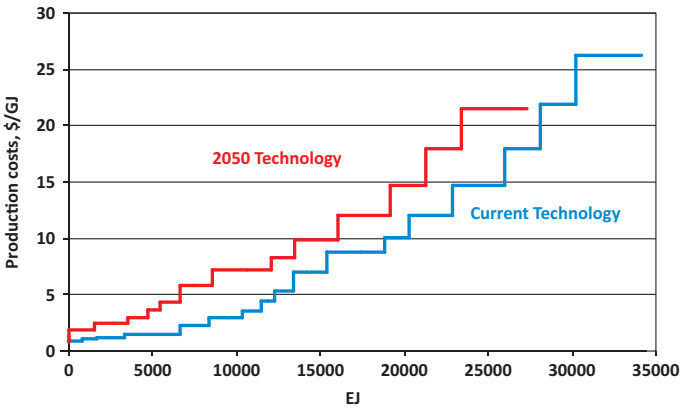

Figure 7.8 | Long-term oil supply curve[7] – combined global conventional and unconventional oil reserves and resources. Source: USGS, 2000; 2008; IEA, 2008a; Deutsche Bank, 2009; Aguilera et al., 2009.

Third, there is the joint problem of poor regulatory enforcement and occasionally associated corruption. Environmental protection requires strong, transparent, and consistent enforcement of regulatory guidelines, often in remote areas. Human fallibility and greed, combined with industry 'capture' of regulatory bodies, has led to unfortunate cases of collusion and corruption, invariably with negative consequences. Neutral third-party annual audits with full publication of results constitute an approach to reducing this problem.

Fourth, ignorance of environmental impacts has led to a general reactive attitude to environmental management rather than to proactive avoidance. Once a severe problem happens, mitigation costs and reputational loss often far exceed the initial investment in avoidance that should have been made. Increasing corporate attention to employee education is reducing this problem.

Recent and continued progress (Marika et al. 2009) suggests that goals of 'minimal impact-quasi zero emissions' are technically feasible and economically attainable, as well as socially desirable.

7.2.6.1 Environmental Issues in Oil Development

Oil development involves, among others, the following activities: seismic exploration, exploratory and development drilling, infrastructure generation,

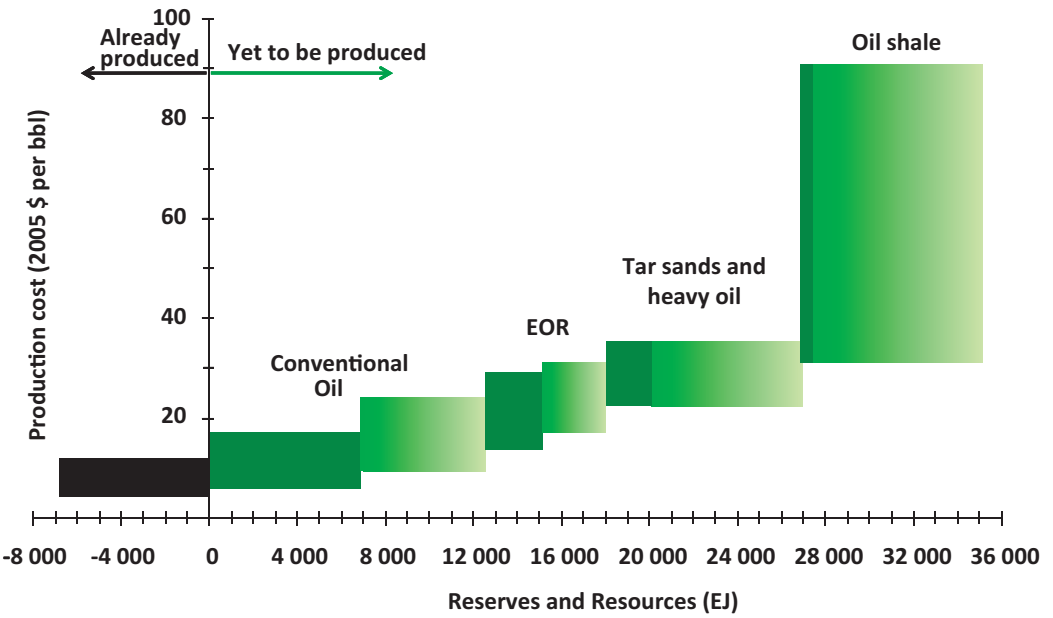

Figure 7.9 | Liquid fuel supply potentials and production costs. The green bars represent the economic cost of extracting fuels. The black bar to the left of the vertical axis represents cumulative past oil production (about 157 Gt). The height of the bars represents the degree of uncertainty of the production costs. The widths of the bars represent how plentiful the resource is, and the lightness of the bars reflects the degree of uncertainty of resource availability. Source: adapted from Farrell, 2008.

7 The 2050 supply curve is net of a hypothetical cumulative production between 2005 and 2050 based on the historically observed production growth rate between 1995 and 2007. The resources exploited during the period up to 2050 are no longer available after 2050. Despite upstream innovation and technology change, the 2050 supply cost curve is higher as resource extraction until 2050 is expected to exploit lower cost occurrences first.

long-term production, transportation (generally pipelines), siting for large upgrading, refining and petrochemical facilities, and postactivity cleanup.

Current liabilities that reside in previously contaminated sites are large, as the industry efforts to rectify the impact of poor historical practices. The full economic implications of poor environmental management is little understood and under heated debate. While issues common to oil and gas development are discussed in this section in a somewhat positive light, with the notion that the industry is doing better, it is clear that it can and must continue to improve.

With regard to climate-change issues, the major CO_2 emissions related to oil products come from their end-use combustion, and these numbers overwhelm the emissions from oil exploration and production activity (Charpentier et al., 2009; IHS-CERA, 2010).

However, there are other major impacts on land and water resources. Seismic work requires access to land areas, generally by cutting paths to allow the use of all-terrain vehicles. Sensitive areas include permafrost regions, forests, and steep terrain where vegetation disturbance leads to permafrost degradation or soil erosion. Low-impact methods reduce damage in these areas by hand-cutting narrow lines, and using helicopters and vehicles with small contact pressure for transport.

Exploratory drilling with light helicopter rigs has reduced road-triggered erosion, and better cuttings and waste-disposal practices, combined with improved site rehabilitation, have significantly reduced waste abandonment and erosion. Directional pad drilling in the North Slope of Alaska and winter-only transport have reduced the surface area needs to about 13%, compared to 30 years ago. Similar improvements have been made in jungle areas (Peru) and in farming regions (Saskatchewan and Alberta). Fossil-fuel exploitation can be compatible with agriculture and sensitive ecosystems.

Vast volumes of produced water (greater than three tonnes of water per tonne of oil worldwide) are now systematically reinjected for water flooding or disposed into deep saline aquifers (Veil and Quinn, 2008). In development plans for the Marañon Basin in Peru, companies are contractually committed to full reinjection without diversion to river courses. Landfills should be avoided for any solid waste that contains species potentially harmful to subsurface potable water because of long-term security issues: all landfills leak or will eventually leak. Other produced liquid wastes, emulsions, and solid wastes can be slurried and reinjected safely, virtually to eliminate environmental liability. After exploitation and beneficiation, sites and spills must be properly cleaned and disposed, and corporations are requested more and more to post bonds (insurance) against future problems. Cleanup must be an ongoing and regulated activity, not reserved for when production is fully terminated.

Pipeline and flowline installations in jungle areas now increasingly use forest canopy preservation, and the Aleyska pipeline from the Alaska North Slope lies largely on elevated beams placed on thermo-siphon piles that do not degrade the permafrost. In built-up areas, pipeline burial, and reuse of rights-of-way as farmland is the rule, and pipeline companies have trained response teams for accident management. Aggressive reseeding of cleared areas using rapidly growing grasses and plants reduces erosion, and in many areas actually provides enhanced grazing for ungulates. Forty years ago all these practices only took place in developed areas; now they are basically the rule everywhere, but regulatory vigilance is vital. In particular, as the pipeline infrastructure ages, better inspections and corrosion-detection methods are needed to identify problems before they become breaks and spills (OGJ, 2010).

Environmental difficulties at large processing centers attract a great deal of media attention, which forces operators to become more vigilant and proactive. Nevertheless, a long history of site contamination blights the reputation of fossil-fuel companies. Many sites around the United States and the Mexico Gulf Coast are in a state of severe contamination (hydrocarbons, chlorinated hydrocarbons, and heavy metals); in some cases, sites (and responsibilities) have been abandoned for several decades. Deep slurried solids injection provides a method for cleaning these and other sites.

During offshore developments, the key to protecting marine environments near production and exploration activities is to plan and enforce zero liquid and solid discharge policies, as adopted by the Government of Norway, for example (Ekins et al., 2007). This is achieved by shipping waste to shore for treatment and by the injection of solids and liquid waste into oil-free saline aquifers. Spill risks must be managed properly and emergency response measures put in place. Old platforms are salvaged or sunk to provide rich environments for marine life, as iron is a limited nutrient in the ocean.

The recent (April 2010) Deep Water Horizon blowout in the Gulf of Mexico is having profound effects on safety practices, both to prevent and to respond to such incidents (OGJ, 2010). At the present time operators in the region have invested large sums to create a joint industry-response approach, and regulatory aspects are being examined carefully. This accident will affect all future offshore practices, and the cost to BP (US$40 billion projected is the most recent estimate) has already triggered improvements in procedures manuals, operational quality control, regulatory management, and response plans. These changes will reduce environmental risk for offshore operations around the world.

7.2.6.2 Oil Sands Mining

In Canadian surface mining of viscous oil, the issues are atmospheric emissions (sulfoxides [SO_x], nitrogen oxides [NO_x], CO_2, and particulates), water use (water sources, tailings ponds, seepage into groundwater), and solid-waste management (sand-tailings management, mature fine-grained oily sludges, long-term coke and sulfur storage, disposal of solid wastes such as pipe scale, tank bottoms, and emulsions). Concerns over massive surface changes can be mitigated through reclamation

efforts with the resultant terrain often more ecologically productive than before. Furthermore, the area amenable to surface mining in Alberta, about 3400 km^2, is no larger than 60% of the greater Los Angeles area; 95% of Alberta's boreal forests will remain unaffected (~470 km^2 of boreal forest has been cleared or mined to date).

One cubic meter of ore weighs 2.2 tonnes and averages 0.68 m^3 of silica sand, 0.23 m^3 of oil, 0.06 m^3 of water, and 0.03 m^3 of fine-grained silt and clay. The products are approximately 0.2 m^3 (0.171 t) of raw bitumen, 1.1 m^3 of bulked sand (35% porosity) that contains water, fine-grained minerals, and residual oil in the pores, 1.6 m^3 of water, much of which is recycled for further extraction, and 0.20 m^3 of oily aqueous sludge containing 60% of the clay minerals in the original raw ore. In addition, for each cubic meter of ore, 0.3 m^3 of overburden is removed, organic soil is stored for future reclamation, and 0.01 m^3 each of coke and sulfur are produced and stockpiled. CO_2 emissions for mining and upgrading are about 700–750 kgCO_2 per tonne of oil, exclusive of transportation and further refining (IHS CERA, 2011).

Of these materials, the large volumes of pond sludge constitute the major waste stream that presents a significant long-term problem, although tailings dams, coke, and sulfur may have local groundwater impacts. Since mining of oil sand in Alberta began 40 years ago, the volumes of sludge per barrel of bitumen produced have halved, and research continues to develop less water-intensive extraction methods. General groundwater drainage toward the large local river (Athabasca) means that management of contamination is feasible through interception and dilution. The recent focus of industry on sludge rehabilitation has resulted in large-scale experiments by corporations (Shell, Suncor, Syncrude) into methods to reduce sludge generation volumes and solidify the remaining sludge.

The incentive arises from a tightening of licensing practices by the Alberta government, but progress remains slow. Some low-volume, difficult wastes are also being disposed into deep salt caverns (e.g., Veil et al., 1999) in Alberta and Saskatchewan to achieve permanent isolation. Nevertheless, final pond closure, elimination of mature fine-grained tailings sludge, and reestablishing a stable productive landscape represent challenges to be met.

Recovery processes for in situ viscous oil

Steam for heavy oil recovery requires heat and water sources, as well as water recycling. Natural gas is by far the main source of heat, but asphaltene and coke (or coal) combustion for heat and H_2 generation will become more common. On average, recovery of one tonne of viscous oil by steam methods requires three tonnes of water as steam at 200–300°C. Steam generation requires water treatment and attendant sludge-disposal needs. Production of viscous oil also generates emulsions that are challenging to treat and are best disposed of through deep injection. Saline boiler subfeed water and other contaminated water can be injected, along with all other contaminated water, into saline aquifers. CO_2 emissions (extraction, upgrading, transportation, and refining only) are 990–1100 kg/t of oil for SAGD methods, and 1170–1390 kg/tCO_2 per tonne oil for cyclic steam stimulation (IHS CERA 2010). About 85% of emissions are allocated to steam generation, H_2 generation, power, and pumping inputs, ranked by size. For comparison, synthetic crude oil from mining requires about 950–1000 kg/tCO_2 to bring the product from the ground to the service station.

In situ combustion processes, by contrast, are anhydrous; CO_2 emissions are estimated at 880–1000 kg/t, generally less than steam projects based on natural gas. Furthermore, lack of significant liquid and solid wastes make in situ combustion processes more benign in terms of environmental impact. However, combustion methods remain far from commercialization at this time.

Oil-shale development

Anoxic in situ pyrolysis of oil shales at high temperatures generates no surface wastes or significant atmospheric emissions. Anoxic surface pyrolysis is also a process with low atmospheric emissions, but solid wastes are generated. If combustion-based in situ pyrolysis or surface retorting is used, CO_2 emissions are likely to be about 1170–1470 kg/t, not counting additional energy sources for heating or transportation. If ore is mined and retorted, spent shale to be disposed of has a volume bulking factor of about 20%, but it is an inert substance without residual oil or environmentally damaging substances. In the vast oil-shale deposits in the United States, as well as for some other oil-shale deposits in Jordan, China, and Australia, an arid climate means that reclamation of mined land is challenging, although the land-use value of these arid regions is low. Water requirements for oil-shale development are low because steam will not be used and retorting is anhydrous. It is unlikely that large-scale exploitation of the vast American oil-shale deposits will ever occur by surface mining methods because of the environmental impacts, solids management costs, and reclamation problems.

Zero emissions targets

Suppressing stack emissions of SO_x, NO_x, and particulates to near-zero levels is currently achievable, but CO_2 emissions will remain an environmental concern for the foreseeable future (see also Chapters 12 and 13). Produced solids, scale, cuttings, pond sludges, tank bottoms, emulsions, and treatment fluids, as well as many other noxious and hazardous wastes, can be slurried with untreated waste water and disposed of safely through deep-well injection. The slurry is injected at depths greater than 400 m into saline aquifers with adequate seals against upward flow. Solids are permanently retained in the stratum once the pressures dissipate, which happens rapidly in permeable strata. Costs are generally far less than those of chemical treatment or washing processes, which often generate other waste streams. An example of a large heavy-oil field approaching zero surface discharge is Duri, Indonesia, where deep-injection practices are used for the great majority of waste streams, including wastes from previous surface pits (Marika et al., 2009). Finally, as noted above, zero saline water discharge is now being practiced widely, and should be mandated in many other areas.

It appears that reasonable cost technologies exist to achieve near-zero discharge in oil and gas exploitation. Regulatory practices and enforcement are key to achieving the environmental goals that are now technically feasible. Good industry and regulatory practices must be promoted in the less-developed world, and the responsibility for this resides both with corporations and with non-industry agencies (governmental and non-governmental organizations) that promote good governance.

7.2.7 Summary

Cumulative global oil production to date is about equal to the current remaining conventional oil reserves. Based on conventional reserves alone, oil production will peak soon and steadily decline shortly thereafter. However, reserves and resources of all types of oil are sufficiently large to meet ever-rising demands for one to two decades until production reaches its peak.

Only the massive development of unconventional oil occurrences would shift peak liquid-fuel supply from oil-based resources to 2050 or beyond. This would require ramped up investments in upstream R&D, followed by the commercialization of new exploration, production, and upgrading techniques. The extraction of unconventional oil is more energy intensive than that of today's conventional oil production, claiming up to 20–30% of the oil's energy content rather than 10–15%, and leaving an emissions footprint that is about 10% higher than conventional oil on a well-to-wheels total CO_2 emissions basis (IHS-CERA 2010).

The investment share in extraction and upgrading of viscous oil is expected to increase slowly, compared to that of conventional oil, raising the issue of finance and timely investment to avoid future shortfalls and excessive upward pressure on prices. The lead time for large-scale viscous oil projects can be 3–5 years for in situ projects and 7–10 years for large mining projects.

Decisions on oil investments depend on several factors, ranging from aggregate demand, the nature of the markets served, to the availability of competitive alternative transportation fuels, as well as issues such as climate change and geopolitics.

7.3 Natural Gas

7.3.1 Overview

Natural gas is a mixture of combustible and non-combustible gases. Its chief combustible component is CH_4; other energy-relevant components include butane, ethane, and propane. Typical non-combustible components of natural gas are nitrogen, CO_2, and hydrogen sulfide (H_2S). Like oil, typically natural gas resources are trapped in porous underground rock formations, predominantly composed of sandstone. It is generally accepted that CH_4 is the result of the anaerobic decomposition of organic material.[8] Organic matter is ubiquitous in all sediments and so is CH_4. Although abundantly available, most of these occurrences are too diffuse to warrant commercial recovery.

Gas reservoirs differ greatly, with varying physical conditions affecting reservoir performance and recovery rates. Over geological time, almost all natural gas migrates upwards through the Earth's crust and eventually leaks to the atmosphere. If its migration is blocked by a geological trap – porous reservoir rock sealed above by impermeable cap rock – commercial quantities of gas can accumulate. This gas usually contains little admixtures of other hydrocarbons and is termed non-associated gas or dry gas.

Commercial amounts of gas can accumulate also as a gas cap above an oil pool or, with high reservoir pressures, dissolved in the oil. Such natural gas is referred to as 'associated gas' because its recovery is generally a by-product of oil production. The associated gas recovered along with oil is separated at the surface. Depending on location, field size, geology, and gas in place, associated gas is either recovered for revenue generation, reinjected for field pressurization and prolonged oil recovery, or flared. Approximately 17% (~135 billion m^3 or 5 EJ) of total recovered associated gas is currently flared because of the lack of harvesting infrastructure, especially for remote or small fields that do not warrant a commercial gas collection and transportation system.

Non-associated natural gas reservoirs are much more abundant than reservoirs with both oil and gas. When there are no significant liquid hydrocarbon components, a larger part of the in-place gas can be recovered by dropping reservoir pressures. Reservoir pressure, however, is often maintained by encroachment of water in the sedimentary rock formation and some of the gas will be trapped by capillarity behind the incoming water. Therefore, in practice, only approximately 60–80% of the in-place gas can be recovered (IEA, 2009).

Compared to oil, the remaining resources of natural gas are abundant. Reserve additions consistently outpace production volumes and resource estimations have increased steadily since the 1970s (IEA, 2010a). Figure 7.10 shows the evolution of natural gas resource estimates since 1950. The biggest uncertainty for future gas supply is thus a question of whether sufficient and timely investment will be made in developing these resources and associated transmission infrastructures to bring them to the market place at competitive costs.

7.3.2 Classifying Conventional Gas and Unconventional Gas

Like oil, natural gas resources are termed 'conventional' when recovery is possible with standard extraction technologies.

8 There exists a different theory (see Section 7.3.7).

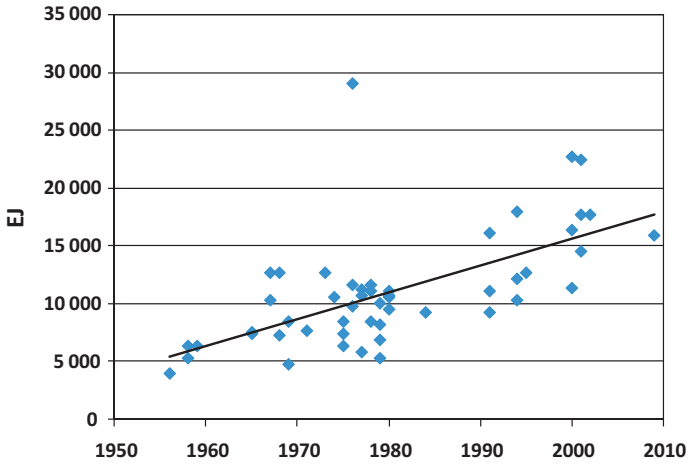

Figure 7.10 | World gas resource (reserves plus resources) estimates, 1950–2007. Source: adapted from Ahlbrandt and Klett, 2005; NPC, 2007; BGR, 2009.

In 'unconventional' gas deposits, additional technical measures are required for a production well to result in commercially viable flow rates and volumes – because of either the low permeability of the reservoir or the gas does not exist in a free gaseous phase. Hydraulic fracturing, horizontal drilling, or multilateral narrow-spaced wellbores are typical methods used to produce commercial flow rates and volumes. Still, per well, an unconventional gas reservoir will produce less gas over longer periods than a conventional higher permeability well (only 10–30% of total gas in place) (IEA, 2009). Thus, reservoir permeability is a key parameter that separates conventional and unconventional gas deposits. International practice suggests an average permeability of 0.1 milli-Darcy (mD) as the upper limit for unconventional gas (IGU, 2003; BGR, 2009).

Typically, unconventional gas can be found in low-permeability reservoirs that consist of sandstone (tight sands), shales (fine-grained sedimentary rock rich in organic material), carbonates, and coal deposits. It can also be found dissolved in groundwater, geopressured aquifers, saline brines, and gas hydrates. These fundamentally different geological settings require distinctly different production methods. Thus, unconventional gas occurrences can be classified further by applying simple criteria based on the host geology and the physics of natural gas in the reservoir.

The International Gas Union suggests grouping unconventional gas sources into two categories:

- 'Really unconventional gas sources,' i.e., where the non-free (solid, liquid) gas content of the reservoir is larger than 5%[9] of the total gas content of the reservoir (excluding conventional reservoirs). This category includes shale gas, CBM, water-dissolved (aquifer) gases, and natural gas hydrates. Independent of actual gas flow rates, the exploitation of these sources requires new technologies and processes.

- 'Pseudo-unconventional gas sources,' i.e., where less than 5% of the total gas content is in a form different from the free state, but the gas is not economically feasible for development for geological or technical reasons. Tight reservoir gases, deep gas (basin-centered gas systems), and permafrost gas fall into the pseudo-unconventional category and can essentially be produced with adapted conventional technology.

The boundary between conventional and unconventional gas is dynamic and more blurred than that for oil. What was unconventional yesterday may, through some technological advance, ingenious new process, regulation, or dramatically different market conditions, become conventional tomorrow. For example, the latest reserve assessments, e.g., by Cedigaz (2009), also include gas from unconventional sources. In fact, the term 'unconventional' is becoming a misnomer as gas from these sources increasingly supplements conventional production, especially in the United States where 'unconventional gas' already accounts for over half its domestic gas supply (IEA, 2009). The recent surge of shale gas production in the United States, mainly through new technology applications (hydraulic fracturing) dramatically lowering recovery costs, was instrumental in bringing wellhead gas prices down from 11 $/GJ in 2008 to around 4 $/GJ in 2010 (US EIA, 2010).

7.3.3 Conventional Natural Gas Reserves and Resources

There have been only a few new assessments of global natural gas resources since 2000. These estimates generally point to a steadily growing resource base and are largely in agreement regarding reserves (see Table 7.10), but diverge for total resource potentials.

While the recent USGS appraisal of the oil and gas resource potential north of the Arctic Circle has boosted assessed resource potentials, it understandably has not yet affected reserves estimates.

Conventional natural gas reserves assessed by different organizations between 2007 and 2009 converge around 180–192 trillion m^3 (6700 EJ to 7100 EJ).[10] More importantly, reserves estimations show a continuous upward trend with reserves expanding faster than production (see Figure 7.11). Reserve growth, new discoveries, and reclassification from resources to reserves have been instrumental in this regard. It is important, though, that approximately 22% of global conventional gas reserves exist in the form of 'associated gas' (IEA, 2009), with its availability thus dependent on future oil production.

9 5% is the approximate maximum share of natural gas adsorbed by a non-organic mineral surface in a reservoir.

10 Total gas production in 2009 was 3.0 trillion m^3.

Table 7.10 | Estimates of conventional natural gas reserves.

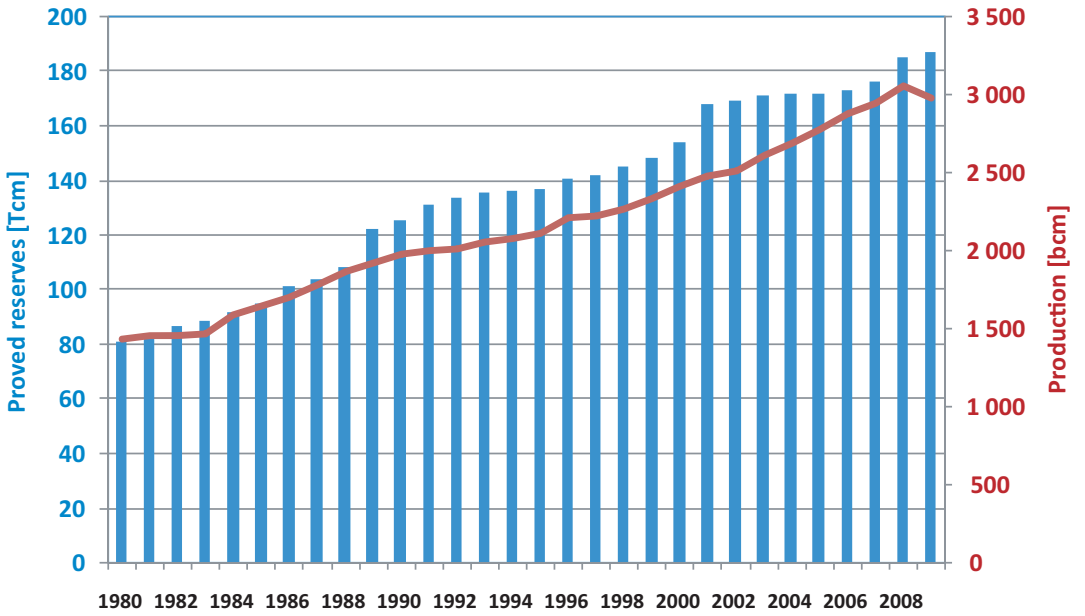

Figure 7.11 | Development of global natural gas reserves and production, 1980–2009. Source: BP, 2010.

While reserves have been steadily increasing, the increases typically result from revised reservoir estimations rather than from new discoveries. With total reserves still growing faster than production, there is little incentive for additional gas-exploration efforts, as the focus for exploration is, in many geographical areas, e.g., Africa, still on oil. Furthermore, knowledge about potential deepwater oil and natural gas resources is evolving fast. Deepwater deposits are basically conventional resources in an unconventional setting, and their potential exploitation will depend mainly on future technology developments.

Table 7.11 summarizes the cumulative historical production of natural gas up to 2009, the production in 2009, and the reserve and resource estimates of the BGR and USGS for the 18 GEA regions (the USGS data are from the year 2000, except for the Circum-Arctic area which was taken from USGS, 2008).

Resource estimations are not as accurate as reserve estimations. Unlike reserve assessments, which are mandatory legal requirements in many jurisdictions, resources are only assessed periodically. The most recent comprehensive assessment by the USGS dates back to 2000 and reflects the resource situation as it existed in 1995 (BGR, 2009). Since then, the USGS has added a comprehensive assessment of the Arctic (USGS, 2008) and updated its assessment for Afghanistan and parts of the Middle East. The gas-resource data in Table 7.11 may be conservative, as it may no longer adequately reflect the advances in geological knowledge and gas-production technologies.

Overall production in 2008 reached an all-time record of 3061 billion m^3 (115.5 EJ), but declined to 2987 billion m^3 (112.7 EJ) in 2009 because of the global economic slowdown and consequent lower demand. Cumulative gas production by 2008 approached 48% of proven

reserves, which has led some analysts to conclude that peak gas production is imminent. When resources are added, however, that percentage drops to less than 22%, and during the first decade of the 21st century reserve additions outpaced production. In contrast to oil, gas resources exceed reserves by almost 30%, which suggests a much more favorable resource position for natural gas.

The geographical distribution of gas resources shows Russia (FSU) in the lead, followed by the Middle East and the United States. These three regions account for more than 70% of global conventional gas reserves and resources (BGR, 2010).

7.3.4 Unconventional Gas

7.3.4.1 Shale Gas

Shale is a common sedimentary rock consisting of clay, quartz and other minerals. Most shales are not suitable sources of natural gas as they have insufficient permeability to allow significant fluid flow to a well bore. In gas-bearing shales, the rock acts as source and reservoir for the gas. The gas occurs in three states: in the pore spaces of the shale, in vertical fractures (joints) which break through the shale, and adsorbed on mineral grains and organic materials. The bulk of recoverable gas is contained in the pore spaces.

In the absence of fractures, it is difficult for gas to escape from the pore spaces, because they are tiny and poorly connected. Gas from naturally fractured shale has been produced for over 100 years in the Appalachian Illinois Basins. However, well production was often marginal. The rate of production increases with well stimulation, such as hydraulic fracturing and horizontal drilling, but because of these extra expenses the gas tends to cost more to produce than gas from conventional wells.

The recent shale-gas boom in North America is the result of technology advances that create extensive artificial fractures around horizontal, rather than vertical well bores. High natural gas prices provided incentives for engineering advances in hydraulic fracturing and horizontal well drilling. The share of shale gas in US gas supplies rose from 1.6% (0.32 EJ) in 1996 to 10% (2.1 EJ) in 2008 (with a growth rate between 2005 and 2008 of 40% per year), as the surprise economic success of the Barnett Shale operations in Texas generated a rush for other sources of shale gas across the United States and Canada.

To date, almost all successful shale-gas wells have been in rocks of Paleozoic age, but shales of other ages are being evaluated, particularly Cretaceous shales in Rocky Mountain basins. In other parts of the world shale gas has not yet been produced commercially because of a limited geological knowledge about shale gas and host reservoirs, as well as higher technical and economic costs. However, since 2006 accelerated shale-gas exploration has occurred in both Europe and Asia.

7.3.4.2 Coal-bed Methane

CBM is gas that is adsorbed into the solid matrix of the coal. Its lack of H_2S content means the gas is considered a 'sweet gas.' It is located in various forms in natural fractures (free form), coal pores (free and adsorbed form), and coal structures (absorbed form). The presence of this gas is well known from its occurrence in underground coal mining, where it presents a serious safety risk. CBM is located at depths that range between 300–2000 m and can be extracted by multi-leg, horizontal wells or wells with massive hydraulic fracturing. As a result of low pressures and low well-head flow rates, the production of CBM is economically feasible only in the vicinity of gas-demand centers. Thus, its production is feasible in countries with considerable coal basins and where substantial populations exist on the territory of these basins: the United States, Canada, Australia, Russia, Ukraine, China, India, and approximately another 35 countries. CBM is produced commercially in the United States from some 40,000 coal-bed gas wells, and accounts for approximately 9% (1.8 EJ) of total domestic gas production.

The development of CBM in countries outside the United States continues to be slow for several reasons, including unfavorable reservoir characteristics, inadequate infrastructure, lack of operating knowledge, and competition from conventional gas. In some cases, leases have changed ownership several times before an operator with the right combination of corporate size, technical know-how, and contractual terms has been able to achieve a successful project.

7.3.4.3 Tight Reservoir (Tight Sands) Gas

Tight sands reservoirs are conventional gas resources located in sedimentary basins with less than 0.1 mD permeability, and at a depth of up to 4500 m. These geological structures can be found practically everywhere in the world. Still, countries with large conventional resources in very permeable reservoirs have had a tendency to pay little or no attention to tight reservoirs. Gas production from these reservoirs is developing in countries with mature gas industries (e.g., the United States, Canada, Great Britain, and Russia) and in countries poorly endowed with conventional natural gas resources (e.g., Japan and China). In fact, the distinction between conventional and unconventional tight gas is increasingly blurred, especially in North America. For example, the US EIA no longer lists the production of tight gas under unconventional gas, and it is now accounted for under conventional gas.

7.3.4.4 Gas in Deep Reservoirs (Basin-centered Gas Systems)

Deep reservoirs are deep sedimentary basins located at depths greater than 4500 m and are usually characterized by high pressures and high temperatures, and the presence of significant acid components (IGU, 1994; 2003; BGR, 2009). Basin-centered gas systems are typically further characterized by regionally pervasive accumulations that are gas saturated, abnormally pressured, commonly lack a down-dip water contact, and have low-permeability reservoirs.

Production from depths larger than 4500 m is technologically challenging. Low porosity and permeability limit gas flow rates to the well bore and require reservoir fracturing and complex horizontal and multilateral production wells. Drilling in tight formations with conventional technology at depths approaching 4500 m becomes increasingly prohibitive, and the extractable gas per well is lower than that for conventional gas at shallower depths. Deep gas has been explored in North America, North Europe, Russia, and some other regions. Exploration and production is technically challenging and there are only a few examples of deep-gas production: in the United States (on old exhausted fields and fields close to the consumer), in the North Sea (an old gas-producing region), and in Russia in the super-giant Astrakhan gas field. In all these cases production is constrained by technical, safety, and environmental restrictions.

7.3.4.5 Water-dissolved (Aquifer) Gas

'Aquifer gas' refers to CH_4 dissolved and dispersed in groundwater. This can be found practically everywhere as almost all porous rock formations below groundwater tables contain small amounts of CH_4. As a result of the low solubility of CH_4 in water, the gas content of water at depths less than 1000 m is low (0.3–3 m^3/m^3 of water) and production is economically unattractive. At greater depths, the CH_4 content can reach 10–15 m^3/m^3. In areas under high tectonic stress, gas concentrations of up to 90 m^3/m^3 can be found (BGR, 2009). The gas contained in aquifers exceeds reserves of conventional gas by two orders of magnitude, but even with new extraction technology only a small share of this gas is expected to become commercially viable in the long run.

Unlike conventional and other unconventional gases, the production of aquifer gas hinges upon the coextraction of the CH_4 substrate water. The process of water lifting and aboveground separation of typically low-concentration CH_4, as well as subsequent water treatment and disposal/recycling, generally has a low energy payback and thus lacks economic attractiveness. The economics may improve, for example in regions with high freshwater demand where gas production would be a convenient by-product, or in cases where geopressure and

geothermal aquifers could be used for combined geothermal energy and gas supply.

7.3.5 Resource Estimates for Unconventional Gas Resources (Excluding Gas Hydrate)

Table 7.12 summarizes the estimated unconventional gas resources in the 18 GEA regions, except for gas hydrate, which is not yet produced commercially. Gas hydrate resource estimates are addressed in Section 7.3.6. The resource potential (omitting gas hydrate) amounts to 40,000 EJ, of which 20,000 EJ are considered potentially recoverable reserves.

7.3.6 Gas Hydrate

Gas hydrate is a solid crystalline substance composed of water and natural gas (primarily CH_4) in which water molecules form a cage-like structure around the gas molecules. The cage structure of the hydrate molecule concentrates the component gas so that a single cubic meter of gas hydrate will yield approximately 160 m^3 of gas and 0.8 m^3 of water at standard pressure and temperature (0.1 MPa, 20°C). Gas hydrate forms under conditions of moderately high pressure and moderately low temperature (Figure 7.12) and is widespread in marine sediments of outer continental margins and in sediments in polar regions. In the marine environment, the pressure and temperature conditions for gas hydrate stability occur at water depths greater than 500 m at mid- to low-latitudes and greater than 150–200 m at high latitudes (Max et al., 2006). At these water depths, gas hydrate may occur within a zone of hydrate stability that extends into the sediment to depths of up to hundreds of meters beneath the seafloor. The thickness of the hydrate stability zone varies with temperature and pressure, typically increasing in deeper water as a result of increasing pressure. The base of the hydrate stability zone is determined largely by the local geothermal gradient – the rate at which temperature increases with depth. At some depth beneath the seafloor, the temperature increases to a point at which gas hydrate is no longer in a stable phase (Figure 7.13). As the geothermal gradient varies considerably within and between depositional basins, the thickness of the hydrate stability zone is highly variable.

In Arctic sediments, gas hydrate may occur within and beneath permafrost zones, with the upper boundary of the hydrate stability zone dependent upon local temperatures and pressures. As with the hydrate stability zone in marine environments, the base of this zone in polar environments is largely determined by the geothermal gradient.

Table 7.12 | Unconventional gas occurrences (without hydrate).

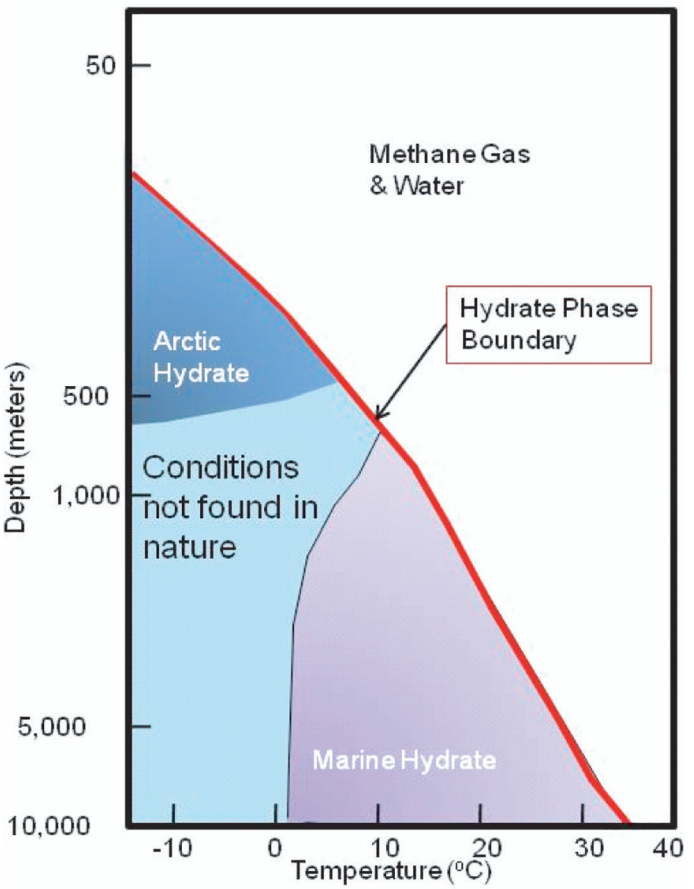

Figure 7.12 | Gas hydrate stability zone.

An important factor in the formation of high-grade gas hydrate deposits is the lithology (rock type) of the host sediment. The highest concentrations of gas hydrate occur in sediment with high porosity and permeability, such as sands and gravels. Cores recovered from such sediments have yielded hydrate concentrations up to 85%. In contrast, fine-grained sediments, such as shales, have concentrations of less than 10% of the bulk volume. The total volume of gas hydrate in fine-grained sediments represents the greatest proportion of the world's gas hydrate occurrences, but the prospects for commercial development of natural gas from such a highly disseminated resource are very poor without a major paradigm shift in technology.

Even in locations with excellent reservoir conditions, gas hydrate will not be present without an adequate supply of a hydrate-forming gas such as CH_4 generated from either biogenic or thermogenic sources. Evaluations indicate that insufficient microbial CH_4 is generated internally within the gas hydrate stability zone to account alone for the gas content of most hydrate accumulations. Most sediments that bear gas hydrate-bearing sediments have never been sufficiently heated or deeply buried to form thermogenic gas. Thus, it is likely that most of the gas that has formed hydrate has migrated into the hydrate stability zone from deeper sediments (Collett et al., 2009).

Current scenarios for the production of gas from hydrate-bearing sediments involve 'dissociating' the hydrate (converting it into its components – water and gas) by depressurization, thermal stimulation, or injection of an inhibitor such as methanol or glycol into the reservoir.

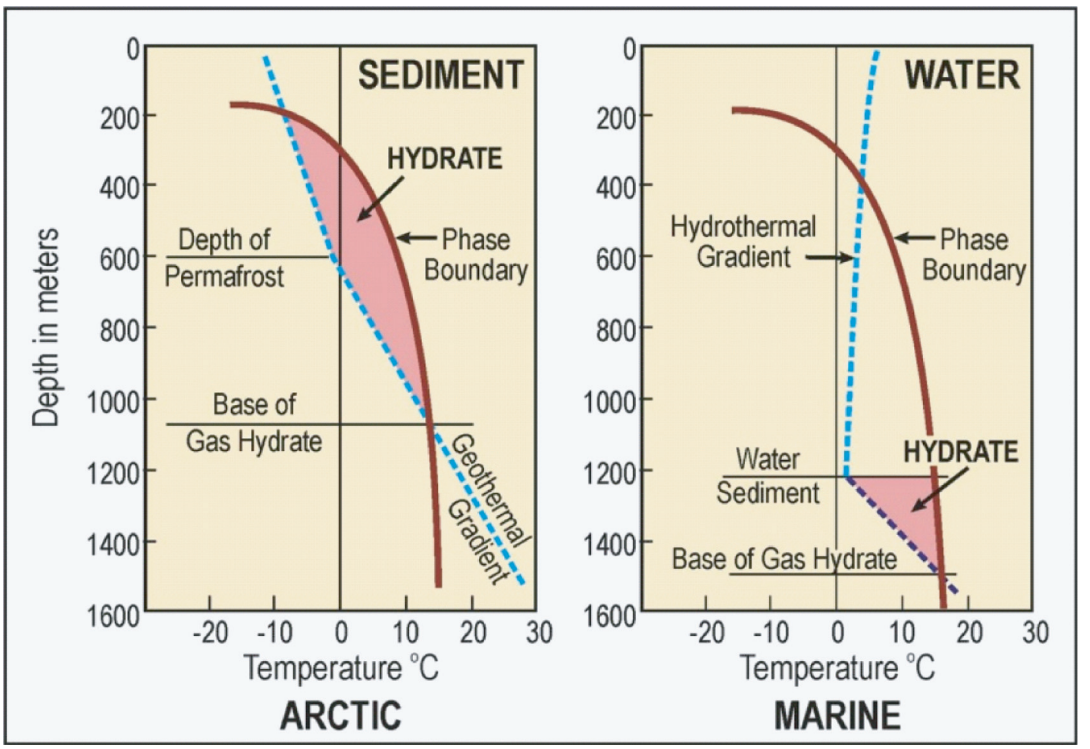

Figure 7.13 | Factors affecting the thickness of the hydrate stability zone.

The method utilized will depend on specific reservoir conditions, including hydrate saturation, porosity, and permeability. Natural gas may also be produced from gas hydrate through a chemical exchange, such as a substitution of CO_2 for CH_4. This approach has the advantage of sequestering CO_2 as well as yielding commercial gas production (Graue et al., 2006).

In summary, the volume of natural gas contained in the world's gas hydrate accumulations greatly exceeds that of known gas reserves (Collett, 2002), although a substantial proportion of that gas hydrate is in low-grade accumulations that are unlikely to be developed commercially. Ongoing research programs in the United States, Japan, India, and elsewhere have made great strides in understanding the formation of gas hydrate, identifying potential reservoirs where hydrate is concentrated, and developing production technologies for commercial exploitation. These programs have identified hydrate-bearing sediments in dozens of locations (Figure 7.14). Thus far, the vast energy potential of gas hydrate resources has not been proven commercially viable. There is, however, growing evidence that natural gas can be produced from high-grade gas hydrate accumulations with existing conventional oil and gas production technology (Moridis et al., 2008).

Estimates of the gas hydrate resource potential for each of the 18 GEA regions was undertaken by first segregating each region into separate subregions based on the local depositional setting. For marine gas hydrate, a range of values for the volume of sediment within the gas hydrate stability zone (corrected for sulfate reduction of CH_4 near the seafloor) was calculated using the model developed by Wood and Jung (2008). This volume was multiplied by a range of parameter estimates of the percentage of sand within the hydrate stability zone, the percentage of those sands that would be hydrate-bearing, sandstone porosity, hydrate saturation of the pore space, and the percentage of the gas that could be recovered from hydrate-bearing sands. This calculation provides an estimate of the technically recoverable gas hydrate resource.

As each of these parameters is poorly constrained in most of the world's depositional basins, the resulting resource estimates extend over several orders of magnitude. A narrower range of values will be obtainable in the future as data are collected. Where detailed analyses have been conducted, the results are integrated into this report.

For Arctic sediments, the estimate of technically recoverable gas hydrate was determined using recent analyses, such as USGS (2008), and extrapolating the range of results to areas where the parameters for a petroleum-systems approach are not available.

The economic resource potential is estimated to be between one and two orders of magnitude smaller than the estimate of technically recoverable gas hydrate because depositional basins typically contain a substantial fraction of thin and/or discontinuous sands and because of the energy required to dissociate hydrates that are at temperature and/or pressure conditions at some distance from the phase boundary. In addition, economic viability is strongly influenced by the presence of existing conventional infrastructure and proximity to markets. The theoretical resource potential is calculated with the inclusion of hydrate deposits that fill veins and fractures.

The combination of lithology and CH_4 flux required for extractable deposits of concentrated hydrate removes most of the world's hydrate from consideration as an energy resource (Figure 7.15). However, the energy potential of the gas hydrate deemed theoretically, technically, or economically recoverable is still extremely large (Table 7.13). In addition to the 18 GEA regions defined for use in this assessment, separate resource assessments are included for the Arctic Ocean without regard for national boundaries, and for the Southern Ocean (from the coast of Antarctica north to 60° south latitude).

Research programs undertaken by international consortia, government programs, and academic institutions have identified proven and

probable gas hydrate locations along continental margins and in polar regions throughout the world, although characterization of deposits is limited to relatively few locations.

7.3.6.1 Overall Unconventional Gas Resources (Including Gas Hydrate)

Table 7.14 summarizes the current understanding of global unconventional gas resources. Gas hydrate and water-dissolved gas are the most abundant, and are also relatively evenly distributed geographically. CBM, shale gas, and deep formation gas appear to be less evenly distributed, but this may well be the consequence of limited geological knowledge through historically low interest. Gas is likely to be found in the tighter formations of all sedimentary basins of the world, but actual quantities can only be confirmed and delineated through dedicated and costly exploration activities.

Table 7.14 | Global unconventional gas resources.

Really unconventional		
Water-dissolved (aquifer) gas (depth up to 4.5 km)	8000–10,000 Tm^3	300,000–370,000 EJ
Gas of hydrates (including permafrost metastable hydrates)	2500–21,000 Tm^3	90,000–780,000 EJ
Shale gas	380–420 Tm^3	14,000–15,500 EJ
CBM (up to depth 4.5 km)	200–250 Tm^3	7500–9300 EJ
Pseudounconventional		
Dense reservoirs (tight sands) gas (depth up to 4.5 km)	180–220 Tm^3	6700–8200 EJ
Deep reservoirs (depth 4.5–7.0 km) gas	200–300 Tm^3	7500–11,200 EJ

7.3.7 Abiogenic Gas Theory

While petroleum (oil and gas) occurrences are commonly thought of as being derived from biological substances, i.e., by the thermal decomposition of organic matter or by microbial processes (Lollar et al., 2002), since the very beginning of the 'petroleum age' there has been a substantial amount of skepticism voiced about its exclusively biological origin (e.g., Mendeleev, 1877; Kudryavtsev, 1951; Gold and Soter, 1980; 1982; Gold, 1999; Kenney et al., 2009). According to the proponents of an abiogenic origin of hydrocarbons, CH_4 and oil are also, perhaps even predominantly, formed well below the usual depths of oil and gas deposits.

By comparing the carbon and hydrogen stable isotope signatures of CH_4 seeping from hard rock mines of Canadian and Fennoscandian shields, with microbial and thermogenic CH_4, Lollar et al. (2002) confirmed the abiogenic formation of hydrocarbons within the Earth's crust. Abiogenic hydrocarbon formation is attributed to the reduction of CO_2 in hydrothermal water-rock interactions similar to Fischer-Tropsch reactions and serpentinization of ultramafic rock. However, the lack of abiogenic isotope signatures in current conventional gases means these authors doubt that abiogenic formation is a significant hydrocarbon source. In contrast, the 'modern Russian-Ukrainian' theory of the origins of hydrocarbons postulates that petroleum is a primordial material of deep origin which is transported at high pressures via 'cold' eruptive processes into the crust of the Earth (Kenney et al., 2002). Much of this theory has developed through chemistry and chemical thermodynamics. One conclusion from the theory is that the origin of hydrocarbon molecules (except CH_4) from biogenic ones in the temperature and pressure regimes of the Earth's near-surface crust is in violation of the second law of thermodynamics (Kenney, 1996).

The abiogenic theory has been applied extensively across the former Soviet Union and has revealed 80 oil and gas fields in the Caspian district with production from the crystalline basement rock. Other examples

have been found in the western Siberian cratonic-rift sedimentary basin with numerous fields producing from the crystalline basement; on the northern flanks of the Dneiper-Donotz basin; and elsewhere in Azerbaijan, Tatarstan, and Asian Siberia.

The theory also postulates that many of the world's oil and gas fields are being continuously recharged from deeper horizons with abiogenic hydrocarbons, so making the fields 'effectively inexhaustible,' and therefore oil and gas fields now considered exhausted should be thoroughly investigated to ascertain the quantities of oil and gas that may have accumulated since the fields were shut-in. In view of the above considerations, Kenney et al. (2009) believe that petroleum abundances are limited by little more than the quantities of its constituent elements that were incorporated into the Earth at the time of its formation and the petroleum industry is only now "entering its adolescence."

Gold (1988) argues that hydrocarbons are of primordial origin without biological derivation. The presence of hydrocarbons in the planetary system, e.g., the atmospheres of Jupiter, Saturn, or Neptune contain enormous amounts of CH_4 and other hydrocarbons, while Titan, a satellite of Saturn, has a CH_4 and ethane atmosphere that is unlikely the result of biological processes. Rather, carbonaceous chondrite meteorites are thought to have brought carbon to the Earth during its formation. Subjected to the appropriate heat and pressure domains present at great depths, e.g., in the vicinity of magma cooling, the carbonaceous material would produce hydrocarbons, chiefly CH_4, as well as hydrogen and CO_2, which is subsequently outgassed to the upper layers of the Earth's crust. Such an environment is also quite amenable for the formation of heavier hydrocarbon molecules.

The discovery of microbial life in ocean vents too deep for photosynthesis is used by Gold (1999) in support of the abiogenic gas theory. Instead of photosynthesis, the large amounts of CH_4 in these hydrothermal vents migrating from deeper levels supply the energy required for life in chemical form. In addition, the existence of anaerobic bacteria in rock structures and CH_4 environments at depths of more than 4 km is another indication of abiogenic CH_4. In turn, bacteria brought along the upward-migrating hydrocarbons explain the existence of certain biomarkers in extracted petroleum commonly associated with the decomposition of organic matter.

The abiogenic origin of hydrocarbon debate dates back to the mid-19th century and since then the theory has undergone extensive development, refinement, and application. More than 4000 articles on the theory have been published (Odell, 2010) and numerous scientific conferences have been held to debate and evaluate the theory. The existence of abiogenic formation of CH_4 and hydrocarbon gases within the Earth has been confirmed (Lollar et al., 2002), but their substantial or exclusive contribution to, and replenishment of, current gas and oil deposits making hydrocarbons a quasi renewable source as proposed by the Russian-Ukrainian theory remains a matter of controversy.

7.3.8 Natural Gas Supply Cost Curves

The aggregate global gas supply cost curve shown in Figure 7.16 plots the potential long-term contributions from conventional and unconventional gas reserves and resources (see Tables 7.11 and 7.12) against their estimated production costs. The costs do not include taxes or royalties, nor do they include external environmental or social costs associated with gas production.

Conventional gas reserves and resources amount to about 12,000 EJ (~300 trillion m^3). In this analysis, the costs of producing conventional resources range from 0.50–3.50 $/GJ. The supply curve suggests some 5000 EJ of conventional gas can be produced for around 1 $/GJ or less at 2007 prices and exchange rates (these supply costs are not the actual prices in the market place). To put this amount of gas into perspective, the cumulative past gas production amounts to 3467 EJ.

Unconventional gas reservoirs are very diverse in their geological structure, location, and accessibility and each deposit requires a specifically tailored extraction technology. Production cost estimates vary considerably, from less than 2 $/GJ for shale gas from very permeable reservoirs, CBM, or onshore gas hydrate to more than 13 $/GJ for offshore deep gas reservoirs. The supply cost curve of Figure 7.16 includes 28,000 EJ of unconventional gas (reserves plus 20% of resources assumed to become resources before 2050) and 5000 EJ of hydrate gas. The production costs of 40% of unconventional reserves are estimated at 2–5 $/GJ, while the remaining 60% of reserves plus 20% of the resources can eventually be recovered for 5–13 $/GJ.

Almost all unconventional resources are characterized by low permeability, and their extraction requires intensive reservoir stimulation through various techniques, e.g., horizontal drilling, multi-leg

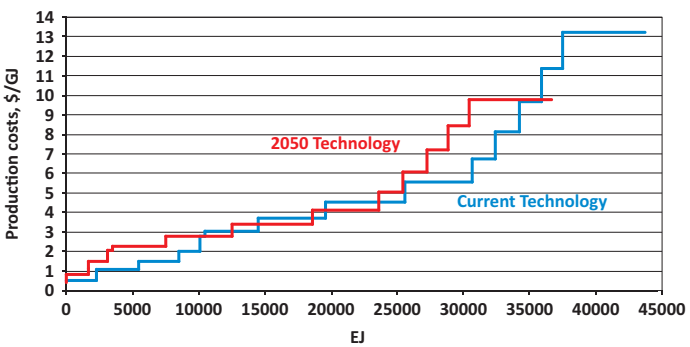

Figure 7.16 | Aggregate world-supply cost curve[11] for conventional and unconventional natural gas. Source: Rogner, 1997; Rogner et al., 2000; USGS, 2000; 2008; Aguilera et al., 2009; BGR, 2009.

11 See footnote 7.

completion, hydraulic fracturing, reservoir acid treatment (for carbonates), and thermal stimulation (for hydrate).

Regarding actual production experience with unconventional gas, the US gas industry is very much in the lead globally. Faced with perpetually declining production from conventional gas reserves, the industry sought alternatives. National fiscal policy created incentives for technological advances in exploration and production of unconventional gas. This led to a 'quiet revolution' in North America, where techniques, such as horizontal drilling and hydraulic fracturing, are allowing access to deposits of unconventional tight and shale gas, and of CBM at much lower costs than thought possible five years ago. In some cases, costs are now lower than those in conventional gas projects.

Costs for the production of gas from hydrate have yet to be delineated and to date no commercial production experience exists. Costs will depend on a variety of factors ranging from geological conditions (e.g., permeability of sediments, reservoir pressure, location, and size of hydrate deposits) to the necessary selective adaptation of exploration and extraction technology. For example, free gas trapped by a hydrate deposit may well be producible with conventional production technology for natural gas. Generally, site development will be more complex, and hence costlier, than that for conventional natural gas. The estimates of economically recoverable gas quantities from hydrate are based inherently on the expected competition with conventional and other unconventional gas occurrences and their respective future costs, and a range of 8–12 $/GJ for gas from hydrate appears plausible.

7.3.9 Environmental and Social Implications

In addition to concerns similar to those relating to oil development, natural gas development raises several other issues.

CH_4, the chief constituent of natural gas, has a very high global warming potential and special care is needed to minimize leaks to the atmosphere. Leakage of gas behind casings of abandoned and 'sealed' oil and gas wells leads to gas entering shallow aquifers, thus degrading potable water resources. This is a significant environmental issue, identified by the US Environmental Protection Agency (US EPA) as a major concern. It can be addressed through better well-abandonment regulations, as well as enforcement of collection or flaring of small and low-grade CH_4 emissions.

Shale-gas development involving deep hydraulic fracturing in the United States has caused serious concerns about drinking water contamination and land degradation (Arthur et al. 2008). The US EPA has undertaken a scientific study to investigate the potential risks to drinking water from hydraulic fracturing and will consider the need for additional health and safety regulations.

Exploitation of sour gas resources requires special attention to escape of H_2S during production and SO_x during processing. Long-term stockage of elemental sulfur from gas plants is of environmental concern in areas such as Kazakhstan and western Canada because of distance-to-sea transportation (costs) and the oncoming world sulfur surplus as more sulfurous feedstocks are processed. For example, Tengizchevroil in Kazakhstan has been fined repeatedly for failure to meet contractual obligations in sulfur management. However, the environmental impact of elemental sulfur is small because it is inert.

Production of gas from hydrate involves potential adverse environmental consequences comparable to those of conventional natural gas. Appropriate environmental management and safety measures exist to minimize potential harmful effects. However, two threats are hydrate specific. First, destabilization of the seabed may cause subsidence and land slippage, including blow outs. Second, gas hydrate utilization may adversely affect the habitat of microorganisms and other forms of biocoenosis systems whose metabolisms depend on CH_4 from hydrate and which form an essential part of the food chain for mussels and beard worms (BGR, 2009). Both threats are generally considered of a local nature and manageable.

7.3.10 Summary

The global occurrence of natural gas is enormous and a significant portion of the total volume occurs in technically exploitable reservoirs. With regard to unconventional gas resources, the recent boom of shale-gas production in the United States is one example of how quickly technical change stimulated by declining conventional reserves and high market prices can reverse the overall supply outlook and price expectations.

The term 'unconventional' is becoming a misnomer, especially with respect to tight gas, shale gas, and CBM. Still, enormous technical challenges exist in the development of innovative exploration and production technology.

Broad-ranging technology impacts can take decades from initial concept to large-scale implementation. In addition, the energy needed to produce unconventional gas is usually higher than that for conventional gas. In the case of gas hydrate, this can reduce the net energy gain by up to 20% or more. Gas hydrate represents the largest of the unconventional natural gas resource options. Yet it is currently unclear how much gas hydrate can be exploited, both technically and economically. Field testing of marine and Arctic reservoirs is planned for the near term, and the results of these tests will determine their commercial viability. The development of gas hydrate has important implications, as it is widespread along the margins of every continent and, as such, includes areas that lack conventional oil and gas resources.

It is important, however, that progress in exploiting unconventional gases will depend on environmental regulation and suitable management

practices, since many of these resources are in remote and ecologically sensitive areas.

7.4 Coal

7.4.1 Overview

Coal is a combustible, sedimentary, organic rock composed mainly of carbon, hydrogen, and oxygen. It is a fossil fuel formed from vegetation lying between rock strata and altered by the combined effects of pressure and heat over millions of years. Coal deposits can be found in sedimentary basins of various geological ages. Dependent on age, depositional conditions, and geological history, the nature of coal deposits and the quality and characteristics of coal vary in terms of heat value, reaction characteristics, and impurities.

The degree of change undergone by coal as it matures from peat to anthracite – known as coalification – defines its physical and chemical properties and is referred to as the 'rank' of the coal. Low-rank coals, such as lignite and sub-bituminous coals, are characterized by high moisture levels, low carbon content, and a consequently low energy content. These coals are typically used locally, predominantly power generation. Higher rank hard coals, i.e., anthracite and bituminous coals, have a higher carbon content and lower moisture content, which result in higher energy quantities per unit mass of coal. Hard coals are produced both for domestic and export markets, including power generation, iron and steel making processes, and chemical industries (WCI, 2008; IEA, 2008a). The large variety of different coal characteristics and specific energy values mean that assessments of reserve and resource are rather challenging.

Efforts to estimate global coal reserves and resources can be traced back to the beginning of the 20th century (Table 7.15). While there has been a steady increase in resource estimates, there has been considerable fluctuation in the estimates of proven hard-coal reserves.

Table 7.15 | Historical development of hard coal resource estimates.

Source	Reserves (Gt)	Resources (Gt)
International Geological Congress (IGC) 1913	312	4399
World Power Conference (WPC) 1936	623	5269
World Energy Conference (WEC) 1974	998	7065
Federal Institute of Geo-Sciences and Mineral Resources (BGR) 2007	736	8818
Federal Institute of Geo-Sciences and Mineral Resources (BGR) 2010	723	17,167[a]
World Energy Council (WEC) 2010	861	–[b]

[a] BGR has included in the 2010 global hard coal resources figures, hypothetical coal resources in Canada and the United States, which have almost doubled the hard-coal resources figures published in 2007.

[b] The World Energy Council does not publish global coal resources figures.

Source: adapted from Fettweis, 1976.

7.4.2 Coal Production

Global hard-coal production amounted to 2.24 Gt in 1950 and has tripled since then, with 6.94 Gt produced in 2009. Three distinct periods occurred. A steady annual increase of about 64 Mt between 1950–1986, a period of stagnation from 1988–2000, and a dramatic increase of 260 Mt/yr or 4.7% from 2000–2009 (BP, 2010). The first period was characterized by a slight growth of coal consumption in the Organisation of Economic Co-Operation and Development (OECD) countries, a static situation in the FSU and marked increases in China, the rest of Asia, and Africa. The period of stagnation coincides with the collapse of centrally controlled economies. The unprecedented 50% increase in coal production since 2000 is primarily because of the economic upsurge of China and East Asia (see Table 7.16). Since 1981, coal production in the European Union (EU) has decreased by more than half and by one-third in the countries of the FSU; it has remained virtually constant in the OECD countries.

The reason for the marked increase in coal production lies in the relative abundance and broad geographical distribution of coal reserves and the comparatively low cost of coal production from shallow coal deposits. Coal is a domestically available energy source in many countries, and offers relative energy independence and foreign exchange savings.

Table 7.16 details the 2008 coal production for the 18 GEA regions. A heat value of 16.5 MJ/kg demarcates hard coal (bituminous and high-energy sub-bituminous coals) and soft brown coal (lignite and low-energy sub-bituminous coals). In 2008 world coal production amounted to 6799 Mt: 5774 Mt of hard coal and 1025 Mt of lignite/brown coal. Table 7.16 shows that:

- China and the United States together account for 56% of world coal production.
- Latin and South America and Africa together produce less than 6% of world coal.
- Asia has developed into the major coal-producing region in the world.

7.4.3 Reserves

Universally applicable, geological, quality, and technological criteria have yet to be uniformly applied, so assessments of global coal reserves and resources are subject to uncertainty. Most importantly, without a clear distinction between the quality or rank of coals and their specific energy contents, which can vary between 5–30 MJ/kg, aggregate

Table 7.16 | Coal production in 2008 by region.

resource assessments will remain fraught with ambiguity. Without a precise definition of the energy contents used, it is impossible to compare any two sets of coal reserves or resources estimates.

Coal deposits that clear the threshold of economic producibility are referred to as mineable reserves. These quantities need to be corrected for the amounts of coal that are likely to be lost during the mining process – on average 10% for surface mining and 50% for underground mining (Fettweis, 1990; Daul, 1995).

It is important to define the separation point between higher and lower rank coals in any estimation. The most comprehensive information on coal reserves and resources is provided by the World Energy Council (WEC) and BGR. Unfortunately, the two agencies use different classifications of higher and lower rank coals that are not directly comparable. WEC publishes data for the categories (a) bituminous coal and anthracite, (b) sub-bituminous coal, and (c) lignite, whereas the breakdown used by the BGR is hard coals (>16.5 MJ/kg) and soft brown coals (<16.5 MJ/kg). Figure 7.17 clarifies the two definitions. A further quality criterion includes the content in the coal of environmentally harmful substances, e.g., sulfur, but is evaluated on a case-by-case basis. Nevertheless, harder coals typically have lower sulfur concentrations.

Coal reserves data also say little about the nature of the coal seams and the associated mining difficulties that determine the actual cost of production. Therefore, a further classification system based on geomining conditions is required. Geomining conditions include the depth of coal seams, the angle of dip of seams, number of seams and degree of disturbance of coal seams, and faulting (Wagner, 1998). Table 7.17 details the geomining descriptions used to classify coal fields (IEA Coal, 1983).

With increasing depth, rock stress conditions become more severe and require more complex and costly mine infrastructures; CH_4, heat, and water hazards also increase. Category D1 (Table 7.17) defines the current depth limit of the widely used drag-line operations in surface mining under conditions of competent overburden strata. The angle of dip adversely affects the operation of trackless coal mining equipment, because of gravity, and hazards associated with mine depth increase with steeper seams. Ground disturbances and faulting adversely affect the extent of mechanization in the coal mining operations, as well as mine safety, design, and layout. Highly mechanized and productive coal mining operations are presently confined to geologically relatively undisturbed coal deposits. Factors such as exceptional gas conditions or permafrost have to be considered as well.

The geological environments and geomining conditions of hard- and lignite/brown-coal deposits tend to be very different. Sandstone and shale formations are the typical rock strata in which hard-coal deposits are located, while soft-coal deposits are typically located in soft rocks and soils.

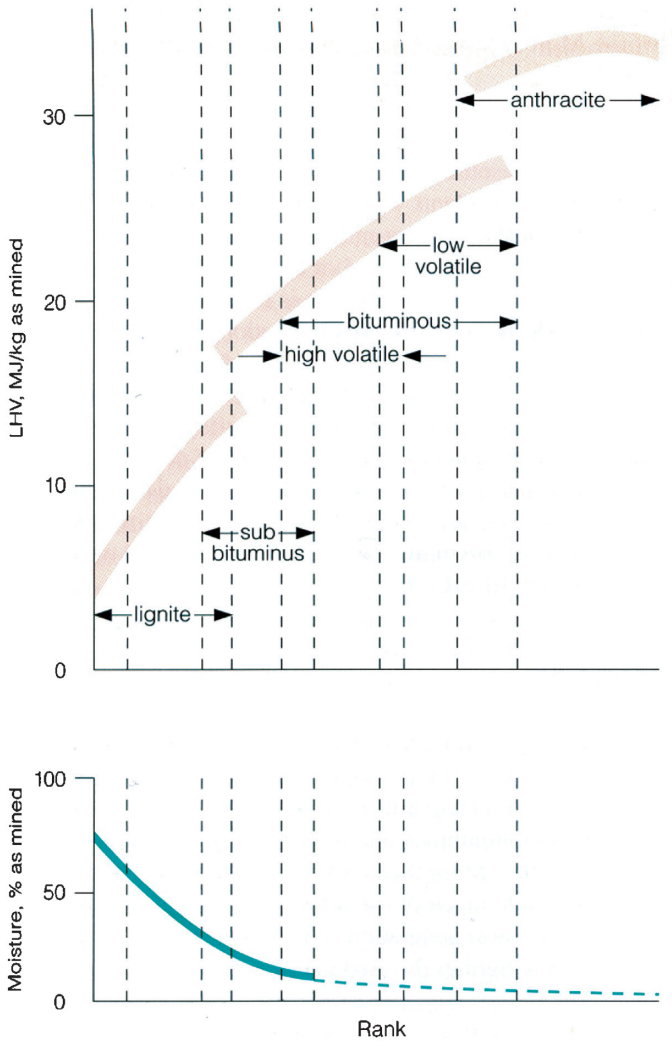

Figure 7.17 | Calorific value and moisture content of various coal ranks. Note: Volatility determines the burn rate of the coal. High volatile coals are easy to ignite but have lower energy content per unit volume than low volatile coals. Source: Couch, 1988.

Table 7.18 shows that approximately 60% of CI and CII hard-coal reserves are situated in the United States and China, whereas the bulk of reserves in Europe and Japan fall into geomining categories CIII and CIV. The geomining conditions in different regions are clearly mirrored by the coal production trend from 1981–2008 shown in Table 7.16. According to Table 7.18, the bulk (categories BI and BII) of soft-coal reserves can be extracted by surface-mining methods and are concentrated in six geopolitical areas; in descending order: FSU, Western European Union (WEU), United States (USA), Oceania (OCN), Eastern European Union (EEU), and China (CHN). Slightly more than half of the soft-coal reserves fall in the most favorable geomining category (BI).

The future development of coal reserves depends on overall coal demand and the rate at which technology change and market conditions shift deposits presently listed in the coal resources category to coal reserves. Furthermore, the easily accessible and favorable coal deposits

Table 7.17 | Geomining characteristics of coal production categories.

Depth (D)	Angle of dip (A)	Degree of disturbance/ faulting (G)
D1, <70 m	A1, <15°	G1, undisturbed
D2, 70–300 m	A2, 15–30°	G2, disturbed
D3, 300–500 m	A3, >30°	G3, highly disturbed, faulted
D4, 500–800 m		
D5, >800 m		
Production category	**Hard-coal deposits**	
CI	Shallow coal seams (D1, D2); favourable conditions (A1, G1)	
CII	Shallow coal seams (D1, D2); less favourable conditions (A2, G1, G2) Intermediate depth (D3); favourable conditions (A1, A2; G1)	
CIII	Intermediate depth (D3); less favourable conditions (A2, G2) Great depth (D4), favourable conditions (A1,G1)	
CIV	Great depth (D4), unfavourable conditions (A2, A3; G2)	
	Lignite/brown-coal deposits	
BI	Few shallow, thick and level coal seams (D1, D2), (A1, G1)	
BII	Several shallow coal seams (D1, D2), (A1, A2), (G1, G2)	
BIII	Several coal seams at greater depths (D2,D3), (A1, G1, G2)	

Source: IEA Coal, 1983.

of categories CI and CII will be exploited first before extracting deposits of categories CIII and CIV.

It is also realistic to assume that coal reserves in categories CI and CII, and in the case of lignite/brown coal in category BI, will be exploited more rapidly – resulting in a change in future coal-reserves distribution toward the more difficult geomining categories. The impact of this development is most profound in geopolitical regions with limited CI and CII reserves, such as EEU, WEU, FSU, and Latin America and the Caribbean (LAC). As information on the coal reserve situation of China and India is uncertain, there could be potential longer term coal reserves difficulties in these regions.

Proven hard-coal reserves amount to 18.2 ZJ, while cumulative past production since the industrial revolution is estimated at close to 7 ZJ. Although there is a relatively broad geographical spread of proven hard-coal reserves, there is a concentration in four geopolitical regions (United States, China, India, and FSU), which together account for 84% of global reserves. OCN (essentially Australia), EEU, and southern Africa (SAF, essentially South Africa) account for 75% of the remaining 13% of hard coal reserves. Proven lignite/brown-coal reserves amount to 2.8 ZJ and are concentrated in the FSU, EEU, WEU, OCN, and the United States. These five regions account for 88% of proven lignite/brown-coal reserves.

7.4.4 Resources

Resources are coal occurrences that are either known to exist but are currently not economically recoverable or amounts that can be expected to exist based on geological indicators (BGR, 2009).

Resources are shown as in situ amounts; the eventually extractable quantities will be significantly lower. As a result of the large reserve base and the considerable costs associated with the exploration and delineation of resources that may potentially be at the cross-over threshold to reserves, there is limited economic incentive to expand the reserve base beyond a certain range, commonly expressed in terms of years of reserves at current production levels. In the case of coal this is more than 100 years (Wellmer, 2008).

The global in situ coal resource data in EJ of Table 7.19 were derived from regional estimates of physical in situ quantities by applying the heating values of coal reserves of these regions areas published by the BGR (Rempel et al., 2007).

While coal resources are 20 times higher than known extractable coal reserves, there is uncertainty about the minable portion of these in situ quantities. Information on the geomining conditions of coal resources is insufficient for a reliable production assessment. For example, most of the better delineated coal resources are situated at greater depths and thus belong to geomining categories CIII and CIV. Extraction ratios in geologically difficult coal deposits can be below 40% (Kundel, 1985; Daul, 1995; USGS, 2009). Since many of the 'in situ' hard-coal resource deposits are in narrow seams at depths of more than 1000 m, an overall recovery rate of 20% may well be achievable practically. For example, 60% of coal resources in China are found at depths deeper than of 1000 m (Pan, 2005; Minchener, 2007). Without new extraction methods, a 20% recovery rate puts the portion of coal resources that eventually could become available as reserves to 87,154 EJ.

7.4.5 Coal Mining Technology

The past 50 years have witnessed remarkable improvements in coal mining technology and productivity. Mechanization and the adoption of engineering-systems approaches resulted in a fourfold increase in labor productivity between 1980 and 2000. In surface mining, bucket-wheel excavators are employed under soft overburden conditions, while drag lines are used under hard overburden conditions, where the overburden strata has to be blasted to expose the coal. In underground mining, manual labor is becoming extinct, except in marginal micromines in developing countries. Coal is now mined by powerful continuous-mining machines in room and pillar mining, and pillar recovery operations. As a result of mechanization, safety in underground coal mining has improved and productivities have increased substantially. Output from individual longwall faces has increased more than 10 times over the past 30 years.

However, these developments have not been achieved without costs. Higher degrees of mechanization make mining systems less flexible and more vulnerable to changes in geological conditions. While mechanization has contributed to substantial improvements in productivity, it has also resulted in significantly lower reserve assessments. Mining operations now increasingly concentrate on the most favorable coal seams in easy geological environments, which results in numerous previously mined coal seams being ignored. In the German Ruhr coal-mining region, inclined coal seams and faulted areas are no longer mined because of low productivity, prohibitive costs, and drastically reduced subsidies (Kundel, 1985; Gesamtverband Steinkohle, 2007). Once closed, it is extremely difficult, dangerous, and costly to reopen and extract any coal remnants. At present there are no mining methods available or known to overcome these difficulties. A recent revaluation of German hard-coal reserves showed a decline of more than 90% from previous assessments (Rempel et al., 2007).

Overall, labor productivity in shallow underground mines that operate under favorable geomining conditions (category CI, see Table 7.17) now approaches 10,000 tonnes per person and year. Yet in deep coal mines operating under difficult geomining conditions (CIII, CIV), overall labor productivities are below 1000 tonnes per person and year, and have improved only marginally over the past 20 years (Ritschel and Schiffer, 2007; Turek et al., 2008; Statistik der Kohlenwirtschaft, 2009). As the depth of mining progressively increases, operations will have to move into more difficult areas, so it is realistic to assume that the cost of coal extraction and reserve losses will increase in the future.

To harvest deep coal deposits, new and innovative technologies are required, including technologies for coping with geological disturbances. Depth-related challenges include the need for an underground roadway support that can withstand high rock pressures and effective cooling,ventilation, and gas-drainage systems. Whereas depth-related challenges are expected to be met by innovation, it is less clear how to solve the problem of extracting coal from highly disturbed and faulted areas. Some promising possibilities are highly flexible mining systems based on conventional mechanized and automated mining technology, or novel concepts utilizing underground coal gasification (UCG).

UCG, the controlled gasification of coal seams in situ, permits the exploitation of deposits where mining is no longer technically feasible. CO_2 from the process can be returned safely to the gasified seam, resulting in zero emissions and very little ground disturbance. Feasibility studies and demonstration projects are ongoing in the United Kingdom, Russia, China, South Africa, New Zealand, and elsewhere. These studies suggest the use of UCG could potentially increase world coal reserves by 500–600 Gt (12.3–14.8 ZJ) (WEC, 2007).

CBM is a relatively large and undeveloped resource in most regions and refers to CH_4 that is adsorbed to the solid matrix of coal (see Section 7.3.4).

7.4.6 Coal Mining Costs

The competitive nature of the international coal market means that detailed coal production costs are difficult to find. Data collected from coal mines in Australia, Canada, Columbia, Indonesia, South Africa, and Venezuela show a wide range of mine operating and capital costs. In 2007, mine costs for steam coal ranged from 15–65 US$/t, with the costs of underground coal some 10% to 20% higher than those of surface-mined coal (Ritschel and Schiffer, 2007). It is important that these cost figures refer to relatively shallow and favorable coal mining conditions, and deep-coal mining costs can be significantly higher (Turek et al., 2008).

As noted earlier, the cost of coal production is strongly influenced by geomining conditions, especially mining depths. Data for major European deep-coal mines reveal rapid cost increases at greater depths, mainly because of the higher costs of supporting and maintaining mine development, mine ventilation, and, in the case of the very deep mines, mine cooling.

Long-term projections of coal production costs need to account for the change in the ratio of surface to underground mining. After coal seams situated close to surface have been exploited, there will be a shift toward underground mining and toward deeper mines within

underground mining. This means increased specific investment costs for new mine infrastructure as well as higher mine-operating expenditures. Technology change and innovation will be needed not only to keep short-term cost increases in check, but also to reduce the costs of long-term marginal coal production.

Highly productive multiple-entry longwall mining, which has been practiced successfully to depths of about 600 m, will reach its technical limits at greater depths and will need to be replaced by single-entry longwall development, which is limited in terms of ventilation and operational efficiency. Geological disturbances further impede longwall mining. Mining losses in faulted areas are expected to lower recovery rates. Without technology changes and innovation, these factors are likely to drive up long-term coal mining costs at a faster rate than those of oil or gas production costs.

7.4.7 Coal Supply Cost Curves

Future supply cost curves are a function of the energy content of coal deposits, geomining conditions, technology changes, overall coal demand, and inflation. Table 7.20 summarizes the current and projected cost of producing 1 TJ of in situ coal under different geomining conditions at constant US_{2007}\$ prices and exchange rates. The 2050 costs reflect the technological improvements between 2007 and 2050.

Further dividing the cost range per geomining category into four classes and applying these classes to the coal reserves of each of the 18 regions (Table 7.18) in a fixed proportion (60%, 25%, 10%, and 5%) leads to a global hard-coal supply cost curve. Figure 7.18 shows two supply curves – one for the current reserves based on performance, productivity, and costs of current mining technology and one for the reserves, performance, and mining technology expected by 2050. The differences between the two supply cost curves reflect the tendency to extract coal frist from deposits having more favorable geomining conditions which over time will result in a reserve shift towards more unfavorable geomining conditions. The reserves in 2050 exclude any replenishment from coal resources potentially made possible by technology change and different market conditions but reflect the coal produced between 2007 and 2050 (assuming constant 2007 production levels).

7.4.8 Environmental and Social Implications

Major environmental and social problems can develop during mining operations, and also after the the coal has been exploited. However, concerns about adverse environmental and social impacts of coal as a primary energy source are often subordinated to the pressures that result from growing energy needs, especially in developing countries.

Surface mining requires the removal of overburden strata for access to the coal seams. Top soil can be destroyed and groundwater tables affected adversely by this removal process. Damage to land and water resources from the overburden removal method of coal mining has particularly destructive impacts on people living in the affected area. Many coal deposits are located in remote, isolated areas, but when

Table 7.20 | Hard- and lignite/brown-coal production costs for different geomining conditions at 2007 US$/TJ.

Geomining category	Production costs 2007		Technology change in %/yr	Production costs 2050	
	Lower bound	Upper bound		Lower bound	Upper bound
Hard coal					
CI	600 $/TJ (15 $/t)	1000 $/TJ (25 $/t)	1.5	310 $/TJ (7.75 $/t)	525 $/TJ (13 $/t)
CII	1000 $/TJ (25 $/t)	1600 $/TJ (40 $/t)	1	650 $/TJ (16.25 $/t)	1040 $/TJ (26 $/t)
CIII	1600 $/TJ (40 $/t)	2800 $/TJ (70$/t)	0.5	1290 $/TJ (32.25 $/t)	2260 $/TJ (56.50 $/t)
CIV	2800 $/TJ (70 $/t)	6000 $/TJ (150 $/t)	0.5	2260 $/TJ (56.50 $/t)	4900 $/TJ (122.50 $/t)
Lignite/brown coal					
BI	680 $/TJ (7 $/t)	1160 $/TJ (12 $/t)	1.5	350 $/TJ (3.60 $/t)	610 $/TJ (6.20 $/t)
BII	1160 $/TJ (12 $/t)	1750 $/TJ (18 $/t)	1.5	610 $/TJ ($ 6.20/t)	910 $/TJ (9.40 $/t)
BIII	1900 $/TJ (20 $/t)	3880 $/TJ (40 $/t)	0.5	1560 $/TJ (16.40 $/t)	3130 $/TJ (32.30 $/t)

The costs quoted are typical 2007 mining costs (Ritschel and Schiffer, 2007; Turek et al., 2008; Landsmann, 2009) and include operating and capital costs, but exclude costs of coal benefication and cost of mine-to-market transportation. The cost ranges reflect differences in geomining conditions within each class. Lignite/brown-coal mining costs are strongly influenced by environmental costs.

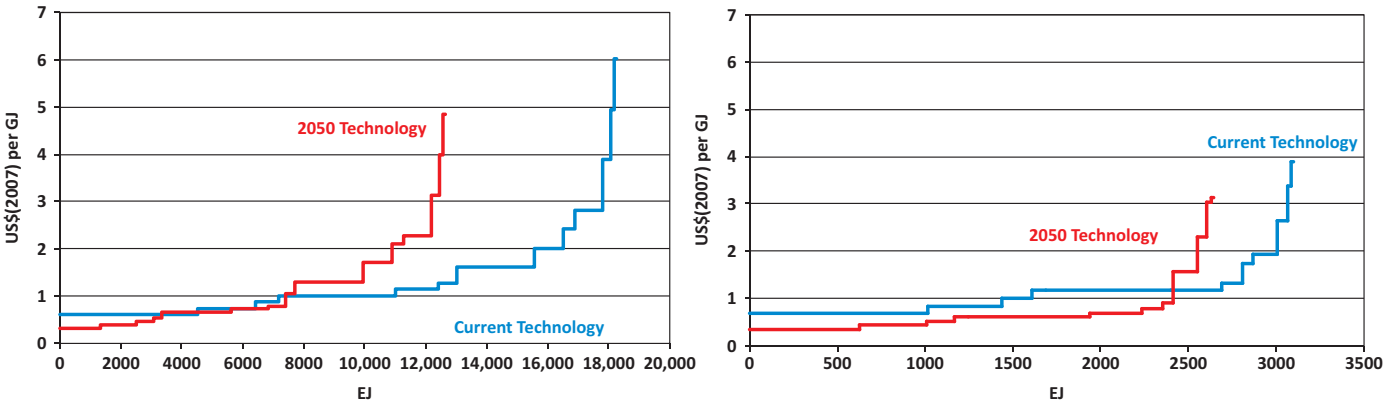

Figure 7.18 | Global coal supply cost curves[12] for 2007 and 2050.

mining operations are undertaken in densely populated areas, resettlement of the population can be a costly and politically sensitive issue. Differences in the cost of lignite mining in Europe and overseas are, to a considerable degree, linked to environmental legislation and the cost of resettlement.

Other environmental impacts of surface mining are ground vibrations and dust caused by overburden blasting. Once production has ceased, the overburden strata is returned to fill the void created by the coal extraction and the land surface is reshaped and rehabilitated. Many jurisdictions mandate rehabilitation to conditions at least equal to those prior to mining operations. As a result, the cost of land rehabilitation can be 20–30% of total mining cost and depends on climatic conditions, prior land use, and applicable mining regulations.

Underground coal mining is generally associated with less-severe environmental impacts, but presents significant health and safety hazards for workers, including mine fires, CH_4 and coal dust explosions, ground instability, and flooding. Coal mining requires a well-qualified and highly specialized workforce. In many countries such skills are not sufficiently available. Training and education of coal-mining personnel and continued mining R&D are essential as the extraction of deep coal resources in difficult geological environments requires new mining systems and technologies. With the demise of the nationalized coal-mining industries in most countries, mining research is left to equipment manufacturers and academic institutions (Wagner and Fettweis, 2001). As a result, research of coal-mine safety has suffered.

Mine subsidence is a critical issue. In the case of room and pillar mining, subsidence is a distinct possibility even many years after completion of mining operations. Caving of the roof strata tends to be less critical with longwall mining, particularly at great mine depths and moderate seam thicknesses. Mine subsidence associated with longwall mining is rather predictable and can be prevented by appropriate engineering approaches. In sensitive areas, mine subsidence can be minimized by applying backfill (stowing).

Mine fires in relatively shallow underground mines can cause major environmental and safety hazards, especially where the sulfur content of coal is high. These fires can develop many years after completion of coal mining operations as a result of air entering through fractures in the overburden strata. Control of mine fires has been a serious challenge in many mining countries, notably China. High sulfur contents in coal seams can also give rise to problems of acidic mine drainage.

Many coal resources in the northern hemisphere are located in areas of permafrost. This creates unique environmental problems that not only impact the environment, but also can give rise to unique technical and social problems. Other environmental concerns include CH_4 emissions from shallow coal-mine workings, and transportation of coal from the remote mining areas to the industrialized areas.

7.4.9 Summary

Proven hard- and lignite/brown-coal reserves are abundant, i.e., 21,000 EJ, of which 18,000 EJ are hard coal. Estimated coal resources exceed proven reserves more than 20 times. Even on the basis of a very conservative assumption of a 20% in situ recovery rate, coal is sufficiently available to support annual coal production increases of 2% for more than 100 years. However, many coal deposits are located in remote areas with little or no infrastructure and often harsh climatic conditions. Bringing these coals to the market will pose immense challenges.

Coal mining technology and productivity have increased significantly in recent years and secured the position of coal as the fossil energy source of lowest cost. The expected increase in the average depth of coal mining and increased environmental regulation of coal mining operations will exert upward pressure on production costs, while advances in mining technology are expected to at least partly offset these increased costs.

12 See footnote 7.

7.5 Nuclear Resource Materials

7.5.1 Overview

Nuclear resource materials include the fuels required for the operation of both nuclear fission and fusion reactors. (For a discussion on nuclear energy technologies, see Chapter 14.)

The primary fuel, uranium, is a naturally occurring element that can be found in minute concentrations in all rocks, soils, and waters, always combined with other elements. It is found in hundreds of minerals, including uraninite (the most common uranium ore), lignite, monazite, and phosphates (Table 7.21).

The average uranium concentration in the continental Earth's crust is about 2.8 ppm, while the average concentration in ocean water is 3 parts per billion (ppb) (Bunn et al., 2003). The theoretically available uranium in the Earth's crust has been estimated at 100 teratonnes (Tt) uranium, of which 25 Tt occur within 1.6 km of the surface (Lewis, 1972). The amount of uranium dissolved in seawater is estimated at 4.5 Gt. However, these occurrences do not represent practically extractable uranium resource (at least not in the short run and without substantial R&D). For that, what matters are abnormal uranium concentrations in the Earth's crust, at levels that can be extracted, both technically and economically (currently about 100 ppm U).

A potential alternative fission fuel is thorium. Thorium is about three to four times more abundant than uranium, and is also found in seawater, soils, and rocks. It occurs in minerals on all continents.

Lithium is a valuable resource for nuclear fusion. Lithium does not occur in an elemental form because it is highly reactive. It is found in all geological strata and is the 25th most abundant element, but is still considered a comparatively rare element. Only a few deposits are concentrated enough to be of any actual or potential commercial value.

While the resource situation of uranium is currently well delineated, thorium and lithium resource profiles are, for different reasons, unclear. Thorium has limited uses and its natural ubiquity makes further exploration unprofitable. Lithium occurrences are concentrated mainly in Central and South America and China.

Table 7.21 | Typical uranium concentrations.

Occurrence	Average concentration [ppm U]
High-grade ore	20,000
Low-grade ore	1000
Granite	4
Sedimentary rock	2
Earth's continental crust	2.8
Seawater	0.003

7.5.2 Uranium

7.5.2.1 Historical Uranium Production

The uranium market has been characterized by a large disparity between global reactor requirements and mine production since the early 1990s when, after decades of production exceeding requirements by an unusually wide margin, mine output slipped below annual reactor requirements (see Figure 7.19).[13] The appearance of so-called secondary supplies, i.e., reactor fuel derived from warheads, military and commercial inventories, re-enrichment of depleted uranium tails, as well as enriching at lower tail assays, reprocessed uranium, and mixed oxide fuel, reduced the demand for fresh uranium. In addition, new entrants to the world uranium market, e.g., the Russian Federation, Kazakhstan, and Uzbekistan, further exerted competitive pressures. As a result of uncertain and low demand plus excess capacity, uranium prices fell, except for short-term aberrations.

As low prices seemed to suggest plentiful supply, utilities began to hold lower uranium inventories. This suppressed both production and prices even further. Requirements were increasingly met by accumulated past production and not from operating capacities, to the point that global operational mining output capacity dropped below the annual reactor requirements. In late 2000, uranium prices reached a historical low of 7.10 \$/lb U_3O_8 (triuranium octoxide) or 18.45 \$/kg U (uranium metal), threatening the economic survival of many mines. At the same time, global production had declined to less than 60% of annual reactor requirements. Low prices and a doubtful future for nuclear energy combined to make uranium exploration and investment in mine capacity a highly unpopular and risky business proposition. Uranium exploration almost totally ceased, mines closed, and institutions routinely reporting

13 The geopolitical landscape caused by the collapse of the Soviet Union accelerated the declining trend in global uranium production. Prior to 1990, information about uranium production from the Soviet Union's area of influence was not publicly available.

uranium reserves and resources became reluctant to do so in a comprehensive manner.

The situation changed dramatically starting in 2000 for four main reasons. First, the license extension of nuclear power plants in the United States generated another 20 years of unexpected uranium demand. Second, the emergence in the uranium market of China and India, potentially major customers for uranium, generated additional demand with consequent pressure on supply capacity.

Third, in the light of volatile fossil-energy prices, energy security concerns, and concerns about climate change, a growing number of countries began to reevaluate the nuclear option thus further adding to potential supply shortfalls. Fourth, when two of the world's top producing mines greatly reduced output because of fire and flooding incidents, the supply/demand imbalance began to impact uranium markets (PCA, 2006). Spot prices instantly shot through the roof and continued climbing, approaching 350 $/kgU in 2007. Exploration expenditures also increased by an order of magnitude, from US$100 million in 2002 to over US$1 billion in 2008. By April 2009 spot prices had dropped to one-third of the peak level or about 110 $/kgU and have not changed markedly since.

7.5.2.2 Conventional Uranium Reserves and Resources

Conventional uranium resources are defined as those occurrences from which uranium is recoverable as a primary product, a co-product, or an important by-product. Uranium reserves are periodically estimated by the OECD's Nuclear Energy Agency (NEA) together with the International Atomic Energy Agency (IAEA), and also the World Nuclear Association (WNA), WEC, and numerous national geological institutions. NEA-IAEA estimates have the widest coverage, so the reserves reported in their latest survey (the so-called Red Book) are given here (NEA/IAEA, 2010). The two organizations define 'reserves' as those deposits that could be produced competitively in an expanding market. This category is called identified resources[14] and, until 2008, included uranium recoverable at less than 130 $/kgU. Stimulated by high spot prices of up to 350 $/kg in 2007, the 2010 edition of the Red Book extended the cost ranges to 260 $/kgU.

What is important for a good comprehension of the long-term availability of uranium is the impact of demand prospects and prices on the volume of reported reserves and resources. The recent uranium-price hike stimulated exploration, prompted institutions to report occurrences long labeled irrelevant, and led companies to consider reopening high-cost mines. The RAR category in the Red Books increased by 27% between 2001 and 2009 (or 43% if reserves up to 260 $/kg production cost are included). In addition, the category of 'uranium that could be expected to be found based on the geological characteristics of known resources grew by 5%. Figure 7.20 shows the historical development of identified resources since the early 1970s.

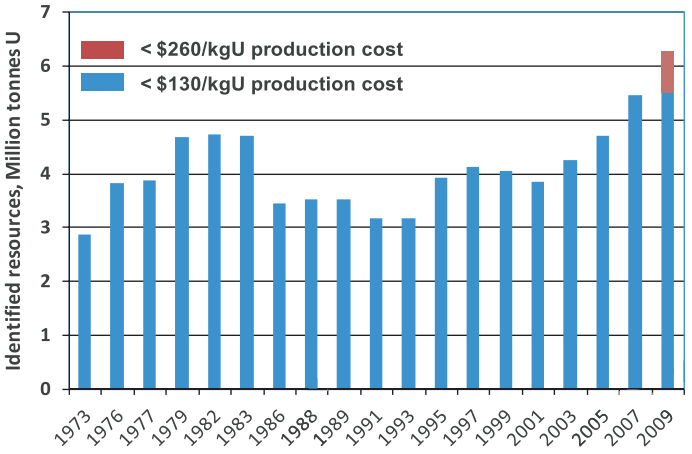

Figure 7.20 | Development of identified uranium resources at less than 130 $/kgU production costs, 1973–2009, and less than 260 $/kgU for 2009. Source: NEA/IAEA, 2010.

Table 7.22 shows the identified uranium resources by region reported in the Red Book 2009 (NEA/IAEA, 2010). Altogether, there are 6.3 MtU (or 3.7 ZJ)[15] of conventional uranium resources available at extraction costs of less than 260 $/kgU. Vast additional uranium occurrences can be mobilized at costs larger than 260 $/kg.

Table 7.23 shows uranium occurrences yet to be discovered based on knowledge derived from already discovered and delineated deposits, as well as from regional geological analogies and mapping activities. Reports on 'prognosticated resources' are usually supported by some hard evidence. These deposits are generally located in known uranium provinces. Data on 'speculative resources' are not supported by direct evidence, but rather based on analogy and other considerations. Hence both categories require substantial additional exploration efforts before their existence can be confirmed and their overall qualities and quantities delineated.

Reporting on undiscovered resources (Table 7.23) is sketchy and incomplete, and recently the number of reporting countries has declined. Several reasons account for this decline, including funding constraints from governmental offices, lack of interest from industries, and plentiful known and accessible uranium occurrences.

7.5.2.3 Unconventional Uranium Resources

The distinction between conventional and unconventional resources is not clearly defined, but generally unconventional uranium resources

14 Until 2003 'Identified Resources' were reported as known conventional resources (KCR), i.e., the sum of reasonably assured resources (RAR) and estimated additional resources category-I (EAR-I). After 2003 Identified resources are the sum of RAR and inferred resources.

15 The thermal energy equivalent of 1 tonne of uranium in average once-through fuel cycles is about 589 TJ (IPCC, 1996).

are those not rich enough to justify mining under current and expected market conditions; for example, where uranium is only recoverable as a minor by-product, or where the occurrence of uranium is at a level of concentration well below the capacity of current technology. Most unconventional uranium resources reported to date are associated with uranium in phosphate rocks, but seawater and black shale are other potential sources.

In some cases when uranium is produced as a by-product, however, it is considered a conventional resource, for example in the multimineral (copper and gold) Olympic Dam mine in Australia, where the average ore grade is about 280 ppm uranium.

Historically, unconventional uranium has been produced predominantly from phosphate deposits. The world average uranium content in phosphate rock is estimated at 50–200 ppm. Marine phosphorite deposits contain averages of 6–120 ppm, and organic phosphorite deposits up to 600 ppm. Although the concentration is of similar magnitude as that found in gold deposits, typically uranium recovered from phosphate rocks has been classified as coming from 'unconventional' resources.

Between 1975 and 1999, Moroccan phosphate rock processed in Belgium produced 690 tU. About 17,150 tU were recovered in the United States from Florida phosphate rocks between 1954 and 1962, and as much as 40,000 tU were recovered from processing marine organic deposits in Kazakhstan (NEA/IAEA, 2010). Estimated production costs for a 50 tU/yr project, including capital and investment, ranged between 40 $/kgU and 115 $/kgU in the United States during the 1980s (NEA, 2006). The estimates of uranium in phosphates vary widely globally, from 7–22 million tU, in large part reflecting the lack of interest in this resource, which is reported only by a few countries on a regular basis.

Other unconventional occurrences can be found in non-ferrous ores, carbonatites, black schists, and lignite. Table 7.24 summarizes the most recent ranges of unconventional uranium occurrences reported in NEA (2008). Even with the limited reporting, these unconventional occurrences represent between 6.6–7.4 ZJ.

Uranium is also an integral component of coal. For the majority of global coal deposits, uranium concentrations range from slightly below 1 ppm to 4 ppm, which is similar to the concentrations found in a variety of

Source: adapted from NEA/IAEA, 2010.

common rocks and soils (see Table 7.21). Since uranium is not combustible, it remains in the ash at concentrations ten times and more than that in the original coal. Current global electricity-generation accumulates on average 3400 tU in the ashes per year.

Of specific interest are the ashes from lignite-burning coal plants located in areas where the lignite resources contain higher than normal levels of uranium. For example, the fly ash at the Xiaolongtang coal power plant in Yunnan Province, China, averages 160–180 ppm, which is only about a quarter of the concentration considered commercially viable for uranium extraction by in situ leaching (ISL), a conventional mining and extraction process. However, coal-ash piles are easier to drill in. In addition, it may be easier to protect local groundwater from contamination. There might also be some monetary value in reducing coal-ash radiotoxicity if regulatory requirements restrict the ash use or require its cleanup. The cumulative ash volume at the Xiaolongtang site is estimated at 5.3 Mt, and contains between 850–950 tU.

Seawater is also a possible unconventional source of uranium. The total mass of uranium in seawater is enormous and amounts to about 4.5 GtU, dwarfing any other exhaustible energy resource. However, because of the low concentration level (3–4 ppb), it is estimated that processing of about 350,000 tonnes of water would be required to produce one kilogram of uranium. In the 1970s and 1980s, recovery from seawater was on the agenda of several countries. Today research is effectively ongoing only in Japan and France. A braid-type recovery system directly moored to the ocean floor recovered about 1.5 g U over a 30-day test period (Tamada et al., 2006; 2009), but the recovery costs of such a system are over 700 $/kgU, several times the current market price (NEA/IAEA, 2008). Other studies quote recovery costs between 260 $/kgU and 1700 $/kgU (Nobukawa et al., 1994; Kato et al., 1999; Bunn et al., 2003).

"The performance of current [uranium] adsorbents is highly dependent on temperature, and they are thus effectively limited to warm surface waters. However, horizontal and vertical mixing of the ocean would make seawater uranium accessible in warm surface waters at essentially constant concentrations for many centuries, so long as the rate of extraction did not exceed ~2 MtU/yr (30 times current global reactor requirements)" (Bunn et al., 2003).

These cost estimates for uranium from seawater do not include the value of the other metals (vanadium, cobalt, titanium, molybdenum) that would be co-recovered with the uranium (Sugo et al., 2001). Depending on the future long-term market prices of these co-recovered materials, their values might be sufficient to reduce substantially the net uranium recovery cost per kilogram of uranium.

7.5.2.4 Extraction Technologies and Production Costs

The extraction costs of uranium reserves are usually reported in categories up to 130 $/kgU. Clearly, this production cost limit prevents the vast majority of low concentration and unconventional occurrences from being reported and accounted. In fact, from a current demand and supply perspective there is little interest in spending funds on a better delineation of these occurrences or on the development of technologies for their extraction on a commercial scale.

Figure 7.21 summarizes the technologies associated with the extraction of conventional uranium reserves and resources. Underground mining is expected to continue to be the dominant extraction process. At lower ore concentrations (and generally higher production costs), ISL becomes the technology of choice. Not surprisingly, mining of uranium as a by-product has the largest potential at the lowest production costs. Small amounts of uranium are also recovered from mine-water treatment and environmental restoration.

Uranium resources are divided into three production cost categories: less than 40 $/kgU, less than 80 $/kgU, and less than 130 $/kgU. The third level is viewed as a price level "not likely to be seen for many decades, if not longer" (Bunn et al., 2003). This continues to be the general perception, even though spot prices in 2007 were more than twice that high for several months in 2007.

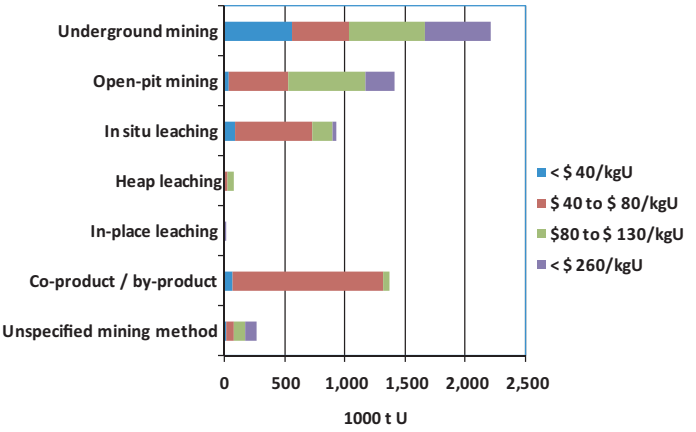

Figure 7.21 | Distribution of uranium reserves and resources by production method. Source: adapted from NEA/IAEA, 2010.

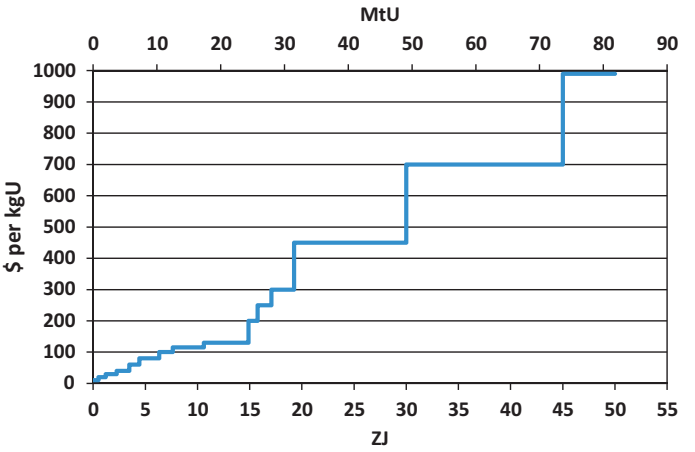

Figure 7.22 | Long-term uranium supply cost curve, in ZJ and MtU.

Figure 7.22 shows a resource cost curve developed from a limited number of indirect observations on the production cost distribution within each category. Costs higher than 130 $/kgU are representative for uranium production from unconventional resources, and for the lowest ore concentration occurrences. Estimated extraction costs of uranium from seawater are now between the optimistically low 200 $/kgU and 1000 $/kgU (Schneider and Sailor, 2008). Although there is abundant uranium in seawater, it is unlikely ever to be produced because at costs consistently higher than 130 $/kgU, reprocessing of spent fuel may become an attractive alternative (particularly in view of waste-disposal considerations).

7.5.3 Thorium

Thorium is a naturally occurring, slightly radioactive metal. It has been considered as an alternative nuclear fuel to uranium, especially by countries with limited domestic uranium resources. Until the mid-1970s, there was interest in the development of thorium deposits

and thorium-based nuclear fuel cycles, in large part because of high growth expectations for nuclear energy and a limited understanding of the global uranium resource endowment. The initial enthusiasm cooled quickly once new discoveries of uranium deposits expanded the availability of uranium well beyond projected reactor requirements.

The average content of thorium in the Earth's outer crust amounts to three to four times the average concentration of uranium. Thorium is widely distributed in rocks and minerals and is found, to some extent, in virtually every continent of the world. There are three principal types of thorium deposits with concentrations of commercial interest: the rare earth phosphate mineral monazite in heavy-mineral, sand placer deposits, thorite ores in vein deposits, and thorium recovered as a by-product of uranium mining.

Current thorium production is based on phosphate mineral monazite deposits with a thorium concentration of 8–10%. Thorium-containing monazite occurs in Africa, Antarctica, Australia, Europe, India, North America, and Latin America (NEA, 2006).

Reliable data on current thorium production is not available, but thorium is produced in small quantities as a by-product of refining monazite for its rare-earth content. Monazite itself is recovered as a by-product of processing heavy-mineral sands for titanium and zirconium minerals. In 2007 Brazil, India, and Malaysia produced an estimated 6780 tonnes of thorium, 80% of which occurred in India. In addition, China, Indonesia, Nigeria, North Korea, the Republic of Korea, and countries of the Commonwealth of Independent States may produce some monazite (Jaskula, 2008).

Thorium is used as an alloying medium in magnesium, in the manufacture of high refractive index glass, in filaments for gas lamps, and as a catalyst. In the absence of demand for thorium as a reactor fuel, its use is expected to decline as the manufacturing industries fear the extra costs and potential liabilities associated with processing radioactive materials (Jaskula, 2008).

The present knowledge of the world's thorium resource base is poor and incomplete. When the global uranium resource situation improved markedly in the 1980s, the nuclear industry lost interest in thorium and thorium exploration effectively ceased, except for some low-key exploration efforts. Most thorium resource assessments date back to the 1970s and 1980s, except perhaps for India and more recently the United States.

There are two sources of information for world thorium reserve and resource estimates, the US Geological Service and the joint reports of the NEA-OECD and the IAEA. The two sources are not in agreement about thorium estimates in several countries. Differences in these estimates are the result of the divergent methodological approaches used, e.g., different costs and degrees of geological assurance, etc. Resource estimates may also vary erratically from one reporting period to another. For example, recent reports have upgraded India's identified thorium deposits from approximately 300 kt to 650 kt without any explanation (IAEA, 2005). Also the resource estimates exclude data from much of the world. The sparse data reported are often based on assumptions and surrogate data for mineral sands, not direct geological evidence. The data in Table 7.25 indicates an identified thorium resource availability of more than 2.5 Mt at production costs of less than 80 $/kg Th. In addition, there are at least further 4 Mt of yet to be discovered thorium occurrences (NEA, 2008).

7.5.4 Fusion Materials

Lithium is a convenient source material for the deuterium-tritium fusion process. (For a discussion of nuclear fusion see Chapter 14).

The non-renewable part of nuclear fusion rests on the global endowment of lithium. The process requires deuterium (^2H) and tritium (^3H) which are naturally occurring isotopes of hydrogen. Deuterium is a stable isotope and as such is universally available in all water bodies at an average concentration of 154 ppm.[16] However, tritium is in short supply; it is radioactive, with a half-life of 12.3 years and is produced by cosmic

16 Deuterium recovery from water, however, is an energy-intensive process based on water electrolysis, laser application, or the Girdler sulfide process.

rays interacting with gases in the atmosphere. Tritium can be bred from lithium by neutron capture within the fusion reactor in an exothermic reaction (Harms et al., 2000; IEA, 2006b).

The availability of lithium, although more limited than that of deuterium, is still large enough to potentially supply the world's energy demand for thousands of years (Ongena and Van Oost, 2004).

Lithium is used in a number of products and processes, such as batteries, ceramics, glass, aircraft alloys, pharmaceuticals, lubricants, and air conditioning. Its use in rechargeable batteries has expanded significantly in recent years, driven by portable electronic devices and electrical tools. Today, batteries for electric cars constitute the largest and fastest-growing market for lithium compounds.

Lithium does not occur 'free,' i.e., purified or uncombined, in nature. It is found joined (ionized) in various salts in nearly all igneous rocks (especially pegmatites), in sedimentary rocks, and hydrated in brines and in seawater. Brines constitute almost two-thirds of the world's lithium resources, followed by pegmatites (26%).

In natural seawater, lithium is found hydrated at low levels, usually ranging from 140–250 ppb. Only near hydrothermal vents under the oceans does natural seawater contain elevated levels of lithium, where it approaches 7000 ppb. Altogether, an estimated 250 Gt of lithium dissolved in seawater represents an enormous resource (Chitraka et al., 2001). Japan and South Korea lead the development of lithium recovery technology from seawater, but these technologies are in their infancy and lithium from seawater is thus not included in most resource estimations.

As in many resource estimations, lithium reserve and resource estimates vary wildly and lack consistency. Recent resource estimates vary between 22 Mt (Tahil, 2007) and 62 Mt (Yaksic and Tilton, 2009) of lithium globally, with the bulk located in Latin America (Bolivia and Chile account for more than 40% of global resources). The discrepancies typically result from varying assumptions, methodologies, use of terminology, and inclusion of deposits.

Table 7.26 shows the geographical distribution of lithium, resources plus reserves, across the 18 GEA regions and at the same time shows the large range in estimations. It was necessary to combine reserve and resources in this table, as different authors use different definitions of reserves. Table 7.27 summarizes some of the reserve and resource estimations.

7.5.5 Environmental and Social Implications

Like all mining, uranium mining affects the environment and carries certain risks. In many respects these are much the same as those of the mining of any other mineral and, like any other mineral, uranium has unique features that must be managed with regard to its specific properties.

One special property of uranium is its radioactive nature. Uranium is mildly radioactive comparable to the levels found in granite. Concern about radioactivity is not unique to uranium mining, but is also a feature of oil and gas production (radium and radon) or the mining of mineral sands (thorium). Although uranium itself is not very radioactive, the ore which is mined contains radium and radon and needs special attention to occupational health and safety protection. This is increasingly regulated by the International Organization for Standardization environmental management system.

Most of the radioactivity is in the tailings – the solid waste product left after uranium oxide has been extracted by milling of the uranium-bearing ore. Tailings include most of the original ore, including all the radium, and contain most of the radioactivity (WNA, 2009).The tailings are deposited in dam-like structures, and during mine operation the tailing dam is usually covered by water to confine surface radioactivity and radon emissions. After mine closure, the tailings are covered with clay, rock, topsoil, and vegetation. The radioactivity of the tailing is about 80–85% of the ore that initially contained the ore body (AUA, 2009) and the cover further reduces potential human exposure.

Run-off water from the mine stockpiles and process water from milling operations contain traces of radium and some other metals, hence this water needs to be prevented from entering biological systems. These liquids are collected in secure retention ponds for isolation and recovery of any heavy metals or other contaminants. The liquid portion is disposed of either by natural evaporation or recirculation to the milling operation. Several mines have begun to adopt a 'zero discharge' policy for any pollutants (WNA, 2009).

Historically, uranium production has principally involved open-pit and underground mining. However, over the past two decades, ISL mining, which uses either acid or alkaline solutions to extract the uranium directly from the deposit (the ore body stays in the ground), has become increasingly important. The uranium-dissolving solutions are injected into, and recovered from, the ore-bearing zone using a system of wells. In 2008, production by ISL exceeded production by open-pit mining and a larger reliance on ISL is expected to continue.

The main environmental consideration with ISL is avoiding the contamination of any groundwater away from the ore body, and leaving the immediate groundwater no less useful than it was initially (WNA, 2009). Apart from groundwater considerations, rehabilitation of ISL mines is very straightforward and much easier to accomplish than that of open-pit mining, making this a technique with lower environmental impact. Upon decommissioning, wells are sealed or capped, process facilities are removed, and evaporation ponds revegetated (WNA, 2009).

7.5.6 Summary

Fissile material resources are plentiful and lack of resource occurrences does not limit the future expansion of nuclear energy. However, a lack of timely investment in exploration and new mining capacities can result in supply shortages and market price volatility, as witnessed in 2007. A sudden shift in demand, such as the unexpected license extensions in the United States and elsewhere, can cause short-term aberrations if uranium producers fail to plan accordingly. Unconventional uranium occurrences (i.e., low concentration ores) exist, but are only economically extractable as by-products of other mining processes, or from coal ash.

Thorium and lithium are both available in large quantities, but require more comprehensive resource assessments and explorations activities. Still, the development of extraction and processing technologies for their large-scale commercial production will only be undertaken if demand prospects warrant such investments. Lithium as a fuel for nuclear fusion will most likely be preceded by its use in batteries for electric vehicles, while thorium, although an alternative to uranium with great potential, will be considered by countries lacking natural endowments of uranium primarily.

7.6 Hydropower

7.6.1 Overview

Hydropower exploits the energy of falling or flowing water by converting it into electricity. It is the most developed and mature renewable technology globally. Current electricity generation by hydropower utilizes some 12.8 EJ/yr of its potential and kinetic energy, from which 3208 TWh were produced in 2008. Hydropower accounts for about 16% of global electricity generation and over 90% of electricity from renewable sources (IEA, 2010a).

The global hydrological cycle is the result of solar energy evaporating water, with oceans having a larger evaporation per unit area than land. Winds transfer the water vapor from oceans to land through precipitation. A global water balance requires that the water precipitated on land eventually returns to the oceans as run off through rivers.

Hydropower projects can be classified by either storage capacity or by purpose. These classifications, however, are not mutually exclusive (IEA, 2000). Run-of-river projects, which have limited storage capacity, generate electricity according to the available hydrological fluctuations of the site. Reservoir-type projects involve damming water and creating reservoirs with significant storage capacity, which allows for the regulation of water flow and electricity production.

Hydropower resources may be designed for electricity generation alone, or for multiple purposes. Multipurpose projects typically have significant reservoir capacity and can provide services such as irrigation, freshwater supply, flood control, and recreation. These uses may affect the volume of water available for electricity generation. In fact, 30–40% of world irrigation is supplied by reservoirs (Lempérière, 2006). This can distort quantitative assessments of the economic potential of hydropower for energy purposes.

Pumped storage projects are used to provide efficient storage of energy, especially for intermittent renewable resources. As they do not generate net electricity, they are excluded from the assessment of hydropower potentials.

7.6.2 Estimating Hydropower Potentials

Assessment methods for hydropower are different to those used for other renewables. For renewable sources such as wind or solar, potentials are assessed by beginning with a theoretical estimate, which is then reduced, by the application of constraints, to define a technical potential, which is further reduced to an economical potential.

Hydropower potential, however, is generally assessed by adding up the potential of individual well-known sites, and many other possible sites are omitted for various reasons. As a result the theoretical potential is underestimated. The inherent subjectivity in determining site suitability plays a significant part in assessments. For example, the US Rocky Mountains are considered 'off-limits,' even though they are similar to the Alps, which have seen large developments. Smaller sites, as well as existing dams not used for hydropower, also were not considered in the United States until recently (UNWWAP, 2006). Finally, multi-purpose issues are not considered. Reservoirs often provide gravity fed irrigation, which is in itself an energy service, as it circumvents the electricity intensive pumping of water.

As a result of social and environmental constraints, it is prudent to assume that not all realistic or economic potential can be developed. It is important, however, that these potentials still be included in the theoretical and technical potentials. Social and political situations are subject to change over time. Climate change, new environmental policies, changed social preferences, and new technologies, especially for transmission, may make remote sites accessible, affect energy supply preferences and demand levels, and lead to a reassessment of previously excluded hydropower locations (and vice versa).

The assessment and reassessment of hydropower sites is a costly affair. Thus in many countries, where many well-known sites are still to be developed, there is less impetus to find additional sites.

7.6.3 Hydropower Potentials

About 1,260,000 EJ (40,000 TW) of the total solar flux of 2,800,000 EJ/yr (89,000 TW) reaching the surface of the Earth is actually used to evaporate water and drive the water cycle (Tester et al., 2005). In contrast to many renewable sources, such as wind or solar, which are characterized by flows of diffuse energy, hydropower benefits from the fact that the water cycle has already concentrated the energy in the form of a high-density flow of water (Shepherd et al., 2003). The theoretical potential energy in the water cycle is thus calculated as 40% of the solar energy used to evaporate water (Tester et al., 2005). Consequently, the theoretical potential of energy in the water cycle is 504,000 EJ (see Table 7.28).

A portion of the energy in the water cycle is held in flowing rivers – the part of the hydrological cycle useable for electricity generation – and several countries have tried to quantify this gross hydropower potential. It is based on average river flows, multiplied by the relative change in altitude of each river (Lehner et al., 2001). This results in an annual theoretical hydropower potential of 200 EJ globally.

The maximum technical potential is based on two sets of data. A few countries assess the total potential of their main rivers, while other countries add up the potentials of all sites, assuming that virtually all the energy at the site can be harnessed. Despite the fact that some sites may not be included in this data, this global estimate of 140–145 EJ is still huge. However, it represents a mix of technical and theoretical potentials.

Another approach to estimating technical potential is based on adding up site potentials, adopting a realistic use factor for each site using detailed information on the location and geographical factors of run-off water (such as available head and flow volume per unit of time). The resulting potential then could be called the 'practical technical potential.' Even if countries do not attribute a development cost to each site, it

Table 7.28 | Estimates of world hydropower potential.

Estimation method	Comments	Hydrootential [EJ/yr]
Energy in the water cycle (Tester et al., 2005)	40,000 TW of instant solar power serving to evaporate water 40% of the time	504,000
Theoretical potential (Lehner et al., 2001)	For most rivers: mass of runoff × gravitational acceleration × height	200
Maximum technical potential, based on rivers and or sites[a]	Technical potential of known sites, assuming a very high use factor	140–145
Technical potential, based on sites at 2–20¢ per kWh[b]	Portion of technical potential, with a realistic use factor, that is sufficiently promising to justify a site assessment	50–60
Economical potential, based on sites at 2–8¢ per kWh[c]	Portion of technical potential, with a realistic use factor, that is competitive with large thermal power plants	30

[a] Few countries provide information on the total potential of main rivers. When these data are not available, the technical potential of known sites, at 100%-use factor, is included.

[b] The 20¢ per kWh threshold is a global estimate.

[c] Economic potential is based on official country assessments. The threshold could be lower in some countries, as the main competitor is often coal fired generation at approximately 5¢/kWh.

is reasonable to assume that this potential is available at a cost between 20–200 $/MWh. This threshold of 200 $/MWh is justified in that a site that would cost more than 200 $/MWh would be considered a very poor site by an engineer, and would likely not be included in the assessment. For many countries, the threshold could be lower, such as 150 $/MWh. It is also important that, in many countries, environmentally sensitive sites were previously excluded from any assessment.

Finally, to assess the economic potential, the expected costs of sites are assessed and compared to the costs of other major sources of electricity, such as coal, gas, or nuclear. If the cost of the hydropower sites is lower or similar, the potential is considered economically viable; if it is not, it is excluded from the estimate. A cost estimate between 20–80 $/MWh is reasonable for this potential, as coal is often the main competitor at 40–60 $/MWh. The economic hydropower potential is estimated at around 20 EJ/yr (see Chapter 11).

7.6.3.1 Regional Data on Technical and Economic Potentials

Table 7.29 presents the maximum technical and practical technical potential, as assessed by each country. These country assessments can be made using different methods. Some countries exclude small hydropower or any development in national or state parks. Moreover, the assessment of remote sites can be expensive and thereby not included or only poorly estimated. These methodological issues do allow for a general conclusion: the data on hydropower potential is probably underestimated by a wide margin.

Table 7.29 | Theoretical and technical potentials for the 18 GEA regions.

World	10.96	143.41	57.41	29.84

[a] When statistics on technical or economic potentials are available only in MW, PJ was estimated by multiplying the MW by the typical use factor of hydro plants within that region.

[b] When the maximum technical potential is not provided, the realistic potential is used instead, assuming a use factor of 100%.

Source: adapted from Hydropower and Dams World Atlas, 2008.

7.6.4 Environmental and Social Implications

The environmental issues surrounding hydropower development are numerous. This is unavoidable when creating a reservoir. However, it can be misleading to make general conclusions, as hydropower plants vary greatly and raise different environmental issues. This section does not review these issues, but discusses a few major constraints that can significantly affect future potential.

Ecosystem impacts usually occur downstream from hydropower sites and range from changes in fish biodiversity and in the sediment load of the river to coastal erosion and pollution. For comparable electricity outputs, GHG emissions associated with hydropower are one or two orders of magnitude lower than those from fossil-generated electricity, but can be non-negligible in cases where sites inundate large areas of biomass and consequent CH_4 releases to the atmosphere.

The land use of hydropower projects (per unit of electricity generated) can be very low for run-of-river plants and very high for plants with large reservoirs and multipurpose water uses. Large hydropower projects requiring large reservoirs and extensive relocation of communities increasingly encounter public resistance and, as a result, face higher costs.

Population density is a major constraint for future development. If a project requires resettlement, the high costs and uncertainty make planning quite difficult. Despite this, creating reservoirs does not mean that future hydropower sites are impossible to develop. With proper planning, consultation, and analysis, hydropower projects can be implemented with much smaller environmental and social impacts. The decision to include a reservoir may well depend on the demand for other services, such as irrigation or flood mitigation.

The effects of climate change may change precipitation patterns in various ways, as the water cycle will be intensified in some regions, causing a higher probability of extreme events and flooding. More reservoirs may be needed for flood impact mitigation, or reservoirs may lack sufficient water to provide enough electricity to meet demand. Evaporation may increase, so some regions may experience more frequent and more intense droughts. Construction of new reservoirs may be needed to adapt to climate change and prepare for additional storage needs. More

storage may be needed for irrigation also, as rain-fed agriculture may become less reliable in some regions.

7.6.5 Summary

There is a large global potential of hydropower for electricity generation, with the annual economic potential estimated at around 30 EJ. Hydropower has very good development potential, in both short and long terms, as it is well adapted to meet future global challenges. The coupling of hydropower with other uses makes it a very versatile option, especially in mitigating and responding to the effects of climate change.

Although most of the suitable sites for large hydropower implementation in OECD countries have already been developed, the potential still remains for further small-scale plants as well as large scale developments in China, Africa, and especially Latin America.

7.7 Biomass energy

7.7.1 Overview

Biomass is biological material derived from living, or recently living, organisms. Biomass as an energy resource can be derived from agricultural crops, forest products, aquatic plants, crop residues, animal manures, and wastes, such as municipal solid waste (MSW). Biomass was the main energy source for humans until about the third quarter of the 19th century when the increasing availability of fossil fuels progressively reduced its dominance. Still, in many of the least-developed countries biomass remains the dominant source of energy and can contribute as much as 80% or more to these countries' energy supplies.

The primary process through which biomass becomes available on Earth is photosynthesis. Plants use solar energy to produce energy-rich organic materials from inorganic inputs (CO_2, H_2O, and plant nutrients such as nitrogen and phosphorous). Globally, current net biomass production of green plants (net primary production, NPP) in terrestrial ecosystems amounts to approximately 118 billion tonnes of dry matter per year (Gt/yr) with a gross calorific value (GCV) of 2190 EJ/yr. Additional biomass is produced by plants in freshwater and ocean ecosystems. A considerable proportion of the NPP is allocated to below-ground parts of plants, most of which cannot be harvested. Aboveground terrestrial NPP currently amounts to 67 Gt/yr or 1241 EJ/yr (Table 7.30).

The amount of biomass produced by terrestrial ecosystems depends on climate, soil, and human management (land use). Rising atmospheric CO_2 levels tend to raise plant productivity, partly as a result of changes in temperature and precipitation, and partly through the CO_2-fertilization effect which is, however, still poorly understood (Müller et al., 2006; Long et al., 2006; Tubiello et al., 2007). This trend might be reversed in the future, because of possible changes in precipitation patterns that might limit productivity. Given unlimited water supply, higher temperatures boost plant growth, but if water supply is limited, rising temperatures may also reduce productivity through increased water stress (Sitch et al., 2008).

Land use may increase or reduce the biomass production of ecosystems. In areas where water availability limits biological productivity, irrigation can considerably increase biomass production per unit area and year. In temperate zones, intensive use of fertilizers and agricultural technologies may boost productivity compared to potential vegetation, i.e., the resulting vegetation in the absence of land use, but generally land use reduces NPP. Globally, agroecosystems, settlement areas, and soil degradation have reduced the biomass produced by green plants in terrestrial ecosystems by almost 10% (Haberl et al., 2007a). As plants in agroecosystems allocate more biomass to aboveground NPP than those in natural ecosystems, the human impact on aboveground productivity is smaller than that on total productivity (Table 7.30).

Globally, humans currently harvest or destroy about 20.1 Gt/yr of biomass (373 EJ/yr), i.e., 17% of the yearly biomass production of terrestrial ecosystems. Above the ground, however, humans currently harvest or destroy 30% of the annual biomass production of terrestrial ecosystems (Table 7.30).[17] About two-thirds of the biomass harvested and destroyed is actually used by humans: one-third is either burned in human-induced fires or left in the ecosystem (below-ground biomass, unused crop residues, and felling losses in forests). Table 7.30 shows that crops and crop residues account for 52% of the biomass harvested by humans. Almost one-third is directly taken up by grazing animals on the world's grazing lands. Wood removal from forests accounts for the rest. Livestock consumes almost 60% of the total amount of used biomass.

Bioenergy accounts for almost half of the final amount of biomass. A considerable fraction of the bioenergy stems from biogenic wastes, by-products, and residues. Fuelwood harvest in the year 2000, according to Food and Agricultural Organization (FAO) figures, had a GCV of 22 EJ/yr. Primary crops used for biofuels were negligible at that time, i.e., contributed about 0.8 EJ/yr in 2000, but since have increased to 3.1 EJ in 2008 (Chum et al., 2011).

7.7.2 The Theoretical Potential for Land-based Bioenergy Production

The point of departure for the estimation of the theoretical production potential for land-based bioenergy is the NPP data of Table 7.30. The

17 This value represents a cautious estimate because it only includes wood harvests according to FAO. Alternative studies suggest that wood harvests could be up to 33% higher than assumed here.

Table 7.30 | Global yearly biomass flows around the year 2000.

[a] NPP and harvest values refer to the aboveground compartment only and exclude belowground biomass.

[b] This version of the theoretical potential was calculated by assuming that all (100%) aboveground NPP of current vegetation except NPP harvested for food, feed and fiber would be used as feedstock for bioenergy.

estimate of the theoretical bioenergy potential is based on the following assumptions:

- Significant increases in NPP (i.e., by >20%) over its natural potential are hardly possible without massive direct and indirect energy inputs (that would result in unfavorable energy returns on investment and high GHG emissions). Moreover, the global productivity of croplands is currently 35% lower than their potential productivity, despite all fertilizer and other inputs (Haberl et al., 2007a). Field et al. (2008) and Campbell et al. (2008) maintain that potential NPP is an upper limit for the large-scale average productivity of energy crop plantations.
- Only those parts of plants aboveground are harvested (for practical reasons).
- Land demand for all other human uses except bioenergy remains constant, i.e., expected future increases in demand for food, animal feed, and fiber have no impact on land allocation. This seems justified because a large part of the projected future agricultural biomass production is expected to come from yield increases rather than from expansions of cropped area (FAO, 2006b; IAASTD, 2009).
- Primary bioenergy (i.e., bioenergy not derived from wastes, by-products, or residues) accounts for approximately 30% of the global final use of biomass (Krausmann et al., 2008).
- 100% of the potential aboveground NPP (NPP_0) not required for food, animal feed, or fiber production can be used to produce bioenergy.

The theoretical bioenergy potential amounts to some 1100 EJ/yr[18] (Table 7.31) and would leave no NPP for heterotrophic food chains

18 The estimate is based on a GCV of dry-matter biomass of 18.5 MJ/kg and assumes a carbon content of dry matter biomass of 50%. The GCV of woody biomass is 19.5 MJ/kg and that of herbaceous biomass is 17.5 MJ/kg. The net calorific value is approximately 10% lower than the GCV. The values refer to the total amount of biomass that might be harvested without consideration of how the biomass will be used as an energy source.

(animals, fungi, microorganisms), with consequent catastrophic impacts on diversity, resilience, and sustainability of ecosystems. As this would entail the clearing of all forests (no biomass left in the ecosystems to build up and maintain long-lasting carbon stocks), the resulting GHG balance would also be very unfavorable. The human appropriation of NPP – approximately 30% of aboveground NPP (Haberl et al., 2007a) – has already contributed to a global reduction in the terrestrial ecosystem's ability to deliver essential ecosystem services (MEA, 2005).

The theoretical potentials of Table 7.31 do not include the potential production of algae in coastal seawaters, industrial installations, and open-sea devices. Their productivity is not limited by land or freshwater availability and could exceed natural NPP per unit area and year by orders of magnitude.

7.7.3 Technical Biomass Potentials

7.7.3.1 Principal Biomass Flow Pathways Relevant for Bioenergy

The necessity to produce food and fiber, the area demand of infrastructure, and sustainability criteria such as biodiversity conservation and the GHG balance, limit the amount of bioenergy that can be produced sustainably. The technical potential is assessed for energy crops (see Chapter 20), as well as for agricultural and forestry residues.

Figure 7.23 shows the main synergies and competition between the demand for bioenergy, food, and fiber. If the demand for food and biomass-based materials is large, then less land is available for energy crops. However, during the food and material production process, residues become available that also can be used for energy applications.

Figure 7.23 distinguishes two types of energy crops plus residues from agriculture and from forestry production. The residues are further split into three categories: primary, secondary, and tertiary residues. Primary residues become available during the harvesting process, e.g., straw or wood from forest thinning. Secondary residues become available during the processing of food, wood, or other biomass, e.g., bagasse or sawdust. Tertiary residues become available after the use of the food or the material, e.g., MSW or waste wood.

The following sections assess the technical biomass potentials for three categories:

- agricultural residues, wastes, and by-products;
- biomass from forestry, including forestry residues; and
- aquatic biomass and/or algae.

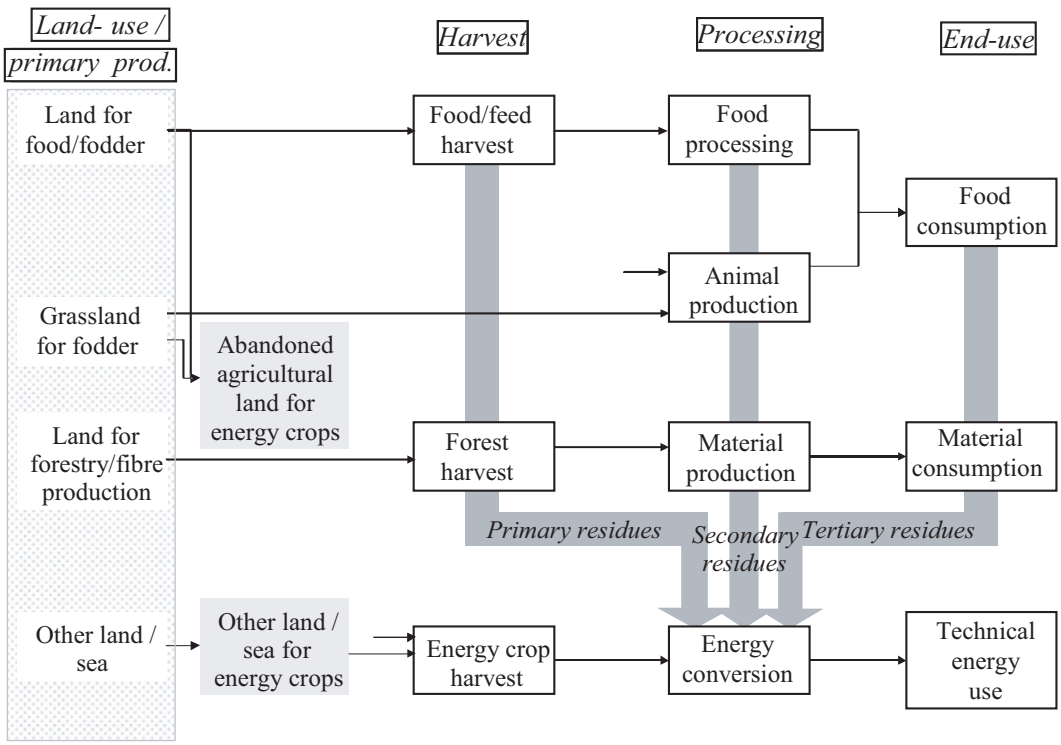

Figure 7.23 | Competition and synergy between different biomass feedstocks.

The energy potential from energy crops on cropland, abandoned agricultural land, or grazing land is discussed in Chapter 20.

7.7.3.2 Crop Residues, Municipal Solid Wastes, and Animal Manures

Overview

Large quantities of organic residues and wastes are produced annually, including crop residues, animal manures, and MSW. Rational utilization of these can produce energy, normally cost-effectively, and minimize environmental impacts that are often caused by other management and/or disposal methods.

Crop residues

Two types of residues are associated with crop production. These are primary, i.e., harvest or field residues, and secondary, i.e., processing residues. The recoverable fraction (RF) of a residue depends on the amount that could be collected practically and, in the case of field residues, on the amount that should be left in the field for maintaining soil quality.

Annual crop production in 2005 was estimated from the FAO online database (FAO, 2009). Values of residue to product ratio (RPR) for different crops are taken from the open literature (Fischer et al., 2007; Koopmans and Koppejan, 1998; Bhattacharya, 1991). The RPR values for primary residues of cereal crops depend on the level of technology used for cereal production. Higher levels of technology, including irrigation and fertilization, result in higher yields per hectare and lower values of RPR; RPR values selected in this study for 2050 correspond to higher levels of technology (Fischer et al., 2007). For the year 2005, region-specific RPR values were selected and assumed based on literature reviews; values corresponding to the average of higher and lower levels of technology are assumed for the regions for which no RPR values could be found in the literature.

Residue generation from cereal crop production for the year 2050 was estimated using projected production growth rates of cereals in developing, industrial, and transition countries from FAO (2006a). For estimating residue generation from the other crops, their production growth rates in different country categories are assumed to be the same as the projected rates for all food and non-food commodities obtained from FAO (2006b).

Table 7.32 shows the estimated energy potentials of crop residues in 2005 and 2050 for the 18 GEA regions. The total world technical potential of crop residues in 2050 is estimated to be 49.4 EJ.

Assuming RF values for different crops in the range 0.5–0.75, Hakala et al. (2009) estimated the world technical potential of field residues in 2050 to be 38–41 EJ; adding the process residue potential of 16 EJ (Smeets et al., 2007), the total technical potential of crop residues would be 54–57 EJ. These estimates for 2050 may be compared with the range 10–32 EJ/yr derived by Hoogwijk (2004) and 46–66 EJ by Smeets et al. (2007).

Differences in crop-residue energy potential estimated by different authors mainly result from differences in their assumed RPR and RF values and crop-production projection methodologies.

Municipal solid wastes

MSW consists of biogenic (i.e., renewable) and non-biogenic (i.e., non-renewable) constituents. The energy potential of the biogenic components was estimated from their energy values (US EIA, 2007), the total generation of MSW, assumed values for the recoverable fraction from MSW for energy, and the MSW composition. MSW composition and generation per capita for different countries/regions for the year 2000 were obtained from IPCC (2006); country/region-specific values were obtained, in some cases, from the literature.

MSW generation per capita is known to increase with growth in gross domestic product (GDP). Adhikari et al. (2006) established a relationship between MSW generation per capita and GDP per capita to project future MSW generation from expected growth in GDP per capita; this approach was used in this study. National GDP values were taken from World Bank (2008a) and the projected future national and/or regional growth rates obtained from IEA (2006a); population data for the years 2005 and 2050 were obtained from United Nations Population Division (2008).

Since an increase in MSW generation is not expected to continue indefinitely, Monni et al. (2006) projected a maximum future annual MSW generation of 900 kg/capita; this value was used in this assessment.

In this study, estimations for recycling of MSW organic matter throughout the world by 2050 are guided by a scenario for the EU-15 countries developed by Smith et al. (2001) for the year 2020: 60% paper recycling and 60% separation of food and yard-trimming wastes (two-thirds of the latter is assumed to be composted) and the remaining one-third used for anaerobic digestion. Thus, 60% of food and yard waste is available for energy purposes.

In 2005, leather and rubber recycling in the United States was 14.3%, while recycling of textiles was 15.3%; 9.5% of wood in MSW in the United States was recycled. It is assumed that 15% of both leather and textiles would be recycled in 2050 in all countries; the amount of wood recycled is assumed at 10%.

The theoretical potential of MSW is assumed to be the energy potential of all MSW produced in a country without any recycling, while technical potential is assumed to be the same as the recoverable potential.

As shown in Table 7.32, the total world recoverable potential of MSW in 2050 is estimated to be 11.02 EJ; this value can be compared with 1–3 EJ in 2050 as estimated by Hoogwijk (2004) and around 17 EJ as estimated by Smeets et al. (2007).

The energy potentials of harvest or field residues and processing residues were estimated as follows:

Residue energy potential (EJ/yr) = bone dry residue production (Mt/yr) × recoverable fraction of residue production × gross heating value of bone-dry residue (EJ/Mt).

Bone dry residue production (Mt/yr) = dry matter of crops produced (Mt/yr) × residue to product (or crop) ratio on dry basis.

Includes residue energy potentials of the following crops:

Cereals: wheat, rice, barley, maize, rye, oats, millets, sorghum.

Sugar crops: sugar beet, sugar cane.

Pulses: peas, chick peas, cow peas, pigeon peas, beans, broad beans, lentils, pulses of minor relevance.

Oil crops: groundnuts, rapeseed, soybeans, sunflower seed, safflower seeds, linseed, sesame seed, castor bean, other oilseeds of minor relevance.

Tree nuts: almonds, brazil nuts, cashew nuts, chestnuts, hazel nuts, kola nuts, pistachios, walnuts.

Fruits: apples, apricots, avocados, bananas, cashew apples, cherries, citrus fruit, dates, figs, fruit grapefruit (including pomelos), grapes, kiwi fruit, lemons and limes, mangoes, mangosteens, guavas, oranges, papayas, peaches and nectarines, pears, persimons, pineapples, plantains, plums and sloes, quinces, raspberries, sour cherries, stone fruit, tangerines, mandarins and clementines.

Tuber crops: cassava, potatoes, sweet potatoes, yams.

Other crops: coffee, cotton, jute.

Notes:

The energy potential of manure generated annually by animal type i is estimated as follows:

Total volatile solid produced annually by an animal of a given type *i*, VS_i (kg/yr) = 365 × animal population (head) × average volatile solids production per head for animal of type *i* per day (kg volatile solid/head/day).

Total dry manure produced annually by an animal of a given type *i*, TS_i (kg/yr) = VS_i/volatile fraction

Total annual energy potential = TS_i × heating value of manure on dry basis.

Animal manures

The number of animals in 2005 was obtained from the FAO database on live animals (FAO, 2009). The number of all animals was assumed to increase at rates corresponding to the projected annual growth in world livestock production (FAO, 2006c) – these are 1.6% during the period up to 2030 and 0.9% in 2030–2050. Values of kilogram of volatile solid/head/day were obtained from the IPCC (2006); the amounts of total dry solids produced were estimated from these, assuming suitable values of volatile fraction. Values of RFs of manures were obtained from TERI (1985) and NRCS (1995). Based on literature reviews, the heating values of dry animal manures were assumed to be 17 MJ/kg for swine: 12.9 MJ/kg chicken, and 16 MJ/kg for other animals.

As shown in Table 7.32, the energy potential of recoverable manures was estimated to be 39.2 EJ in 2050. Johansson et al. (1993) estimated the heating value of annual recoverable manures in 2050 to be 25 EJ. Based on a literature review, Hoogwijk (2004) estimated the recoverable potential of animal manures to be 9–25 EJ.

Differences in the energy potential of animal manures reported by different authors appear to result mainly from differences in projected manure-generation values and assumed RFs, as well as heating values.

Technical potential of forestry residues

Figure 7.23 distinguishes three categories of forestry residues: primary (available from additional fellings or as residues from thinning or final fellings), secondary (available when processing the forest products, e.g., sawdust), and residues (available after end use, i.e., waste wood).

Various studies have assessed the future potential for forestry residues (e.g., Berndes et al., 2003; Smeets and Faaij, 2007; IPCC, 2007; Anttila et al., 2009). The Anttila et al. (2009) study estimates a primary forestry residue potential ranging from 5 EJ/yr to 9 EJ/yr globally, including logging residues from present cuttings, the stemwood from supplementary cutting, and the logging residues from supplementary cutting. This range is low compared to other estimates for the year 2050, e.g., 28 EJ/yr (Smeets et al., 2007) or 12–74 EJ/yr (IPCC, 2007). The difference largely results from the inclusion or not of secondary and tertiary residues. Secondary and tertiary residues can be 3–5 times higher than the primary residues Smeets et al. (2007). To estimate the regional potential for all forestry residues, the data from Anttila et al. (2009) were increased by a factor of four to include the other residues (see Table 7.33).

7.7.3.3 Aquatic Biomass

Land use constraints, competition with food, and demand for biomass with high caloric value have made marine-based biomass an attractive alternative supply option over past years. However, land-based biomass systems are far more developed than sea-based systems whose economic viability has yet to be determined. In addition, estimates of algae energy potentials are scarce and quite uncertain, as most are extrapolations from small-scale (pilot) projects.

Aquatic biomass can be grouped into three categories: microalgae, seaweed, and sea grass. The production of aquatic biomass depends on various factors, such as irradiation, limpidity, temperature, sea conditions, and nutrients. Naturally, regional variations can be significant. Promising concepts for aquatic biomass include (1) land-based open ponds for microalgae, (2) horizontal lines between offshore infrastructure, e.g., wind farms for macroalgae (seaweed), (3) vertical lines near shore in densely used areas and nutrient-rich areas for macroalgae, and (4) macroalgae colonies at open sea up to 2000 km offshore (Florentinus et al., 2008). The total potential at a global scale is assessed at over

Table 7.33 | Estimate of technical potential of forestry residues in comparison with the forestry residue estimates from IPCC (2007), Anttila et al. (2009), and Smeets et al. (2007). Anttila et al. (2009) only includes primary residues.

6000 EJ/yr. For the first three production categories the potential is 235 EJ/yr. Algae production at open sea has by far the largest potential, but is also the most complicated.

7.7.4 Summary of Global Technical Bioenergy Potential Estimates

Table 7.34 summarizes the various bioenergy supply potentials. The total global technical bioenergy potential for the year 2050 varies between 162–267 EJ/yr – a range considerably lower than previous analyses, which suggested global bioenergy potentials around 400 EJ/yr by 2050. This lower estimate largely results from lower expectations about the overall potential to grow dedicated bioenergy crops. In general, these potentials are highly uncertain. However, it is increasingly recognized that land demand for food production and feed supply, urban and infrastructure areas, biodiversity conservation, and the need to maintain a favorable GHG emission balance (i.e., no deforestation) pose definite limits on land availability for bioenergy production. Moreover, new studies suggest that the productive potential of land areas available for bioenergy is much lower than previously thought (Johnston et al., 2009).

7.7.5 Economics of Bioenergy Production and Supply Cost Curves

7.7.5.1 Supply Cost curves of Bioenergy Crops

Costs for energy crops include capital costs for equipment and infrastructures, plant and seed material, land rent, labor costs, energy (e.g., for drying and transport), material expenditures (e.g., fertilizer and water), and storage. Bottom-up studies indicate that costs for drying and storage are the least certain and therefore are often excluded (de Wit and Faaij, 2010). Future production costs will depend on productivity developments, labor costs, land rental, and experience. Lignocellulosic energy crops have the lowest cost of all energy crops because of the low input requirements and relative high productivities. Costs in Europe range from 1.5–4.5 €/GJ,[19] while other crops, such as starch, sugar, and oil crops, cost between 5–15 €/GJ (de Wit and Faaij, 2010). Similar results are found for the United Kingdom (E4Tech, 2009), where costs for energy crops in 2030 are generally estimated at 2.0–3.5 £/GJ. The cost curves for Europe and the United Kingdom as reported by de Wit and Faaij (2010) and E4Tech (2009) are all relatively flat in the longer term. In the EU about 90% of lignocellulosic crops are available at costs between 1.5–3 €/GJ by 2030, with the remaining amount between 3–6 €/GJ (de Wit and Faaij, 2010). For the United States projected costs for delivered biomass in 2025 are very low for forest residues (US_{2005}1.0–2.0/GJ) for limited amount (up to 1.5 EJ/yr). For larger supplies (up to 7 EJ/yr) energy crops have costs around US_{2005}3.5–4.0/GJ (Chum et al, 2011).

Table 7.34 | Summary of global technical bioenergy supply potentials in 2050.

Resource	MIN [EJ]	MAX [EJ]	Comments
Dedicated bioenergy crops	44	133	High uncertainty, depends on yields, diets, technology, and climate change
Crop residues	49		Soil conservation issues need to be addressed; GHG balance might depend on soil carbon balance (currently poorly understood)
Manures	39		Relatively small uncertainty and few, if any, environmental issues
Municipal solid waste	11		Relatively small uncertainty and few environmental issues
Forestry	19	35	Competition for other uses may reduce availability of residues
Total, excluding aquatic	162	267	

Projected costs for energy crops include capital costs for equipment and infrastructures, plant and seed material, land rent, labor costs, energy (e.g., for drying and transport to conversion facilities), material expenditures (e.g., fertilizer and water), and storage. Bottom-up studies indicate that costs for drying and storage are the least certain and therefore are often excluded (de Wit and Faaij, 2010). Future production costs will depend on productivity developments, labor costs, land rental, and experience. Lignocellulosic energy crops have the lowest cost of all energy crops because of the low input requirements and relative high productivities. Estimated costs in Europe range from 1.5–4.5 €/GJ and a production volume of about 7 EJ/yr, while other crops, such as starch (3 EJ/yr), sugar (6 EJ/yr), and oil crops (3 EJ/yr), cost between 5–15 €/GJ (de Wit and Faaij, 2010). Similar results are found for the United Kingdom (E4Tech, 2009), where costs for energy crops in 2030 are generally estimated at 2.0–3.5 £/GJ. The lignocellulosic cost curves for Europe and the United Kingdom as reported by de Wit and Faaij (2010) and E4Tech (2009) are all relatively flat in the longer term. In the EU about 90% of lignocellulosic crops are available at costs between 1.5–3 €/GJ by 2030, with the remaining amount between 3–6 €/GJ (de Wit and Faaij, 2010).

Long-term global economic supply potentials for dedicated energy crops were assessed by Hoogwijk et al. (2009). This study analyzed four distinct land-use scenarios using a production function approach with costs for labor, capital, land, and transport to the main distribution centers. Regional differences reflect differences in productivity, labor, and land costs. The bioenergy production cost ranges shown in Figure 7.24 are based on the production cost distribution of that land-use scenario with its cost distribution representing the middle of all the scenario distributions and applied to the technical potentials

19 Note that the market for lignocellulosic crops in particular is still small and costs in many literature sources are based on desktop data.

Table 7.35 | Technical and economic potential of energy crops.

	Technical potential		Potential cost categories

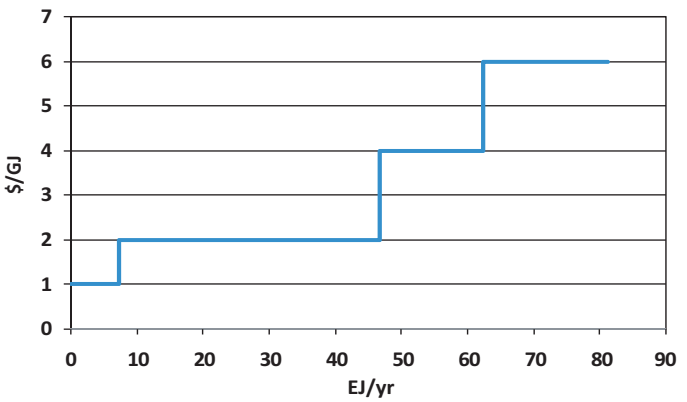

Figure 7.24 | Bioenergy crops supply cost curve (average biomass supply of Table 7.35).

summarized in Table 7.35. (The ranges are lower than those reported in the aforementioned studies.)

Figure 7.24 shows the aggregate global biomass supply cost curve based on the 'mean' regional supply volumes and the production-cost distribution data of Table 7.35.

7.7.5.2 Supply Cost Curves of Agricultural Residues and Municipal Solid Waste

In general, the cost of biomass residues is site-specific. Approximate values of residue costs are assumed for the purpose of this study. Based on Haq and Easterly (2006), the following cost values, including transportation and payment for a farmer premium, are assumed to be valid for the United States and all other developed countries and regions for the year 2005: 46 $/t for corn stover, wheat straw, and field residues of sorghum, barley, oats, rye, and cotton field trash, and 41 $/t for rice straw and processing residues. The cost of all other crop residues is assumed to be 46 $/t.

Based on Purohit et al. (2002), the cost of residues in India in 2005, including transportation, is estimated to be 25 $/t. The average cost of cellulosic biomass, including transportation, is assumed to be 22 $/t in China (Yang et al., 2005). The estimated cost of field residues in Nigeria has been reported as 23.1 $/t (Jekayinfa and Scholz, 2007). Based on the cost values of India, China, and Nigeria, the average cost of all agricultural crops in all developing countries, except India and China, in the year 2005 has been assumed to be 23.5 $/t.

The farm-gate cost of residues in United States mostly reflects the cost of their collection, i.e., delivering them in bales at the edge of the field. It has been projected that improvements in collection technology will significantly reduce the collection cost of residues below the 2005 level (Walsh, 2008). Farmer premiums, however, are likely to increase in the future. Based on the above considerations, it is estimated that the cost of residues in 2050 will remain at the 2005 level for all developed countries.

In developing countries, residues collection in 2050 is assumed to be based on machines similar to those used in developed countries; considering that the cost of labor involved in collection and transportation would remain lower in developing countries, the costs of residues in these countries in 2050 is assumed to be 80% of the estimated costs for developed countries.

MSW may have negative costs because of tipping fees. The average fee per tonne in the United States was $33.74 in 2002 and $34.29 in 2004 (Repa, 2005); the tipping fee was assumed to be 35 $/tonne in 2005. Based on the fees of six sites in Canada (Statistics Canada, 2005), the average fee for Canada is about 49 $/t. The following average 2005 tipping fees per tonne were assumed: Europe, $100; Japan, $150; OCN region, $32; China, $20 (based on the range 10–30 $/t, reported by Themelis and Themelis (2007)); developing countries of Asia, $5; and Latin America, $15; while India and the remaining regions have no tipping fees.

The tipping fee to breakeven in case of plasma gasification of MSW in Canada has been estimated to be $35 (Young, 2006); the value is likely to be less in the future because of improvements in technology. For this

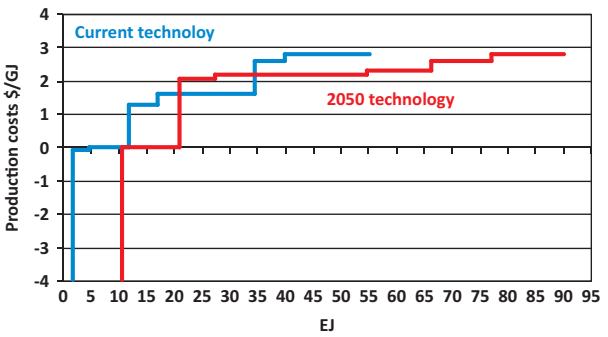

Figure 7.25 | Aggregate supply cost curve[20] for MSW, animal wastes, and crop residues. Negative costs are avoided tipping fees.

assessment, uniform tipping fees are US_{2005}40/t in 2050 and have been assumed for all countries and regions by 2050, while animal manures are assumed to be available at zero cost. The supply cost curve for agricultural residues and MSW is shown in Figure 7.25.

7.7.5.3 Economic Potential of Bioenergy from Forestry

Forest residues are currently traded internationally, mostly in the form of wood pellets. The dominant raw material for wood-pellet production has traditionally been processing residues as sawdust. The prices of wood pellets for Europe range from 170–270 €/t (10–16 €/GJ) in a two-year period (UNECE/FAO, 2009) and for the Russian market from 95–165 €/t (6–10 €/GJ) (Junginger et al., 2009). The pellet market is integrated in the entire wood system and therefore influenced by the economic crisis, i.e., some wood-pellet producers have had problems with raw material supply (UNECE/FAO, 2009).

No global potential estimates include the production costs of forestry residues or pellets. Some assessments of the costs in Europe indicate levels ranging from 2.2–7.4 $US_{2000}$$/GJ (Lindner et al., 2005). Extensive cost curves at a country level from (Asikainen et al., 2008) taking transport distance as the main varying parameter, result in comparable levels of around 2.5–7.5 €/GJ. For Denmark, costs have been assessed below 1 $US_{2000}$$/GJ (Nord-Larson and Talbot, 2004). Estimates for Japan indicate costs in the order of 10–35 $/GJ (Yoshioka et al., 2006).

No studies include cost reductions caused by technological progress. Some cost curves for residues are known at the country level, e.g., for the United States (Walsh, 2008) and for some European countries (Asikainen et al., 2008). In general, costs are largely a function of transport distance, but a detailed breakdown is not provided. For the global potential it is assumed that 100% can be delivered at costs below 50 €/GJ and 10% at costs below 1 €/GJ.

20 See footnote 7.

7.7.5.4 Cost Estimates of Aquatic Biomass

The costs for algae cultivation are still high. Florentinus et al. (2008) estimate costs for biomass in the range of 300–700 €/t or even 1000 €/t of dry matter, or 18–60 €/GJ assuming a lower heating value of 16 GJ/t and significant technological improvements.

7.7.6 Social and Environmental Aspects of Bioenergy Use

Bioenergy is either produced by planting dedicated bioenergy crops or by using by-products, residues, and wastes from agriculture, forestry, food processing, and other economic activities (see Figure 7.23). These pathways can have environmental effects that are fundamentally different (Cherubini et al., 2009). The two pathways are therefore discussed in turn.

7.7.6.1 Environmental and Social Effects of Bioenergy Crop Plantations

Growing dedicated bioenergy crops can have positive and negative environmental and social impacts. For example, growing bioenergy crops increases the demand for agricultural products and creates income in the agricultural sector. However, demand for bioenergy crops may lead to rising agricultural prices (World Bank, 2008b) and reduce affordable food supply, in particular for the poor.

Likewise, bioenergy can help to reduce GHG emissions, but when emissions from direct and indirect land-use changes (e.g., deforestation) are included, GHG emissions of bioenergy can be large, indeed even higher than those of fossil-fuel based alternatives (Searchinger et al., 2008; WBGU, 2008).

To establish how much bioenergy can be produced without harming the environment, and without adverse social and economic impacts undermining gains, requires a systems approach that takes into account the relevant interactions between various land uses and socioeconomic functions of biomass (food, fiber/materials, energy).

The environmental effects of bioenergy plantations are species-specific as well as site-specific. Perennial grasses such as switchgrass, miscanthus, and short-rotation coppice are ecologically less demanding than food crops in terms of impacts on soils, soil erosion, biodiversity, nutrient leaching, pesticide application, etc. (Cherubini et al., 2009). Conversion of grasslands or forests for bioenergy production may cause dire ecological consequences. The environmental impacts of bioenergy depend only to some extent on the specific bioenergy plant and more on the previous use of the land on which it is planted (Gibbs et al., 2008).

Land demand is a central environmental issue associated with the expanding use of bioenergy crops (Sagar and Kartha, 2007; Firbank,

2008). Once considered a local environmental issue, it is increasingly recognized that land use has become a pervasive driver of global environmental change (Foley et al., 2005). The Millennium Ecosystem Assessment (MEA, 2005) concluded that land use has already reduced the ability of ecosystems to deliver vital ecosystem services. Large-scale bioenergy plantations would increase humanity's pressures on global terrestrial ecosystems and contribute to biodiversity loss (Haberl et al., 2009).

Bioenergy plantations usually reduce the amount of carbon stored in ecosystems compared to undisturbed ecosystems (Schimel, 1995; Watson et al., 2000), while land conversion and biomass harvest can lead to loss of soil organic matter and significant net emissions (Pulleman et al., 2000; Lal, 2004; see also Chapter 20). In addition to the emissions from land use, GHG emissions also result from the energy required to produce bioenergy, and from the production and use of fertilizers, pesticides, and all other activities of the full process chain. Gibbs et al. (2008) concluded that the expansion of bioenergy into carbon-rich ecosystems (e.g., forests) leads to 'carbon payback times' of decades to centuries, whereas GHG avoidance is almost instantaneous if degraded or already cultivated land is used. For areas with lower embedded carbon such as grasslands or savannahs and for high yield biomass feedstocks payback periods can be less than a decade.

Water demand of bioenergy crops may cause environmental and social problems. Humans already use or regulate more than 40% of all freshwater resources globally (MEA, 2005). Global water demand grows by 10% per decade adding to water supply stress in many regions. Agriculture currently demands some 70% of all freshwater use (UNEP, 2009), of which 2% was used for bioethanol production (WBGU, 2008).

The production of bioenergy uses 70–400 times more water per unit of energy than other primary energy carriers, excluding hydropower, and ranges from 24–143 m^3/GJ, with Jatropha having the largest water footprint among 12 bioenergy crops analyzed in a recent study (Gerbens-Leenes et al., 2009). The amount of water per unit of energy is highly dependent on the crops used, the efficiency of the cropping system, and the local hydrological and soil conditions. On a positive note, bioenergy plantations in marginal areas may alleviate water-related problems, i.e., local water harvesting and run-off collection may reduce water-related erosion (Berndes, 2008).

Bioenergy produced on currently grazed lands can have large-scale impacts on livestock-rearing subsistence farmers. These may be positive or negative, depending on the implementation strategy. Large-scale bioenergy plantations owned and operated by international, vertically integrated corporations tend not to benefit the local farming communities as most of the revenue is generated in the production stage that involves sophisticated biochemical conversion technologies (Sagar and Kartha, 2007). However, small-scale locally owned and operated plants, as well as sustainability certification systems, might help ensure that benefits accrue to the local farming communities (Lewandowski and Faaij, 2006).

7.7.6.2 Environmental and Social Implications of Using By-products, Residues, and Wastes

In contrast to bioenergy crops, bioenergy production from agricultural by-products, residues, and wastes does not (1) require additional land or land use changes, (2) compete with food or fiber production, (3) affect agricultural and food prices, and (4) require large amounts of additional scarce inputs such as freshwater (Berndes, 2008). On the contrary, using biomass residues may help alleviate energy shortages, reduce landfill requirements, and create employment opportunities. However, there may also be negative environmental effects, depending on the respective biomass flow as well as on technology and management.

The agricultural residue straw can deliver substantial amounts of energy. However, straw plays a vital role for soil fertility, soil carbon pools, and the mitigation of water and wind erosion (Lal, 2005, 2006; Wilhelm et al., 2007). WBGU (2008) assumes about half of all crop residues could be used to produce bioenergy without compromising soil fertility. Still, the science underlying such assumptions is weak and more research is required. Removal of crop residues for energy production could also affect the GHG balance of cropping systems.

The removal of biomass from forests, including forest residues, may affect forest ecosystems, e.g., the coarse woody debris is essential for biodiversity and ecosystem functioning (Krajick, 2002; Shifley et al., 2006), and forest conservation objectives – the use of fuelwood and forestry residues – have to be jointly optimized.

Well-managed use of animal manures for biogas production can have significant positive environmental and social impacts. It reduces CH_4 emissions,[21] while returning most plant nutrients and parts of the carbon back to the soil, thereby mitigating land degradation and helping to maintain soil fertility (Rajabapaiah et al., 1993; Stinner et al., 2008). Moreover, energy from biogas can help to substitute for traditional biomass energy that has tremendously negative health and environmental effects and currently contributes to millions of premature deaths from respiratory diseases that result from indoor pollution (Jaccard, 2005).

Using MSW for energy production lowers CH_4 emissions from waste deposits (landfills). In the absence of effective air-pollution control technology, however, incineration of MSW can result in large

21 Conversion of animal manures into biogas plants and subsequent application of the residues as fertilizer reduce CH_4 compared to the storage and direct application of manures (Bhattacharya et al., 1997; Clemens et al., 2005).

emissions of toxic pollutants such as dioxin. Tight air-pollution regulation that vigorously enforces the use of the most advanced abatement technologies to reduce toxic emissions is required to minimize possible negative environmental effects from the combustion of MSW (McKay, 2002).

7.7.7 Summary

The global theoretical biomass is undoubtedly large at 1100 EJ/yr, not including the potential from aquatic biomass. However, while this value is more than double the current global energy consumption, harvesting even half of this biomass potential would result in severe adverse impacts on biodiversity, resilience, and sustainability of the Earth's ecosystems, humans included. How much biomass can or should be used for energy purposes is therefore less a question of the available theoretical potential than of ecological sustainability and socioeconomic desirability.

Thus, to quantify the harvestable portion of biomass potential, it is important to understand (a) the annual rates at which biomass for energy becomes available and (b) the competing land uses, such as food production, settlement, and infrastructures. Regarding biomass flows, these can be in the form of crops grown specifically for energy use (on various land types), residues (agricultural and forestry), wastes (agricultural and municipal), and by-products. The global technical potential ranges between 162–267 EJ/yr. Although the greatest portion of this technical potential is provided by dedicated bioenergy crops, it is also these crops that potentially have the greatest socioeconomic effects. However, use of residues, manures, and wastes could still have adverse effects on ecosystems, although with good management should be able to provide more benefits than costs.

Regarding competing land uses, it is important that both the technical and economic estimations of potential are significantly lower than previous assessments, as it is increasingly recognized that land demand for food and feed production, urban and infrastructure areas, and biodiversity conservation, as well as the need to maintain a favorable GHG emission balance, pose definite limits on land availability for bioenergy production.

As aquatic biomass is not limited by freshwater availability, this biomass feedstock could exceed terrestrial-based systems by orders of magnitude. However, as aquatic biomass systems are still in their infancy, this study omits their potentials in the final estimates.

Biomass is the most diverse energy feedstock, and it is also the most integrated into our everyday lives. For this reason, the potential exploitation of biomass for energy relies much more on the interplay between the demand for affordable energy, food and water, our ability to adapt to climate change, and social development.

7.8 Wind

7.8.1 Overview

While the total kinetic energy of the Earth's winds is enormous, the exploitable technical and economic potentials of wind energy depend on technology development on the ground, at sea and potentially at high altitudes. It is impossible to estimate a renewable resource potential without including explicit assumptions on the technology's technoeconomic performance profile. These technologies are discussed further in Chapter 11.

The theoretical potential delineates the total kinetic energy within the troposphere. The technical potential defines the upper limit of wind energy that can be harnessed effectively by technologies. Constraints include the theoretical maximum efficiency of power extraction by a wind turbine (the Betz conversion limit), as well as identifying locations where the average wind speed is strong enough for wind turbines to operate.

Finally, the economic potential takes into account limitations on the potential locations for wind converters, including costs, conflicting land uses, and the distance limitations of electricity transmission. As wind-technology performance has been quite dynamic, with substantial technology learning over recent years, wind's economic potential is certainly a moving target (see Chapter 11).

7.8.2 Theoretical Potential

The total energy in the winds at a given instant is defined as the sum of the kinetic energy of each air molecule in movement in the troposphere, from the surface all the way up to the top of the tropopause. This has been estimated as 11.8–13.9 J/m^2, corresponding to 604–711 EJ on average at each instant in time (Peixoto and Oort, 1992; Li et al., 2007).

What actually constrains wind-power extraction is the natural rate at which kinetic energy is dissipated in the atmosphere via friction. This is a difficult number to calculate directly, but it can be derived from the global energy budget of the Earth and other theoretical considerations. Estimates vary by orders of magnitude, from 113.5 ZJ/yr (3600 TW) (Lorenz, 1967) to 11,700 EJ/yr (370 TW) (Hubbert, 1971). A more recent estimate (Sørensen, 2004) suggests a natural dissipation of 63–160 ZJ/yr (2000–5100 TW).

7.8.3 Technical Potential

The estimation of technical potential adds further constraints based on the fundamental limitations of the application of turbine technologies. The first technical limit is a safety factor that prevents the significant

modification of the Earth's climate, i.e., the fraction of the theoretical potential which can be exploited without adversely affecting natural global equilibria. Not all the energy available in wind can actually be extracted, as otherwise the air flow would stop and the air mass would pile up where the wind turbines are. Gustavson (1979) suggests a factor of no more than 10%, which, using Sørensen's (2004) theoretical potential estimate, would bring an initial technical potential maximum to 200–510 TW, or 6300–16,000 EJ/yr.

The Betz limit, the theoretical maximum efficiency of power extraction by a wind turbine, is 59% of the total power available in the wind going through the area swept by the turbine blades (Burton et al., 2001). The most efficient wind turbines nowadays can achieve efficiencies of about 50%. Even taking the Betz limit into account, the technical wind power output potential is 3700–9500 EJ/yr.

A further limitation is determining locations, both on the horizontal and vertical plane, where sufficient wind energy exists to turn wind turbines. The power in a wind stream is proportional to two factors: the cube of its speed (V^3) and the air density of the stream (ρ). Thus, doubling the wind speed increases the power by a factor of eight and decreasing the air density by 50% decreases the power by 50%. To take both factors – wind speed and air density – into account, the variable generally used is wind power density ($0.5\ \rho V^3$), measured in W/m^2, which indicates how much power is available at a given site to drive a wind turbine, per unit area swept by blades perpendicularly to the wind.

Wind power density is not evenly distributed in the atmosphere. It varies by altitude and geographical location. In general, more power is available at high altitudes than near the ground. Also, near the surface more power is available over water than over land. Lastly, wind varies not only with aboveground height and terrain type, but also with the time of day and season. Figure 7.26 shows a map of median wind power density over a year at 80 m and 10,000 m above the ground. These two altitudes were selected because the former is representative of traditional technologies (i.e., wind turbines 80 m high), and the latter is of interest for emerging wind power technologies, e.g., kite- or rotor-based high-altitude devices (Canale et al., 2007; Roberts et al., 2007; Archer and Caldeira, 2009).

As wind energy is linearly proportional to the area swept by the turbine blades, and because wind speed generally increases with height, modern wind turbines have become taller. Hubs are now typically located at 80–100 m, and have longer blades (over 70 m in diameter) than those of 10 years ago, when the standard wind turbine was 50 m high with 30 m blades. Such large, tall, and heavy blades cannot be turned by weak winds, but typically need at least a wind speed of 3–4 m/s. As such, wind power is technically feasible (for large-scale applications) only in locations with average wind speeds at 80 m of 6.9 m/s or greater, corresponding to wind power class 3 or greater (Table 7.36). Thus, a threshold of 6.9 m/s is applied in this report to identify 'windy' sites. Classes of wind power density for three standard wind-turbine hub heights (10, 50, and 80 m) are listed in Table 7.36.

The global technical wind power potential from windy sites near the surface (i.e., 80 m wind speed ≥ 6.9 m/s) over land and offshore has been estimated as 72 TW (Archer and Jacobson, 2005), corresponding to a global annual energy from winds of 2256 EJ.

To extract this potential, a total area of about 16.5 million km^2 would be required (i.e., 1.5 times the area of China), covered with six 1.5 MW wind turbines per square kilometer. Figure 7.27 indicates locations where 80 m wind speeds exist in Europe and North America. Similar maps were also developed by the US National Renewable Energy Laboratory for land-based sites worldwide at 50 m above ground level (Denholm and Short, 2006).

Using the same wind speed data as Archer and Jacobson (2005), 8144 reporting sites are considered in this report, with the assumption that they are representative of the wind conditions in their areas. The fractions of windy sites can be used as proxies for the fractions of windy land in each region. Because the technical potential depends on the size of the turbines used, two modern turbines are used as benchmarks in this report, namely a 1500 kW (77 m diameter) turbine and a 5 MW (126 m diameter) turbine. Their rated power and blade size are used to calculate the yearly average wind power output as a function of the yearly average wind speed via the method in Jacobson and Masters (2001). Table 7.37 summarizes the values of relevant parameters in each of the 18 regions, including the range of technical potentials obtained from the two wind turbines. The data coverage, i.e., the number of reporting sites per unit area, can be used as a proxy for reliability of the calculated potentials. The greater the data coverage, the more representative are the data and wind power estimates. Japan and Europe have the best data coverage (more than three reporting sites per Mha), whereas Africa and some regions in South Asia have the lowest (less than 0.3 per Mha).

Small-scale wind turbines (~10 kW rated power) that can extract winds at modest wind speeds for single household applications are not considered in this study. Also, the intermittency of the wind resource is not considered in these estimates.

7.8.4 Practical Potential

The practical wind potential is calculated from the technical potential taking into account the following limitations:

- conflicting land uses – urban areas, protected natural areas, military exclusion areas, etc., – cannot be covered with wind turbines;
- remoteness – too remote locations (i.e., mountainous areas) cannot be reached via transmission or distribution electric lines.

All these constraints depend on the geographical, political, and socio-economic conditions of each location and are therefore difficult to

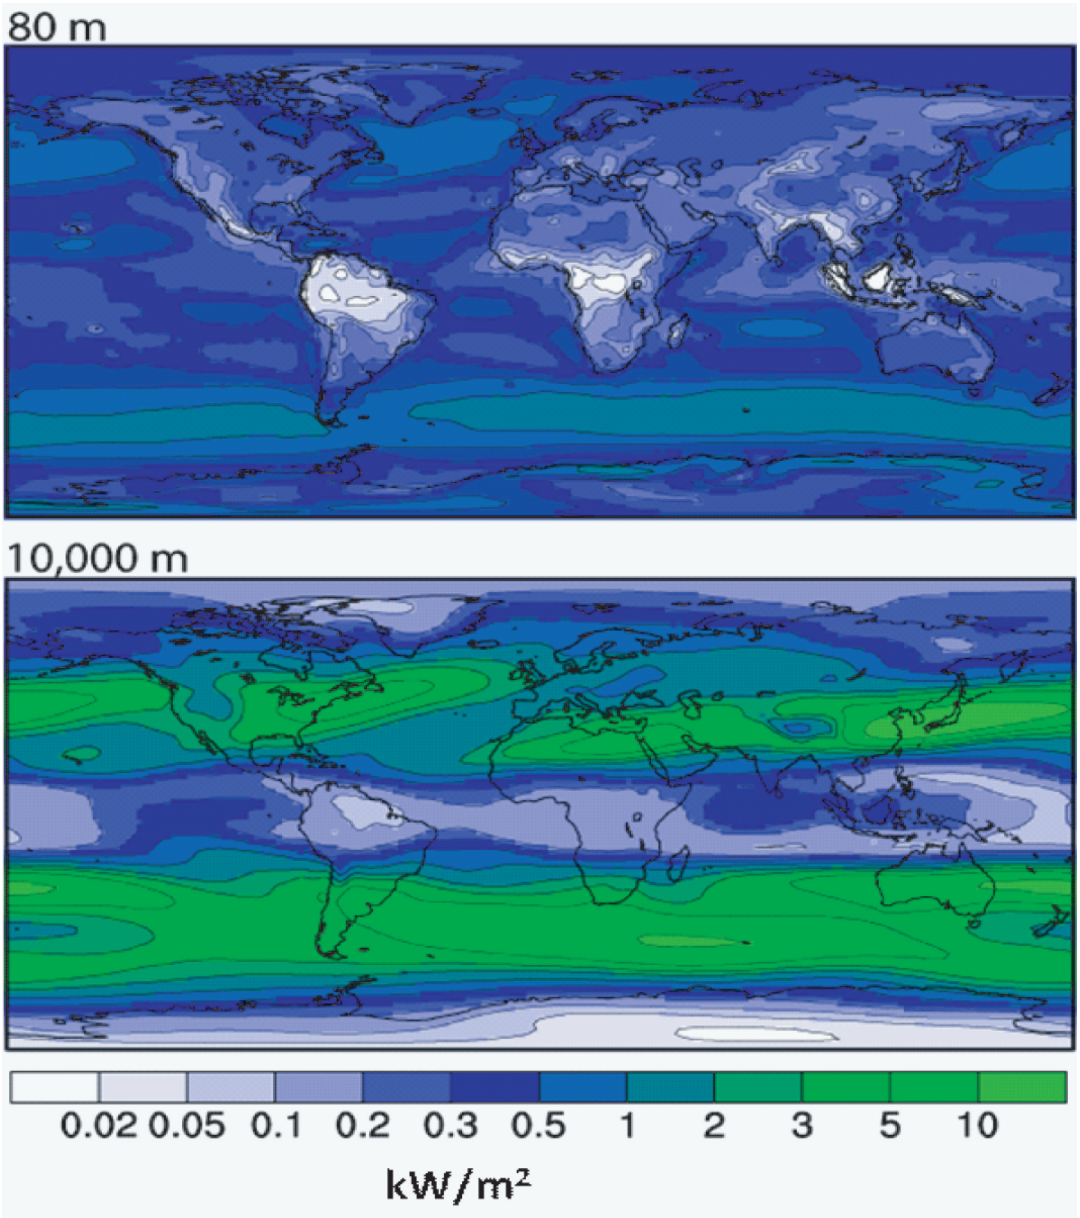

Figure 7.26 | Map of the median wind power density available in the winds near the surface (at 80 m) and near the jet streams (10,000 m) during 1979–2006. Source: Archer and Caldeira, 2009.

evaluate on a global scale. Hoogwijk et al. (2004) used suitability factors, i.e., the fraction of areas that can be devoted to wind harnessing, between 0% (bioreserves and tropical forests) and 90% (savannah). They calculated a practical onshore wind potential of 96 PWh/yr, or 346 EJ/yr, corresponding to about 20% of the technical output potential and over five times the total electricity production worldwide of ~73 EJ in 2008 (IEA, 2010a). The low-end values of the ranges for the practical potential shown in the last column of Table 7.37 were obtained by including fewer windy sites (determined with a cost analysis).

Offshore energy is excluded in this study because insufficient wind speed data are available to justify a proper analysis. Furthermore, suitable locations for offshore wind are dependent on factors such as sea conditions and shipping lanes, etc. Nevertheless, previous studies have assessed the global offshore potential at 37 PWh/yr at 50 m height (Hoogwijk, 2004).

Both the technical and the practical potentials of high-altitude wind power are zero at the moment, because it is still a prototype technology.

7.8.5 Environmental and Social Implications

The exploitation of wind energy has impacts on the environment that depend on the conversion technologies and their locations. These include disturbances to delicate ecosystems and impacts on birds and

Table 7.36 | Definition of wind power classes.[a]

Wind power class	10 m above ground		50 m above ground		80 m above ground	
	Wind power density	Wind speed	Wind power density	Wind speed	Wind power density	Wind speed
	[W/m^2]	[m/s]	[W/m^2]	[m/s]	[W/m^2]	[m/s]
1	<100	<4.4	<200	<5.6	<250	<5.9
2	100–150	4.4–5.1	200–300	5.6–6.4	250–375	5.9–6.9
3	150–200	5.1–5.6	300–400	6.4–7.0	375–500	6.9–7.5
4	200–250	5.6–6.0	400–500	7.0–7.5	500–625	7.5–8.1
5	250–300	6.0–6.4	500–600	7.5–8.0	625–750	8.1–8.6
6	300–400	6.4–7.0	600–800	8.0–8.8	750–1000	8.6–9.4
7	>400	>7.0	>800	>8.8	>1000	>9.4

[a] Wind speed is assumed to have a Rayleigh distribution and to increase with height according to the power law with a friction coefficient of 1/7 and air density of 1.225 g/m^3.

other wildlife. In addition, there are social concerns about noise pollution and landscape aesthetics. However, as previously mentioned, the exploitation of wind energy resources depends entirely on conversion technologies. The environmental and social impacts of wind turbines are discussed further in Chapters 3, 11, and 20.

7.8.6 Summary

The theoretical potential of wind energy was determined to lie in the range 110,000 ± 50,000 EJ/yr. Adding technical constraints, including fundamental conversion maximums, as well as wind power density minimums, a technical potential was estimated as 1500–5700 EJ/yr. Including the winds blowing across Antarctica adds approximately another 2100 EJ/yr. Finally, practical limitations on the technical potential were imposed, which took converter performance characteristics, land use conflicts, and electricity transmission into account. The practical potential for onshore wind utilization was thus found to be 250–1200 EJ/yr (or about 20,000–100,000 TWh of electricity per year).

7.9 Solar

7.9.1 Overview

Solar energy is by far the most abundant energy resource on Earth and is ubiquitous over the Earth's surface. To put in perspective the enormity of the sun's energy, the average irradiation that hits the Earth's surface in one hour is about equal to that of the energy consumed by all human activities in a year (IEA, 2010c). Solar energy conversion technologies

Table 7.37 | Technical and practical wind (input) potentials for the 18 GEA regions.

[c] This value does not include Antarctica. Including Antarctica (55 reporting sites), the world technical potential is 2256.2 EJ (or 7650 EJ input equivalent).

have the capability to provide electricity generation as well as a variety of energy services, including heating, cooling, and natural lighting.[22]

As the sun's radiation travels through the Earth's atmosphere toward the surface, it is reduced because of the reflection, scattering, and absorption of particles in the atmosphere. The fraction of radiation reflected back into space is considered the atmospheric albedo, or reflection coefficient, and is estimated to be between 30–35%. Thus, sunlight hits the Earth's surface both directly and indirectly. On a clear day, the direct irradiation accounts for between 80–90% of total irradiation, while on a foggy day, the direct irradiation approaches 0% and the ambient light is made up of indirect, i.e., diffused or scattered, light. As a result of the ubiquity of direct and diffuse radiation, photovoltaics (PV) and solar thermal collection systems can literally be placed almost anywhere on the surface of the Earth to generate electricity and heat, respectively.

As with other renewable resources, the availability of solar energy does not determine its role in the global energy spectrum; rather, it is a matter of the conversion technologies and their market competiveness. However, as it is impossible to assess technical or economic potentials without a basic presumption of technology performance, this chapter aggregates technical potentials with respect to two technologies that directly contribute to the capture and application of solar energy: concentrating solar power (CSP) and PV providing electricity (see Chapter 11). Conversion of solar energy into heat can be quite straightforward, as any object placed in the sun will absorb some thermal energy, however, it is important to note that certain techniques and technologies exist to maximize absorbed energy and minimize losses. The wide variety of different techniques and the diffuse nature of their employment make it very difficult to quantify a technical potential for such technologies.

7.9.2 Theoretical Potential

The theoretical potential is defined as the total solar irradiation reaching the Earth's surface in a year. The incoming solar electromagnetic radiation upon reaching the Earth's atmosphere, the solar constant, is 1366 W/m^2 (Iqbal, 1983). The Earth's albedo and atmospheric absorption mean only approximately 51% of the incoming radiation reaches the Earth's

22 For a more in depth discussion on the various solar energy conversion technologies, see Chapter 11.

surface. The average irradiance thus reaching the surface is 697 W/m^2, which multiplied by the Earth's total land surface area results in a theoretical potential estimate of 3,300,000 EJ/yr. Including the oceans, the total solar irradiation reaching the Earth is over 11,000,000 EJ/yr. These estimates, however, do not take into account localized weather conditions. Hoogwijk (2004) estimated the theoretical potential using a bottom-up approach with average irradiance data from the Climate Research Unit, which records empirical irradiation data for the past 30 years. This study estimates the theoretical input potential of solar energy to be lower, at around 630,000 EJ/yr.

7.9.3 Technical Potential

Several factors reduce the practically harvestable potential of this vast energy source. The amount of solar energy available at a given location is subject to daily and seasonal variations. Geographical variation is another important factor. Areas near the Equator generally receive more radiation than those at higher latitudes. Weather (atmospheric) conditions are typically the strongest factors that influence solar energy availability. While solar tracking systems exist to reduce the impact of geographical variations, these can only harvest direct sunlight, which is most affected by weather conditions. As irradiation is often diffuse, large-scale generation of solar energy can carry significant land requirements.

Siting issues combine with all three of the above factors. Not all surfaces are suitable for solar energy conversion, even if they have suitable geography and weather conditions. Land use conflicts (man-made infrastructure, agriculture, or forests), geomorphology, topology, and protected or restricted areas pose siting constraints for larger solar installations. However, building structures provide interesting local siting possibilities for small-scale solar energy use.

These siting issues cause discrepancies in the various estimations of the global technical potential for solar energy, as different models have different criteria and methods for assessing site suitability.

7.9.3.1 Direct Irradiation Potential

The German Aerospace Center (DLR) models the optical transparency of the atmosphere to calculate the direct normal irradiance (DNI) on the ground at any time and any site, by detecting and quantifying those atmospheric components that absorb or reflect the sunlight (clouds, aerosols, water vapor, ozone, and gases). The DNI serves as a reference for CSP systems and is defined as the solar radiation received per unit area by a surface that is always held normal, or perpendicular, to the rays that come in a straight line from the direction of the sun at its current position in the sky (DLR, 2009).

CSP systems track the sun using mirrors and lenses to concentrate the solar energy for the operation of steam cycles. Diffuse solar energy cannot be used, as it has no uniform direction. Heat loss means that for CSP systems to operate efficiently, they require a minimum input of direct sunlight (IEA, 2010b).

Thus, to plan a CSP plant, both site-specific radiation data and historical data are required to classify the actual ground-measurement radiation, taking year-to-year variations into account. Suitable areas, i.e., with high DNI, are usually found in arid and semiarid areas, between 15° and 40° latitude, and at higher altitudes, where both the air density and scattering absorption are lower (IEA, 2010b). In locations close to the equator it is too wet and cloudy during the rainy seasons, and nearer the poles it is often too cloudy. Figure 7.28 shows the DNI for 12 annual irradiation levels for the entire world.

Figure 7.28 shows that northern and southern Africa, the Middle East, parts of Chile, the southern United States, Mexico, and Australia are all suitable locations for CSP projects regarding DNI. The next constraint, then, is to find suitable land availability for the CSP systems. This is assessed by excluding land areas that are unsuitable because of ground structure, land cover, water bodies, slope, shifting sand, protected or restricted areas, forests, agriculture, urban areas, etc. The exclusion criteria can be strict and non-negotiable, or optional and thus subject to competition. Nevertheless, geographical characteristics and specific exclusion criteria, including competition for land use, jointly determine the viability of potential CSP project sites (Broesamle et al., 2001; Trieb et al., 2009).

Land areas with potentially suitable CSP sites, combined with the local DNI data, generate different classes of areas with a specific level of DNI. Table 7.38 shows the land area available for 13 DNI levels ranging from 1500–2800 kWh/m^2/yr for all 18 GEA regions.

Most of the world's regions, except for CAN, EEU, JPN, and PAS, have significant areas with good CSP potential. Although developers typically set the bottom DNI threshold for CSP at 1900 kWh/m^2/yr, locations with higher DNIs, everything else being equal, will be more economically attractive. OCN, NAF, MEE, SAF, and OSA are regions where more than 50% of the CSP-suitable areas have DNI levels larger than 2300 kWh/m^2/yr. Nevertheless, the global technical potential is found to be 277,000 EJ/yr. This is considered the available input energy for CSP systems worldwide.

In total, 33.6 million km^2 of land is technically suitable to host CSP systems, corresponding to about 26% of the world's total land area. Without storage, CSP plants require around 2 ha/MWe, depending on the DNI and the technology. Even though the Earth's 'sunbelts' are relatively narrow, the technical potential for CSP is huge. If fully developed for CSP applications, the potential in the southwestern United States alone would meet the electricity requirements of the entire United States several times over. Potential in the Middle East and North Africa would cover about 100 times the current demand of the Middle East, North Africa, and the EU combined (IEA, 2010b).

7.9.3.2 Direct and Diffuse Irradiation Potential

PV systems use semiconductors to convert solar energy directly into electricity. As these systems are able to exploit both direct and diffuse solar radiation, they are much more versatile in their application and a much lower irradiance boundary determines their effectiveness.

There are two types of PV systems, centralized (grid connected) and decentralized (stand alone). Centralized systems can also be defined as large scale (>10 Kilowatt peak (kWp) capacity), are installed on the ground, and are subject to competing land uses. Decentralized (100 Wp to 10 kWp) systems are typically for domestic energy supply and are installed close to settlements, utilities, or industry, and installation surfaces can include rooftops and facades (Hoogwijk, 2004). Although PV systems use diffuse and direct light, their orientation still plays an important role in both centralized and decentralized applications, as they cannot track the sun. Centralized systems can require large land footprints. For small-scale installations, shading from neighboring buildings as well as orientation of the roof are taken into account.

There are numerous studies on the future potentials of PV systems in local, national, and subregional contexts. Only three major studies assess the global technical potential of PV (Hofman, 2002; Hoogwijk, 2004; de Vries et al., 2007). A comprehensive assessment of the technical and economic potentials at a level close to the 18 GEA regions could not be found in the literature except for that by Hoogwijk. Even in this case the data for several regions had to be supplemented from national assessments (Table 7.39). The potentials are influenced heavily by the definitions and boundaries of the suitability factors, which for centralized systems were based, in part, on Sørensen (1999), and for decentralized systems on Alesma et al. (1993) and IEA (2001).

The input energy technical potential for diffuse and direct irradiation was found to be 12,300 EJ/yr.

7.9.3.3 Economic Potential of Large-scale Solar Plants

Constructing a solar energy plant is dependent on a variety of other economic and market factors other than the irradiance intensity and suitability areas. Factors include the distance of the plant from demand centers, competition from alternative energy sources, and land use competition. Nonetheless, the economics of solar energy depend not only on the energy capturing and conversion technologies, but also on the ability to transport this energy to demand centers. A key challenge for solar energy, as well as other renewable

resources, is that electricity demand centers are not always situated close to the best sources.

7.9.4 Environmental and Social Implications

The environmental and social implications of solar energy depend on the technologies used and the amount of land covered. There is the potential concern of a significantly altered terrestrial albedo, particularly in regions where a lot of solar energy capture would exist. Land use conflicts, particularly affecting soils and biodiversity (Dubreuil et al., 2007), and landscape aesthetics are social issues that could spark debate.

For CSP there are concerns over impacts on fragile desert ecosystems, although some systems could have a positive impact on the surrounding microclimate through enhanced shading (Tsoutsos et al., 2005). There is also the possibility of thermal pollution to water resources, especially in arid regions.

7.9.5 Summary

Solar energy is not only in itself directly the most abundant energy resource on Earth, but it is also indirectly responsible as the ultimate source for hydro, wind, and, of course, biomass. The theoretical potential of solar energy, taking weather conditions into account, is enormous at 630,000 EJ/yr, while the practical potential is estimated at 12,300 EJ/yr for PV applications and at 277,000 EJ/yr for CSP. However, offshore solar potential was not taken into account in this assessment, and neither was the potential of small PV (<10 kWp), as these systems have almost no land suitability issues and their potential is thus very difficult to characterize. The economic potential of solar energy relies heavily on conversion technologies, as well as localized factors such as siting and transmission issues, and these are not addressed in this assessment.

7.10 Geothermal Energy

7.10.1 Overview

Geothermal energy, in the broadest sense, is the natural heat of the Earth due to primarily the decay of the radioactive isotopes of uranium, thorium, and potassium. Immense amounts of thermal energy are generated and stored in the Earth's core, mantle, and crust. At the base of the continental crust, temperatures range from 200–1000°C, and at the center of the Earth the temperatures may be in the range of 3500–5500°C (Alfé et al., 2001). The heat is transferred from the

interior toward the surface, mostly by conduction, and it this conductive heat flow that causes a rise in temperature with increasing depth at a rate, on average, of 25–30°C/km. This is called the geothermal gradient. In the most promising locations, typically along fault lines, the average gradient can be up to 5–10 times the average, with very significant increases of temperature even at shallow depths.

Although the total heat content of the first few km under the Earth's surface is immense, only a fraction can be utilized. Essentially, the Earth's crust acts as an insulating blanket, which can best be accessed through fluid conduits, magma, water, etc., to exploit the underground energy and transfer it to the surface.

Despite the inherent uncertainties in developing estimates of geothermal potential, it is possible to identify a range of estimations, also taking into consideration the possibility of new technologies, such as permeability enhancements, drilling improvements, enhanced geothermal system (EGS) technology, low temperature electricity production, and the use of supercritical fluids (Ledru et al., 2007).

7.10.2 Present Utilization of Geothermal Resources

Water from the deep wells and/or cold water from the surface is transported through this deep reservoir using injection and production wells, and recovered as steam or hot water or both. Injection and production wells, and surface installations, complete the circulation system. The utilization of geothermal energy is divided into two categories, electricity production and direct application, depending on fluid temperature.

Electricity is currently produced by geothermal energy in 24 countries. Five of these countries obtain 15–22% of their national electricity production from geothermal (Costa Rica, El Salvador, Iceland, Kenya, and the Philippines). There is ample opportunity for an increased use of geothermal energy both for direct applications and electricity production (Gawell et al., 1999).

Table 7.40 shows the recently observed rapid expansion in the utilization of geothermal energy for 18 world regions. In 2010, geothermal energy is expected to supply some 67 TWh/yr of electricity and 428 PJ/yr of heat for thermal applications (see Table 7.40).

7.10.3 Theoretical Potential

The notion of geothermal resources refers to all of the thermal energy stored beneath the Earth's surface and is in the order of 10^{31} J (Fridleifsson et al., 2008). Even just the energy stored in the Earth's crust up to a depth of 5000 meters, estimated at 140×10^6 EJ (WEC, 1994) is still an enormous theoretical base. A detailed estimation of the heat stored 3 km deep under the continents by the EPRI (1978) applied an average geothermal temperature gradient of 25°C/km for normal geological conditions and accounted separately for diffuse geothermal anomalies and high-enthalpy regions located near plate boundaries or recent volcanism. High-enthalpy regions cover about 10% of the Earth's surface. The total amount of available heat was estimated to be about 42×10^6 EJ.

This number can be the cause of some confusion about the nature of geothermal resource, as it represents the static component of energy stored under the Earth's surface. The dynamic component, i.e., the terrestrial energy component or recharge of the crust's energy through thermal conduction from deeper, higher temperatures regimes, is much lower. The weighted average of conductive heat flow was estimated to be 87 mW/m^2 globally (Pollack et al., 1993), which corresponds to about 1500 EJ/yr (of which about 315 EJ on terrestrial surfaces), taking into account the additional flow rate caused by volcanic activity (Sigurdsson, 2000). Using the definition of renewable energies, this can be assumed as the theoretical potential. Importantly, heat flow through the continents is much lower (65 mW/m^2) than that at the ocean floor (101 mW/m^2). However, convection processes at tectonic plate boundaries restore energies much faster, and thermal recharge is thus a localized factor.

7.10.4 Technical Potential

Until recently, geothermal energy was considered exploitable only in areas where naturally occurring water or steam is found concentrated at depths less than 3 km, and at temperatures above 180°C (Cataldi, 1999; Fridleifsson, 1999). This view has changed in the past two decades with the development of technologies that can economically utilize lower-temperature resources (around 100°C) and the emergence of ground-source heat pumps using the Earth as either a heat source or as a heat sink, depending on the season (Curtis et al., 2005). Furthermore, EGS technologies have become more viable. EGS, also known as hot dry rock geothermal energy, precludes the condition of naturally occurring water in place. It also allows for the potential use of more efficient thermodynamic fluids.

The assessment of technical potential must take the following limitations into account. Not all the available stored heat can be extracted from the rock through fluid circulation (whether natural or artificially induced). The greater part of the heat remains in rocks with low porosity and not connected to the fracture network. Not all surfaces are suitable for industrial development, because of inaccessibility of the area (mountains, desert, remoteness), presence of infrastructure (urban developments, grids, etc.), and restrictions through environmental protection. Finally, the localized nature of the geothermal gradient characteristics means that not all heat will be available at an economic temperature at reasonable depth.

A technical potential was evaluated (Stefansson, 2005), starting from a general correlation between the existing geothermal high-temperature resources and the number of volcanoes, inferring a total heat input potential suitable for electricity generation of 190 EJ/yr. However, this value considers only traditional geothermal resources, and does not account for emerging technologies, which allow for a more general global exploitation of the geothermal gradient.

The distribution between wet and dry systems and the recent statistical analysis of the lognormal heat distribution were used to calculate the technical potential of a 70% probability of adding up to 1000 MWe of EGS (Goldstein et al., 2009). According to the effective efficiency in the transformation from heat to electricity for different temperature classes (10% for 120–180°C, 20% for 180–300°C, 5% for EGS system), it is possible to evaluate the temperature-weighted average of the amount of equivalent heat extracted per year of about 660 EJ/yr. This assumes that locations with suitable conditions for electricity generation will be used for that purpose.

From the distribution of the geothermal resources over different temperature regimes, it is possible to estimate the low temperature potential (for direct thermal utilization only) using an empirical function reported in Stefansson (2005). The value of 153.5 EJ/yr has been split among the 18 GEA regions accordingly to the amount of low-temperature areas as described by the EPRI (1978). This sums to a total technical potential (for electricity generation and direct thermal uses) of 810 EJ/yr.

Finally, given the enormity of the heat stored within the first 10 km of the Earth's crust, the technical potential is not practically limited by the annual heat replenishment of 1500 EJ/yr and much higher technical potentials (than the annual rate of replenishment) have been reported in the literature (WEA, 2000).

7.10.5 Economic Potential

Over the short-to-medium term, the economic potential of geothermal energy can be estimated based on sites that are known and characterized by current drilling or by geochemical, geophysical, and geological evidence. Despite the promising prospect of EGS, the effective geothermal economic potential for the year 2050 is about 4.5 EJ/yr. EGS technologies are only now becoming commercially viable, and the first commercial plant only went online in Germany in 2010.

However, it is assumed that, in the coming years, EGS will become a leading technology, enabling the dissemination of geothermal electricity all around the world. Using the aforementioned statistical analysis of the lognormal distribution of the underground heat (Goldstein et al., 2009), and assuming for 2050 the exploitation of at least additional 70 GWe from EGS with 95% probability, the final value of 66 EJ/yr in 2050 has been evaluated. The economic potential of direct geothermal heat utilization depends to a large part on the technology associated with its utilization (heat pumps, binary cycles, etc.). By 2050 the global potential is estimated at 10 EJ/yr.

The results of the geothermal potentials (theoretical, technical, and economic) are presented in Table 7.41.

7.10.6 Cost Structure of a Typical Geothermal Electricity Project

Three major activities determine the cost structure of a geothermal project (GEA, 2005): exploration, resource confirmation and characterization (drilling and well testing), and site development (facility construction).

Table 7.41 | Geothermal heat supply potentials for the 18 GEA regions.

GEA region	Theoretical potential	Technical potential		Economic potential	
		Heat for direct utilization	Heat for electricity	Heat for direct utilization	Heat for electricity
	[10^6 EJ]	[EJ/yr]	[EJ/yr]	[EJ/yr]	[EJ/yr]

Source: Adapted from Bertani, 2009.

Exploration is the process of locating geothermal fields, identifying fields at distinct levels of depths, and evaluating the overall prospects. It comprises several surface exploration surveys and eventually drilling of slim holes and/or geothermal gradient wells.

Site development covers all the remaining activities for the commercialization of a geothermal resource: drilling, plant permitting, gathering system, etc. Site development costs vary considerably from project to project depending on the well productivity and/or temperature and the depth to the geothermal reservoir. Recently, drilling costs have increased significantly (in some cases doubled) because of rising steel prices and competition from oil and gas activities for drilling-rig availability. In addition to factors common to exploration and confirmation, drilling costs are dominated by others, such as the permeability of the rock, depth of the reservoir, chemistry of geothermal fluid, resource temperature and pressure, and the liquid and steam gathering system.

The European Geothermal Energy Council (EGEC) collected the average of (all included) geothermal generation costs, in €/MWh, for different geothermal resource and sites, both for the present and projections for the year 2050. The EGEC data were reviewed for this publication and are presented here in Table 7.42. However, they have been modified to omit surface-equipment costs.

Table 7.42 | Geothermal production (heat supply) cost.

Category	Relative weight	Present cost [€/MWh]	Expected 2050 cost [€/MWh]
EGS	50%	120	25
Low temperature (100–180 °C)	33%	60	25
Medium temperature (180–250 °C)	12%	50	15
High temperature (>250 °C)	5%	30	10

Note: the relative weight has been taken from the temperature distribution of the geothermal resources of Stefansson (2005). This cost is only for the mining component. Plant and other surface equipment (approximately 50% of the total cost) are not taken into account.

Source: adapted from EGEC, 2009.

Table 7.43 | Geothermal direct utilization generation heat supply cost; the cost is for the mining only (approximately 10% of the total cost).

Category	Relative weight	Present cost [€/MWh]	Expected 2050 cost [€/MWh]
District heating	30%	5.00	4.50
Other shallow resources	70%	2.00	1.50

Source: modified from EGEC, 2009.

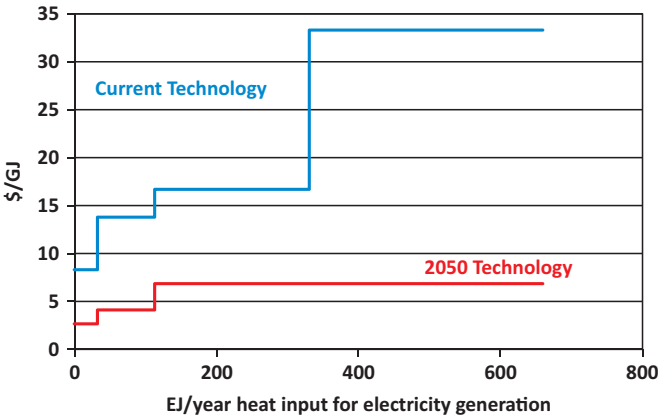

Figure 7.29 | Calculated geothermal heat supply curve suitable for electricity generation with present and expected (2050) technology.

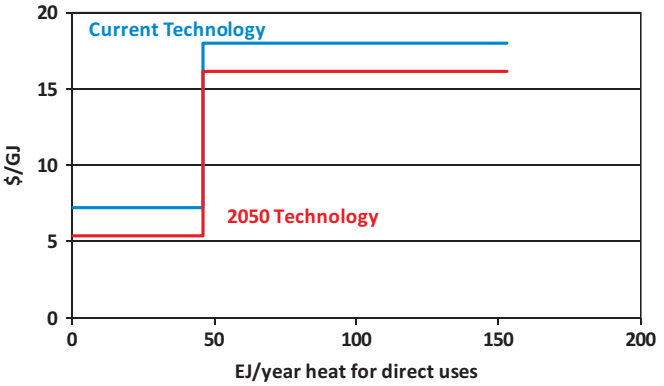

Figure 7.30 | Calculated geothermal direct heat utilization supply curve with present and expected (2050) generation cost.

Using the data of Table 7.42 it is possible to arrange the energy cost supply curve (Figure 7.29). The amount of heat available for each category according to its relative weight was considered, with lowest cost categories taking priority.

For direct utilization, the EGEC publication presents a very wide average value of present expected generation cost; the data are given in Table 7.43, and a cost curve is shown in Figure 7.30.

7.10.7 Environmental and Social Implications

Compared to other energy resources, the exploitation of geothermal energy exhibits a relatively low environmental footprint. Potential impacts range from the drilling of boreholes and of exploratory and production wells to some gaseous pollution releases during drilling and

field testing. The installation pipelines may incur similar environmental impacts to those of drilling.

During plant operation, geothermal fluids (steam or hot water) usually contain gases as well as dissolved chemicals, the concentrations of which usually increase with temperature – with H_2S being one of the main pollutants. Various processes exist, however, that can reduce emissions significantly. Waste waters from geothermal plants also have higher temperatures than the surrounding environment and are therefore a potential thermal pollutant. The total reinjection of the used geothermal fluid is able to reduce strongly any impact of any potential liquid pollution. Adopting closed-loop systems essentially avoids any gaseous emissions.

The extraction of large quantities of fluids from geothermal reservoirs may give rise to subsidence phenomena, i.e., a gradual sinking of the land surface. This is a slow process distributed over vast areas and represents a low risk, if any. It takes years before such effects can be detected, but they need to be monitored systematically, as subsidence could damage the stability of buildings in the vicinity. In many cases subsidence can be prevented or reduced by reinjecting the geothermal waste waters.

The withdrawal and/or reinjection of geothermal fluids may trigger or increase the frequency of seismic events. However, these are microseismic events that can only be detected by means of instrumentation and to date no serious occurrence has been reported.

The high-pitched noise of steam traveling through pipelines and the occasional vent discharge are further potential adverse impacts. Finally, the scenic view can be affected adversely, although in some areas such as Larderello, Italy, the network of pipelines crisscrossing the countryside and the power-plant cooling towers have become an integral part of the panorama and are, indeed, a famous tourist attraction.

7.10.8 Summary

Geothermal energy is a renewable energy source that has been utilized economically in many parts of the world for decades. A great potential for an extensive increase in worldwide geothermal utilization exists, because new technologies allow for the exploitation of geothermal energy in many more locations. Still, the limiting factor for geothermal development rests in its geographical distribution, as high temperature gradients are available only in limited locations, even if the increasing role of binary fluids can strongly enlarge the possibility of using medium-to-low temperature areas.

The theoretical geothermal potential is not considered as the static heat content within the Earth's crust, but the conductive heat flow from deeper, higher temperature areas, and is estimated at 1500 EJ/yr. Extracting more than this theoretical potential would result in a progressive cooling of the Earth's crust, and would no longer meet the principles of a renewable energy source. The technical potential was estimated to be 720 EJ/yr. This value approaches the upper limits of previous assessments of geothermal potential, as aggregated in Bertani (2003). This is because the current estimation assumes the inclusion of dry-rock system extraction technologies, which can exploit the general geothermal gradient and are not dependent on existing, naturally occurring fluids. The economic potential, 75 EJ/yr, takes into account the limited number of areas suitable for geothermal extraction due to geological constraints.

7.11 Ocean energy

7.11.1 Overview

Ocean energy refers to the kinetic energy carried by the waves, currents, and tides, as well as the potential energy stored in the ocean's salinity and temperature differences. The oceans are a tremendous source of energy, especially as many of the world's most concentrated populations are located close by. Ocean energy resources have an advantage in that they are more reliably available, especially compared to solar and wind.

7.11.2 Ocean Thermal Energy Conversion

Ocean thermal energy conversion (OTEC) takes advantage of the temperature difference that results from solar radiation warming the surface water and cooler deeper ocean currents. By using a heat engine, this natural temperature difference can be exploited to produce electricity.

The oceans are the world's largest solar energy collector and energy storage system. Although the average solar irradiation absorbed by the ocean is around 240 W/m^2, Vega (1995) used an estimate of the average solar flux as 95 W/m^2, which corresponds to the latent heat flux of the ocean. Using this average over the 360 million square-kilometer area of the Earth's oceans, the total theoretical potential of ocean thermal energy is estimated to be 1,000,000 EJ/yr.

However, as with any heat engine, larger temperature differences generate greater conversion efficiencies. A temperature difference of about 20 °C between the surface and 1000 m depth is required for OTEC systems to produce significant quantities of power (Binger, 2010). Figure 7.31 shows a world map indicating the ocean temperatures gradients.

The temperature irradiance generally increases with decreasing latitude, i.e., it is greatest near the equator. Various studies have estimated

23 These potentials are the input energy and do not include electricity-conversion efficiencies.

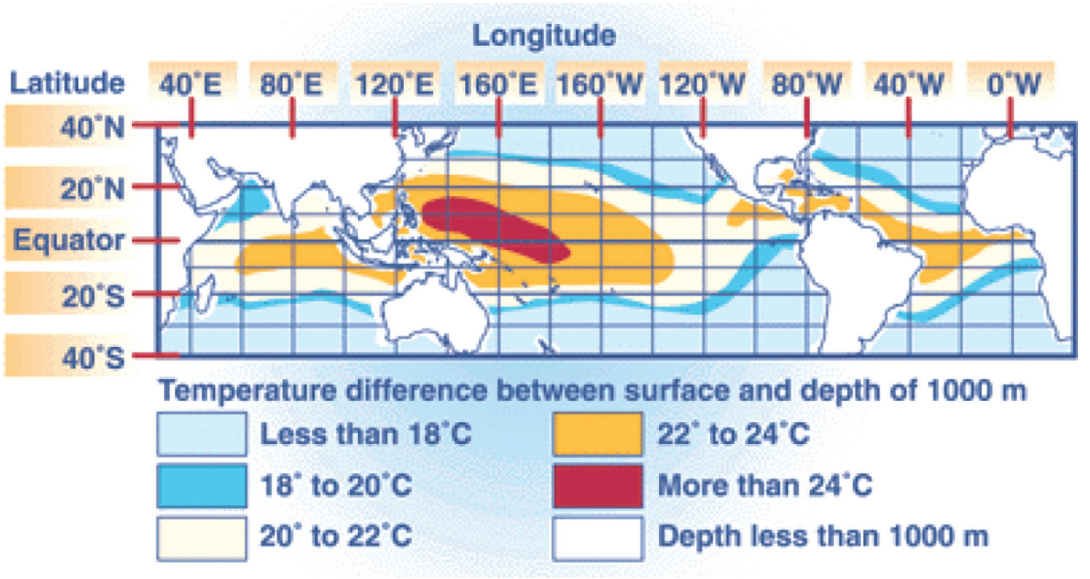

Figure 7.31 | Ocean temperature differences between surface and 1000 m depth. Source: NREL, 2011.

the technical potential of ocean thermal energy. Taking just the tropics into account, Penney and Bharathan (1987) and Masutani et al. (2000) estimated a potential between 100,000–575,000 EJ/yr.[19] Other estimations have built upon these previous studies and assessed the technical potential as the maximum thermal energy extractable from the oceans without incurring significant environmental effects, with values between 15,500 EJ/yr (Pelc and Fujita, 2002) and 30,000 EJ/yr (Avery and Wu, 1994). One of the main discrepancies in these assessments is the viable ocean area for OTEC systems, as some estimations use 60 million km^2, while others use 100 million km^2. Finally, Nihous (2005) assesses the technical potential to be much lower than other studies, at 3150 EJ/yr. Nihous takes into account the disruption of the vertical thermal structure of the oceanic water columns that would likely occur if large-scale OTEC systems were put in place. Thus, the maximum thermal energy available for OTEC systems is on the same order of magnitude of the average upwelling of cold water in the oceans (Nihous, 2005).

7.11.3 Wave Resources

Wave energy is generated by the wind passing over the ocean surface, so that energy is transferred through frictional mechanisms into propagating instabilities in the free surface. It is these traveling instabilities that we refer to as waves.

Wind resources are greatest where the predominant wind directions pass over substantial ocean areas prior to heading toward coastal regions. The strongest winds are found in temperate latitudes, north and south, between 40° and 60°, and on the eastern ocean boundaries (Pelc and Fujita, 2002). The resource, which can be measured in terms of kW/m, is typically greater offshore than it is close to the coastline. However, the technology for harnessing the resource at distances beyond a few tens of meters from the coast is more complex than that for coastal applications.

Pelc and Fujita (2002) estimate that up to 2 TW electricity could be provided by ocean waves. This corresponds to 68 EJ/yr, which, assuming an 80% conversion efficiency, leads to a technical potential of 78 EJ/yr.

7.11.4 Tidal Energy

The tides are cyclic variations in the level of the seas and oceans. Water currents accompany these variations in sea level, which, in some locations, such as the Pentland Firth to the North of the Scottish mainland, and the Bay of Fundy in Nova Scotia, Canada, can be extreme. Tidal energy is even more reliable than wave resources.

The availability of tidal energy, although predictable, is very site specific, and requires locations where the tides are amplified by topographical characteristics of the location. For large-scale plants, i.e., tidal barrages, this is an essential factor. However, tidal fences and turbines (basically underwater wind turbines) can be placed anywhere where the tide causes reliable currents greater than 2 m/s. The total worldwide technical potential of tidal energy amounts to approximately 3.4 EJ/yr (Pelc and Fujita, 2002).

7.11.5 Osmotic Energy

Osmotic energy, also known as salinity gradient energy, is the energy available by harnessing the osmotic pressure difference between seawater and freshwater, i.e., their different salt concentrations. Osmotic energy is available wherever significant amounts of freshwater and

seawater come into contact, e.g., estuaries. The global discharge of freshwater to the seas is about 44,500 km^3/yr. Using a potential energy of 2.35 $MJ/s/m^3$ of freshwater (van den Ende and Groeman, 2007), a theoretical potential of 105 EJ/yr is determined. Van den Ende and Groeman (2007) assume that about 10% would be considered technically feasible, leading to a technical potential of 10 EJ/yr.

7.11.6 Environmental and Social Implications

The exploitation of ocean energy, as with any energy resource, is not without its downsides. For very large OTEC systems, thermal pollution, toxic releases, and impingement and entrainment of organisms on the plant itself pose potentially harmful sources. While the magnitude of thermal pollution would be small, even 3°C shifts in temperatures are known to cause high mortality to corals and fishes (Hoegh-Guldberg et al., 2007). Sensitive ecosystems could be affected further through nutrient loading caused by the drawing of deep coldwater. OTEC systems also release a small amount of CO_2, because gas solubility is reduced in warmer water. OTEC systems have the greatest potential for small island developing states, which need both a reliable energy source and freshwater (Binger, 2010).

Large-scale wave energy systems have the potential to disturb ocean ecosystems and harm marine life. They may also have a significant impact on ocean-atmospheric interactions. Wave energy devices alter the ocean's currents, typically slowing them down and calming the sea. While this could be used in conjunction with wave-break systems, especially around harbors, it will cause reduced mixing of ocean layers, and could reduce food supplies, particularly for bottom feeders. Finally, dampened waves could alter erosion patterns of the coastline, in either a positive or negative way, depending on location (Boehlert et al., 2008).

Tidal barrages could pose threats to sensitive ecosystems, especially in estuaries, by altering the flow of saltwater. Ecosystems could be further affected by slower currents, reduction of the intertidal area, and limited ocean layer mixing. Tidal turbines, however, are more benign. Although they could be potentially dangerous to fish and crustaceans, slow-turning turbines could allow fish to swim through, and larger sea-life could be protected by undersea fences or nets (Boehlert and Gill, 2010).

As the main discharge waste of osmotic energy systems is brackish water, discharges of brackish water could cause salinity fluctuations outside those typical of the ecosystems, and so lead to loss of biodiversity. There is also the danger of impingement and entrainment of marine and estuarine organisms.

7.11.7 Summary

As the ocean covers almost 75% of the Earth's surface, it is Earth's largest collector of solar energy. This thermal potential accounts by far for the largest share of theoretical and technical ocean potentials. Ocean resources have the advantage over other renewables in that they are often more reliable and predictable. While the resource potential may be more than sufficient to meet global requirements (total technical potential, 3240 EJ/yr), special care must be given with regard to ocean ecosystems.

Executive Summary

The industrial sector accounts for about 30% of the global final energy use and accounts for about 115 EJ of final energy use in 2005.[1] Cement, iron and steel, chemicals, pulp and paper and aluminum are key energy intensive materials that account for more than half the global industrial use.

There is a shift in the primary materials production with developing countries accounting for the majority of the production capacity. China and India have high growth rates in the production of energy intensive materials like cement, fertilizers and steel (12–20%/yr). In different economies materials demand is seen to grow initially with income and then stabilize. For instance in industrialized countries consumption of steel seems to saturate at about 500 kg/capita and 400–500 kg/capita for cement.

The aggregate energy intensities in the industrial sectors in different countries have shown steady declines – due to an improvement in energy efficiency and a change in the structure of the industrial output. As an example for the EU-27 the final energy use by industry has remained almost constant (13.4 EJ) at 1990 levels. Structural changes in the economies explain 30% of the reduction in energy intensity with the remaining due to energy efficiency improvements.

In different industrial sectors adopting the best achievable technology can result in a saving of 10–30% below the current average. An analysis of cost cutting measures for motors and steam systems in 2005 indicates energy savings potentials of 2.2 EJ for motors and 3.3 EJ for steam. The payback period for these measures range from less than 9 months to 4 years. A systematic analysis of materials and energy flows indicates significant potential for process integration, heat pumps and cogeneration for example savings of 30% are seen in kraft, sulfite, dairy, chocolate, ammonia, and vinyl chloride.

An exergy analysis (second law of thermodynamics) reveals that the overall global industry efficiency is only 30%. It is clear that there are major energy efficiency improvements possible through research and development (R&D) in next generation processes.

A comparison of energy management policies in different countries and a summary of country experiences, program impacts for Brazil, China, India, South Africa shows the features of successful policies. Energy management International Organization for Standardization (ISO) standards are likely to be effective in facilitating industrial end use efficiency. The effective use of demand side management can be facilitated by combination of mandated measures and market strategies.

A frozen efficiency scenario is constructed for industry in 2030. This implies a demand of final energy of 225 EJ in 2030. This involves an increase of the industrial energy output (in terms of Manufacturing Value Added (MVA)) by 95% over its 2005 value. Due to normal efficiency improvements the Business as Usual scenario results in a final energy demand of 175 EJ. The savings possibilities in motors and steam systems, process improvements, pinch, heat pumping and cogeneration have been computed for the existing industrial stock and for the new industries. An energy efficient scenario for 2030 has been constructed with a 95% increase in the industrial output with only a 17% increase in the final energy demand (total final energy demand for industry (135 EJ)). The total direct and indirect carbon dioxide emissions from the industry sector in 2005 is about 9.9 $GtCO_2$. Assuming a constant carbon intensity of energy use, the business as usual scenario results in carbon dioxide (CO_2) emissions increasing to 17.8 $GtCO_2$ annually in 2030. In the energy efficient scenario this reduces to 11.6 $GtCO_2$. Renewables account for 9% of the final energy of industry (10 EJ in 2005). If an aggressive renewables strategy resulting in an increase in renewable energy supply to 23% in 2030 is targeted (23 EJ), it is possible to have a scenario of constant greenhouse gas (GHG) emissions by the industrial sector (at 2005 levels) with a 95% increase in the industrial output.

1 This includes energy for coke ovens, blast furnaces and feedstock for petrochemicals.

Several interventions will be required to achieve the energy efficient or constant GHG emission scenario. For the existing industry measures include developing capacity for systems assessment for motors, steam systems and pinch analysis, sharing and documentation of best practices, benchmarks and roadmaps for different industry segments, access to low interest finance etc. A new energy management standard has been developed by ISO for energy management in companies. Its adoption will enable industries to systematically monitor and track energy efficiency improvements. In order to level the playing field for energy efficiency a paradigm shift is required with the focus on energy services not on energy supply per se. This requires a re-orientation of energy supply, distribution companies and energy equipment manufacturing companies.

Planning for next generation processes and systems needs the development of long term research agenda and strategic collaborations between industry, academic and research institutions and governments.

8.1 Introduction

The industrial sector is an important end-use sector, since all industrial processes require energy for the conversion of raw materials into desired products. The objective of this chapter is to assess the end-use efficiency of different industrial processes and systems. Earlier assessments include the End-Use Efficiency chapter of the World Energy Assessment (UNDP, 2000), the Industry chapter of Working Group III to the Fourth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) (2007) and the Energy Technology Perspectives 2008 scenarios and strategies for 2050 (IEA, 2008a).

The present analysis uses 2005 as the base year. We document time-series trends as well as regional variations in industrial energy use. The aim is to provide insights to understand parameters that affect global industrial energy use, review technological options, and identify potential for energy efficiency improvements. A review of industrial energy efficiency policies is also included.

Based on the status review, an energy efficiency scenario for 2030 is developed and the savings in energy and carbon dioxide (CO_2) emissions compared with respect to a frozen efficiency scenario and a business-as-usual (BAU) scenario.

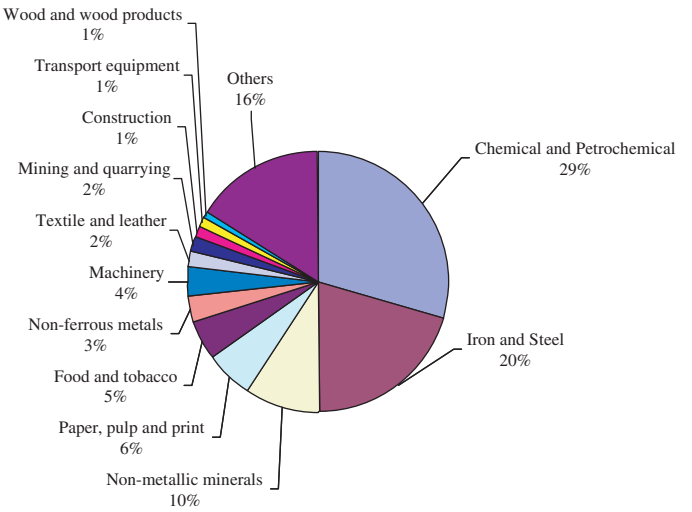

Figure 8.1 | Share of industrial final energy use in 2005. Source: data based on IEA, 2008a.

8.2 Analysis of Industrial Energy Use Trends

The industrial sector accounted for 27% of the total global energy use in 2005 (IEA, 2008a). The total energy use by industry in 2005 was about 115 EJ (excluding traditional biomass and wood, which may add another 17 EJ). The share of final energy use by different industrial sectors in the world is shown in Figure 8.1.

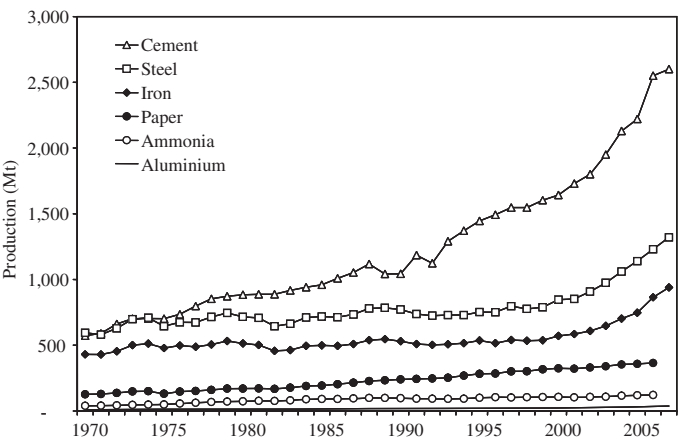

Figure 8.2 | Global production of key materials from 1970–2007. Source: data based on USGS, 2005; 2007; 2008 (cement, iron, steel, aluminum); IFA, 2009 (ammonia); FAO, 2009.

8.2.1 Trends in Material Usage

Industry produces several products that are used by society on a daily basis. These products contain materials extracted from the environment. The conversion of the extracted feedstocks consumes large amounts of energy. A small number of key materials – cement, iron and steel, chemicals (plastics, fertilizer), pulp and paper, and aluminum – account for half of the global industrial energy use. Figure 8.2 shows trends in the global production of these materials.

Today, developing countries produce the majority of primary materials such as cement, steel, and fertilizers for infrastructure development. China alone produces about 46% of all the cement and 31% of the iron and steel in the world. As the industrial sectors of developing countries continue to grow, the same trend is likely to occur for other materials. Table 8.1 shows the comparison of production quantities of key energy-intensive materials in different countries. Among the developing countries, China and India show much higher growth rates and would be responsible for the increased demand for materials in the future. Understanding future industrial energy use is based on future trends in material consumption and production. Generally, per capita materials demand increases with economic development and income, and is assumed to stabilize at a given level (following a so-called Kuznets curve; Mills and Waite, 2009). However, differences in the material intensity of different economies and regions suggest the potential to improve the efficiency with which we use materials.[2] Figures 8.3 and 8.4 depict the material intensity for cement and steel of various world regions.

2 Note that data availability also affects the material intensities. Consumption figures are given as apparent consumption, which equals domestic production plus imports minus exports of the material. Trade in products containing these materials (e.g., steel in a car) is not included in the apparent consumption. Hence, national-level data should be interpreted carefully. At a regional level, the data may provide a more consistent result.

Table 8.1 | Comparison of material production and growth rates in selected countries (2000–2007).

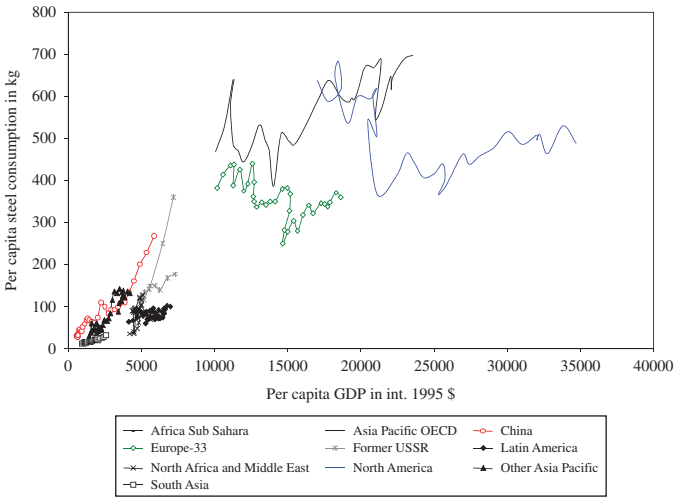

Figure 8.3 | Apparent steel consumption (expressed as kg/capita/yr) as a function of income (expressed as US_{1995}/capita) for different regions in the world.

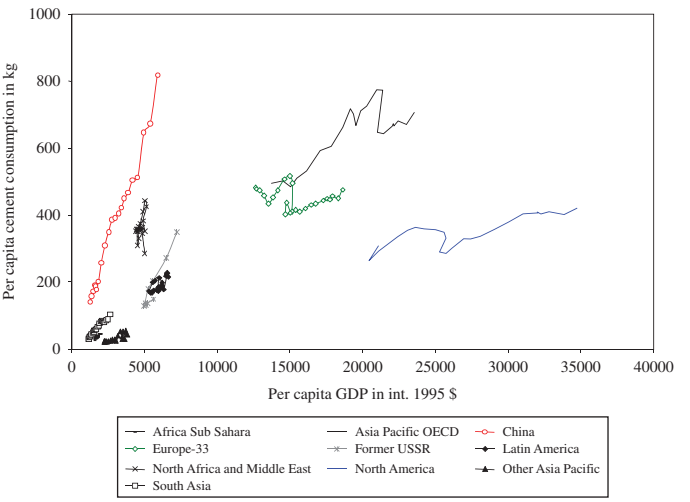

Figure 8.4 | Apparent cement consumption (expressed as kg/capita/yr) as a function of income (expressed as US_{1995}/capita) for different regions in the world.

The figures show that consumption levels in industrialized countries seem to stabilize at about 400–500 kg/capita for cement and about 500 kg/capita for steel. However, it also shows the rapid growth of China as a major consumer due to high growth in the infrastructure and industrialization policies. The apparent consumption numbers shown are affected by exports. For instance China's apparent steel consumption also includes the steel that is used in automobiles and other products that are exported. It may be noted that other developing regions have relatively low consumption levels.

Table 8.2 shows the conclusions obtained by Jänicke et al. (1992) for bulk material consumption and production per capita for different countries as a function of per capita Gross Domestic Product (GDP). De Vries et al. (2006) analyze trends in the per capita use of bulk materials including paper and board (see Figure 8.5), ammonia, bricks, polymers, and aluminum, in addition to cement and steel. For materials such as paper and aluminum, there does not appear to be a saturation level. This could be due to an increase in the growth of the information and communications technology and aircraft sector.

The structure of the GDP and growth of the service sector for industrialized countries affect the overall trends. De Vries et al. (2006) conclude that there is no general trend for decoupling between physical and economic growth for industry.

The case of China is atypical. For example, China's 2005 production of cement of 1064 million tonnes (Mt) corresponds to a per capita production of 806 kg/capita. The cement industry in China is growing at more than 10%/yr. This is probably due to the high share of industry in China's GDP, high growth rates of infrastructure, and its export-oriented industrial development strategy. It is unlikely that other developing countries will reach this level of consumption/growth, as illustrated by the trends

Table 8.2 | General trends of per capita bulk materials production and consumption for 32 industrialized countries 1970–1990.

Product	Parameter	General trend
Paper and Paperboard	per capita production	increasing production at all income levels
Cement	per capita production	increasing producing until per capita GDP levels of US$5000–8000 generally decreasing production at higher GDP levels
Chlorine	per capita production	increasing production at all income levels
Pesticide	per capita production	increasing production at all income levels
Fertilizer	per capita production	increasing production until per capita GDP levels of US$9000 generally stabilizing production at higher GDP levels
	per capita consumption	increasing consumption until per capita GDP levels of US$8000 stabilizing consumption at higher GDP levels
Crude Steel	per capita production	increasing production until per capita GDP levels of US$6000–10000 decreasing or stabilizing production at higher GDP levels
	per capita consumption	increasing consumption until per capita GDP levels of US$5000–9000 Stabilizing or slightly decreasing consumption at higher GDP levels
Aluminum	per capita production	increasing production at all income levels
	per capita consumption	strong increase of consumption at all income levels

for India and Brazil, unless they focus on increasing their manufacturing capacity of cement for exports.

Despite this, the implication of these trends is the likely predominance of developing countries as major consumers (and producers) of energy-intensive materials during the next few decades. Investments in new, energy-efficient processes and plants, and efficient material usage (dematerialization) in developing countries will be important for managing the global industrial energy use.

8.2.2 Regional Variations

Table 8.3 shows a comparison of industrial energy use for select countries of the world. The Manufacturing Value Added (MVA) per capita, total primary energy supply, and final energy and electricity use by industry are compared for different countries.

Different countries have different mixes of energy supply and sectoral energy use patterns. One of the factors affecting future global industrial energy use patterns is the growth of industry in developing countries. This is exemplified by the high growth rate of China in the production of energy-intensive materials, as shown in Table 8.4.

The trends of growth in developing countries and saturation in the energy-intensive industries of developed countries have implications on the future energy mix.

8.2.3 Structural Change

Overall in the economy there are structural shifts from agriculture to manufacturing to services. As countries develop, these structural shifts also result in changes in the overall energy intensity. Many countries have achieved a significant reduction in energy intensity in the industrial sector. Some of this effect has been due to a change in the structure of the industry, with a shift to less energy-intensive industry. These effects can be separated by decomposition analysis.

In the European Union (EU), the final energy use of industry in the 27 EU countries has remained almost constant since 1990 at 320 Mtoe (13.4 EJ). This has been possible through a 30% improvement in energy efficiency from 1990 to 2007 (2.1%/yr). For the EU-27, about 30% of the reduction has been due to structural changes. There are differences in the EU Member States. Figure 8.6 shows the changes in energy intensity for EU Member States from 2000–2007.

The example of the former Soviet Union illustrates the impact of structural change on industrial energy use. Olshanskaya (2004) revealed

that in the Russian industrial sector there were changes toward a more energy-intensive industry between 1994–1997 which contributed positively to the increase in industrial energy intensity in that period. The trend reversed in the late 1990s, and until 2002 the aggregated contribution of structural changes within industry on industrial energy intensity was insignificant. Resulting positive changes in industrial energy intensity may be attributed to improvements in industrial energy efficiency per se (see Figure 8.7).

A decomposition analysis by Howarth et al. (1991) showed that the energy intensity of manufacturing declined by 45% in Japan during 1973–1987 (11.5% decline due to structure; 36.4% due to energy efficiency improvements), while for the United States the decline was 44.3% (14.8% due to structure; 32.4% due to energy efficiency improvements). An analysis of energy intensity trends in the US economy (Huntington, 2010) between 1997 and 2006 shows that structural change (within industries) accounted for more than half of the total energy intensity reduction in the United States.

In most economies there is a structural change where the share of energy-intensive industries is reducing in the total industrial mix. In order to account for this in an aggregate analysis, the decomposition analysis can

Table 8.5 | Energy use in the chemical and petrochemical industry, 2004 (excluding electricity).

	Amount	LHV	Feedstock Energy Needed	Fuel		Total Fuel + Feedstock

be used to reveal the actual impact of energy efficiency improvements in industry, as illustrated by the example shown in this section.

8.3 Consumption and Opportunities: Key Sectors

Industrial processes have significant variations in the energy use per unit of output depending on the vintage (age), process technology employed, quality of input new materials, and scale. Revamping old process plants often requires significant capital investment. In most industrial processes there is a learning curve effect with newer plants being more energy efficient than earlier process plants. A few decades ago, developing countries often only had access to second hand plants and outdated technologies, and hence were often more inefficient than process plants in developed countries. This generalization is no longer possible with the world's most efficient aluminum smelters located in Africa and the most efficient cement plants located in India. Globalization has also resulted in new capital stock being of larger capacity with cutting edge

4 The Fisher ideal index is the geometric average of the Laspayre's and Paasche's price indices (Boyd and Roop, 2004).

technologies. In some countries, (e.g., Russian Federation and Ukraine) the existing process plants that are inefficient have not been modernized due to the lack of capital investments (IEA, 2007a). This section provides an overview of chemicals and fertilizers, iron and steel, cement, pulp and paper, and aluminum, and discusses the factors affecting the energy use in these sectors.

8.3.1 Chemicals and Fertilizers

The chemical industry is highly diverse, with thousands of companies producing tens of thousands of products in quantities varying from a few kilograms to thousands of tonnes (t). Due to this complexity, reliable data on energy use are not available (Worrell et al., 2000a). However, a small number of (intermediate) products make up a large share of energy use in this sector – e.g., ammonia, chlorine and alkalines, ethylene, and other petrochemical intermediates. The chemicals and petrochemicals sector has a large number of products. Table 8.5 (IEA, 2007a) lists the major products that account for about 80% of the total energy use of the chemicals and petrochemicals sector.

Ethylene is a basic chemical that is used in the production of plastics and other chemical products. This is produced by steam cracking of hydrocarbon feedstocks. During this process several by-products are obtained like hydrogen, methane, propylene and other heavier hydrocarbons. Steam cracking consumes about 65% of the total energy used in ethylene production (Worrell et al., 2000a; Ren et al., 2006). Technology options like improved furnace and cracking tube materials, and cogeneration using furnace exhaust can result in 20% of total energy savings (IPCC, 2007). Improved separation and compression techniques (e.g., absorption technologies for separation) can result in 15% of total energy saving. Instead of steam cracking, alternative processes have been developed for converting methane in natural gas to olefins. However state of the art stream cracking of naphtha is more efficient than these processes (Ren et al., 2006).

Global ammonia (NH_3) production (mainly for fertilizer production) was estimated at 125 Mt in 2007. The main producers are China, Russia, India, the United States, Trinidad and Tobago, Indonesia, and Ukraine. The fertilizer industry accounts for about 1.2% of world energy use, and more than 90% of this energy is used in the production of ammonia. Modern

Table 8.8 | Summary of process-specific energy efficiency opportunities.

Process Specific Measures	
Process	**Measures**
Ethylene	More selective furnace coils
	Improved transfer line exchangers
	Secondary transfer line exchangers
	Increased efficiency cracking furnaces
	Pre-coupled gas turbine to cracker furnace
	Higher gasoline fractionator bottom temperature
	Improved heat recovery quench water
	Reduced pressure drop in compressor inter-stages
	Additional expander on de-methanizer
	Additional re-boilers (cold recuperation)
	Extended heat exchanger surface
	Optimization steam and power balance
	Improved compressors
Aromatics	Improved product recovery systems
Polymers	Low pressure steam recovery
	Gear pump to replace extruder
	Online compounding extrusion
	Re-use solvents, oils and catalysts
Ethylene Oxide / Ethylene Glycol	Increased selectivity catalyst
	Optimal design EO/EG-sections
	Multi-effect evaporators (Glycol)
	Recovery and sales of by-product CO_2
	Process integration
Ethylene Dichloride / Vinyl Chloride Monomer	Optimize recycle loops
	Gas-phase direct chlorination of ethylene
	Catalytic cracking EDC
Styrene	Condensate recovery and process integration

ammonia plants are designed to use about half the energy per tonne of product than those designed in the 1960s, with energy use dropping from over 60 GJ/t of ammonia in the 1960s to 28 GJ/t of ammonia in the most recently designed plants (Worrell et al., 2009). Benchmarking data indicate that the best-in-class performance of operating plants ranges from 28.0 GJ/t to 29.3 GJ/t of ammonia (Chaudhary, 2001; PSI, 2004). Individual differences in energy performance are mostly determined by feedstock (natural gas compared with heavier hydrocarbons) and the age and size of the ammonia plant (Phylipsen et al., 2002; PSI, 2004).

Ammonia plants that use natural gas as a feedstock have an energy efficiency advantage over plants that use heavier feedstocks, and a high percentage of global ammonia production capacity is already based on natural gas. China is an exception, in that 67% of its ammonia production is based on coal (CESP, 2004) and small-scale plants account for 90% of the coal-based production. The average energy intensity of

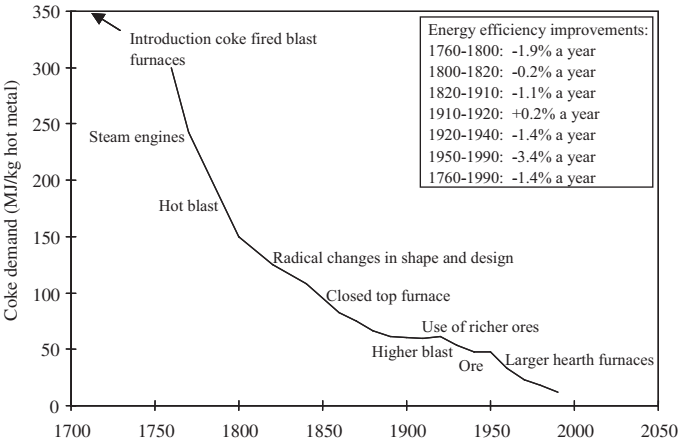

Figure 8.8 | Change in coke demand due to efficiency improvement in the blast furnace process. Source: de Beer et al., 1998.

Chinese coal-based production is about 53 GJ/t, compared with a global average of 41.4 GJ/t (Saygin et al., 2009). A summary of process-specific options for ammonia is shown in Table 8.6, while Table 8.7 from Rafiqul et al. (2005) shows the investments and energy-saving possibilities available from revamping ammonia plants.

A summary of process-specific energy efficiency opportunities in the petrochemical industry is shown in Table 8.8 below. The selection is limited to commercially available technologies and excludes emerging and cross-cutting technologies. Process integration offers significant scope for energy savings and is discussed in a subsequent section.

The use of nanocomposites as a filler material can help in reducing the energy use in polymer manufacture by 20% (Roes et al., 2010).

8.3.2 Iron and Steel

Steel is an important metal. The total global production of steel in 2007 was about 1350 Mt. The major steel producers were China (36% of global steel production), EU25 (15%), Japan (9%), and US (7%) (IISI, 2008). The main route used for steel making is the blast furnace route using coke or coal to reduce iron-ore oxides in a blast furnace to molten iron that is then processed to steel. About 60% of the global steel production is from this route (IPCC, 2007). Another important route accounting for 32% of steel production is the production of steel from melting scrap steel in an electric arc furnace (EAF). Since the raw material used in this route is scrap steel, the specific energy use in this process is only 30–40% of the blast furnace steel process route.

An alternative route is the use of natural gas or coal to produce direct reduced iron (DRI) that can be used in an electric arc furnace. DRI use and production is expected to grow as the share of electric arc furnaces grows in industrialized countries and globally. At present DRI accounts for only about 3% of total steel production.

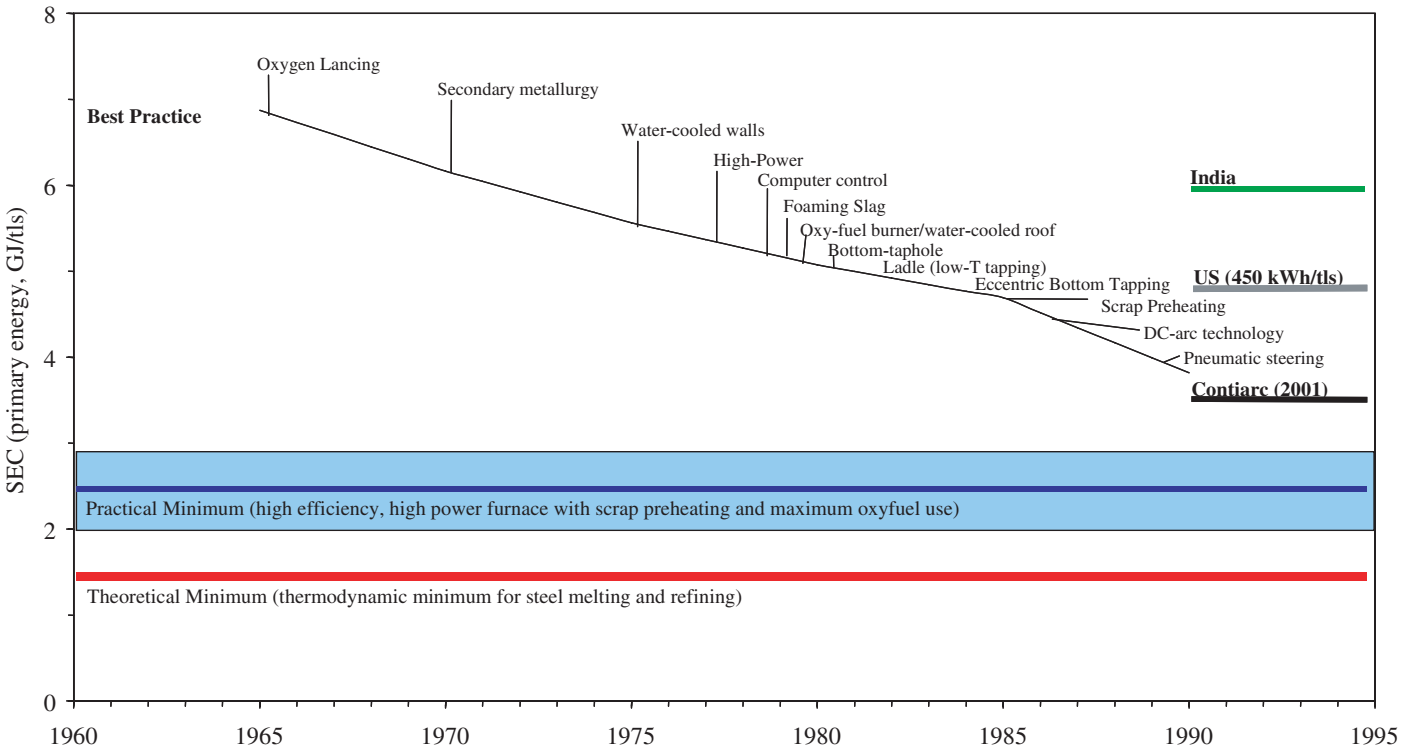

Figure 8.9 | Time-series trend of specific electricity consumption (SEC) values for the EAF process. Note: The Contiarc electric arc furnace was introduced in 2001 and provides an energy efficient option for the production of cast iron. tls = tonne of liquid steel.

Iron and steel making traditionally includes several batch processes. The introduction of continuous casting in steel making in the 1970s and 1980s resulted in significant energy and material savings. Continuous casting now accounts for about 93% of the world's steel production (IISI, 2008). Some major energy efficiency measurement adopted by the steel industry are enhancing continuous production processes to reduce heat loss, increasing recovery of waste energy and process gases, and efficient design of electric arc furnaces – for example, scrap preheating, high-capacity furnaces, foamy slagging, and fuel and oxygen injection. The effect of efficiency improvements on coke demand in the blast furnace process is shown in Figure 8.8. A time-series trend of specific energy use improvement is also shown for the EAF process in Figure 8.9.

Energy savings can be achieved by a combination of stock turnover and equipment retrofit. An analysis of electric arc furnaces in the US steel industry from 1990–2002 showed an efficiency improvement of 1.3%/yr (0.7% due to stock turnover and 0.5% due to equipment retrofit) (Worrell and Biermans, 2005).

Process modifications like near-net shape casting and smelt reduction, which integrates ore agglomeration, coke making and iron production in a single process, offering an energy-efficient alternative at small to medium scales (de Beer et al., 1998) offer scope for further improvements in energy efficiencies.

POSCO, a Korean steel producer, has developed a technology to replace the blast furnace (FINEX process technology) and constructed a demonstration plant with a capacity of 600,000 t/yr in 2003. The coal consumption is about 770 kg/t of hot metal. (Siemens VAI, 2009).

A summary of process-specific energy opportunities in the iron and steel industry is shown in Table 8.9.

8.3.3 Cement

Cement is needed in the construction sector and is important for the growth of any economy. Cement is produced in almost all countries of the world. Developing countries account for about 73% of the global cement production (2811 Mt in 2007). China (1361 Mt in 2007) accounts for almost half of the global cement production (USGS, 2011).

Cement production is also highly energy- and CO_2-intensive. Clinker is the output of the cement kiln. Depending on the type of cement to be manufacture the clinker is further processed in a set of finishing operations. The production of clinker, the principal component of cement, consumes virtually all the fuel and emits CO_2 from the calcination of limestone. The major energy uses are fuel for the production of clinker and electricity for grinding raw materials and the finished cement. Coal dominates in clinker making.

The technical potential for energy efficiency improvements is about 40% (Worrell et al., 1995; Kim and Worrell, 2002b). An analysis of the US cement industry identified 30 opportunities for energy saving in the

Table 8.9 | Summary of process-specific energy opportunities in the iron and steel industry.

Iron Ore and Ferrous Reverts Preparation (Sintering)	
Heat recovery from sintering and sinter cooler	Use of waste fuel in sinter plant
Reduction of air leakage	Improve charging method
Increasing bed depth	Improve ignition oven efficiency
Emission Optimized Sintering (EOS®)	Other measures
Coke Making	
Coal moisture control	Coke dry quenching (CDQ)
Programmed heating	Coke oven gas (COG)
Variable speed drive coke oven gas compressors	Next generation coke making technology
Single Chamber System (SCS)	
Iron Making – Blast Furnace	
Injection of pulverized coal	Recovery of blast furnace gas
Injection of natural gas	Top gas recycling
Injection of oil	Improved blast furnace control
Injection of plastic waste	Slag heat recovery
Injection of coke oven gas and basic oxygen furnace gas	Preheating of fuel for hot stove
Charging carbon composite agglomerates (CCB)	Improvement of combustion in hot stove
Top-pressure recovery turbines (TRT)	Improved hot stove control
Steelmaking – Basic Oxide Furnace	
Recovery of BOF gas and sensible heat	Improvement of process monitoring and control
Variable speed drive on ventilation fans	Programmed and efficient ladle heating
Ladle preheating	
Steelmaking – EAF	
Increasing power	Refractories using engineering particles
Adjustable speed drives (ASDs)	Direct current (DC) arc furnace
Oxy-fuel burners/lancing	Scrap preheating
Post-combustion of flue gases	Waste injection
Improving process control	Airtight operation
Foamy slag practices	Bottom stirring/gas injection
Casting and Refining	
Integration of casting and rolling	Tundish heating
Ladle preheating	
Shaping	
Use efficient drive units	Installation of lubrication system
Gate Communicated Turn-Off (GCT) inverters	
Hot Rolling	
Recuperative or regenerative burners	Integration of casting and rolling
Flameless burners	Proper reheating temperature
Controlling oxygen levels and variable speed drives on combustion air fans	Process control in hot strip mill
Avoiding overload of reheat furnaces	Heat recovery to the product
Insulation of reheat furnaces	Waste heat recovery from cooling water
Hot charging	
Cold Rolling	
Continuous annealing	Inter-electrode insulation in electrolytic pickling line
Reducing losses on annealing line	Automated monitoring and targeting systems
Reduced steam use in the acid pickling line

cement industry with an economic potential of 11% savings in energy and 5% savings in emissions (Worrell et al., 2000b; Worrell and Galitsky, 2005). Blending of clinker with alternative cementitious materials like blast furnace slags, fly ash from coal fired power plants and natural pozzolanes can result in reduced energy and CO_2 emissions (IPCC, 2007). Worrell et al. (1995) and Humphreys and Mahasenan (2002) estimate that the use of blended cement has the potential to reduce CO_2 emissions by more than 7%.

Geo polymers and other alternatives to limestone-based cement are being studied (Humphreys and Mahasenan, 2002; Gartner, 2004) but are currently not economical for widespread deployment.

The energy use of the cement industry in China in 2005 was about 50% of energy consumption of the building materials industry, and became the largest energy consumer in the industry. From 2000 to 2005, the cement industry's energy consumption dropped from 5.0 GJ/t in 2000 to 4.36 MJ/t in 2005 (as shown in Table 8.10).

The small-scale cement industries in India had an average fuel consumption of 3.7 GJ/t of clinker and an average electricity consumption of 104 kWh/t of cement, while the average fuel consumption for large cement industries was 3.29 GJ/t and electricity consumption was 92 kWh/t (Bhushan and Hazra, 2005). The Indian cement industry is among the most efficient in the world. But there is still considerable scope for improvement in the energy use per tonne of output compared to the world's best, due to the potential of more blending in the cement, as shown in Figure 8.10. The blending of fly ash in the cement results in a reduction in the specific energy use. The figure also shows a high clinker content compared to the world's most efficient cement industries. The energy-efficient practices and technologies in cement production are shown in Table 8.11.

An analysis of ten large cement plants in India that account for 16% of total production has been carried out based on data from projects implemented between 2001 and 2006 (Bureau of Energy Efficiency Awards, 2006). The measures have been grouped into different categories, and the conservation supply curve is shown in Figure 8.11. About 8% of annual electricity consumption has been saved by these measures. The cost of saved energy (CSE) is computed by annualizing the cost of the measure and dividing by the annual electricity saving. The CSE varies from INR0.1–1.7/kWh, which is lower than the average price of electricity (INR4.5/kWh or US$0.10/kWh).

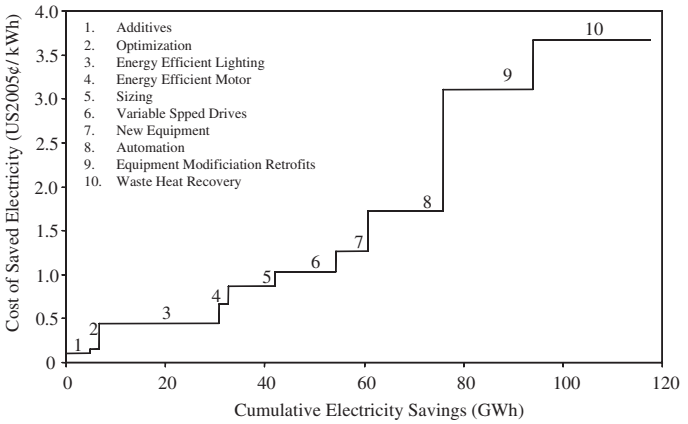

Figure 8.11 | Conservation supply curve for electricity savings in the Indian cement industry. Source: Rane, 2009.

The graph shown in Figure 8.12 covers 80% of global cement production. Note that the lower energy intensity of cement production is the effect of energy efficiency and the use of additives to blend cement. The low energy intensity does not necessarily mean that a country is more energy efficient. The Colombia Kiln (Zeman and Lackner, 2008) proposes a reduced-emission oxygen kiln for cement production. The concept is to use oxyfuel combustion and integrate with carbon capture and storage to reduce CO_2 emissions from the plant by 90%.

8.3.4 Aluminum

Global primary aluminum production was estimated at 38 Mt in 2007 and has grown by an average of 5%/yr over the last 10 years. The key producing countries are China, Russia, Canada, Australia, Brazil, India, and Norway.

Table 8.12 | Energy use in the Brazilian aluminum industry, 2002–2006.

		2002	2003	2004	2005	2006
Production	(10^3 t)	1318.4	1380.6	1457.4	1497.6	1603.8
Domestic consumption	(10^3 t)	715.5	666.0	738.5	802.3	837.6

Source: data based on ABAL, 2008.

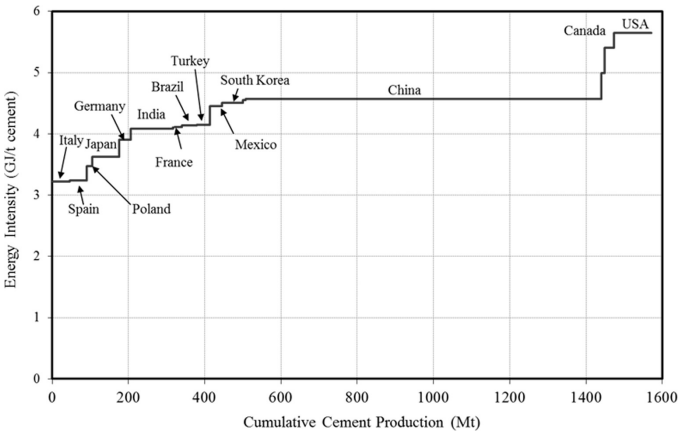

Figure 8.12 | Energy intensity of cement production in selected key cement-producing countries, expressed as primary energy (GJ/t).

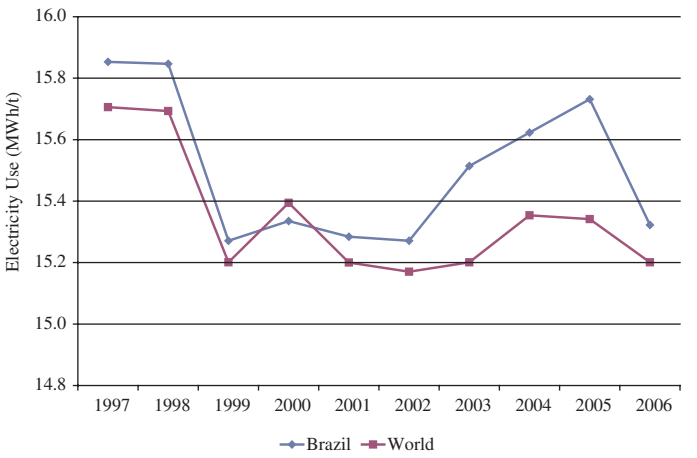

Figure 8.13 | Specific electricity consumption of the aluminum industry (MWh/t) – Brazil and world average, 1997–2007. Source: data based on ABAL, 2008.

Aluminum is produced by the electrolytic reduction of alumina (Al_2O_3). The process is energy intensive, using electricity. Apart from the CO_2 emissions associated with the electricity used, the process also results in emissions of perfluorocarbons (PFCs), carbon tetrafluoride (CF_4), and hexafluoroethane (C_2F_6) (IAI, 2007), which are all greenhouse gases (IAI, 2007). The International Aluminum Institute, a group of aluminum producers (accounting for 70% of the global production) committed to reducing their smelting energy use by 10% between

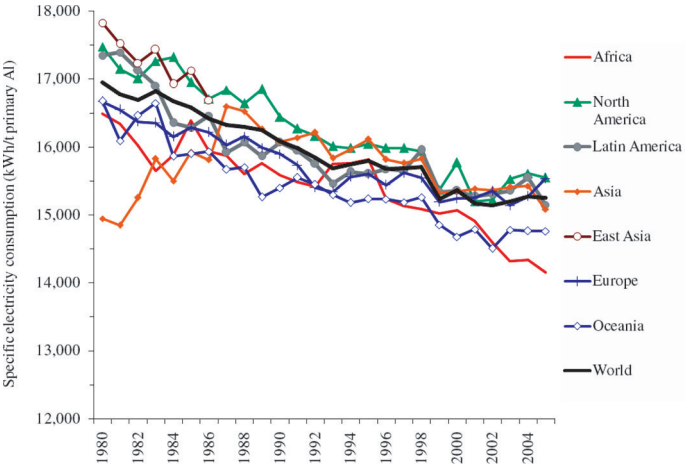

Figure 8.14 | Specific electricity consumption of the aluminum industry (kWh/t) by Region and for the world (black), 1980–2005. Source: data from IAI, 2007. Al = aluminum.

1990 and 2010 (IAI, 2007), achieved an actual reduction of 6% by 2004 (IPCC, 2007).

Additional energy efficiency improvements are possible through increased penetration of state-of-the-art, point feed, prebake smelter technology (replacing Söderberg cells), process control, and an increase in recycling rates for old scrap (IEA GHG, 2001). Figure 8.13 shows the trend in the specific electricity consumption in the aluminum industry in Brazil along with the world trend. Table 8.12 shows the trend in aluminum production and domestic consumption in Brazil. Almost 50% of production is for the export market. The time-series trend of electricity intensity of the aluminum industry across the regions of the world is shown in Figure 8.14.

Ongoing research to develop an inert anode is expected to reduce the energy used for anode baking and electrolysis. Though inert anodes are currently not viable, it is projected that commercially viable designs may be developed by 2020 (IAI, 2011).

Figure 8.15 shows the average specific electricity consumption for aluminum production in different regions of the world. Note that the International Aluminium Institute (IAI) data do not cover China completely. Hence, Figure 8.15 underestimates the relatively high specific electricity consumption for aluminum production in China. Europe includes the EU, Russia, and other countries. The high specific electricity consumption in Europe is due to Russian production capacity.

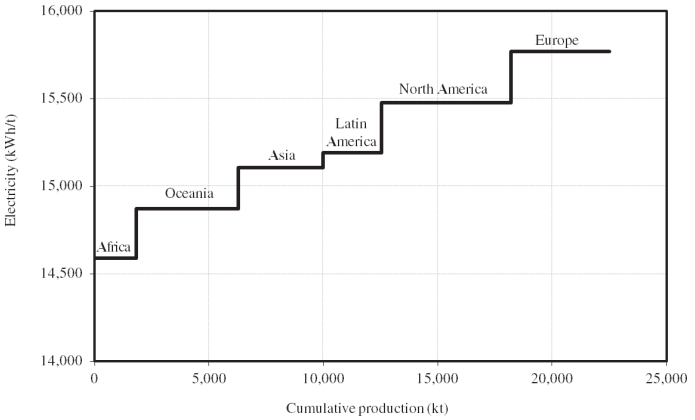

Figure 8.15 | Specific electricity consumption vs. production for world regions. Source: Production data based on USGS (2005; 2007; 2008) and electricity consumption data based on IAI, 2007.

8.3.5 Pulp and Paper Industry

The global pulp and paper industry is an important industry in many countries, from both an economic and an energy use perspective, consuming globally around 6.5 EJ (including printing). This makes the sector one of the largest energy-using sectors in industry after chemicals, iron and steel, and cement. The four largest paper-producing regions (the EU, the US, China, and Japan) account for 80% of energy use and CO_2 emissions. Despite recent changes in the drivers for paper demand, global paper demand is still growing at rates of over 3%/yr over the past 40 years.

The industry is also unique in its reliance on biomass as the key feedstock (besides recycled paper) and primary energy source. This means that while the energy intensity of the sector is high, the CO_2 intensity is far less. The most important processes are pulping (both mechanically and chemically) and papermaking. Energy is used in the pulping of the wood to prepare the fiber, which is processed in the paper machine, the other key energy-using process. About half of the energy is used in pulping, while the other half is used in papermaking. Energy use in the paper machine varies with the paper grade produced. Paper can be made in integrated mills (pulping and papermaking), in standalone pulp (for market pulp) or in paper mills (using imported pulp and recycled paper). Most energy is used in the form of heat (steam) and power. This makes the sector a large user of cogeneration (both using biomass as fossil fuels), but it still also provides a large opportunity for energy efficiency improvements.

Benchmarking and other studies (see, e.g., IEA, 2007a) have demonstrated a substantial potential for efficiency improvement, if best practice technology would be used (see, e.g., Worrell et al., 2008), both in heat use (varying between 0–40%) and electricity use (globally around 20–30%). Combined heat and power (CHP) use varies from 20% of the share of power use to highs of 60% or more (e.g., the United Kingdom, the Netherlands). The countries with the largest potential for energy efficiency improvement typically operate small-scale mills (e.g., China, India) or outdated process equipment (e.g., the United States), while energy-efficient countries operate modern, large-scale mills (e.g., Japan, Scandinavia). China is an interesting example. Just a few decades ago, the majority of the paper industry consisted of very small, inefficient and polluting mills mainly using straw as the main fiber source. Today, China's share of global production is rapidly increasing, and this expansion is based on large, modern paper machines using (imported) recycled paper.

Table 8.13 provides a summary of process-specific energy efficiency opportunities (based on Martin et al., 2000; Kramer et al., 2009). Beyond these opportunities, cross-cutting options exist in motor systems and steam generation and distribution. New technology is being developed, of which black liquor gasification is the most important in pulping, and various new drying technologies are under development for papermaking. Moreover, paper recycling is an important option to reduce energy use (reducing the need for wood pulping) and save resources. Some paper-producing countries rely almost completely on the use of recycled fiber as feedstock (e.g., in Europe).

8.3.6 Small- and Medium-Sized Enterprises

The definition of Small- and Medium-Sized Enterprises (SMEs) varies by country. In some countries it is based on the value added, in others, it is based on the number of employees. Typically these are companies with up to a few hundred employees and a turnover of less than US$100 million. Some of the SME activities are energy intensive (see also Chapter 6). Substantial amounts of energy are used for the production of ferrous and non-ferrous foundries, ceramics, bricks, glass, lime, concrete, wood processing, food and beverages, small-scale pulp and paper mills, cement kilns, steel production and steel rolling mills, and DRI production. Reliable statistics in terms of economic activity and energy use are lacking. However, it is possible to make a rough estimate based on the physical production volume and the typical energy use per unit of product (Table 8.14 and Figure 8.16).

SMEs make economic sense in several sectors where there are no economies of scale. SMEs are adaptable and a source of technology innovation. Rapidly growing economies usually have a large share of SMEs. Access to large-scale production technology is an issue in certain countries. In countries that are members of the Organisation for Economic Co-operation and Development (OECD), where capital is cheap, labor expensive, and technology development has been targeting upscaling for decades, SMEs play a secondary role. However, in many developing countries they are the cornerstone of industrial development. In the context of the changing mix of global industrial output, SMEs in developing countries deserve special attention.

Estimated current final energy use of selected SMEs and small-scale clusters of the manufacturing industry is between 18–32 EJ. This is equivalent to 14–25% of the total final energy use of the manufacturing sector including feedstock use in 2007 (127 EJ), and 17–30% of the total process energy use when feedstock use is excluded (106 EJ).

Table 8.13 | Summary of process-specific energy efficiency opportunities in the pulp and paper industry.

Raw Material Preparation	
Cradle debarkers	Automatic chip handling and screening
Replace pneumatic chip conveyors with belt conveyors	Bar-type chip screening
Use secondary heat instead of steam in debarking	Chip conditioning
Chemical Pulping	
Pulping	
Use of pulping aids to increase yield	Digester blow/flash heat recovery
Optimize the dilution factor control	Heat recovery from bleach plant effluents
Continuous digester control system	Improved browstock washing
Digester improvement	Chlorine dioxide (ClO2) heat exchange
Bleaching	
Heat recovery from bleach plant effluents	Chlorine dioxide (ClO2) heat exchange
Improved brownstock washing	
Chemical Recovery	
Lime kiln oxygen enrichment	Improved composite tubes for recovery boiler
Lime kiln modification	Recovery boiler deposition monitoring
Lime kiln electrostatic precipitation	Quaternary air injection
Black liquor solids concentration	
Mechanical Pulping	
Refiner improvements	Increased use of recycle pulp
Refiner optimization for overall energy use	Heat recovery from de-inking plant
Pressurized groundwood	Fractionation of recycled fibers
Continuous repulping	Thermopulping
Efficient repulping rotors	RTS pulping
Drum pulpers	Heat recovery in thermomechanical pulp
Papermaking	
Advanced dryer controls	Waste heat recovery
Control of dew point	Vacuum nip press
Energy efficient dewatering – rewetting	Shoe (extended nip) press
Dryers bars and stationary siphons	Gap forming
Reduction of blow through losses	CondeBelt drying
Reduction air requirements	Air impingement drying
Optimizing pocket ventilation temperature	

Source: Kramer et al., 2009.

Policymakers can affect the sector's energy use. Interventions can be in the form of energy pricing, energy cost information systems, energy audits, workshops and conferences organized in cooperation with industry associations, technology cooperation schemes with technical universities and research institutes, and energy technology knowledge systems (centers, books, curricula, etc.).

One program considered successful at providing technical assistance comes from the US Department of Energy (US DOE). The program targets SMEs and has created a number of Industrial Assessment Centers housed within US universities. Engineering students from the centers are "seconded" to SMEs to provide relevant technical assistance, such as conducting energy audits and assessing potential energy efficiency projects (Mallett et al., 2010). SMEs like the program, as there are no costs involved on their part, and it also provides practical experience for the students. Many participating firms undertake the energy efficiency opportunities presented to them by the students, and some firms hire the students to continue working at their firm after graduation. An assessment of the program found that it helped to overcome informational barriers – there were significant changes in decision-making on energy efficiency within a relatively short period of time (Mallett et al., 2010).

Table 8.14 | Estimated total final energy use of the selected SMEs and small-scale clusters worldwide, 2007.

SMEs and small-scale clusters	Final Energy (PJ/Year)
Ferrous and non-ferrous metals	950 – 1750
Non-metallic minerals	7400 – 12,500
Bio-based chemical products	200 – 400
Food and beverage	2150 – 4400
Textiles and leather	950 – 1800
Building and construction	1450 – 2500
Wood processing	1200 – 2000
Energy transformation processes	925 – 1800
Small-scale energy-intensive sectors in developing countries	2450 – 5000
Total final energy use of SMEs and small-scale clusters	**17,675 – 32,150**

Table 8.15 shows the summary of a study by the Confederation of Indian Industry and Forbes Marshall of fuel, electricity, and water in several SMEs in India. It is clear that significant savings are possible with respect to the best performance in each sector. The options considered in this study do not include process changes. An analysis of brick kilns shows significant potential for savings by introducing energy-efficient vertical shaft brick kilns. There is a need for increased efforts for benchmarking and analytical studies for energy efficiency in SMEs.

8.3.7 Industrial Benchmarking: A Tool for Realistic Assessment of Energy Efficiency Potentials

Benchmarking is a management tool that is used to compare similar plants. This is done for many operational aspects such as energy use and energy efficiency.

Benchmarking is primarily a tool that helps plant managers to gauge their improvement potential. However, if it is done for a representative set of plants or for a significant share of the total production volume, it can be used to estimate the improvement potential for the whole sector compared to best process technology. This is valuable information for policymakers.

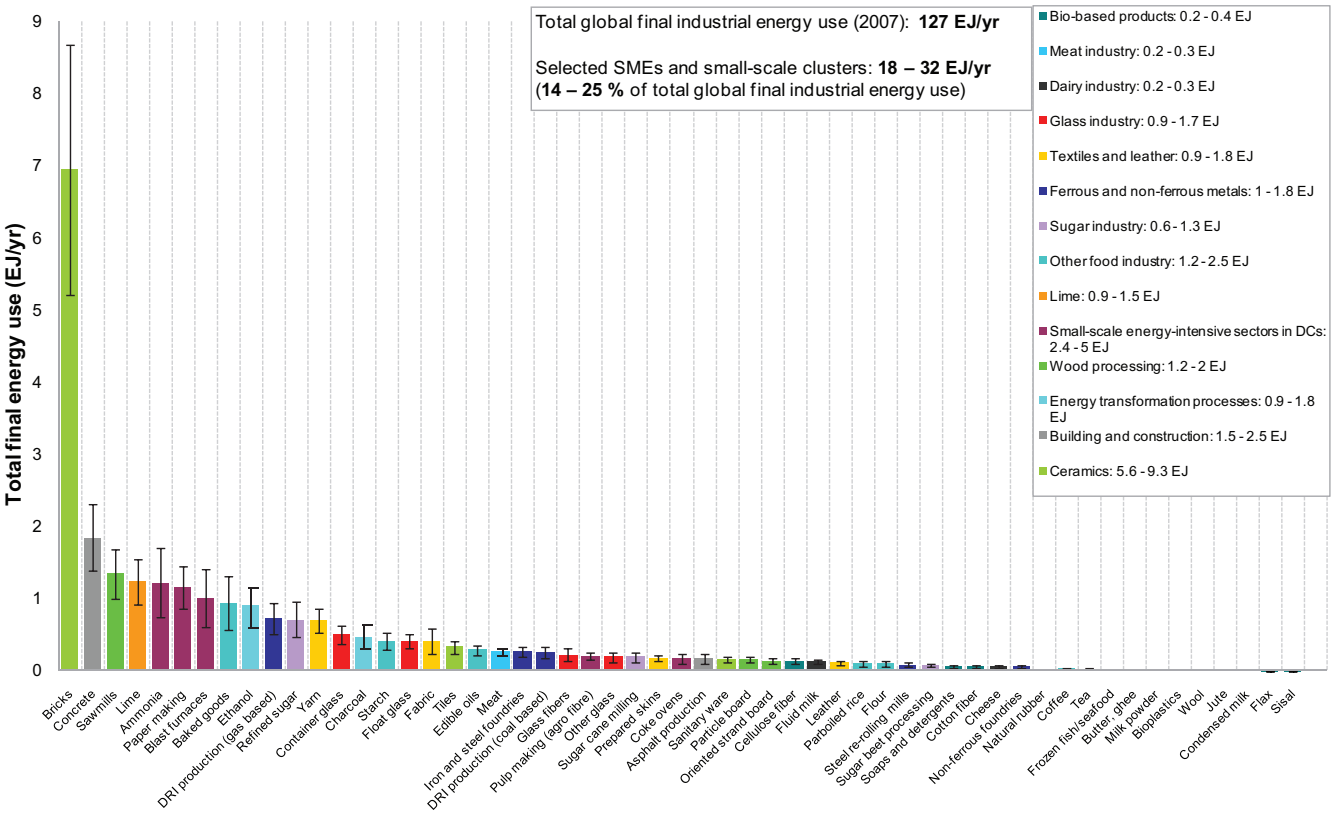

Figure 8.16 | Estimated total final energy use of selected SMEs and small-scale clusters worldwide, 2007.

Table 8.15 | Specific energy use savings for SMEs in India.

SMEs in India		Fuel			Electricity (kWh)			Water (m^3)		
	Unit for Fuel	Average	Best	Savings	Average	Best	Savings	Average	Best	Savings
Breweries	Fuel L/kL Beer	58	44	24%	156	100	36%	9.1	7.9	13%

The fact that benchmarking only considers measured data avoids a lengthy discussion about best available technology. As technology evolves over time and new technologies are gradually introduced, there is always a grey area between proven technology that can be applied in the short term in practice and technologies that are not yet fully mature or commercially available.

A challenge for benchmarking is the comparability of individual units. For example: feedstock quality may differ, the product quality may not be exactly the same and local climate conditions or opportunities for process integration may differ. Therefore, care must be taken to compare "like with like." For benchmarking curves, a widely used approach is one where the 10th percentile is used to define the best available technology. Typically the benchmarking curves show a virtually linear rise from the 10th to the 90th percentile. This allows a comparatively straightforward estimate of the improvement potential: the average efficiency/energy use of the 10th and 90th percentile is the average for the whole group of plants, and the improvement potential is the percentage gap between this average and the 10th percentile.

This approach has been applied for primary aluminum, ammonia, cement clinker, and ethylene, as shown in Figure 8.17. A similar effort

Table 8.16 | Comparison between sectoral average energy intensities, best values, and potential savings.

is ongoing for iron and steelmaking as part of the Task Force under the Asia-Pacific Partnership.

Typically the benchmarking curves suggest an average 10–20% efficiency potential. However, it should be considered that the coverage varies. China is missing from these datasets, and the average efficiency in China is relatively low. This raises the efficiency potential by a quarter to a half.

But what these numbers suggest is that the efficiency potentials based on best available technology in key energy-consuming sectors are significantly lower than other parts of the economy, such as buildings (typically with an average improvement potential of over 50%; see Chapter 10) and the power sector. Table 8.16 shows average energy intensities (GJ/t) in select industries and comparisons with international best averages.

Benchmarking curves do not account for the efficiency potential based on new technology. In all these sectors there are efforts to improve efficiency further. Inert anodes in combination with drained cells for aluminum smelters, new gas separation membranes for ammonia plants, low-temperature heat recovery for cement kilns, and gas turbines and new separation systems for steam crackers are examples of such developments. The theoretical minimum energy use is typically half of the global average today. This does not mean that this minimum can be reached, but it indicates that further improvements can be expected as technology improves. Most benchmarking studies are based on statistical techniques by comparing existing plants. An alternative approach is model-based benchmarking (Sardeshpande et al., 2007) applied to industrial furnaces for glass manufacture. The model is used for predicting an achievable minimum energy use for a given furnace configuration based on design and operating parameters. This approach provides a rational basis for target setting and energy performance improvements for existing processes and can be extended to other industrial processes in metallurgical, cement, paper, petrochemical, and textile industries.

However, the large gains will not come from narrow process efficiency improvement but from the application of broader systems optimization strategies. Use of electricity outside the plant boundaries is often excessive, and here significant savings can be achieved. Also, options such as heat integration, cogeneration, recycling, and a change of process inputs can contribute to savings. Improved materials use efficiency does not contribute to savings per tonne of materials produced, but it reduces the materials production volume. Benchmarking curves do not capture all these improvement options or may do so only partially. Data are sketchier, but typically they can raise the average efficiency potentials by 5–10 percentage points. However, the economics of these improvements are not well established and they may vary widely.

The energy-saving potentials based on benchmarking and indicator data for OECD and non-OECD regions are shown in Table 8.17.

In 2007, the global manufacturing industry used 127 EJ of final energy (40% in industrialized countries and 60% in developing countries). More than half of the industrial energy use is due to the activities of

Table 8.17 | Energy efficiency improvement potentials in the manufacturing industry based on benchmarking and indicator data, 2007.

	Improvement potential (%)		Total Savings Potential (EJ/yr)		Global Subtotal (EJ/yr)
	Industrialized countries	Developing countries	Industrialized countries	Developing countries

the energy-intensive sectors: chemicals and petrochemicals (selected processes in Table 8.17), non-ferrous and ferrous metals, non metallic minerals, and pulp and paper (66 EJ/yr including feedstocks). According to benchmarking and indicator data, best practice technologies can reduce energy-intensive industry's final energy use by 11–17 EJ. This is equivalent to an improvement potential of 17–26% including feedstock use.

Additional energy efficiency potentials in light industries (e.g., textiles, food, beverages, and tobacco, etc.) are estimated at 12–16 EJ. This adds up to a total industrial energy-saving potential of 22–31% EJ if all industrial processes were to adopt best practice technologies (or 22–31 EJ improvement potentials excluding feedstock use).

Approximately three-quarters of this energy-saving potential are located in developing countries (17–23 EJ), with the estimated improvement potentials higher than worldwide, between 30% and 35%. The remaining 6–9 EJ of the potential is in industrialized countries. In the coming decades, industrial energy use is projected to increase much more in developing countries than in industrialized countries. Given the high improvement potentials in developing countries and the future growth projections, improving energy efficiency at process level is a key measure to reduce energy demand and related carbon emissions.

Benchmarking has grown as an industrial management tool. Its use for sectoral agreements or for target setting raises new needs. For example, today in all benchmarks individual plant data are confidential for anti-trust and competitiveness reasons. Also, participation is voluntary, coverage is incomplete, and the process is driven by consultancies that have a natural interest to keep information confidential. These aspects need to be addressed to make the benchmarking tool more useful for the climate policymaking process.

Industries have recognized the importance of the benchmarking tool for a rational decision-making process. Certain sectors such as the European Chemicals Industry have devised innovative schemes for integrating benchmarking with emissions trading. In recent years efforts have been increased in iron and steel, cement, pulp and paper, and other sectors. More attention is needed for the use of benchmarking in the

1 Does not include offsite losses.

2 2002 MECS – plants indicated energy management activities for 6.3% steam, 16.6% compressed air, 7.5% process heating systems.

SME sector. The inclusion of broader system boundaries is also a theme that deserves policy attention.

The use of benchmarking curves is less established for sectors such as pulp and papermaking, SMEs, and less energy-intensive sectors. Typically these sectors account for 25–50% of total global industrial energy use. The issues are often very different than for large companies. Small-scale operations are in many cases operated intermittently, often based on outdated equipment and without much attention to energy use. As a consequence, the efficiency potentials in percentage terms tend to be much higher than for large industries.

As an example, a benchmarking effort for an Indian iron casting cluster is shown in Figure 8.18. While the larger plants in this cluster tend to be more efficient than the smaller ones, at the same time the small plants show a wide range of efficiencies, reflecting differences in operational practices. A shift to large plants would be an option to increase efficiency, but such an approach would be politically and socially unacceptable. An alternate approach would be to focus on energy efficiency improvements in smaller plants. Such considerations must be taken into account when estimating the improvement potential.

8.4 Consumption and Opportunities: Cross-Cutting End-Uses

8.4.1 Industrial Systems: Overview

System energy efficiency affords industrial facilities the opportunity to readily identify energy efficiency projects that can contribute to continuous improvement for energy management (UNIDO, 2007). However at present, most markets and policymakers tend to focus on individual system components (e.g., motors and drives, compressors, pumps, boilers) with an improvement potential of 2–5% – which can be seen, touched, and rated – rather than systems. While systems have impressive improvement potentials – 20% or more for motor systems and 10% or more for steam and process heating systems (see Figure 8.19) – achieving this potential requires engineering and measurement (US DOE, 2004a; IEA, 2007a).

Though equipment manufacturers are steadily increasing equipment efficiencies, the effect on the system efficiency needs greater attention.

A study of 41 completed industrial system energy efficiency improvement projects in the US between 1995 and 2001 documented an average 22% reduction in energy use. In aggregate, these projects cost US$16.8 million and saved US$7.4 million and 106 million kWh (0.38PJ), recovering the cost of implementation in slightly more than two years (Lung et al., 2003).

8.4.2 Motor Systems

Motor systems account for about 60% of industrial electricity use and about 15% of global final manufacturing energy use (17 EJ in 2005). The International Energy Agency (IEA) estimates global potential from motor system energy efficiency to be of the order of 2.6 EJ annually of final energy use for motor electricity consumption of 13 EJ (IEA, 2007a). Motor systems lose on average approximately 55% of their input energy before reaching the process or end-use work (US DOE, 2004c). Some of these losses are inherent in the energy conversion process – for example, a compressor typically loses 80% of its input energy to low-grade waste heat as the incoming air is converted from atmospheric pressure to the desired system pressure (US DOE, 2004d). Other losses can be avoided through the application of commercially available technology combined with good engineering practices (see Table 8.18) (UNIDO, 2007b). These improvements are cost-effective, with costs typically recovered in two years or less. Figure 8.20 provides an illustration of how a system approach can result in a substantial improvement in system operating efficiency.

Table 8.18 | Energy savings potential by compressed air improvement.

Compressed Air System Improvement Option	% Potential Energy Savings
Replace current compressor with more efficient model	2
Reconfigure piping to reduce pressure loss	20
Add compressed air storage	20
Add small compressor for off-peak loads	2
Add, restore, upgrade compressor controls	30
Install or upgrade distribution control system	20
Rework or correct header piping	20
Add, upgrade or reconfigure air dryers	1
Replace or repair air filters	10
Replace or upgrade condensate drains	5
Modify or replace regulators (controls at the process)	20
Improve compressor room ventilation	1
Install or upgrade (ball) valves in distribution system	10

Source: US DOE, 2004d.

In some industrial processes and utility compressed air systems where the delivery pressures are high (greater than 12 bar) it is better to opt for multi-stage compressors. Multi-stage compressors are a move toward the ideal isothermal compression process and results in significant electricity savings.

Even modern, well-maintained industrial systems can benefit from optimization. For example, the Canadian utility, Manitoba Hydro, offers industrial facilities system assessments through its PowerSmart program. System optimization projects completed and documented in 2004 reduced the energy requirements of compressed air systems at a milk plant and a garment manufacturer by more than 60%. One compressed air system was only nine years old with well-maintained, energy-efficient equipment (see Manitoba Hydro, 2011).

The total savings potential in motor systems is expected to range between 15–25%. It is estimated that this will result in a 3.5 EJ of final energy saving from the existing industry. The study by de Keulenaer et al. (2004) estimated annual savings of 202 TWh (0.72 EJ) in the EU with an investment of US$500 million and annual savings of US$10 billion. This would imply an investment requirement of US$2.4 billion for energy efficiency in motors globally for the 3.5 EJ savings.

* In calculation of energy savings, equipment 1000 hp or greater are excluded

Source: UNIDO, 2010a.

Motor system efficiency supply curves have been developed for the United States, Canada, the EU, Thailand, Vietnam, and Brazil (UNIDO, 2010a). Table 8.19 shows a summary of the results. Cost-effective savings of 172,600 GWh/yr are estimated in these six regions, accounting for 28% of the electricity use. Figures 8.21, 8.22, and 8.23 show the EU's pumping system efficiency curve. The discount rate used is 10%. Similar conservation supply curves have been drawn up for all the six regions studied.

8.4.3 Steam and Process Heating Systems

Steam systems are estimated to account for 38% of global final manufacturing energy use or 44 EJ in 2005. The IEA estimates global potential from steam system energy efficiency to be of the order of 3.3 EJ annually of final energy use for steam energy use of 33 EJ (IEA, 2007a). For steam systems, the losses are only marginally better than motor systems, with 45% of the input energy lost before the steam reaches point of use (US DOE, 2004c).

The best option for improving the energy efficiency of a steam system (Figure 8.24 shows a typical steam system) is through a CHP system. Particularly in more mature industries, excess steam production is fairly common and may be a cost-effective source for on-site generation. Higher-efficiency boilers currently under development offer the promise of higher efficiencies.[5] Sometimes other processes can be used in lieu of steam to perform the same work; for example, in recent decades the chemical industry has successfully developed new catalysts and process routes that reduce the need for steam.

In 2006, the US DOE created the Save Energy Now program based on more than a decade of experience in industrial system energy efficiency. The program offers system assessments to companies with an energy use of 1 TBtu (1.1 PJ) or more annually (over 50% of US industrial energy use). DOE energy experts work with plant energy teams to identify opportunities for improving steam, process heating, pump, or compressed air systems through Energy Savings Assessments. There is a focus on transferring skills to plant personnel and identifying specific energy efficiency opportunities from one system type. The first year of program implementation focused on steam and process heating systems, with motor systems added in the second year. A total of 717 assessments have been completed, with implemented energy savings of US$135 million and planned energy savings of US$347 million. Recommended energy-saving projects totaled 87.2 TBtu (92 PJ), with more than US$937 million in energy cost savings and total potential reductions in CO_2 emissions of 7.9 $MtCO_2$. The payback periods from the measures are very cost-effective, as illustrated in Figure 8.25.

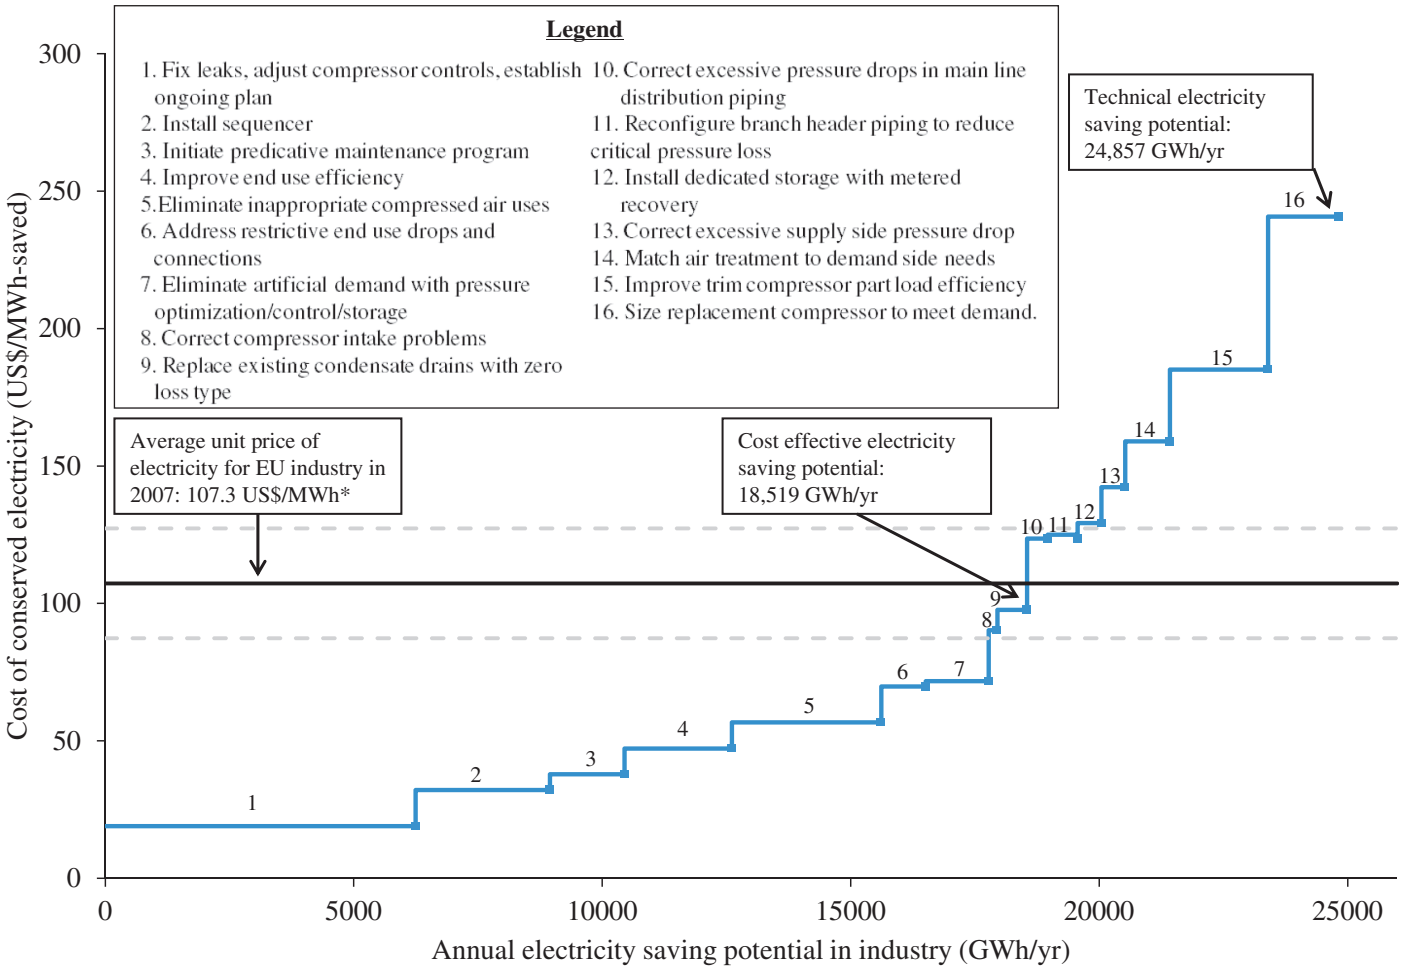
A study conducted in India in several industry segments revealed a potential for steam savings of 25% in breweries, 36% in paper, 28% in starch, 23% in tires, 28% in textiles, and 21% in starch. It is estimated that there is a savings potential of 20% or 8.8 EJ from cross-cutting measures in steam systems from the existing industry in 2005.

8.4.4 Barriers to Improving System Efficiency

The use of Energy efficient components does not guarantee the efficiency of the overall industrial system. Oversizing and incorrect application of energy efficient equipment such as Variable speed drives is common. System assessment to identify the end uses and optimization to determine the best configurations to meet these requirements can help improve energy efficiency (UNIDO, 2007).

System assessment services can provide high value to an industrial facility both in terms of lower operating costs and greater reliability.

5 US DOE is supporting the development of a 94% efficient boiler.



* The dotted lines represent the range of price from the sensitivity analysis.

NOTE: this supply curve is intended to provide an indicator of the relative cost-effectiveness of system energy efficiency measures at the regional level. The cost-effectiveness of individual measures will vary based on site-specific conditions.

Figure 8.21 | EU compressed air system efficiency supply curve. Source: UNIDO, 2010a.

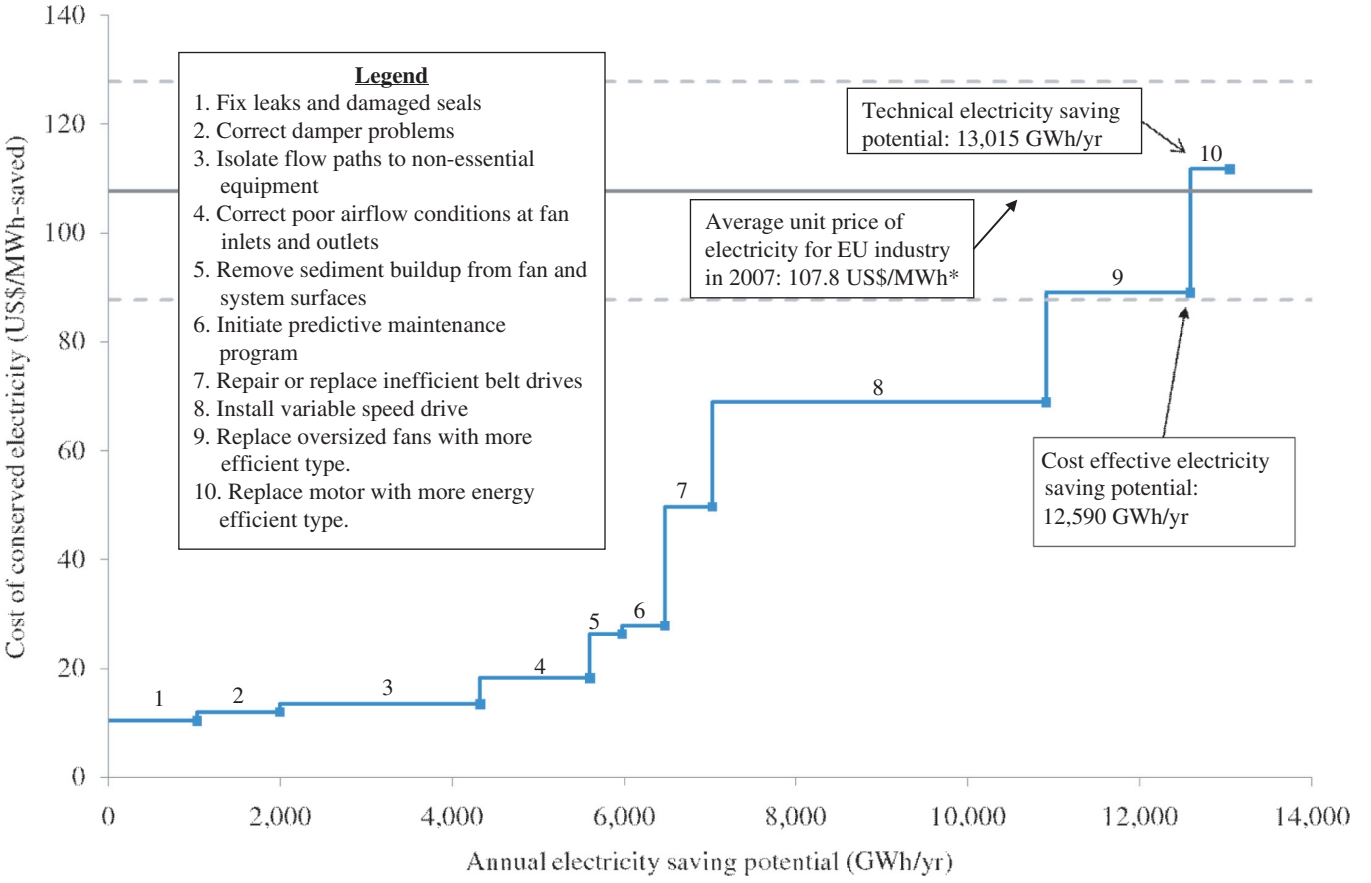
However, it is difficult for plant personnel to easily identify quality services at market-appropriate prices. A typical facility engineer does not have time to research the detailed system-specific information necessary for an informed, but infrequent, purchase of these services. The lack of market definition also creates challenges for providers of quality system assessment services to distinguish their offerings from others that are either inadequate to identify energy efficiency opportunities, or thinly-veiled equipment marketing strategies.

Furthermore, little data are available to support trending of performance for motor, steam, and process heating systems. Measuring the energy efficiency of the components (motors, furnaces, and boilers) is reasonably straightforward and well documented, allowing that some differences in the testing and rating of components still exist. The same is not true in the measurement of system energy efficiency, where most of the energy efficiency potential resides. Few industrial facilities can quantify the energy efficiency of motor, steam, or process heating systems without the assistance of a systems expert. Even experts can fail to identify large savings potentials if variations in loading patterns are not adequately considered in the assessment measurement plan. If permanently installed instrumentation such as flow meters and pressure gauges are present, they are often non-functioning or inaccurate. Often orifice plates or other devices designed to measure flow actually result in restricting flow, as they accumulate scale with age (UN Energy, 2010).

8.4.5 Realizing System Energy Efficiency Potential

Expert knowledge based on assessments carried out in industrial systems in the United States, United Kingdom, and Canada have resulted in the identification of best practices. These assessment techniques have been further refined in recent years in the United States.[6]

6 US DOE's Energy Savings Assessments and Industrial Assessment Center Programs and the Compressed Air Challenge™. As an example, the Compressed Air Challenge's Best Practices for Compressed Air Systemscontains an appendix entitled "Detailed Overview of Levels of Analysis of Compressed Air Systems."



* The dotted lines represent the range of price from the sensitivity analysis.

NOTE: this supply curve is intended to provide an indicator of the relative cost-effectiveness of system energy efficiency measures at the regional level. The cost-effectiveness of individual measures will vary based on site-specific conditions.

Figure 8.22 | EU fan system efficiency supply curve. Source: UNIDO, 2010a.

Best practices that contribute to system optimization are system-specific but normally include:

- evaluating work requirements and matching system supply;
- eliminating or reconfiguring inefficient uses and practices (throttling, open blowing);
- identifying and correcting maintenance problems;
- upgrading ongoing maintenance practices; and
- documenting these practices.

These systems remain inefficient primarily due to a series of institutional and behavioral barriers. Some of the important barriers are the limited awareness of the energy efficiency opportunities by industry, consultants, and suppliers, lack of understanding on how to implement energy efficiency improvements; and, most importantly, absence of a consistent organizational structure within most industrial facilities to effectively manage energy use.

Since energy use is rarely measured at the system level, there are few data available. Without performance indicators that relate energy use to production output, it is difficult to document improvements in system efficiency. If the facility also uses energy as a feedstock, even large system energy efficiency improvements can be lost in the "white noise" of overall plant energy usage, especially if production levels vary. System energy efficiency offers large improvement potential but is complex; a "one size fits all" approach will not work (McKane et al., 2007).

The Superior Energy Performance partnership, a collaboration involving the US DOE's Industrial Technologies Program, industrial companies, the American National Standards Institute (ANSI), nonprofit organizations, the US Environmental Protection Agency (US EPA), and the US Department of Commerce's National Institute of Standards and Technology, is facilitating the development of a market-based program for certifying industrial plants for energy efficiency (UN Energy, 2010). As part of this effort, a portfolio of System Assessment Standards has been published by the American Society of Mechanical Engineers (ASME) for compressed air, process

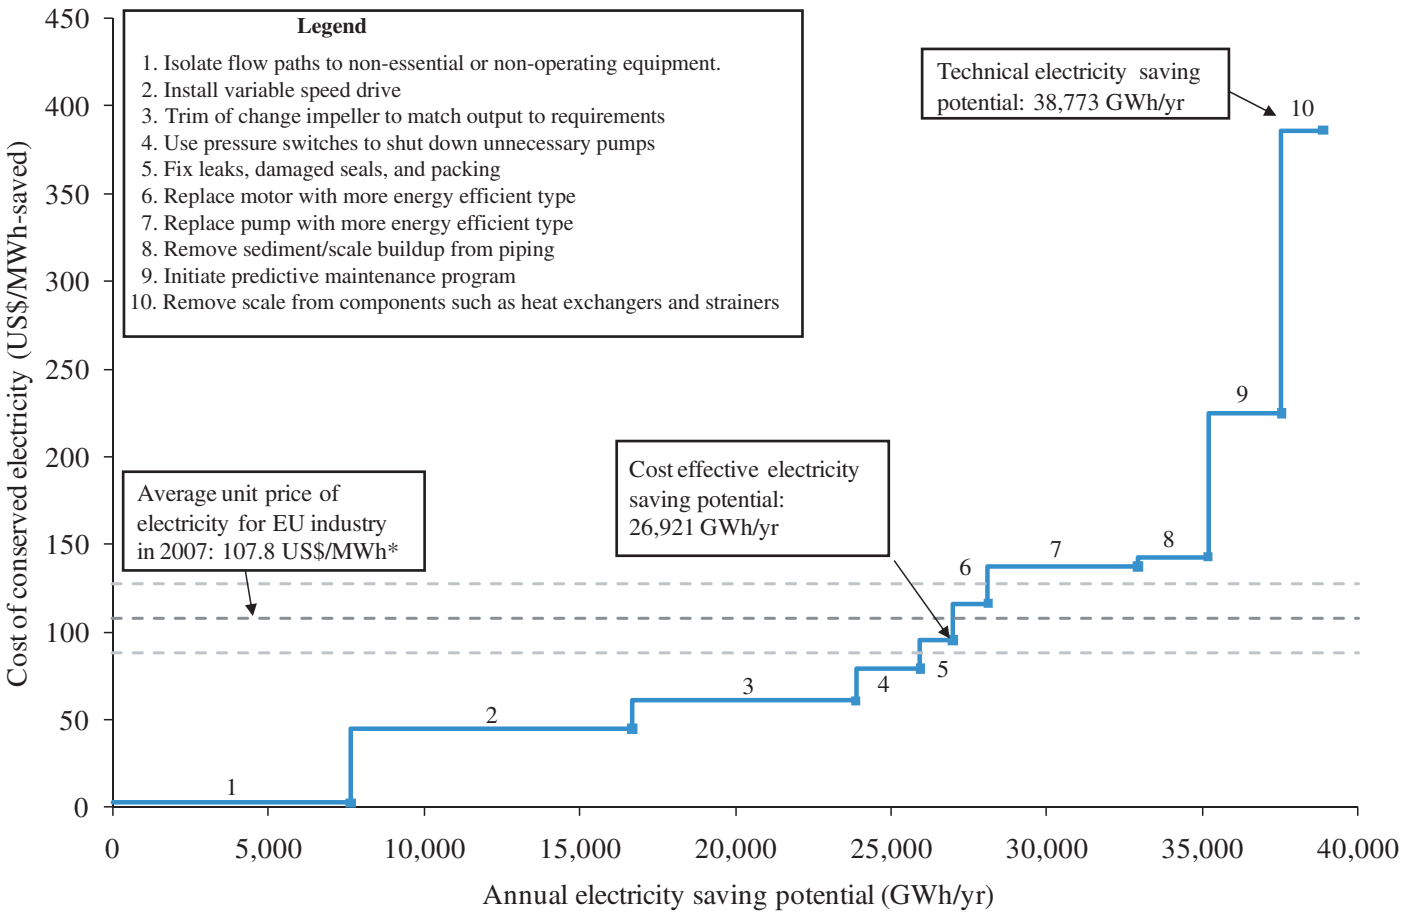


Figure 8.23 | EU pumping system efficiency supply curve. Source: UNIDO, 2010a.

heating, and pumping. Collaboration has already begun for one system type (compressed air) to develop an International Organization for Standardization (ISO) standard modeled on the approach used in the ASME standard.

The System Assessment Standards are designed to create a market threshold for industrial system energy efficiency assessments from the current body of expert knowledge and techniques. The standards will provide a common framework for conducting assessments of industrial systems that will help define the market for both users and providers of these services. By establishing minimum requirements and guidance for scope, measurement, and reporting, these standards will offer greater transparency and higher value to industrial facilities by providing assurance to plant managers, financiers, and other non-technical decision-makers that a particular assessment meets or exceeds a best practice threshold for accuracy and completeness. The existence of System Assessment Standards will also assist in training graduate engineers and others desiring a higher level of skill in the area of system optimization for energy efficiency. To assist industrial firms in identifying individuals with the necessary skills to apply the standards correctly, the US initiative will also include the creation of a professional credential with the working title of Certified Practitioner for each system type.

8.4.6 Process Integration, Heat Pumps, and Cogeneration

Industrial processes are systems (see Figure 8.26) in which raw materials are converted into products and by-products. Such transformations are realized by a succession of process units that use water or solvents and in which energy is the transformation driver. To realize the transformation, energy resources are first converted before being distributed and used in the process units. Applying mass and energy balances to the system shows that what are not useful products, goods, or services leave the system as waste in solid, liquid, or gaseous form, or as waste heat radiated to the environment.

By systematically analyzing the materials and energy conversion processes in the different unit operations in the system and representing their possible interactions, process integration aims at identifying synergies between the process units by allowing the following processes:

- *Recycling of materials and energy*: reuse materials – for example, by converting a waste into a product, to recycle waste streams, or to convert waste streams into useful energy.

- *Heat recovery*: utilization of the heat of the hot streams (streams to be cooled down) to heat up cold streams (streams to be heated up).

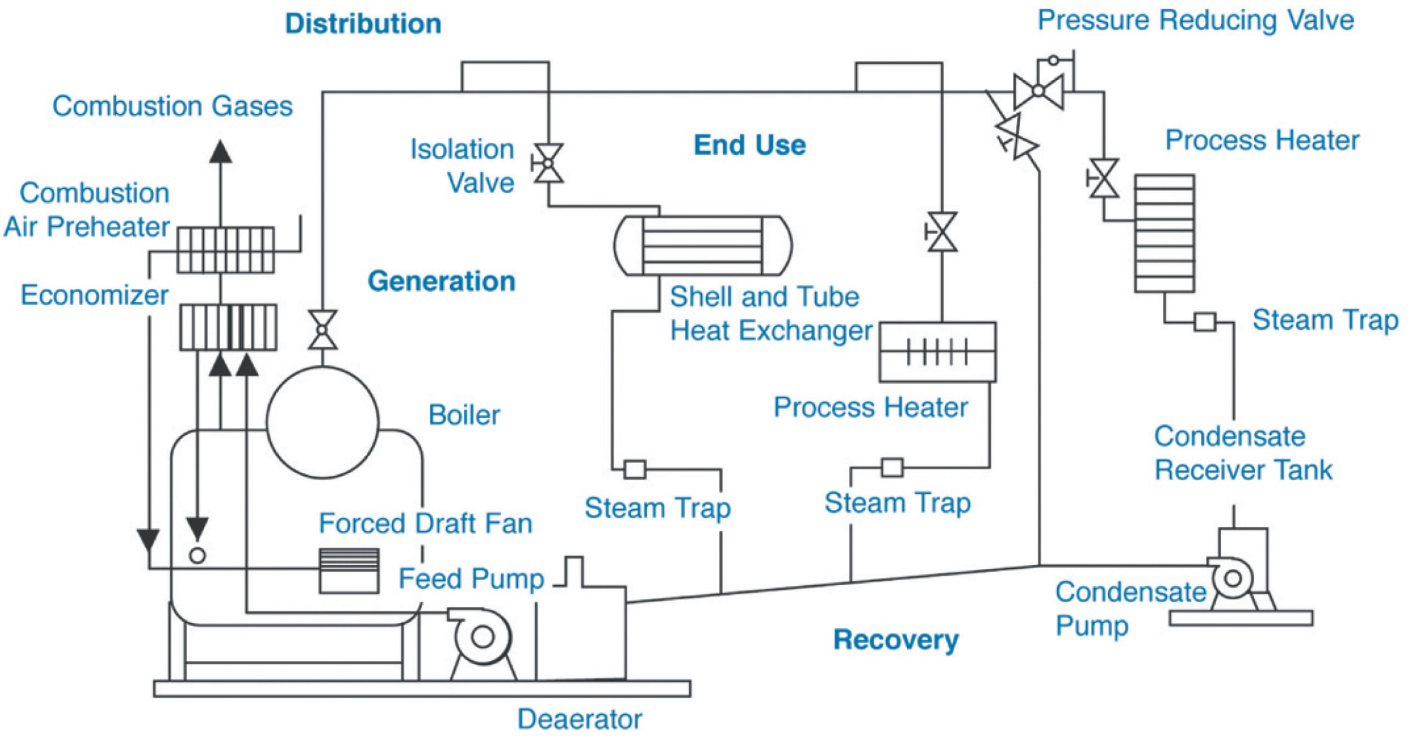

Figure 8.24 | Steam system schematic. Source: based on US DOE, 2002.

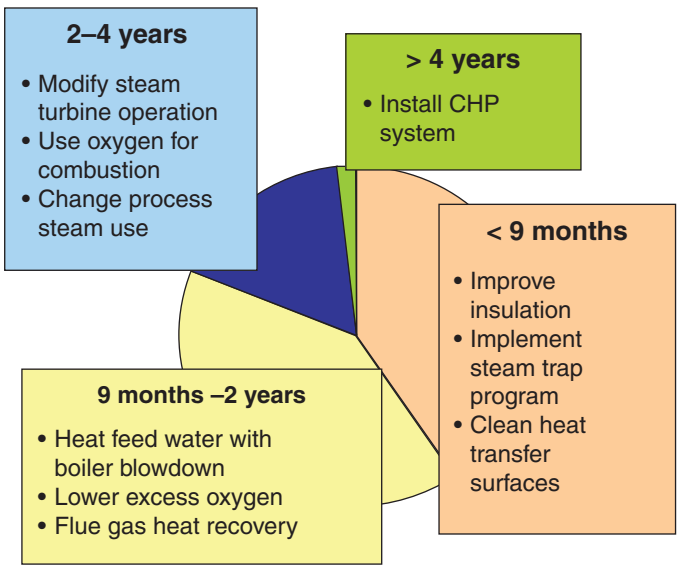

Figure 8.25 | Estimated payback periods for steam-based systems in 2006.

- *CHP production*: CHP – or, more generally, polygeneration – production is typically used to convert fuels into useful heat/cooling and electricity as a by-product or to convert the available exergy in the heat exchange system into useful mechanical power.

- *Waste heat utilization/upgrade in the system*: when the temperature level of waste heat is sufficient and the heat support media is available (e.g., hot water), waste heat can be converted into mechanical power by thermodynamic cycles or can be upgraded by increasing its temperature level using heat pumping systems.

- *Waste heat upgrade*: by extending the system boundaries to other energy users, such as other processes or district heating systems.

Although there is a hierarchy between these different energy efficiency options, they have to be considered simultaneously within a systemic framework and applied considering local conditions and boundaries of the technically and economically accessible system. Extending the system boundaries may change the impact of the energy-saving actions and lead to different solutions. For example, if the waste heat of a process can be reused to heat up other processes in the surroundings, the use of a heat pump to recover waste heat for the reference process will become counterproductive at the system level.

8.4.6.1 Pinch Analysis

Recovering heat from hot streams to preheat cold streams is constrained by the temperature levels of the heat required, by topological constraints, and by the investment in heat exchangers. Pinch analysis is used to estimate the maximum heat recovery that can be realized in a system (without limitations on the number of streams

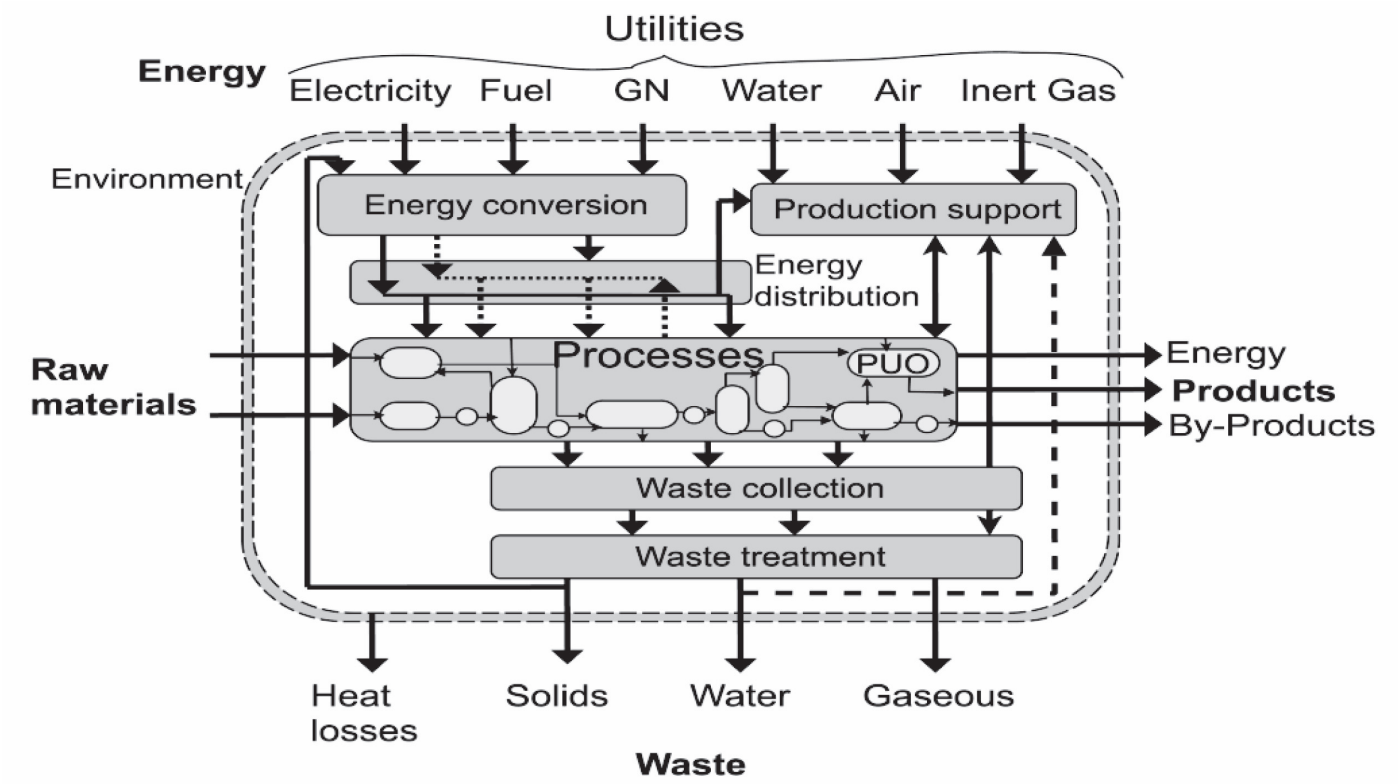

Figure 8.26 | The systemic vision of an industrial process.

and the size of the system) and without having to practically define the heat exchange interconnections. Pinch analysis takes into account the temperature levels of the heat requirement and uses a parameter to represent the energy recovery/capital trade-off that limits the heat exchanger cost by setting a minimum temperature difference (ΔT_{min}) between the hot and the cold streams considered for the heat recovery. The maximum heat recovery is obtained by calculating the integral of the heat available in the hot streams of the system and of the heat required by the cold streams as a function of the temperature. This draws respectively the hot and cold composite curves (see Figure 8.27) that represent the system as one overall hot and overall cold streams between which counter current heat exchange will be used to recover heat.

The maximum heat recovery is obtained by considering that the temperature difference between the two curves must always be higher than the ΔT_{min}. The point at which the curves are the closest is the pinch point. It divides the system into two subsystems: above the pinch point, the process features a deficit of heat (heat sink), and below it, the process has a surplus of heat (heat source). Having defined the maximum heat recovery, the minimum energy to be supplied and removed from the system is obtained by energy balance, while the heat cascade defines their corresponding temperature levels in the grand composite curve. Comparing the minimum energy requirement with the present energy use defines the amount of energy that is directly transferred from the resources to the environment without having any real use in the process, as if this energy were brought to heat up the environment.

8.4.6.2 Optimizing Process Operating Conditions

The process composite curves can be used to adapt the process operating conditions in order to maximize the heat recovery potential. Based on the location of the pinch point location, the goal is to transfer heat excess from below the pinch point to above the pinch point, or heat demands from above to below the pinch by changing the process operating conditions. Important unit operations concerned are chemical reactors and evaporation systems (distillation or evaporators), in which the pressure can be modified to change the temperature of the evaporation and/or condensation. Multi effect evaporation is a good example of this mechanism: changing the operating pressure of the evaporation allows the recovery of the condensation heat to evaporate water in an effect with a lower pressure. Staging the evaporation in multi stages allows one to reduce the energy use for evaporation. For example, a three stage evaporation process will allow the reduction of 60% of the heat needed for evaporation. When considered along with process integration, the use of multi effect evaporators has to be considered with a holistic vision, considering the possible heat recovery and use elsewhere in the process, leading to even higher energy savings. Examples show that a well-integrated multi-effect

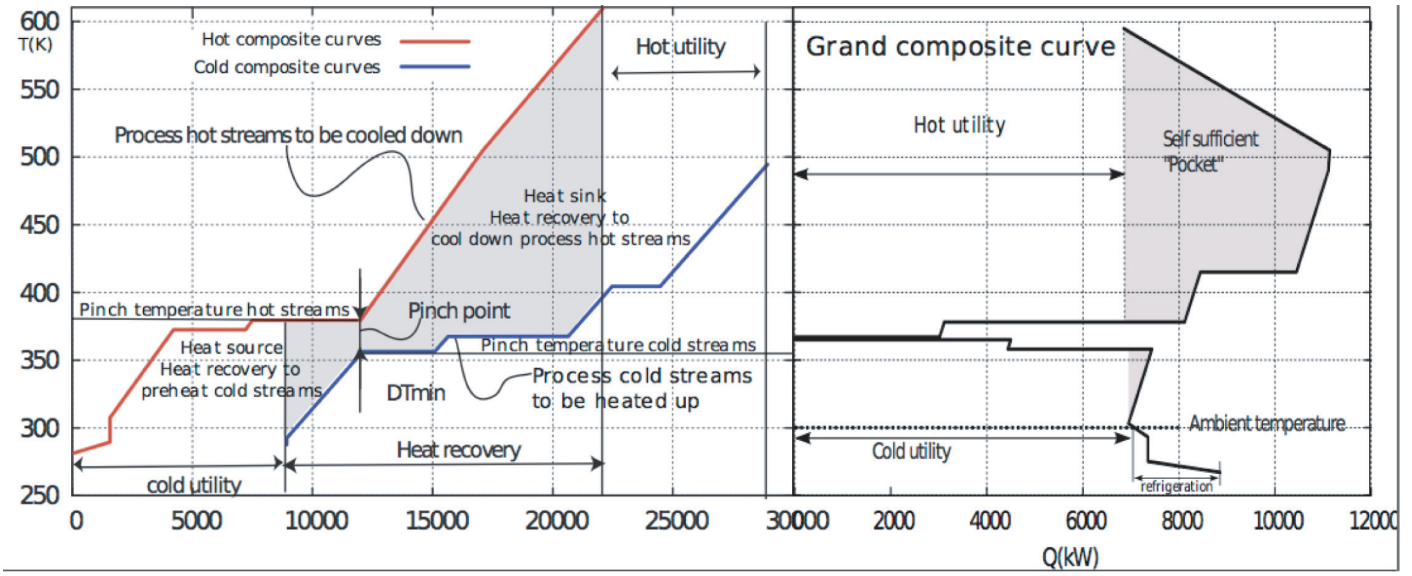

Figure 8.27 | Hot and cold composite curves and possible heat recovery in the system.

evaporation system can save an additional 30% of the remaining heat required.

8.4.6.3 Combined Heat and Power Production

In a CHP production system, energy resources are converted into useful process heat, and electricity. As the heat is supplied to the process by heat transfer, it must have a temperature level compatible with the heat requirement of the process as defined by the grand composite curve (see Figure 8.27) resulting from the pinch analysis. Only the heat of cogeneration that is compatible with the heat sink above the pinch point will create a cogeneration effect.

The different type of cogeneration units are given in Table 8.20. The specific investment, and the electrical (η_e) and thermal (η_{th}) efficiencies depend on the size of the unit. The primary energy savings related to the integration of a cogeneration unit depends on how the co-produced electricity is accounted. One may distinguish the avoided electricity import that substitutes a centralized electricity production facility and that is accounted with the electricity mix efficiency (η_{grid}) from the electricity export that could be considered as an additional electricity production unit. In addition, one may also consider the fuel substitution effect. When the overall heat available from the cogeneration unit is used in the process, the primary energy saving (see Equation 1) is calculated by comparing the resource consumed in the cogeneration unit with the one that would have been consumed for the separate production of heat in a boiler and of electricity from the grid.

$$\text{Energy savings [\%]} = 1 - \frac{1}{\frac{\eta_e}{\eta_{grid}} + \frac{\eta_{th}}{\eta_b}} \quad (1)$$

with η_e – the electrical efficiency of the cogeneration unit

η_{th} – the thermal efficiency of the cogeneration unit

η_{grid} – the efficiency of the grid electricity production [38%]

η_b – the efficiency of the boiler replaced by the cogeneration unit [90%]

Rankine cycle-based CHP systems have several industrial applications. A typical example is the steam network of industrial processes, where high-pressure steam is produced in boilers or in the process, and is expanded in steam turbines to produce mechanical power before being condensed to supply heat to the process. Rankine cycles are also used to upgrade waste heat below the pinch point. In this case, the heat excess of the process is converted into mechanical power, and the environment is used as a heat sink. When operated under low temperature conditions (typically below 100°C), the fluid used in the cycle is an organic fluid such as the one used in refrigeration or heat pumping.

It is important to mention that the CHP unit will produce its benefit only when it is located entirely above (in the heat sink sub-system) or below (in the heat source sub-system) the pinch point. The heat that crosses the pinch point has no useful CHP effect. In addition, the CHP system allows one to convert the exergy available in the process hot streams.

8.4.6.4 Heat Pumping

In industrial processes, heat pumps are used to upgrade the temperature level of a heat source. Referring to the pinch analysis, heat pumping will be profitable only if it allows transfer of heat from below to above the pinch point, i.e., if it transforms excess heat from the system heat source into useful heat for the system heat sink. All the other situations do not lead to an overall saving. When operated only above the system

Table 8.20 | Examples of cogeneration units to supply heat to processes.

Type	Typical size	η_e	η_{th}	Investment	Energy Savings
	MWe	%	%	US$/kWe	%
Gas turbine	[1:50]	[30:40]	[40–45]	[1000:2500]	[29:36]
Gas turbine combined cycle	[10:100]	50	35		[41]
Engines	[0.1:10]	[30:50]	[55:40]	[800:4000]	[29:43]
Steam turbine	[0.1:15.0]	[20:25]	[74:69]	[69–71]	[26:30]
SOFC fuel cell	0.1	40	40	[NA]	[33]
Hybrid Gas turbine fuel cell	0.2	70	15	[NA]	[50]

pinch point, the heat pump is an expensive electrical heater for the system, while when operated only below the pinch point, the heat pump is an electrical heater that heats up the environment. The integration of a heat pump must therefore be studied with care.

Heat pumping systems may also use the environment as a heat source and the process as a heat sink. The different types of heat pumps are:

- *Mechanical vapor recompression (MVR):* a vapor stream of the process in the heat source is compressed before being condensed to supply heat to the heat sink. MVR heat pumps are typically used in evaporation, distillation, or drying processes.
- *Mechanical heat pumps*: a fluid (typically a refrigerant) is evaporated using heat from the process heat source and compressed before being condensed to supply heat to the process heat sink.
- *Absorption heat pumps*: instead of using mechanical power, the absorption heat pumps are tri-therm systems. High-temperature heat is used as a driver to raise the temperature of a fluid that is at a lower temperature in the heat source. The heat is sent back to the process at a medium temperature in the process heat sink.
- *Heat transformers*: heat transformers use the same principle as the absorption heat pump, but the driver in this case is at a medium temperature (evaporation from the process heat source) and sends the heat back at a higher temperature (in the heat sink), while the remaining heat is sent back at the lowest temperature (typically to the environment).

Especially in mechanical heat pumps, the temperature level of the heat delivered and the temperature lift define the heat pump's performance. The coefficient of performance (COP) of a heat pump represents its amplifying effect and is used to compute its primary energy saving. Considering constant temperature for the heat source ($\bar{T}_{source}$) and for the heat sink ($\bar{T}_{sink}$), the COP of the heat pump is given by Equation 2, where η_{COP} is the efficiency of the heat pump with respect to the theoretical COP. Typical values for η_{COP} are around 50%.

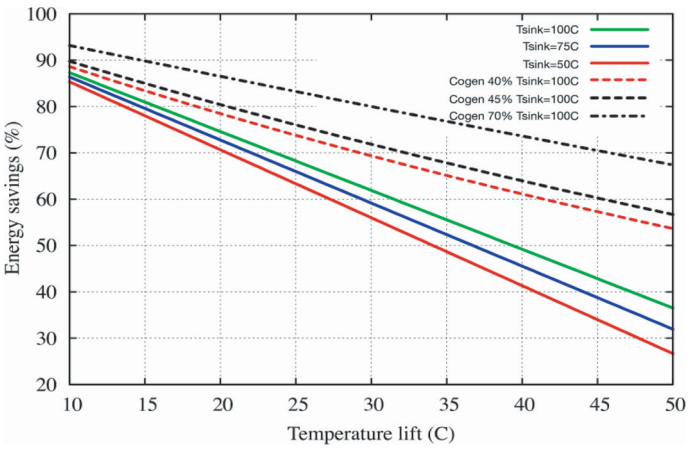

Figure 8.28 | Primary energy savings by the integration of heat pumps (η_{grid} = 38%, η_{boiler} = 90%. η_{COP} =50%) and of a cogeneration unit and heat pumps ($\eta_{electrical}$ = 40%, 45% and 70% with $\eta_{electrical} + \eta_{thermal}$ = 85%). Where η_{COP}= efficiency of the heat pump with respect to the theoretical COP.

$$COP = \frac{\dot{Q}_{th}}{\dot{E}_{hp}} = \eta_{COP} \frac{\bar{T}_{sink}(K)}{\bar{T}_{sink}(K) - \bar{T}_{source}(K)} \quad (2)$$

In integrated systems, the flow of the heat pump and heat recovery are limited by the heat which is available and required by the process. Heat pumps are mainly used in processes with low to medium temperatures (up to 120°C), especially in processes with evaporation systems such as in the food industry or in drying processes. On the grand composite curves, the flow limitation corresponds to the activation of a new pinch point in the system and, therefore, introduces the possibility of cascading heat pumps.

The primary energy saving of a heat pump depends on the heat pump COP and on the efficiency of the grid electricity production, as shown in Figure 8.28. When the temperature level of the CHP permits, then the integration of heat pumps together with CHP units is an attractive option. In this case, the electricity required by the heat pump is produced by the CHP unit that supplies an additional amount of heat to the process. The primary energy savings in this case are even higher (see Figure 8.28).

Table 8.21 | Case studies of process integration, polygeneration, and heat pumping. In this Table the numbers are normalised so that the fossil fuel use in the present situation is taken as the base (100). All other quantities are computed with reference to the fossil fuel use. The savings for the improved scenarios are compared as a percentage of the existing scenario.

Kraft process	**Present situation**	**Process modification**	**Heat exchangers**
Fossil fuel	100	28.5(71.47%)	2.3 (97.74%)
Biomass	269.2	269.2	269.2

Electricity	0	13	–3
Primary energy (38%)	100	71 (29%)	70 (30%)
Primary energy (58%)	100	60 (40%)	73 (27%)

8.4.6.5 Case Studies

The Kraft process is the dominant paper making process based on chemical pulping using sulfate. Case studies of a typical kraft pulp and paper process, the food industry (chocolate and dairy), and industrial chemicals (ethylene and ammonia) show benefits of applying process integration concepts, heat pumps, and cogeneration.

Table 8.21 shows the savings obtained against existing practice. It is clear that savings of more than 30% are possible through process integration, polygeneration, and heat pumping. It is, however, difficult to extrapolate the potentials, since most of the results refer to specific systems and conditions.

8.5 Renewables in Industry

In the present mix of energy use in industry, renewables account for about 9% of the final energy. This is mainly due to bagasse and rice husk in sugar and other traditional industries, biogas from sewage and farms, and black liquor in pulp and paper. It is technically feasible to plan a significant share of renewables for industry for process heating, cooling, and power. An analysis by UNIDO (2010b) estimates that renewable energy use in industry is likely to grow to about 50 EJ/yr of final energy by 2050. In 2006, cement manufacturers reported that 10% of total fuel use was from alternative fuels, of which 30% was biomass (CSI, 2006). IEA's analysis (IEA, 2006) reveals that more than 80 solar thermal plants with total collector areas of about 34,000 m^2

were being used for industrial heating, mainly in textiles, the food industry, chemical plants, car washing, and metal treatment facilities.

At present, solar-based thermal energy for low-grade steam and biomass-based thermal energy are feasible for replacing oil. In India, successful examples of thermal applications of biomass gasifiers are in steel rolling mills, the ceramic tile industry, and CO_2 manufacture. Solar thermal systems have been installed in dairies (a 160 m^2 dish replaced the 1 t/hour oil-fired boiler in a dairy in western India). The payback periods for thermal applications for gasifiers is one to two years, while for solar-based heating or steam systems for oil replacements the payback period ranges between four and six years. Biomethanation plants have also been applied in dairies, brewery waste, distillery waste, etc. These have been used for power generation; for example, the biomethanation plant at Haebowal Dairy in Ludhiana, Punjab, India (MNRE, 2010) generates a steady power output of about 1 MW of electricity based on the collection and use of 235 tonnes of animal waste per day. The cost of the plant installed in 2004 was INR134 million (US$3 million). This provides for cogeneration of heat and power and also provides stabilized organic manure. In sugar factories, bagasse-based cogeneration systems are cost-effective and can provide significant surplus power to the grid.

It is possible to increase the share of renewables in industry. In order to do this, it is proposed that a number of demonstration systems be financed in different industrial segments. This would facilitate the dissemination of renewables in the industrial sector. Bio-based renewables can also be used as a feedstock for chemicals (Hermann et al., 2007; Shen et al., 2010), resulting in energy and emissions reductions in the industrial sector.

8.6 Thermodynamic Limits

8.6.1 Analysis of the Global Industrial Sector

In this report, the focus is on the global industrial sector, which is composed of many industries. The energy used by each of these industries in 2005 is shown in Table 8.22. The most significant industries, based on quantity of energy used in 2005, are seen in Table 8.22 to be iron and steel; chemicals and petrochemicals; non-metallic minerals; paper, pulp, and printing; and food and tobacco. With this and other data, energy and exergy utilization in the global industrial sector is evaluated and analyzed. Note that all of the energy forms in Table 8.22 are primary

Table 8.22 | Energy input for the global industrial sector by industry and energy type, 2005 (in PJ).

Industry[1]	Coal and coal products	Crude, NGL and feedstocks	Petroleum products	Natural gas	Geothermal	Solar, wind, other	Combustible renewables and waste	Electricity	Heat	Total

Note: For the overall global industrial sector and all industry categories within it, there are no inputs of nuclear energy, or hydro, or heat production from non-specified combustion fuels. Units are petajoules (PJ), which is equal to 1015 Joule (see Chapter 1, Figure 1.3).

1 excludes feedstocks (non-energy use), see Chapter 1, Section 1.2.2.

Source: IEA, 2007a and 2007b.

energy resources or refined versions of them, except for electricity and heat, which are secondary energy carriers.

8.6.1.1 Methodology and Energy Data for the Global Industrial Sector

Each industry category in the industrial sector is analyzed separately, and then combined in a comprehensive assessment of the sector. To simplify the analysis of energy and exergy flows and efficiencies for a complex sector such as the one considered here, the most significant industries, in terms of proportion of total sector energy use, may be taken as representative of the overall sector. Many industries have been assessed individually (Brodyanski et al., 1994).

In the global industrial sector, most of the input energy is used to generate heat for production processes, mechanical drives, lighting, and air conditioning. Heating processes for each industry can be further divided into low-, medium-, and high-temperature categories. This differentiation is important in exergy analysis, as the temperature at which heat is supplied and used greatly affects the exergy associated with the heat.

Several steps are used to derive the overall efficiency of the sector:

- Energy and exergy efficiencies are obtained for process heating for each of the product-heat temperature categories.
- Mean heating energy and exergy efficiencies for the main industries are calculated using a two-part procedure:
  - (i) weighted mean efficiencies for electrical heating and fuel heating are evaluated for each industry; and
  - (ii) weighted mean efficiencies for all heating processes in each industry are determined with these values, using as weighting factors the ratio of the industry's energy use(electrical or fuel) to the total consumption of both electrical and fuel energy.
- Efficiencies are determined for other processes (i.e., heating, mechanical drives, and other processes).
- Weighted mean overall efficiencies for each industry are evaluated using as the weighting factor the fractions of the total sector energy input for heating, mechanical drives, and other processes (Dincer et al., 2004).
- To determine the industrial sector's efficiencies, weighted means for the weighted mean overall energy and exergy efficiencies for the major industries in the industrial sector are obtained, using as the weighting factor the fraction of the total industrial energy demand supplied to each industry (Utlu and Arif, 2008).

In the present analysis, a simplified approach is taken to evaluate exergy parameters. Here, we utilize global energy data for the industrial sector in 2005 as provided by IEA (2007a; b), which provides energy inputs, in terms of energy type, to each industry category in the global industrial sector. We then incorporate the energy and exergy efficiencies for the utilization of the different energy commodities in the industry sector, as determined in a previous global energy and exergy analysis (Nakicenovic et al., 1996). The assumption incorporated here is that efficiencies have not changed significantly on a global scale over the last ten to 15 years for the different industries in the global industrial sector. This assumption may not introduce significant inaccuracies, because although the efficiencies of technologies utilized in highly developed countries may have risen over the last decade, the same phenomenon may not be true in many developing countries, where the focus has been on increased energy use to drive economic development. In addition, the observation of Nakicenovic et al. (1996) that heat input to the industrial sector is predominantly for low- and medium-temperature heating, as well as process heating, is used, so the exergy of the heat input to the sector is thus taken to be 28% of the energy.

8.6.1.2 Energy and Exergy Flows and Efficiencies for the Global Industrial Sector

The energy and exergy inputs and outputs for the overall global industrial sector are presented in Table 8.23. For simplicity, exergy and energy values are assumed equal for commodities that normally exhibit an exergy-energy ratio of approximately one (e.g., most fossil fuels). Also, it is assumed for biofuels that the energy-exergy ratio is unity, and that the energy-exergy ratio for biofuels is representative of that for all renewables. In the present analysis, a reference environment which emulates the actual physical environment is utilized.

Energy and exergy flow diagrams for the overall global industrial sector for 2005 are presented in Figures 8.29 and 8.30, respectively. The input energy to the 2005 global industrial sector of 87.6 EJ shown in the present energy and exergy analyses (Figures 8.29 and 8.30) is less than 115 EJ reported in Section 8.1 (IEA, 2008a). The difference is due to the exclusion of coke ovens, blast furnaces and feedstock energy for petrochemicals from the industrial sector in the present analysis. The addition of the energy inputs for these sub-sectors provides a final energy input of 115 EJ in 2005.

This difference does not affect the overall results and conclusions as the efficiencies and fractional conversions of energy and exergy in the present analysis do not change significantly if coke ovens, blast furnaces and feedstock energy for petrochemicals are included. These figures illustrate the variations in flows shown on the basis of energy or exergy. In these figures, losses and wastes of energy involve only emissions, while losses and wastes of exergy involve emissions and internal destructions (with internal destructions normally being the most significant). It can be seen that the energy and exergy values of most of the inputs (except

Table 8.23 | Energy and exergy flows (in EJ) in the global industrial sector by energy commodity type, 2005.

Energy commodity	Input energy[1]	Product energy	Input exergy	Product exergy
Coal and coal products	21.5	9.3	21.5	3.3
Crude, NGL and feedstocks (including petroleum products)	13.6	3.4	13.6	3.0
Natural gas	18.1	10.2	18.1	3.7
Electricity	22.3	15.7	22.3	12.7
Heat	4.6	4.6	1.3	1.3
Renewables (including combustible renewables and waste, geothermal, and solar/wind/other)	7.5	1.5	7.5	1.0
Total	87.6	44.6	84.3	25.1

Note: Columns may not sum exactly due to round-off errors.

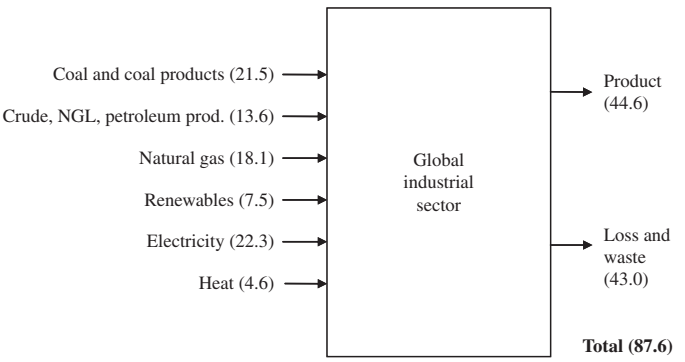

Figure 8.29 | Energy flows (in EJ) for the global industrial sector, 2005. Note: Final energy data excludes feedstocks (non-energy use), see Chapter 1, Section 1.2.2.

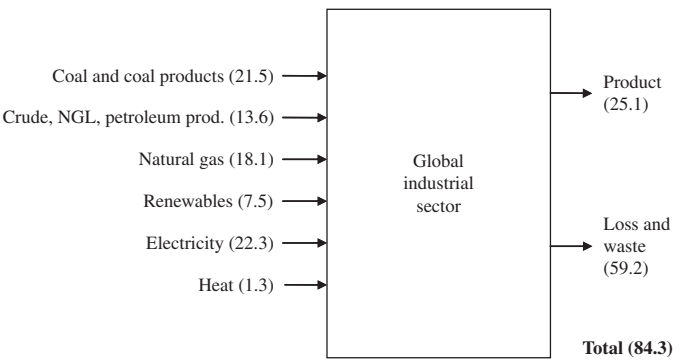

Figure 8.30 | Exergy flows (in EJ) for the global industrial sector, 2005.

heat) are similar, but the product and waste flows have significantly different energy and exergy values.

The overall efficiencies for the global energy sector, evaluated as the ratio of product to input using values from Table 8.23, are found to be 51% based on energy and 30% based on exergy. Consequently, exergy analysis indicates a less efficient picture of energy use in the global industrial sector than energy analysis does. A larger margin for improvement exists from an exergy perspective, compared to the overly optimistic margin indicated by energy.

An energy analysis of energy utilization in the global industrial sector does not provide a true picture of how well energy resources entering it are utilized. An assessment based on energy can be misleading because it often indicates the main inefficiencies to be in the wrong sectors, and a state of technological efficiency higher than actually exists. To accurately assess the true efficiency of energy utilization, exergy analysis must be used. Exergy parameters provide a powerful tool for indicating to industry and government where emphasis should be placed in programs to improve the use of the exergy associated with the main energy resources (Dincer et al., 2004). This analysis provides important insights about potential priorities for future research and development (R&D) initiatives and directions.

It is instructive to compare energy and exergy utilization for the industrial sector with that for other sectors, based on previous analyses of all sectors. Two key points are noted:

- Significant variations are usually exhibited between energy and exergy efficiencies in the residential/commercial and industrial sectors, but not in the utility and transportation sectors. This observation is mainly attributable to the high degree of heating and cooling processes that occur in the residential/commercial and industrial sectors.

- The industrial sector is relatively efficient on an exergy basis compared to other sectors. The reason for the low exergy efficiencies in some sectors is inefficient utilization of the quality of the input energy. The residential/commercial sector, in particular, has a notably low exergy efficiency, mainly because much of the primary use of energy is to produce cold or heat at near environmental temperatures, whereas in the industrial sector high-quality energy is used to produce higher-temperature heating and lower-temperature cooling (which are higher-quality energy forms). Thus the high quality of energy inputs, as reflected by their exergy values, is better utilized in the industrial sector. The production of low-quality products from a fossil fuel or electricity leads to a loss in energy quality that is only reflected properly with exergy analysis. Exergy methods clearly

demonstrate that the closer the temperature of the environment to the temperature of the heat produced, the lower the exergy efficiency of the process.

Clearly, exergy provides important insights into the behavior and efficiency of the industrial sector in terms of efficiency limits and margins for improvement. Energy and exergy losses can be viewed as representing, respectively, perceived and actual inefficiencies. It is seen that actual inefficiencies in the residential/commercial and industrial sectors are much higher than the perceived inefficiencies. For the transportation and utility sectors, the actual inefficiencies are lower than the perceived inefficiencies.

8.7 Industrial Energy Efficiency and the Economy

8.7.1 Industrial Energy Efficiency and Economic Growth

At first sight, increased industrial energy efficiency should encourage economic growth. In fact, there is quite a lot of evidence that it has done so in the past by cutting costs, leading to lower prices of goods and, ultimately, increased demand for those goods or for new products and services that did not exist previously. Nielson's use of preheated air made blast furnaces more efficient and cut the cost of pig iron dramatically in the early 19th century. This, in turn, made wrought iron rails much cheaper and helped in the spread of railroads. Later, Bessemer's clever way of decarbonizing molten iron by blowing air through it to make steel was a tremendous gain in efficiency and made steel much cheaper than the older processes. The result was to substitute steel rails for iron rails, and to create immense new markets for steel products, especially in construction, ship-building, and, later, the manufacture of automobiles.

The invention of steam turbines in the 1880s made steam power cheaper and more efficient. The main application was for electric power generation. Cheaper electricity resulted in the rapid spread of electric lighting, replacing gas lights, candles, and acetylene lamps, and the substitution of electric motors for steam engines in factories and on railways. Cheap electric power also created new markets, including the aluminum and chlorine industries, the use of electric furnaces to refine metals with high melting points such as chromium and nickel (for stainless steel), tungsten (for light bulbs), and synthetic carbides to permit high-speed grinding machines that are essential for manufacturing complex automobile engine parts such as cam-shafts and crank-shafts. Electrification was arguably the single most important driver of economic growth in the first half of the 20thcentury.

Aluminum followed a similar trajectory. In the mid 19th century, aluminum was an expensive luxury metal used, for example, to put the cap on the Washington Monument in Washington DC. After the introduction of the more efficient electrolytic process, however, the price of aluminum dropped rapidly, creating new markets such as pots and pans, window frames and beer cans, electrical transmission lines (replacing copper), as well as aircraft and truck bodies. Cheap plastics from petrochemicals have also created vast new markets for packaging materials, furniture, toys, and so on.

Plastics derived from petrochemicals have contributed significantly to economic growth in the second half of the 20thcentury. However, exergy efficiencies at the process level are now approaching 50% for some primary products, such as ammonia. While some further gains can be expected, the best that can be hoped for in the basic materials subsectors is typically an improvement in the range of 15–30% beyond the current best available technology. Gains of that magnitude will not lead to cost or price reductions sufficient to create significant new products, and only minor increases can be expected in price-driven demand for existing industrial products.

The most promising approach to reducing industrial energy use in the future is to sharply increase recycling (in the case of metals, glass, paper, and some plastics), and to use secondary materials, such as fly-ash, in the manufacture of cement. Another promising approach, albeit several decades in the future, will be to find ways of skipping intermediate process steps and/or to develop plastic substitutes from waste biomass, such as ligno-cellulose. Recycled metals from scrap are far less energy intensive than virgin metals. In the case of aluminum and copper the difference is more than a factor of ten. Unfortunately, there has been little progress in remanufacturing or recycling technology in recent decades (notwithstanding their potential importance) because of a lack of sustained support for the necessary collection and sorting activities by governments. The major exception seems to be some progress in recovering precious metals (mainly gold and silver) from electronic waste. But even in this case, most electronic waste is processed inefficiently by unskilled labor, with little or no concern about pollution or public health hazards.

However, all things considered, the energy intensity of new manufactured products cannot be expected to decrease significantly in the coming decades. The only way to cut energy use by industry more than marginally is to use much less of the products of industry and to sharply increase the rate of product reuse, renovation, remanufacturing, and recycling. This is technically feasible but will be politically difficult. The case of ammonia, the primary source of all nitrogen fertilizers, offers a possible example. The excessive use of nitrogen fertilizers is responsible for several environmental problems, such as pollution of ground water and eutrophication of rivers and streams. Precision agriculture offers the potential for actually cutting nitrogen fertilizer use by reducing waste and simultaneously reducing environmental harm.

8.7.2 Energy, Exergy and Economic Growth

As increased efficiency cuts costs and prices, it also follows that shortages and price increases will have a negative impact on economic growth, at

least in the short and medium term. There have been many observations of growth slowdowns following energy price spikes (Hamilton 1983; 2003; 2005). While it is true that shortages induce invention and innovation, this is a slow process. The slow introduction of renewables (especially wind and solar photovoltaics), which may be the long-term substitutes for fossil fuels, illustrates the problem. Renewables only account for a tiny fraction of global electricity generation, and still cost considerably more per unit of delivered power than conventional coal-burning power plants. Introduction would be faster if the price of fossil fuels reflected the unpaid environmental damages they cause, but governments seem generally unwilling to impose those costs on the producers.

Parenthetically, it seems very likely that the high oil prices of the first half of 2008 hastened the end of the US real estate price boom by squeezing household expenditures at a time when many people already had credit card debts and no savings. This, in turn, caused an increase in foreclosures. That may have triggered the financial meltdown, which followed from the realization that mortgage-based securities could not be priced realistically, which meant that many financial institutions and banks were over-leveraged.

More importantly, in the long run, the forthcoming advent of "peak oil," whether it has already happened or whether it occurs ten or 20 years in the future, must have a significant negative impact on future global economic growth, at least until energy-related innovation creates a new boom (or "bubble"). The reason is that energy in general, and oil in particular, are essential to virtually all economic activity, with marginal productivity (output elasticity) far greater than its still small – though increasing – cost share. As the price of oil (and oil substitutes, such as they are) rises, the demand for energy-intensive products will fall, as happened in late 2008. That brings the price of oil temporarily back down, which encourages renewed consumption but discourages investment in energy conservation measures that depend on higher prices. This, in turn, delays needed economic adjustment while accelerating the onset of the next crisis.

Skipping over the details, in our multi-sector, multi-product economy there is econometric evidence that the output elasticity of an essential (non-substitutable) input, such as petroleum, or more generally, energy, tends to be much larger than its cost-share, whereas the output elasticity for labor in the industrialized countries tends to be much smaller than its cost-share. Simply put, it can be argued that raw (unskilled) labor is over-priced in modern economies, whereas flows of energy, especially petroleum, have been relatively underpriced up to now. The econometric evidence for this would take us far afield. However, the simple observation that most firms are able to increase profits by reducing employment seems to suggest that employment is being kept artificially high, partly for social and political reasons, and partly as a way of supporting consumption.

The non-equality of output elasticities and cost-shares has important consequences for the standard theory of economic growth. The first implication is that the Cobb-Douglas production function must be discarded, because it assumes that output elasticities are equal to cost-shares and that the latter are constant. Dropping this assumption implies that the output elasticities of factor inputs must be functions of all the input variables, namely capital, labor, and energy or energy services. Kuemmel et al. (2008) have shown that the simplest functional form for a production function that allows for non-constant output elasticities, takes into account the energy flows in a physically plausible way, and permits an explicit parametric formulation of the constraints is the so-called LINEX production function (Kuemmel et al., 2002; 2008; Ayres and Warr, 2005). Its mathematical characteristics have been discussed elsewhere and need not be recapitulated here.

When growth theory is suitably modified to reflect the true importance of energy as an input, it turns out that the primary driver of growth, apart from capital deepening, is the increasing supply of "useful work" (mechanical work, chemical work, electrical work, etc.) in the economy (Ayres et al., 2003; Ayres and Bergh, 2005; Ayres and Warr, 2005; 2009). This has been a consequence of two past trends: (1) the discovery of huge oil and gas reserves, and (2) the increasing efficiency of conversion of primary energy (fossil fuels) into various forms of useful work, such as electric power and motive power.

The advent of peak oil means that, as the supply of oil and gas cannot be expected to continue to increase in the future, driving energy prices down – as it did for most of the last two centuries – future economic growth will depend more than in the past on technological progress, especially in the area of increasing energy (exergy) efficiency in the economy. Yet, the rate of exergy efficiency increase (in the United States, at least) has been slowing down since the 1970s. The bottom line here is that either US economic growth will slow down permanently (with global consequences) or effective measures to increase the rate of increase of exergy efficiency must be undertaken to compensate for the coming decline in the availability of natural resources. Such an acceleration of technological progress vis-à-vis exergy efficiency is technically possible but politically difficult due to resistance from entrenched special interests, especially the electric utility monopolies.

8.8 Realizing the Opportunities – Policies and Programs

The principal business of an industrial facility is production, not energy efficiency. High energy prices or constrained energy supply will motivate industrial facilities to try to secure the amount of energy required for operations at the lowest possible price. However, price alone will not build awareness within the corporate management culture of the potential for energy use and cost savings, maintenance savings, and production benefits that can be realized from the systematic pursuit of industrial energy efficiency. It is this lack of awareness and the corresponding failure to manage energy use with the same attention that is normally provided to production quality, waste reduction, and labor costs, i.e., at the root of the opportunity.

To be effective, energy efficiency programs need to engage industry at the management level as well as facilities engineering. Since industrial decision-making is largely driven from the top, failure to engage management results in missed opportunities for energy efficiency improvement, even when the technical staff is educated and aware of the opportunities.

A number of countries have demonstrated the value of effective industrial energy efficiency programs. The IEA's (UN Energy, 2010) World Energy Outlook Policy Database has compiled information on industrial energy efficiency programs from the IEA Climate Change Mitigation Database, IEA Energy Efficiency Database, IEA Global Renewable Energy Policies and Measures Database, the European Conference of Ministers of Transport, and contacts in industry and government (IEA, 2008b). The IEA's Energy Efficiency Database contains 170 industrial energy efficiency policies and measures in 32 countries and the EU (IEA, 2008c).

Barriers to improved energy efficiency include lack of information regarding energy efficiency, limited awareness of the financial or qualitative benefits arising from energy efficiency measures, inadequate skills to implement such measures, capital constraints and corporate culture leading to more investment in new production capacities rather than energy efficiency, and greater weight given to addressing upfront (first) costs rather than recurring energy costs, especially if these costs are a small proportion of production costs (Monari, 2008).

In addition, for developing countries the marginal cost of adopting an industrial policy can be substantially greater than in a developed country that already has supportive institutions in place (Monari, 2008). For new technologies, the slow rate of capital stock turnover in many industrial facilities (Worrell and Biermans, 2005), coupled with the perceived risks of adopting new technologies, can hamper adoption. Table 8.24 (below) provides an overview of industrial needs and goals addressed by industrial policies and programs.

8.8.1 Energy Management

The implementation of successful national energy management programs is dependent on legislation, incentives and policies, and the institutional mechanisms for energy efficiency.

8.8.1.1 International Energy Management Standards

The purpose of an energy management standard is to provide guidance for industrial facilities to integrate energy efficiency into their management practices, including fine-tuning production processes and improving the energy efficiency of industrial systems (UN Energy, 2010). Energy management seeks to apply to energy use the same culture of continuous improvement that has been successfully used by industrial firms to improve quality and safety practices. An energy management standard is needed to influence how energy is managed in an industrial facility, thus immediately reducing energy use through changes in operational practices, as well as creating a favorable environment for adopting more capital-intensive energy efficiency measures and technologies. Although the focus of this chapter is industrial energy efficiency, it is important to note that the energy management standards mentioned here are equally applicable to commercial, medical, and government facilities.

An energy management standard requires a facility to develop an energy management plan. In companies without a plan in place, opportunities for improvement may be known but may not be promoted or implemented because of organizational barriers. These barriers may include a lack of communication among plants, a poor understanding of how to create support for an energy efficiency project, limited finances, poor accountability for measures, or a perceived change from the status quo. Without performance indicators that relate energy use to production output, it is difficult to document improvements in energy intensity (UNIDO, 2007).

Companies that have voluntarily adopted an energy management plan (a central feature of an energy management standard) have achieved major energy intensity improvements. Some examples include:

- Dow Chemical achieved a 22% improvement (saving US$4 billion) between 1994 and 2005, and is now seeking another 25% from 2005 to 2015.
- United Technologies Corp. reduced global GHG emissions by 46% per dollar of revenue from 2001 to 2006, and is now seeking an additional 12% reduction from 2006 to 2010.
- Toyota's North American Energy Management Organization has reduced energy use per unit by 23% since 2002; company-wide energy efficiency improvements have saved US$9.2 million in North America since 1999.

Denmark, Sweden, Ireland, South Korea, Spain, Thailand, and the United States have national energy management standards. Japan has a legal requirement for its more energy-intensive industrial facilities to have an energy manager and an energy management plan. These requirements also extend to large commercial facilities and parts of the transportation sector. The Netherlands has an energy management specification closely linked to long-term agreements. The European Committee for Standardization and the European Committee for Electrotechnical Standardization developed a common standard for the EU in mid-2009. China and Brazil both have national energy management standards under development.

Table 8.25 compares the elements of the energy management standards in seven countries or regions with existing energy management standards (or specifications), two under development, and one country for

which energy management is a legislated practice for many industries. In all instances, the standard has been developed to be entirely compatible with the ISO quality management program (ISO 9001:2000) and environmental management program (ISO 14001).

Typical features of an energy management standard include:

- a strategic plan that requires measurement, management, and documentation for continuous improvement for energy efficiency;
- a cross-divisional management team led by a representative who reports directly to management and is responsible for overseeing the implementation of the strategic plan;
    - policies and procedures to address all aspects of energy purchase, use, and disposal;
    - projects to demonstrate continuous improvement in energy efficiency;
- creation of an energy manual, a living document that evolves over time as additional energy-saving projects and policies are undertaken and documented;
- identification of key performance indicators, unique to the company, that are tracked to measure progress; and
    - periodic reporting of progress to management based on these measurements.

As shown in Table 8.25, the existing energy management standards have many features in common. ISO now identifies energy management as one of the top five fields meriting the development and promotion of international standards.[7] Energy management received this priority focus based on its enormous potential to save energy and reduce GHG emissions worldwide.

The United Nations Industrial Development Organization (UNIDO) recognized the industry's need to mount an effective response to climate change and to the proliferation of national energy management standards. In March 2007, UNIDO hosted a meeting of experts, including representatives from the ISO Central Secretariat and nations that have adopted energy management standards. That meeting led to the submission of a formal request to the ISO Central Secretariat to consider undertaking work on an international energy management standard.

In February 2008, ISO's Technical Management Board approved the establishment of a new project committee to develop the new ISO Management System Standard for Energy. ANSI and the Associação Brasileira de Normas Técnicas are jointly serving as the secretariat to lead development of ISO PC 242, Energy Management.

The new ISO 50001 establishes an international framework for industrial plants or companies to manage energy, including all aspects of procurement and use. The standard provides organizations and companies with technical and management strategies to increase energy efficiency, reduce costs, and improve environmental performance (ISO 50001, 2011). Based on broad applicability across national economic sectors, the standard could influence up to 60% of the world's energy demand (US EIA, 2007). Corporations, supply chain partnerships, utilities, energy service companies (ESCOs), and others are expected to use ISO 50001 as a tool to reduce energy intensity and carbon emissions in their own facilities (as well as those belonging to their customers or suppliers) and to benchmark their achievements. ISO 50001, published in June 2011, is expected to promote industrial energy efficiency globally.

A successful program in energy management provides an organizational framework for a company to respond effectively through a program of continuous improvement to a national program that establishes energy intensity improvement and/or GHG reduction targets. UNIDO has identified a package of policies described as the "Industrial Standards Framework" that outlines the policy relationships among target-setting agreements, energy management standards, system optimization, and their intended impact on industrial markets (see Table 8.26).

UNIDO is currently engaged with ten countries in the development of industrial energy efficiency programs based on the framework described in Table 8.26.

8.8.1.2 Country Experiences in Energy Efficiency Implementation

A review of the national experiences of a few selected countries on industrial energy efficiency policies illustrates the state of energy policies in the world. The countries selected are Brazil, China, India, South Africa, and the United States. These countries account for almost half of total industrial consumption. Table 8.27 provides a summary of the country experiences for a few select countries in different regions of the world in energy efficiency implementation and impacts.

Brazil

Although a national electricity conservation program (Programa Nacional de Conservação de Energia Elétrica (PROCEL)) was implemented in 1985, energy policies have never addressed energy efficiency

7 Priorities also include calculation methods, biofuels, retrofitting and refurbishing, and buildings.

as a relevant issue. In particular, there has been very little attention to industrial energy efficiency policies, despite industry being the most important energy-consuming sector.

More comprehensive energy efficiency policies were only implemented in the country after a severe electricity supply crisis occurred during 2001–2002. Two main regulatory and legislative achievements which took place in the late 1990s and after the energy crisis were important to establish basic instruments for further advancement of energy efficiency in the country: the creation of a public benefit wire charge, and the energy efficiency law created after the energy crisis.

The public benefit wire charge sets aside 1% of electricity revenues to investments in energy R&D and energy efficiency. Since 1998 about R$2 billion (US$980 million) has been invested in energy efficiency utility programs. However, only 10% of these resources have been dedicated to the industrial sector so far. Energy efficiency programs are implemented by utilities under the regulator's oversight and also by a public fund called CTenerg.

During the crisis a series of measures were taken which saved 26 TWh (of a total national consumption of 284 TWh) and 13,000 MW peak, compared to PROCEL's estimated savings during 1994–2000 of 10.7 TWh and 640 MW peak (Maurer et al., 2005). In 2001, a national law was approved that introduced legal instruments to establish energy efficiency standards for appliances, buildings, and motor cars commercialized in the country. Electrical motors (three-phase) were the first equipment to receive mandatory minimum energy efficiency standards. More stringent standards and concentrated efforts in R&D (with the use of the public benefit funds) have the potential to accelerate the improvement of energy efficiency in the country, particularly in the industrial sector.

In general, energy efficiency has not been a priority for the industrial sector. There have been very few energy efficiency programs initiated by the local industries themselves using their own investment capital. In most cases, they are part of corporate policies related to environmental protection and improving the quality of their products, and have been restricted to larger corporations.

There is a preference for investments with a short payback (less than two years). Energy efficiency achieved has been the result of changes in production lines and products. However, there is a lack of expertise in industry in general, particularly in SMEs. Projects that have combined public and private funds have produced significantly better results. In some cases, there has been an increase in the specific energy use in energy-intensive industries due to stricter environmental rules and quality demand in the international market.

Since 1998, utilities have been required by the National Regulator to invest part of their revenues in energy efficiency programs. Up until 2007, a little less than US$1 billion was invested in energy efficiency programs, but only 10% of this was targeted at the industrial sector, achieving an estimated savings of 376 GWh/yr. Figure 8.31 shows a supply curve for end-use efficiency in the electricity sector for Brazil in 2020.

Recent studies in Brazil have estimated opportunities to introduce energy efficiency measures and fuel substitution away from fossil fuels. A supply curve of conserved electricity for 2020 (base year 2004) is presented in WWF-Brazil, 2007 and shows a potential of 55 TWh at a cost of R$130/MWh (approximately US$80/MWh) with the replacement of motor systems (Figure 8.31). This was the largest potential depicted by this study.

Energy subsidies persist in the industrial sector and distort the cost-effectiveness of existing opportunities. For the most part, industrial energy costs are still irrelevant when compared to other inputs, taxes, and personnel costs. National energy conservation programs have focused more on the residential and public sectors, rather than the industrial sector. There are significant opportunities for more efficient technologies and processes in industry that have not been implemented on a significant scale. Opportunities to combine water and energy efficiency seem to be a better way to accelerate the improved use of resources in the industrial sector, since water usage is increasingly coming under the scrutiny of both policymakers and the population. Regulatory barriers still exist to impede energy companies from investing in efficiency programs for their end-use customers.

China

In 2005, China's government raised a strategic target to reduce its energy use per GDP by 20% by 2010. Industrial energy efficiency is expected to provide 80% of the reduction. To achieve this target, the Chinese government developed a series of initiatives:

- It emphasized regulation of the industrial structure. The government issued policies to import equipment and keep free import and export tariffs and VAT; release loans and lands dependent on energy efficiency standards; and phase out inefficient production capacities in iron and steel, cement, power generation, coal mining, etc. It is expected that 50 million kW in small thermal power units, 100 Mt of iron, 55 Mt of steel, and 250 Mt of cement will be phased out during China's 11th Five-year Plan.

- It established a responsibility mechanism to ensure that disaggregated energy conservation targets are achieved in each province. The central government signed energy-saving target responsibility agreements with 30 provincial governments and the top 1000 enterprises, which consumed energy of over 180,000 tonnes of coal equivalent (tce) annually (approximately 5.28 PJ), and set up a performance assessment system to track and evaluate energy-saving activities under the responsibility agreement mechanism. In May 2008, the National Development and Reform Commission and six other ministries implemented on-site assessment and evaluation of the performance of energy conservation target implementation for 30 provincial governments and released the results. The central

1 Certification is required for companies participating in voluntary agreements (also specified interval in Sweden). In Denmark, Netherlands & Sweden linked to tax relief eligibility.

2 As of 2002, latest date for which data is available

3 Japan has the Act Concerning the Rational Use of Energy, which includes a requirement for energy management

4 Korea invites large companies that agree to share information to join a peer-to peer networking scheme and receive technical assistance and incentives

5 Netherlands has an Energy Management System, not a standard, per se, developed in 1998 and linked to Long Term Agreements in 2000.

6 800 companies representing 20% of energy use have LTAs and must use the Energy Management System. The 150 most energy intensive companies, representing 70% of the energy use, have a separate, more stringent, bench marking covenant and are typically ISO 14000 certified, but are not required to use the EM System.

7 Thailand has made the energy management standard is mandatory for large companies, linked it to exisitng ISO-related program activities, coupled with tax relief; program evaluation not yet available

8 To date, the US government has encouraged energy management practices, but not use of the standard. A program was initiated in 2008 to address this which also includes validation; program evaluation results anticipated in 2011.

government will reward the best-performing provinces and penalize the provinces which underperformed.

- It set up an energy conservation supervision and monitoring mechanism. Energy Conservation Supervision Centers were established in more than 19 provinces and cities. The centers are responsible for ensuring that enterprises and buildings follow the updated Energy Conservation Law, as well as mandatory energy efficiency standards and codes.

- It launched the Top 1000 Enterprises Energy Conservation Action. The 1000 enterprises are those 998 enterprises with annual energy use at or over 180,000 tce (5.28 PJ). According to statistics, comprehensive energy use of the 1000 enterprises in 2004 was 670 million tce (19.6 EJ) – 33% of the nation's total energy use and 47% of total industrial energy use. The purpose of the program is to encourage enterprises to carry out energy audits, work out energy saving plans, strengthen the implementation of energy efficiency standards, implement energy efficiency benchmarks, and to achieve the target of 100 million tce (2.9 EJ) of energy savings in 2010.

- Due to these policies, the following results were obtained:

- Energy use per GDP was reduced by 1.37% by 2006 and continued to decline (as shown in Figure 8.32).

- The specific energy use for key products from energy-intensive sectors has declined since 2006. Specific energy use per unit of thermal

power, crude steel, cement, petro-processing, crude copper, alumina, sodium carbonate, and ethylene declined by 3–10.5% by 2006. The energy intensity of steel and cement declined by about 3% by 2007, and thermal power-generating units over 6000 kW consumed 335 gce per kWh – 10 g lower than in 2006.

India

The Energy Conservation Act 2001 enacted by the government mandated the creation of the Bureau of Energy Efficiency (BEE) which promotes energy efficiency. The BEE has taken the following initiatives in the industrial sector:

- *National awards scheme* – an annual awards scheme which provides a mechanism to reward industries in different sectors based on their performance and initiatives in energy efficiency. This resulted in the creation of a database on the BEE website of energy conservation measures and their costs, encouraging other industries to adopt similar measures.
- *Designated consumers* – eight sectors have been designated as energy-intensive sectors: power plants, steel, cement, fertilizers, pulp and paper, chlor-alkali, textiles, and railways. For these sectors, all industrial units with total energy use above specified limits have to provide annual data regarding their energy performance. Designated consumers need to have certified energy managers employed in their plant and have

audits carried out at specified intervals. BEE plans to establish benchmarks in the future for energy use for designated consumers.

- *National energy managers and auditors certification* – BEE initiated a process for the creation of certified energy managers and energy auditors. A syllabus has been drawn up and an annual examination carried out. About 4500 certified energy managers qualified through this process (3400 of them are also certified energy auditors). This process is expected to provide the skilled manpower needed to implement energy efficiency schemes in the country. Apart from these schemes, BEE plans to establish state energy conservation funds to facilitate and strengthen the implementation of energy efficiency by the state nodal agencies. BEE also plans to launch an initiative for small- and medium-sized industries.

India launched a National Mission on Enhanced Energy Efficiency (NMEEE) in April 2010 as a part of the National Climate Change Action Plan. The NMEEE includes a market-based mechanism to enhance energy efficiency in large energy-intensive industries and facilities (the Perform, Achieve and Trade scheme). This involves setting goals for specific energy use for each plant for reduction below the baseline. Industries are expected to meet their reduction targets within a three-year period. Industries which exceed their targets will be credited with tradable energy permits. Industries that fail to meet targets can either buy energy permits or pay penalties. The NMEEE will set up two fiscal instruments – the Partial Risk Guarantee Fund (PRGF) and the Venture Capital Fund for Energy Efficiency (VCFEE). The PRGF will provide commercial banks with partial coverage of risk exposure against loans made for energy efficiency projects. The VCFEE will facilitate the

availability of venture capital to energy supply companies and other companies investing in energy efficiency and demand-side management (DSM).

The Indian government has announced the establishment of Energy Efficiency Services Limited (EESL) with equity of INR1.9 billion (about US$43 million) from four public-sector companies: National Thermal Power Corporation, Power Finance Corporation, Rural Electrification Corporation, and Power Grid. EESL will work as an ESCO and lead the market-related actions of the NMEEE.

South Africa

In 2005, the South African government in the form of the Department of Minerals and Energy (DME) launched the "Energy Efficiency Strategy of the Republic of South Africa." This strategy addresses all sectors within South Africa and targets an overall improvement in energy efficiency of 12% by 2015. Specifically, the industry target is 15%. These targets do not refer to a baseline at a particular date. Instead, they refer to reductions against the projected use in 2015 if energy efficiency measures are not employed.

Although the strategy was divided into phases for implementation over the period, little to no funding, encouragement, or incentives were put in place to ensure a significant take-up. The DME did not have the resources to "make things happen."

There is generally low awareness in South Africa of the benefits of energy efficiency, and the cost of energy as a fraction of business expense is usually very small and, consequently, does not attract management's attention to reduce it. During times of economic well-being (as in recent years), business owners do not see the value in releasing additional profit in this way. Yet energy efficiency is cost-effective and very quickly pays back the initial investment.

In 2005 an (Industrial) Energy Efficiency Accord was signed between the DME and 30 of the country's largest energy users and business associations. No such accord was mentioned in the strategy, but it effectively became the mechanism for encouraging energy efficiency in industry. Many of the participants regularly attended meetings, particularly the Technical Committee meetings. The very large users of energy had an inherent incentive to reduce energy use, but the only financial incentive available to less energy-intensive users was the one generally available to all under the Energy Efficiency and Demand-Side Management (EEDSM) program. The rules were published by the National Electricity Regulator (subsequently the National Energy Regulator of South Africa) in 2004.

The EEDSM program is administered by Eskom, a vertically integrated national electricity monopoly. The energy efficiency component attracted a subsidy of 50% of the cost of implementation up to a maximum value set at a fraction of the cost of constructing a new power station. The approval process at Eskom became unacceptably long for many potential customers, and few Energy Efficiency Accord members ultimately used this route. The programme has been recently restructured and a number of options are now available in an attempt to simplify and facilitate adoption The National Energy Efficiency Agency was established in 2006. It was initially envisaged that it would oversee the implementation of DSM and energy efficiency projects undertaken by Eskom and other entities in the country. However, the agency was never appropriately resourced and did not grow beyond having a single staff member.

South Africa is now in a position where electricity demand often exceeds the supply capability, and a power curtailment program is in place. Legislation has recently been enacted that will require more attention to energy-saving and efficiency measures.

The national electricity utility, Eskom, has been piloting DSM for a number of years. In 2001 it began to formalize the process and procedures. The program is specified and monitored by the National Energy Regulator of South Africa, and Eskom acts as the facilitator. The early mechanism was to uses ESCOs as agents to "pull through" projects which the ESCOs had found. Measurement and verification teams were established at several universities with the express purpose of providing independent auditing of the results of the ESCO projects. Progress was very slow initially because there are not enough skilled ESCOs in South Africa. Many ESCOs have come from the realms of lighting suppliers, as there has been considerable attention paid to replacing the incandescent lamps with compact fluorescent lamps. Many of the linear fluorescent fittings with electro-magnetic ballasts have been replaced with electronic ballasts and small-diameter tubes.

Eskom lacks the capability to manage the program, and the extremely slow rate of project approval has frustrated many ESCOs, some of which no longer serve the program. It can be argued that a program that forces a supplier to curtail its supply without compensation is not properly located within a utility.

The DSM program is financed from public funds in the form of a levy on the tariff. Initially the need was to reduce or shift peak demand, but the emphasis has now moved to energy efficiency. A Rand/MW hurdle rate was established for various interventions, and ESCO proposals had to fall below this rate to be eligible for further consideration. Funding is at 100% of the project value up to the hurdle rate for load-reduction projects and at 50% for energy-reduction projects.

United States

Since 1993, the US DOE has been developing and offering an extensive array of technical training and publications to assist industrial facilities in becoming more energy efficient through its Best Practices program. As a result of these program activities, the US has developed a great deal of technical capability in industrial energy efficiency, especially motor, steam, and process heating systems (UNIDO, 2007). Under the program name of Save Energy Now, the US DOE initiated a series of program activities beginning in 2006 with the Energy Saving Assessments previously described in Section 8.3.3 (US DOE, 2010) also includes the Industrial Assessment Centers, a university-based program with a successful 30-year track record of training engineering students while conducting approximately 500 walk-through energy assessments annually, primarily of small- to medium-sized industries.

In 2002, the US EPA began a voluntary program called "Climate Leaders," which works with companies to develop long-term comprehensive climate change strategies. Using the GHG emissions protocol developed by the World Resources Institute and the World Business Council for Sustainable Development, 59 companies have set and report progress on a corporate-wide GHG reduction goal to be achieved over five to ten years. These goals are evaluated against the projected performance of the relevant sector. In 2003, the US EPA began offering information on energy management guidelines and benchmarking as part of its ENERGY STAR for Industry program.[8] The US ENERGY STAR has developed a benchmarking tool called the Energy Performance Indicator for the cement, corn refining, and motor vehicle assembly industries that ranks a facility among its peers based on energy use, normalizing for specific activities or factors that influence energy use (UN Energy, 2010).

In 2007, the US DOE and EPA joined together with industry, ANSI, and the National Institute of Standardization and Technology to develop Superior Energy Performance, a collaborative program to certify plants for energy efficiency based on implementation of an energy management system and improvements in energy intensity measured against a baseline.[9] This program is centered on ANSI MSE 2000:2008, the national energy management standard developed by the Georgia Institute of Technology, which will be supplanted by ISO 50001. The Superior Energy Performance program creates a framework for fostering energy efficiency at the plant level and a methodology for measuring and validating energy efficiency/intensity improvements in a process that is voluntary, performance-based, and technically sound. The proposed approach can be integrated into existing corporate management systems, such as ISO 9001:2000 and 14001:2004. Certification will also position plants to be recognized by the financial community for superior energy management practices and their contribution to climate change mitigation. The strategic goals of Superior Energy Performance are:

- to foster an organizational culture of continuous improvement in energy efficiency;
- to develop a transparent system to validate energy intensity improvements and management practices; and thus
- create a verified record of energy source fuel savings and carbon emission reductions with potential market value that could be widely recognized both nationally and internationally.

Use of the ASME System Assessment Standards (see Section 8.3.5) is not required for participation in Superior Energy Performance, but the standards provide a clearly defined pathway for quickly achieving energy savings. Superior Energy Performance underwent an 18-month pilot period in Texas and launched in 2010.

8.8.2 Demand-side Management

Industries can participate in utility DSM programs to reduce their energy costs and contribute to the efficient operation of the energy supply system (see Chapter 15 for a description of DSM and its implementation).

8 See www.energystar.gov/index.cfm?c=in_focus.bus_industries_focus.

Industrial programs can result in energy efficiency, load shifting and peak clipping, cool storage, cogeneration, deferrable interruptible load, and viable options for the industrial sector. Utility incentives can help facilitate widespread adoption of industrial DSM programs and can be part of the least-cost power plan for society.

8.8.3 Co-benefits for Industrial Energy Efficiency

Most industrial energy efficiency improvements also have additional benefits (co-benefits). These include reduced emissions and waste, improved product quality, increased product output and reduction of operation and maintenance costs (Worrell et al., 2003; IPCC, 2007).

Pye and McKane (1999) found that industrial efficiency projects adopted through the "Motor Challenge" program resulted in improved operations, extended lifetime of system components, and reduced expenditures and capital costs.

Worrell et al. (2003) quantified the monetary value of productivity benefits from 52 case studies. This revealed that the payback period for the measures based on energy savings only was 4.2 years. This reduced to 1.9 years when non-energy benefits were included.

Figure 8.33 shows the conservation supply curve for 14 measures in steelmaking with only energy benefits and including productivity benefits.

8.8.4 Financing

Energy efficiency is a largely invisible and nascent market. The financial benefits of energy efficiency accrue to end-users, representing a cost savings, rather than a financial return. Cost savings are difficult to collateralize, which makes it difficult to secure external financing for energy efficiency projects. Therefore, industrial energy efficiency is normally financed internally and is not generally identified as an investment or structured as a separate project.

In 2006, US$1.1 billion was invested in energy efficiency technologies, compared with US$710 million in 2005 (UNEP and New Energy Finance, 2007). These figures include both supply- and demand-side energy efficiency measures across all sectors. This is only a small fraction of the total investment in the industrial sector in 2005 of US$1379 billion (UNFCCC, 2007).

8.8.4.1 IEE Financing Requirements

Based on the IEA World Energy Outlook 2006 Alternative Policy Scenario (APS),[10] industrial energy demand in 2030 will be 337 million tonnes of oil equivalent (Mtoe) (9% lower than in the Reference Scenario). Over half of global energy savings in the industry sector can be achieved as the result of more energy-efficient production of iron and steel, chemicals, and non-metallic products.

The additional demand-side investment in APS amounts to US$360 billion to be financed by various industrial end-users, including about three-quarters to purchase more energy-efficient electrical equipment (see Table 8.28).

The UNFCCC (2007) estimates that an additional US$19.1 billion[11] of annual investments will be needed in 2030 to stabilize energy-related CO_2 emissions at the 2005 level (as set out in the IEA Beyond Alternative Policy Scenario (BAPS)).[12] This additional investment on the demand side can, however, is offset on the supply side by a decreased need for investment in new power-generation capacity and fossil fuel (US$60 billion less). The BAPS assumes that to achieve the GHG stabilization targets, industrial energy efficiency would need to improve by a further 7% compared to APS.

According to the UNFCCC (2007), most projected industrial energy efficiency measures can be achieved, as they assume very short payback periods (less than four years), and further additional investment needs

10 The APS considers how the global energy market can evolve by 2030 if countries are to adopt all policies they are considering related to energy security and energy-related CO_2 emissions (note: in APS global GHG emissions are 8Gt higher in 2030 than in 2006).

11 US$11.5 billion in OECD and US$8 billion in non-OECD countries.

12 The BAPS considers policies and changes in global energy market which need to be effected to stabilize GHG emissions at the 2004 level of 26.1 $GtCO_2$.

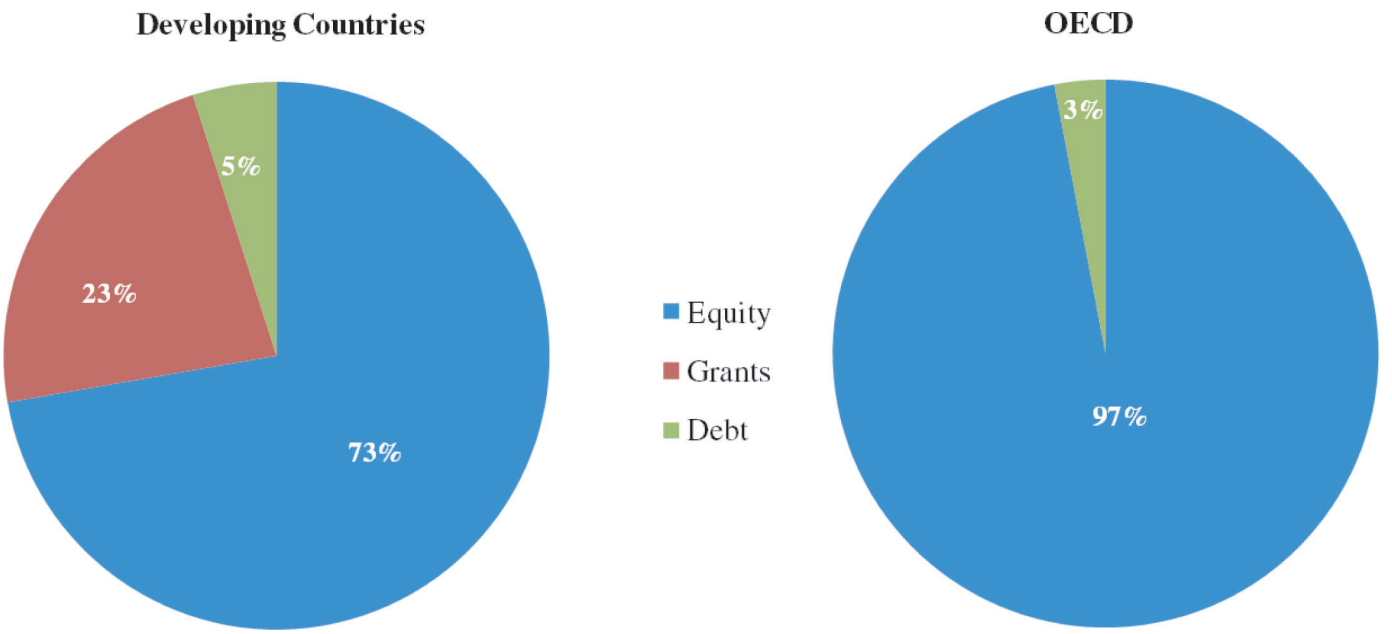

Figure 8.34 | Sources of energy efficiency investment in OECD and developing countries. Source: data based on UNFCCC, 2007.

constitute a small share (1%) of the total projected investment in the industrial sector.

The key bottleneck is that 75% of savings are projected to occur in non-OECD countries, where availability of capital is scarce, political and economic risks are high, financial markets are not sufficiently developed, and an enabling policy environment and technical skills are lacking.

8.8.4.2 Traditional Sources of Financing for Industrial Energy Efficiency

Patterns of investment in industrial energy efficiency (see Figure 8.34) generally mirror those for investment in the industrial sector in general, where the largest part (72%) comes from domestic sources, particularly in developing and transition economies. Foreign direct investment provides 22% of the global total, but more in OECD countries (up to 37% in North America). Debt plays a small role, while Official Development Assistance (ODA) barely registers as a source of industrial investment (UNFCCC, 2007).

Private equity/venture capital – as for energy efficiency financing, venture capital (primarily in OECD countries), and private equity (in developing and transition countries) provide the largest share of the total investment flows. Venture capital funds backed by the public sector can also be found in the United States, the United Kingdom, and Australia. For example, roughly one-third of the technology start-ups incubated by the United Kingdom's Carbon Trust operate in energy efficiency (UNEP and New Energy Finance, 2007).

Self-financing – in developing and transition economies, investment in industrial energy efficiency is mostly undertaken with companies' own funds. Key limitations in this respect are: energy efficiency is not part of the companies' core business and hence it has a low priority and needs to compete for scarce capital with other strategic projects; a lack of internal capacity for energy audits, project design, and implementation; and a lack of an enabling policy environment and motivation stemming from low/subsidized energy prices or an absence of mandatory energy performance targets.

Debt finance plays a very small role in financing industrial energy efficiency projects. This is due to the high cost of debt finance; the lack of long-term funds in the financial sector to invest in energy efficiency projects; the lack of understanding of how to evaluate energy efficiency investments on the part of the financial institutions and hence a higher perception of risk; and a lack of experience in structuring energy efficiency investment projects by companies, combined with a scarcity of competent local consultants and/or other intermediaries (e.g., ESCOs – see below) who could assist potential clients.

International Financial Institutions are an important source of funding for energy efficiency in developing and transition economies. In 2006, the World Bank (WB) committed more to energy efficiency projects (US$447 million) than to renewable energy (US$412 million) (WB, 2008). More than half of the WB's energy efficiency investment went into Central and Eastern Europe. Other important players are the European Bank for Reconstruction and Development, the Asian Development Bank, and the Global Environment Facility (GEF).

Public funds and other types of state financial support to industrial energy efficiency play a critical role in promoting investment in industrial energy efficiency in both developed and developing countries.

Following are examples of public support schemes and their impacts in developing countries.

It is very unlikely that initiatives in energy efficiency and energy (R&D) in Brazil would have taken place without the regulators' enforcement of compulsory programs in 1998 and later with the implementation of Law 9.991/00 by the National Congress. This initiative allocated 1% of annual utilities' revenues to energy efficiency and R&D programs. In 2000, a national law was approved by the congress that changed the allocation of the resources from the 1% obligation and created a national fund called CTEnerg, responsible for investing in energy efficiency and energy R&D in the public interest. Reforms in the power sector in Brazil provided the opportunity to enhance support and, in fact, increase significantly the level of funding in these areas. While PROCEL, the national electricity conservation program initiated in 1985, invested an annual average of US$14 million during 1994–2003, utilities' compulsory investments averaged US$57 million/yr during 1998–2004.

8.8.4.3 New Financing Sources for Industrial Energy Efficiency

ESCOs can be effective models for private-sector delivery of energy-efficient technologies and services. They had a global market volume of approximately US$2.5 billion in 2000 (Goldman et al., 2005; Vine, 2005). The role of an ESCO in structuring financing is to take on (fully or partially) energy efficiency project risks by guaranteeing with its own assets that a certain level of energy and cost saving will be achieved, thereby reducing project risks vis-à-vis potential financiers (a bank or the company itself). The ESCO model proved particularly successful in the United States, which still accounts for 75% of global ESCO operations (Goldman et al., 2005), and is gaining momentum in the EU (Bertoldi et al., 2005), but its prospects in developing and transition countries are limited by several factors: weak financial markets, companies without credit histories, the absence of risk-hedging instruments, and the absence of supportive governmental policies, which were critical for the success of ESCO business in the United States and the EU.

ODA is needed to overcome numerous barriers preventing cost-effective industrial energy efficiency measures from materializing in developing and transition economies (where countries lack resources and capacities to do so on their own). These include supporting governments in designing and implementing energy efficiency policies; building capacity of companies and other market participants to identify, structure finance for and implement projects; and promote technology transfer from developed to developing countries. All in all, the main role of ODA is to reduce risks of investment in energy efficiency, thereby making projects more attractive to financiers (see Figure 8.35). Figure 8.35 shows the effect of ODA in reducing the risk associated with a project (movement in the horizontal direction along the x-axis). The additional benefit of carbon finance results in an improved rate of return (movement in the vertical direction along the y-axis). The combination of these two effects can result in changing a low return high risk industrial efficiency project to a high return low risk viable project. The GEF is the largest source of ODA for industrial energy efficiency projects.

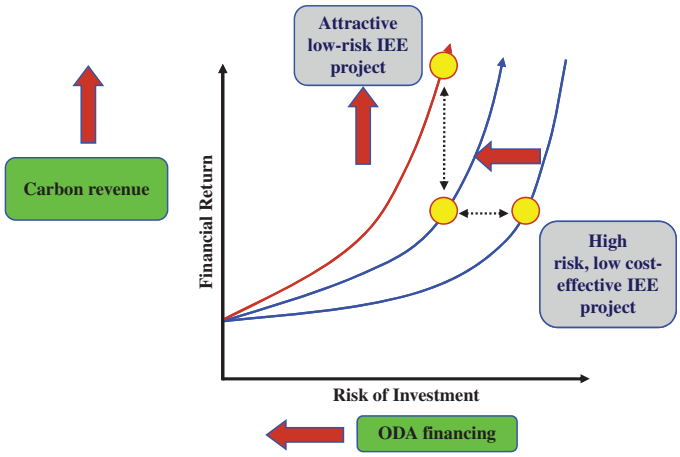

Figure 8.35 | Use of ODA and carbon finance for IEE projects. Source: modified from Glemarec, 2011.

Carbon finance is a new and rapidly growing market for clean energy financing and was valued at US$64 billion in 2007 (WB, 2008), including US$8 billion for projects under the Clean Development Mechanism (CDM). In contrast to ODA, the role of carbon markets in securing financing for industrial or other types of clean energy projects is to increase project profitability (i.e., Internal Rate of Return) or decrease the investment payback period by adding an additional revenue stream to the project (and in the case of industrial energy efficiency, the only cash revenue stream) through commercialization of CO_2 reductions associated with the project (see Figure 8.33). Despite early criticism, the volume of energy efficiency projects[13] constituted 44% of all projects in the CDM pipeline in 2007, compared to only 1% in 2005. Still, industrial energy efficiency projects represent a very tiny share of the market both in terms of size and volume (see Table 8.29).

Why is the carbon market slow to deliver the expected boost for investment in industrial energy efficiency? There are a number of barriers: first and foremost, industrial energy efficiency projects are less cost-effective than other alternatives for GHG mitigation. Average CO_2 abatement costs for industrial energy efficiency amount to €22/Certified Emissions Reduction (CER), while current prices for CDM in various market segments are between €10/CER and €20/CER (PointCarbon, 2008). In addition, projects are normally small, while transaction costs of structuring CDM projects are high (especially if new monitoring methodology needs to be designed), which prohibits their wide-scale application.

13 Including both energy-efficient supply- and demand-side measures in all economic sectors.

Table 8.29 | Industrial energy efficiency projects in the clean development mechanism pipeline.

CDM projects in the pipe-line	Projects, number (%)	kCERs till 2012 (%)
Cement	36 (1)	35,484 (1)
EE in industry	159 (5)	30,868 (1)
TOTAL	*3498 (100)*	*2,639,741 (100)*

Source: UNEP Risø, 2008.

In the post-2012 (post-Kyoto) scenario there are several carbon finance schemes to help carbon trading at the national and international level. For example, the European Investment Bank (EIB) has a Multilateral Carbon Credit Fund in Europe and Central Asia; the EIB/KfW Carbon Purchase Program to help SMEs to comply with the EU's emissions trading schemes, the WB-EIB Carbon Fund for Europe, and the Fonds Carbone Capital Maroc (in French-speaking Africa) (Garcia and Roberts, 2008), with a total fund in these programs of more than €600 million.

Global carbon markets were worth about €40 billion in 2007 (PointCarbon, 2008), with the EU emissions trading scheme contributing to a trading volume of 1.6 $GtCO_2$-eq of carbon and a value of €28 billion, while the CDM market saw a volume of 0.95 $GtCO_2$-eq and a value of €12 billion.

Energy efficiency financing is a largely "invisible" market that represents a tiny share of global investment flows to the industrial sector but mirrors its structure. To move to a sustainable energy pathway, investment flows need to shift from west to east (from OECD countries to the developing world) and from the supply to the demand side. Projected increases in investment flows will be offset by decreased needs on the supply side (due to decreased energy demand compared to BAU). Given the variety and magnitude of risks facing industrial energy efficiency investment projects in developing countries, more attention needs to be paid to creating an enabling policy framework and support mechanisms to reduce these risks.

8.8.5 Technological development, R&D, and Technology Transfer

The thermodynamic analysis clearly reveals that industrial energy systems have relatively low exergetic efficiencies and significant potential for improvement. R&D can help in designing more efficient processes and utility systems. Most national energy efficiency programs focus on identifying and replicating "best practices." This is important from an implementation perspective, as it will result in significant energy savings in the short term. In addition to this, there should also be a focus on the evolution of "next practices" or future generation equipment and processes resulting in drastic reductions in energy use. A combined strategy that combines moving from existing processes to best practices and also invests in R&D to evolve next practices is desirable. This will combine medium- and long-term energy efficiency needs.

The major portion of industrial energy use is accounted for by the production of a few energy-intensive materials. Demand for these materials in developed countries has become saturated, and the growth in consumption is mainly in developing countries. Developing countries such as China and India account for the largest share of these materials. If future capacity is to be more energy efficient, it is important that developing countries have access to these technologies.

In process plants, the energy use targets depend on local conditions such as ambient temperatures, raw materials, and scale. It is essential to develop the capability for R&D in developing countries for benchmarking and setting ambitious energy efficiency targets. Innovation in energy-efficient equipment or processes needs a critical amount of R&D funding. Most of the intellectual property and new technology know-how is available in the private sector, predominantly in developed countries. In the United States, the EU, and Japan there have been government-funded R&D programs to support industrial innovation to develop energy-efficient and clean technology.

Many countries have bilateral grant and assistance programs in the area of clean technologies. However, these are usually tied to the promotion or licensing of technologies developed by the donor country. For example, the Japanese Green Assistance plan resulted in the transfer of dry coke quenching technology from Japan to China. However, the technology was not to be adapted or indigenized by Chinese industry for a period of ten years.

Privately funded research initiatives usually have a short-term focus. Long-term initiatives for new materials, equipment, and process design need to involve researchers at universities. The evolution of road maps for the development of energy-efficient technology needs strategic partnerships between competing industries and academic and research organizations.

The challenge is to develop mechanisms to provide access to new technologies and build R&D capacity in the developing countries where the majority of the future industrial energy growth is likely to occur.

8.8.5.1 Dematerialization, Substitution and Eco Design

As material usage saturates, it is expected that there will be trends towards dematerialization. It is also expected that energy-intensive materials will be substituted by less energy-intensive materials. Table 8.30 shows an example of materials substitution in automobiles in the United States. The weight of the car decreased from 1663 kg in 1997 to 1524 kg in 2003 (8.4% dematerialization). The shares of aluminum, plastics, and composites have increased, while the share of conventional steel has decreased.

Table 8.30 | Examples of weights of materials used in cars.

Material	1977		1987		2003	
	kg	%	kg	%	kg	%
Conventional steel	904.9	54.4%	661.8	45.9%	614.6	40.3%
High-strength steel	56.7	3.4%	103.4	7.2%	171.9	11.3%
Stainless steel	11.8	0.7%	14.5	1.0%	25.6	1.7%

Source: American Metal Market, 2003.

There are no aggregate estimates of the impacts of dematerialization and substitution on the energy required in the industrial sector. An analysis of buildings and selected industrial products would be useful to understand the potential for dematerialization and substitution.

A study by Fraunhofer and Eichammer (2010) shows that industrial energy use in Germany could be reduced by 13% through material efficiency. Germany has set up an agency for material efficiency[14] that document several case studies of targeted and achieved improvements in material and energy efficiency in German industry. Case studies include the use of structured composites, nano-coatings in automobile components, and biogenic raw materials.

The eco design process in the EU was mandated by a directive of the European Parliament in October 2009. This establishes a framework for setting eco design requirements for energy-related products. The commission supports life cycle thinking and has currently included more than 30 energy-using product categories with an eco-design regulation[15] that sets minimum energy efficiency requirements and environmental performance norms based on a life cycle approach. The systematic information dissemination mechanism followed for the introduction of eco design can be extended to other countries and regions and for other industrial products.

14 See www.demea.de.

15 See www.inforse.org/europe/eu_Ecodesign.htm#Products.

8.8.6 Capacity-building for Energy Efficiency

Energy systems and institutions are supply focused. The dominant principle is increased affluence, which requires increased consumption and, therefore, production of materials and products. The industrial system projects new manufacturing capacity and new utility systems to cater to increasing future demand. This results in an increasing amount of fuel and electricity used.

To level the playing field for energy efficiency, a paradigm shift is required with the focus on energy services – not on energy supply *per se*. This requires a re-orientation of energy supply, distribution companies, and energy equipment manufacturing companies.

What are the skills required to identify and implement the energy efficiency potential in industry? It is important to promote a systems approach and thinking. Motors, steam systems, cogeneration, and process integration need systems analysis capabilities. The US approach to developing systems assessment training modules is a replicable model. Several countries have evolved mechanisms for training and certification of energy auditors and energy managers (e.g., India's BEE has set up a syllabus, examination, and certification for energy auditors and managers). The development of ESCOs is also important for the success of industrial energy efficiency. ESCOs should be able to provide a complete energy efficiency solution to industry and should be able to take on the performance and financing risks of energy efficiency projects. ESCOs have not taken off in many markets. Most of the future growth in industry is expected in developing countries, which lack capital. Monitoring

and verification of savings for performance contracting also needs independent assessment, measurement, uncertainty analysis, quantification of effect of production changes and product mix, and clearly enforceable contracts for benefit-sharing.

Many countries have developed energy efficiency cells in regions or provinces (e.g., China has more than 400 energy management cells in provinces). These cells need access to information, training, research results, and support to plan their audits and energy management plans.

Regulators and government officials who deal with energy supply sectors and energy planning for the future need to be trained to integrate DSM and energy efficiency into the future supply mix.

There needs to be training for industry personnel at different levels. Short (half-day or one-day) workshops for top management (Chief Executive Officers and other key decision-makers) should ensure that energy efficiency and sustainability receive the necessary attention in the boardroom. Hands-on training modules need to be developed for technicians to inculcate the necessary skills for efficient operating and maintenance practices (steam trap maintenance, leakage reduction in compressed air systems, etc.) and retrofitting for energy efficiency. Plant engineers and managers should be familiarized with life cycle costing and sustainability analysis.

Planning for next-generation processes and systems needs the development of a long-term research agenda and strategic collaborations between industry, academic and research institutions, and governments.

International best case studies of new energy-efficient technologies and systems should be publicized and made available for industry. Searchable databases with information on plant-specific measures should be provided with translations into major languages.

8.8.7 Implementation Strategies

Investments in energy efficiency of even 1.6% of the present global fixed capital investment annually up to 2020 would provide an annual average return of 17%/yr. Investments of US$170 billion would result in US$900 billion a year in energy cost savings in 2020 (Farrell and Remes, 2008; UN Energy, 2010).

Country examples illustrate the importance of national energy efficiency action plans. Proprietary energy-efficient technologies and policies should be identified and methods to facilitate their access and deployment in developing countries should be supported. Capacity-building and information dissemination needs to be strengthened. Adoption of global ISO energy efficiency standards should be encouraged.

Policies need to address and overcome multiple barriers that exist at different levels. (Brunner et al. 2009) present an analysis of barriers to business at the sector level, to manufacturers at the original equipment manufacturer level, and regarding wholesale planning, engineering, investment and energy management for electric motors. Figure 8.36 shows an approach to having multiple policy instruments in different parts of the product life cycle for electric motors. The adoption of life cycle costing would be an important step in promoting industrial energy efficiency, as the annual energy cost predominates in the life cycle cost for most energy utilization equipment in industry (motors, boilers, furnaces) but gets hidden in the conventional simple payback period analysis.

A locally organized energy efficiency network was created in Switzerland in the 1990s (Jochem and Gruber, 2007). This was facilitated by a stimulus from the Swiss Energy Agency for Industry to exempt participating industries from a fossil fuel surcharge of CHF 25/tCO_2. Participating companies agree to reduce energy-related CO_2 emissions to a negotiated target and undergo yearly evaluations.

The Swiss experience was replicated by an energy efficiency learning network in Baden-Württemberg in Germany in 2002 with 17 companies. The total energy use of the companies was 731 TJ in 2001. Participants agreed to 7% energy savings and 8% CO_2 emission reductions within four years (by 2005). Figure 8.37 shows the target and achievements of the companies (Jochem and Gruber, 2007). Encouraging the establishment of learning networks locally in different countries can help to facilitate sharing of experiences, increasing industrial energy efficiency, and setting group wide voluntary targets. National emissions trading schemes may provide a mechanism for funding and incentivizing industrial energy efficiency.

8.9 World Industrial Energy Projections up to 2030

8.9.1 Business-as-usual Scenario

Industrial energy use depends on the output of the industry sector. The Manufacturing Value Added (MVA) is used as a proxy to measure this output. The MVA for industry is disaggregated into developing and developed countries. The average annual growth rate in MVA of developing countries during 2000 to 2005 was 6.1%, and an average growth rate of 6%/yr was used to project the MVA in 2030. Zero growth rate in MVA has been assumed for industrialized countries (i.e., saturation).[16]

Energy intensity is the industrial energy use per unit of MVA. It is seen that in the past ten years the energy intensity value declined at a rate of 1.6%/yr. An annual decline of 1% in energy intensity is assumed as the BAU trend till 2030. Based on these assumptions, the industrial energy demand of the world in the BAU case is 175 EJ for 2030, as shown in Table 8.31.

16 The MVA values have been taken from the UNIDOdatabase (UNIDO Database, 2011) and the industrial energy consumption values from the IEA database (IEA Database, 2011).

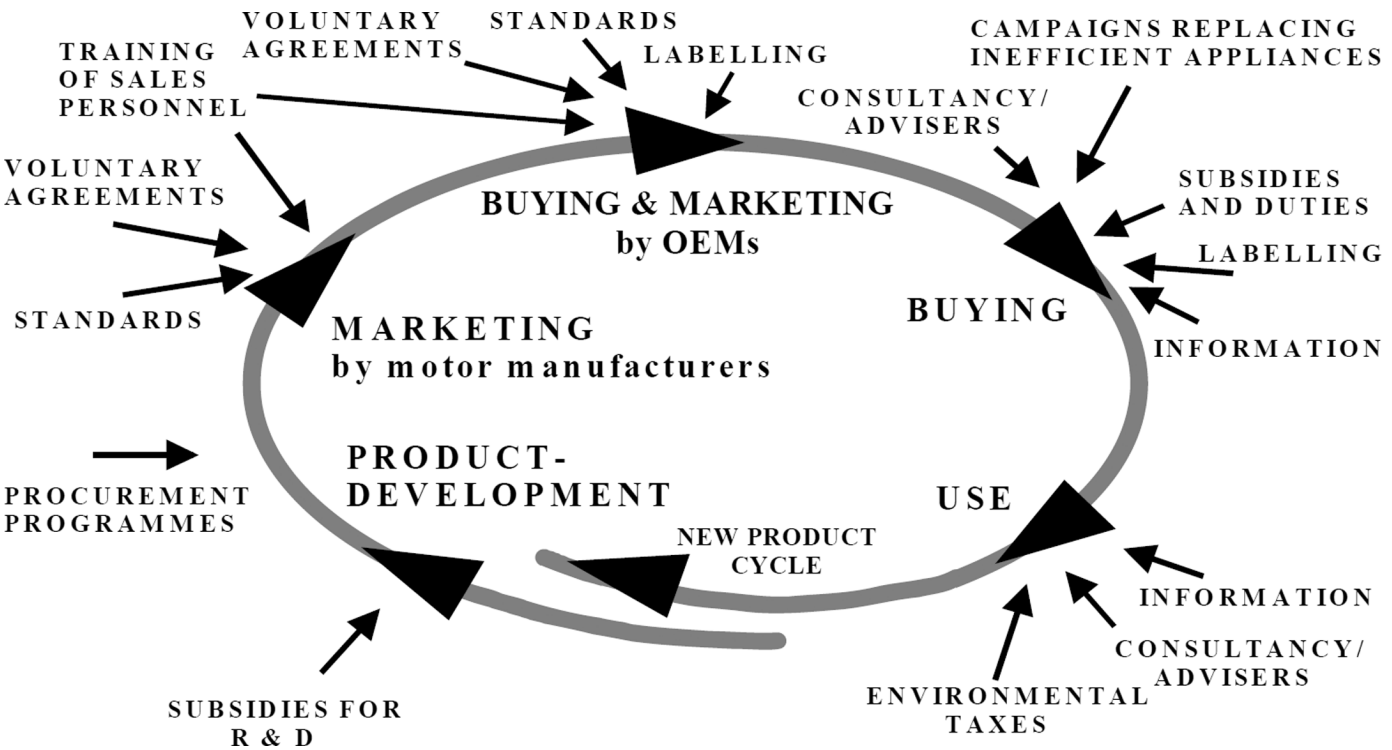

Figure 8.36 | Obstacles influencing the diffusion of highly efficient electrical motors. Source: IEA, 2011. ©OECD/International Energy Agency 2011.

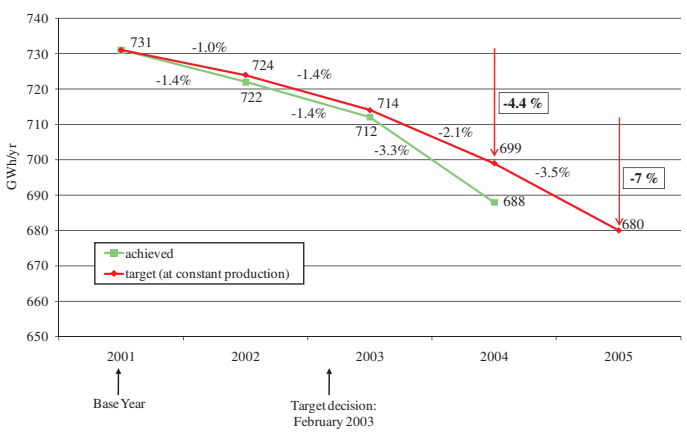

Figure 8.37 | Joint energy efficiency target path of 17 companies of the efficiency table and achieved energy savings (temperature adjusted). Source: Jochem and Gruber, 2007.

The country estimates are obtained from national plans and included for comparison. The forecasts for 2030 for the world are given in Table 8.32.

Predicted industrial final energy use and its share of total energy demand for selected countries in 2030, according to government estimates, are summarized in Table 8.33.

Material production growth estimates for 2030 by country, according to the countries' official projections, are listed in Table 8.34. The selected industries presently account for about 40% of the world's energy use.

The specific energy consumptions for the countries are projected up to 2030. The data are given in Table 8.35, based on government estimates.

The CO_2 emission projections for 2030 for the world are given in Table 8.36. The figures for 2030 are based on the assumption of no improvement in specific energy consumption and the same fuel mix for material production.

8.9.2 Energy-efficient Scenario

The exergy analysis shown earlier reveals that industrial processes are not near the thermodynamic limits and significant potential for improvements exist. The exergy efficiency of 30% reveals the potential for further process improvements. Based on this potential in 2030 it is assumed that there is a 40% reduction in the energy intensity for the new stock with respect to the existing frozen efficiency (exergy efficiency of 50% for the new processes).

To compute the energy-efficient scenario, we differentiate between new stock (NS) and existing stock in 2005 (ES_{2005}). Of the existing stock in 2005, some fraction (f) will be retired or replaced. We consider a fraction

Table 8.31 | Basis for industrial energy demand in the BAU scenario.

World	20.6	17.6	–1.6%	–1%	13.7
Industrial Final Energy in 2030 (EJ)	175				

Note: CAGR- Compound Annual Growth Rate

Source: Based on UNIDO Database, 2011; IEA Database, 2011.

Table 8.33 | Projected final energy use by country up to 2030.

		US	China	India	Brazil	SA	World
Final Energy use by Industry1 (EJ)	2005	16.6	24.6	5.7	2.9	1.23	115
	2030 (B)	12.6	66.8	30.6	8.1	3.38	175
Industry % of Total Final Energy demand	2005	34%	51%	34%	45%	42%	30%
	2030 (B)	32%	54%	40%	38%	–	–

1 includes feedstocks (non-energy use), see Chapter 1, Section 1.2.2.

Source: Digest of South African Energy Statistics, 2006; Brazil Ministry of Mines and Energy, 2007; IEA, 2008a; TERI, 2008; China Government Estimates, 2011.

of 20% as the retirement rate up to 2030 (approximately 1%/yr). The output in 2030 (MVA_{2030}) would be from both existing equipment and new equipment, thus:

$$MVA_{2030} = MVA(ES_{2005}) * f + MVA(NS) \quad (3)$$

Hence the existing industries (from 2005) account for US$5229 billion of MVA in 2030. The remaining MVA of US$7537 billion is produced from new stock.

Table 8.37 shows the details of the frozen efficiency scenario, BAU scenario and the energy-efficient scenario. The frozen efficiency scenario is computed assuming that the same energy intensity (17.6 MJ/US$) will continue in 2030. This results in a total final energy use for industry in 2030 of 225 EJ. For the existing surviving industry we compute the potential for energy efficiency in motor drive systems, steam systems, process improvements in energy-intensive industries and SMEs, and pinch and process integration. The basis and numbers are shown in Table 8.37. A total saving of 37 EJ is possible from the existing surviving industry. For the new industry an energy intensity improvement of 40% over the existing frozen efficiency scenario is assumed (corresponding to an energy intensity of 10.6 MJ/$). This includes process improvements, pinch and process integration, and efficiency in motors and steam systems. A saving of 53 EJ in the new stock is possible compared to the frozen efficiency scenario. This results in a total final energy use of 135 EJ in the energy-efficient scenario.

Table 8.34 | Material consumption growth rates country-wise until 2030.

Table 8.36 | World industrial CO_2 emission quantities.

Industry (Million Tonnes of CO_2)	2005	2030
Iron and steel	1992	3598
Non-metallic minerals	1770	3287
Paper, pulp and print	189	262
Non-ferrous metals	110	189
Industry total – direct and process CO2 emissions	6660	12,031
Industry total – direct and indirect CO2 emissions	9860	17,812

Source: IEA, 2008a.

If industrial output were to increase by 95% of its 2005 value in 2030, in the frozen efficiency scenario this would require an input of 225 EJ of final energy input. In the BAU scenario, due to normal efficiency improvements, the final energy input required is 175 EJ. Hence industry would require 60 EJ in 2030 more than current consumption. Under the energy-efficient scenario an additional 40 EJ can be obtained through energy efficiency. Hence it is possible to target 95% growth in industrial output by 2030 (in MVA terms) with only a 17% growth in final energy input. Figure 8.38 shows the existing, frozen efficiency, and BAU scenarios and the savings in 2030.

Total direct and indirect CO_2 emissions from the industrial sector in 2005 were about 9.9 Gt (IEA, 2008a). Assuming the same carbon intensities for the industrial sector, under the BAU scenario total CO_2 emissions would increase to 17.8 Gt, and under the energy-efficient scenario to 11.6 Gt, in 2030. It is possible to stabilize the CO_2 emissions from the industry sector at 2005 numbers by a combination of the energy-efficient scenario and an increase in the share of renewables in the industrial mix. Renewables currently account for 9% of the total or about 10 EJ of final energy supply. This needs to be increased to about 32 EJ in 2030 to account for 23% of the final energy supply to the industrial sector. This would imply a compound annual growth rate of 4.8%/yr.

Table 8.37 | Industrial energy demand estimates for 2030 in the EE scenario.

World		2005	Fraction retirement 2030 (f)	2030 (FE)	2030 (BAU)
MVA (billion US$2000)		6536.6	20%	12,766	12,766
EI (MJ/$)		17.6	-	17.6	13.7
Energy (EJ)[1]		115	-	225	175
MVA (2005 surviving in 2030)		5229	US$ billions		
MVA (New Stock)		7537	US$ billions		
Energy-Efficient Scenario (EE)					
Energy required by existing surviving stock (in FE in 2030)				92 EJ	
End-uses		**Share**	**Potential Savings**	**EJ**	
A.	Motor systems	15%	20%	2.8	
B.	Steam systems	38%	20%	7.0	
C.	Process improvements in energy-intensive industries	66%	9%	5.5	
D.	Process improvements in SMEs	34%	10%	3.1	
Total Savings (A+B+C+D)				18.3	
Energy use in existing stock after A+B+C+D				73.7	
E.	Saving through pinch	100%	25%	18.4	
F. Total savings in existing stock (A to E)				37	
New Stock energy consumption				133	
G. Reduction in New Stock vs. FE scenario (EI – 10.6 MJ/US$)			40%	53	
Total savings obtained				90	
Energy required in EE scenario				135	

1 includes feedstocks (non-energy use), see Chapter 1, Section 1.2.2.

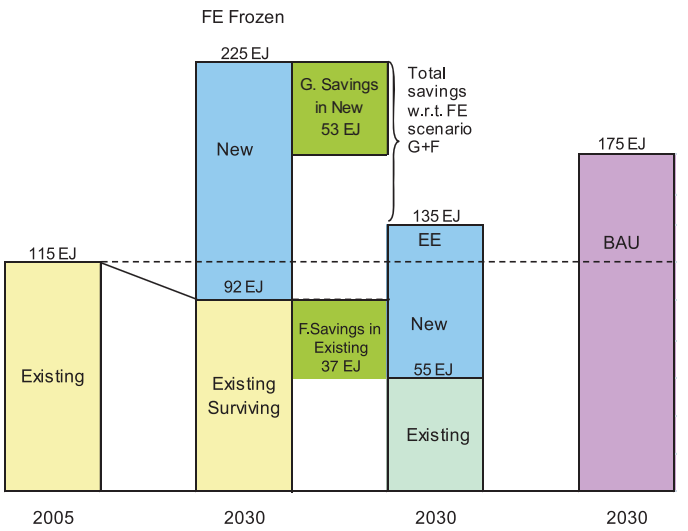

Figure 8.38 | Existing, frozen efficiency and BAU scenarios and the savings in 2030. Note: Final energy data includes feedstocks (non-energy use), see Chapter 1, Section 1.2.2.

- An energy-efficient scenario is possible which results in the required industrial growth till 2030 (95% increase over 2005 values) with only a 17% increase in the final energy required.
- If the energy-efficient scenario is coupled with a growth in the use of renewables for industry, it is possible to meet the growth in industrial output without any increase in the total CO_2emissions of the industrial sector in 2030.
- Most of the growth will occur in developing countries. At present, developing countries account for 29% of industrial output; in 2030 they will account for 64%. Most investments in future industrial production capacities are likely to be in developing countries.
- Several interventions will be required if the energy-efficient scenario or the zero CO_2 growth scenario for industry are to be achieved, and the following interventions are suggested:

8.10 Conclusions and Recommendations

The key messages emerging from the analysis of end-use efficiency for the industrial sector are:

I. Realizing the potential for energy efficiency in existing industry:

(a) Incentivize DSM: regulatory commissions can provide incentives for motor efficiency programs and process improvements.

(b) Information gaps to be reduced: promote sharing and documentation of best practices.

(c) Develop capacity for system assessment: motors, steam, pinch, process. Recent efforts by ASME to develop System Assessment Standards for motors and steam systems in the US need to be extended to other regions of the world.

(d) Provide access to low-interest finance: investments in energy efficiency compete with investments in process improvements and enhancements in plant capacity. Separate credit lines should be provided especially for funding industrial energy efficiency in developing countries.

(e) Special efforts to focus on industry clusters of SMEs – for example, steel rolling, brick making: SMEs normally do not have the engineering capability to design and implement energy efficiency programs. Interventions that facilitate building this capability would be useful. Training workshops and energy efficiency manuals should be developed and tailor-made for different industry clusters. Sharing of best practices across industry groups is likely to result in new ideas for efficiency improvements. Multilateral agencies such as UNIDO can help facilitate this by creating regional information centers and funding dissemination workshops.

(f) National Energy Conservation Funds: governments should be encouraged to create National Energy Conservation Funds. These could be provided by a tax on all new supply (power plants, refineries). Funds should be used to provide a level playing field for energy efficiency vis-à-vis new supply.

(g) Energy management standard: industry should be encouraged to adopt the new ISO energy management standard.

(h) Benchmarking efforts: initiatives from industry organizations, such as Cement Sustainability Initiative (CSI) for cement, World Steel Association for steel, and IAI for aluminum, to draw up road maps and benchmarks for industry need to be encouraged.

(i) Risk guarantee and venture capital: there should be a mechanism to encourage commercial banks to invest in energy efficiency projects in industry. This could be in the form of guarantees for risk or special funding for venture capital.

II. New industry – Most of the new industrial growth will occur in developing countries. Under the BAU scenario, a mix of technologies would be installed with varying specific energy consumption. It is suggested that regional centers for industrial energy efficiency be set up to disseminate information related to specific energy consumption and best available technologies for different processes. There should be a (web-based) facility where any industry that is being proposed can compare its designed energy performance with the best available technologies. Consultants can be provided to undertake energy integration and efficiency improvement studies at the design stage itself. An incentive scheme should provide funding for energy performance analysis at the design stage. Financing of the incremental costs of energy-efficient technologies should be provided as low-interest loans through commercial banks.

III. Dematerialization and substitution – To encourage studies and analysis for new products, it is proposed that design challenges be announced for some important products that may result in reduced usage of material and an overall reduction of energy-intensive materials. The potential for substitution and dematerialization needs to be studied in different sectors and end-uses.

IV. Next-generation processes and technologies – Most of the energy-intensive materials produced by industry have not reached their limits for efficiency improvements. To move from the best available technologies to next-generation technologies, it is essential to facilitate R&D in new processes. Industry groups such as CSI, World Steel Association, and IAI can play a role in bringing together industry and researchers to facilitate this. Pre-competitive consortia of industries and research institutions should be facilitated by funding from government and multilateral agencies. The funding for R&D for energy-efficient processes is sub-critical and needs to be enhanced. Financing of next-generation technologies may occur from national emissions trading schemes.

V. Increased use of renewables in industry – Funding should be available for demonstration and pilot projects for innovative applications of renewables in industry. Biomass- and solar-based process heating, cogeneration, cooling and power-generation applications need to be designed, implemented, and assessed for different industrial applications. Dissemination of information related to renewable case studies in industry should be facilitated internationally. Focused attempts to bring down the costs of renewable systems would imply setting up initiatives for technology development and consortium approaches.

Acknowledgements

Executive Summary

The world's demand of fuels for transportation has multiplied over the last decades due to the concurrent fast expansion of population, urbanization, and global mobility. The global transport sector is responsible for 28% of total final energy demand. The majority of the energy used in transportation – 70% – is utilized on the movement of passengers and goods on roads locally, nationally, and across regions. Transportation weighs heavily on climate, energy security, and environmental considerations, as 95% of transport energy comes from oil-based fuels. Transportation is the cause of other critical challenges due to its supporting role in local and global economies, as well as the implications of increasing transportation on human health and social interactions. The immense and multi-faceted challenges of a global transportation system deeply rooted in fossil fuels are compounded by the quickly evolving aspirations of a worldwide population that is increasingly on the move and has learned to regard mobility, in particular by motorized modes, as an important component of the modern lifestyle they have or are seeking to attain.

This chapter evaluates the roots of these challenges and outlines the options for a feasible major transformation of the global transportation system over the next 30–40 years. The goal of this transformation is the development of a robust path for the consolidation of transportation systems around the world that can deliver the mobility services needed to support growing economic and social activity while also creating the conditions for enhanced energy security, rigorous climate change mitigation, improved human health, better environment, and urban and social sustainability. This approach is in line with the GEA normative understanding of the consensus embodied in international negotiated agreements and plans of action, and in the more generally accepted aspirations of the international community. The goals of transforming transportation presented in this chapter cut across technical, planning, and policy issues of interest to public and private sector stakeholders and decision makers. A summary of key findings from the assessment are:

- The transformation of transportation systems locally and globally must start now. Time is of the essence. Immediate steps must be taken to define a multi-goal, multi-level, and multi-actor framework of action to identify context-specific "levers of change," or areas that are subject to policy intervention and can help sustain a positive rate of change for this transformation. Achieving multiple goals is possible, as transportation impacts all other areas in society. This will require strengthening institutional capacity and the consolidation of knowledge-based decision support systems to inform policy and decision making about impacts, cost, benefits, and potential trade-offs. The strengthening of institutional capacity will be necessary to deal with solutions that require merging concepts to improve energy and transport systems interaction, technology, urban and regional spatial planning, infrastructure development, and economic and social innovation.

- To remain consistent with the GEA multiple objectives, the transformation of the transport sector, requires that oil products peak before 2030 and are phased out over the long term. This is made possible in the medium term by adopting a policy mix to minimize fossil fuel use in transport, as well as rapidly introducing alternative sources such as renewable-based electricity transportation technologies. Technological choice and lifestyle changes in the long term are more uncertain and depend critically on the nature and direction of technological breakthroughs, but they must be made with the intention of complementing policies and in consideration of future climate impacts.

- Transportation goals for reducing fossil fuel consumption need to be pursued while simultaneously increasing and maintaining the provision of satisfactory economical and social levels of transportation services. Technological improvement is vital, but it is equally important to secure a timely and uninterrupted policy and decision making framework for action. This policy framework is necessary to establish clear conditions so that investments can be planned. Similarly, this framework should also provide context-specific feasibility information to assess local opportunities for creating a sustainable interaction between the transport and energy systems. The framework must also adequately assess conditions for the provision of a diversified set of choices and intelligent mobility services that can improve the efficiency of the transportation network for passengers and goods within all cities and regions.

- The many chances available today for improving conventional technologies require sustained attention. Enhancing the energy efficiency of all modes of transportation can help reduce transport fossil fuel use. Increasing efficiency can be effectively and immediately pursued through widespread adoption of current best available technologies and practices. In the longer term, this can be achieved through the subsequent systematic and comprehensive adoption of a range of new vehicle and other modal technologies. For example, introducing incremental efficiency technologies, improving drive train efficiency, and recapturing energy losses and reducing loads (e.g., weight, rolling, and air resistance and accessory loads) on the vehicle can approximately double the fuel efficiency of "new" light-duty vehicles by 2050. Fuel economy standards have been effective in reducing fuel consumption, and therefore should be tightened and adopted worldwide. The overall effectiveness and political feasibility of standards can be significantly enhanced if combined with fiscal incentives and consumer information. Taxes on vehicle purchase, registration, use, and motor fuels, in combination with the revamping of road and parking pricing policies, can influence vehicle energy use and emissions.

- The fuel efficiency of aviation can be improved by a variety of means, including technology, operation, and management of air traffic. Technology developments might offer a 40–50% improvement by 2050. As aviation's growth rate is projected to be the highest of the transport subsectors, such improvements will not be enough to keep energy use from increasing.

- In the maritime sector, a combination of technical measures could reduce total energy use by 4–20% in older ships and 5–30% in new ships by applying state-of-the-art knowledge, such as hull and propeller design and maintenance. Reducing the speed at which a ship operates brings significant benefits in terms of reduced energy use. For example, cutting a ship's speed from 26 to 23 knots can yield a 30% fuel saving. A similar rationale can be applied to aircraft. Improving the efficiency of aircraft on a global scale is essential.

- Reducing the use of fossil fuel energy in transport can potentially be achieved through the adoption of alternative energy sources such as advanced biofuels, fuel cells, and electric vehicles. Most of the barriers relate to cost, although there are also substantial performance barriers, especially for advanced batteries and infrastructure. Strong policies can ensure rapid uptake and full use of these technologies and will require encouraging sensible changes in lifestyle and behaviors. Life cycle assessment (LCA), together with social and environmental impact assessments, are useful tools to establish a level playing field comparison between different technologies. Significant uncertainties corresponding to modeling choice of system boundaries and modeling assumptions prohibit straightforward policy implications – especially in the case of biofuels. The future biomass potential strongly depends on production efficiency, the development of advanced techniques, costs, and competition with other uses of land. Current biofuels development needs to resolve its many sustainability challenges. Advanced biofuels are considered to have much greater potential for the future, not only for road transport but also for aviation and shipping.

- Electricity produced from renewable sources can provide a significant stronghold for the global transformation of the transportation system. Plug-in hybrid electric vehicles (PHEVs) allow for zero-tailpipe emissions for small vehicle driving ranges, e.g., in urban conditions. Hybrid electric vehicles (HEVs) can improve fuel economy by 7–50% compared to comparable conventional vehicles, depending on the precise technology used and driving conditions. All-electric or battery-powered electric vehicles (BEVs) can achieve a very high efficiency (up to four times the efficiency of an internal combustion engine vehicle) but have a low driving range and short battery life. If existing fuel-saving and hybrid technologies are deployed on a broad scale, significant fleet-average fuel savings can be obtained within the next decade. Increasing the performance of high-energy batteries for PHEVs could subsequently lead to higher market penetration of BEVs. Hydrogen fuel cell vehicles (FCVs) could alleviate the dependence on oil and reduce emissions significantly. For BEVs and FCVs, the emissions are determined by the production of hydrogen and electricity. Further technological advances and/or cost reductions would be required in fuel cells, hydrogen storage, hydrogen or electricity production with low- or zero-carbon emissions, and batteries. Substantial and sustained government supports are required to reduce costs further and to build up the required infrastructure.

- Reducing transport energy use can also be achieved by favoring those modes that are less energy-intensive, both for passenger and freight transport. Strong local and regional urban planning policies, practices, and implementation should aim to enhance the diversification and quality of public modes of transport. Spatial local plans aimed at reducing both the need for travel and the distances traveled can reduce energy demand and also improve the quality of urban life through improved accessibility, affordable mobility services, and improved traffic safety. In cities worldwide, a combination of push and pull measures and traffic demand management can induce a modal shift from cars to the more prevalent use of public transit and cycling, which has multiple benefits. In particular, use of non-motorized transportation (NMT) can improve the efficiency of the transport system and overall people's health. Parking policies and extensive car-sharing options can become key policies to reduce the use of private cars. Cities can be planned more compactly, with less urban sprawl and a greater mix of land uses and local markets. Neighborhood design and street layout can encourage walking and public transport access to schools, hospitals, shopping centers, and other places that attract people on a regular basis. Employers in many sectors can locate themselves strategically, with the goals of enhancing the job-housing balance for their employees and providing incentives for substituting non-essential work-related travel with information and communication technologies.

9.1 Introduction: Transportation and Energy – A Global Perspective

Broad accessibility to services, people, and goods is an essential and basic human need and a precondition to economic well-being in modern societies. The petroleum-fueled motor vehicle and the airplane are technologies that have presented opportunities for greatly increased mobility, flexibility and reduced travel times. Automobility, as a self-reproducing system, has created unprecedented flexibility and fostered profound changes in lifestyles and in the physical landscape of cities worldwide (Whitelegg, 1997; Urry, 2007). The enhanced potential for travel created by these transport innovations resulted in an unprecedented rate of growth of the volume of personal travel and the volume of goods moved (WBCSD, 2002; Schäfer et al., 2009; Sperling and Gordon, 2009).

At the close of the 20th century, the world witnessed both unprecedented urbanization in the developing world and the suburbanization of many cities in the developed world (for more, see Chapter 18). Motorized forms of mobility, particularly automobility, were favored as the principal means for personal and social accessibility in urban areas. Along with technological shifts and economic development, transport activities scaled up in distance and participants. This growth, and the reliance on individual motorized forms of urban transport, has resulted in many local social and environmental consequences, including congestion, air pollution, noise, olfactory and visual intrusion, disruption of ecosystems and landscapes, water and soil degradation, ozone depletion, social and urban fragmentation, road deaths and injuries, asthma, and obesity (Rothengatter, 2003; Whitelegg and Haq, 2003; Gilbert and Pearl, 2007, Schäfer et al., 2009).

The scale of growth in the movement of people and goods around the globe has been immense. But not all populations and geographic regions have participated evenly in the technological advances that facilitated this development. The average citizen in wealthy nations and urban areas can travel faster and further than ever before and overcome long distances in comfortable and reliable ways (van Wee et al., 2006). Conversely, average citizens in poor nations, living in areas with differentiated urban growth characterized by large differences in income levels and social disparities, face hurdles to meet their most basic transportation needs. These citizens witness an urban transport situation that, for the most part, is unbearable and only deteriorates over time (Newman and Kenworthy, 1999; Gwilliam, 2005; Tiwari, 2006, Figueroa, 2010).

The global expansion of mobility encompasses great innovations that have linked transportation and intelligent communications systems, transforming the way in which people organize their travel and communication considerably. The interplay of these systems has redefined the core of social interaction and urban life (Castells, 2001; Sheller and Urry, 2003; Castells 2004). The evolving transport mobility of the last century has converged into a dynamic system that includes new forms of virtual communications and is firmly rooted in a number of key components, including motorized modes and the automobile, aviation, rail, ships and oil industry, consumerist lifestyles, energy and environmental resource use, global procurement of oil, spatial and infrastructure planning, urban and street design, and societal values that embrace mobility as part of what constitutes high quality of life standards (Urry 2004; 2007).

As economies grow, transport activity continues to increase around the world. In many areas of the developing world where globalization is expanding, trade flows and personal incomes are rising, leading to an increased demand for enhanced personal mobility. Mobility of people and goods has significant global economic benefits. A prime example is global travel for tourism, which constitutes the largest industry in the world. It is worth US$6.5 trillion and directly and indirectly accounts for 8.7% of world employment and 10.3% of world gross domestic product (GDP) (Urry, 2007).

9.1.1 The GEA Approach to Transportation and Energy: Acting on Multiple Goals to Realize Multiple Benefits

An efficient transportation system is crucial for economic development and an asset for the growing integration of international markets. This assessment follows GEA's normative approach in highlighting the necessity of realizing certain concrete goals that reflect part of the shared aspirations of the international community. These goals are related to economic growth and equity, improved environmental health, climate change mitigation, and enhanced energy security (see Chapters 2–6, as well as Chapter 17, for more detailed definitions). This assessment asserts that a global transformation of the transportation and other energy-using systems can help meet the major GEA goals. A complementary relationship exists between these goals, as summarized in Table 9.1. Two premises follow this approach. First, to meet the larger objectives, multiple goals must be addressed simultaneously and effectively. Strong and immediate actions need to be initiated and sustained at different scales to effectively achieve a radical, global transformation of the transportation and energy systems. Secondly, as transportation is deeply linked to other sectors, actions undertaken to achieve one goal can have directly calculable, and also unintended, effects on the other goals (Goodwin, 2003). Multiple benefits can be calculated in reference to how policies that promote clean air, walking and biking can contribute to control obesity, limit chronic disease and reduce air pollution emissions including greenhouse gases (Alliance for Biking & Walking, 2010; Nazelle et al., 2011). Facilitating walking and biking creates benefits for improved accessibility and energy security. Consequently, extensive follow up assessments to policy implementation are necessary to adequately measure these ripple effects. A framework that clearly outlines the multiple goals and benefits of a sustainable transformation can offer a variety of options and policy leverages for major stakeholders, governmental or otherwise, to take direct and immediate action. The policies, actions and actors are context dependent, but the long-term goals and expectations for this transformation are then made clear.

Table 9.1 | GEA framework for sustainable transportation multiple goals and benefits.

GEA systemic goal for Transport	Multiple goals and benefits of sustainable transportation systems (a)	Indicative approach to assess progress toward goal
Economic Growth and Equity	Functionality, Efficiency	Reduced travel time, cost and uncertainty, secures operationality and resilience
	accessibility	ease of reaching opportunities throughout the urban area (jobs, shops, medical and social activities); reduced access time, travel cost, and trip uncertainty
	affordability	% of income used to pay for transport services (<20%)
	acceptability	public acceptability; participation in decision-making process
Health and Local Ecosystems Protection	road safety	reduction of traffic deaths and injuries
	universal access	access provided for the elderly, very young, and people with disabilities
	personal physical activity	increased public health benefits from more physical activity
	reduce air pollution	air pollution reduction and public health benefits of reduced air pollution
	reduce noise	noise reduction
Climate Change	reduce GHG	GHG mitigation
Energy Security	diversification of fuel sources	use of alternative fuels
	independence from fossil fuels	% reduction in use of fossil fuels

(a) The general GEA goals for the global energy system are here adapted in attention to the specific services and goals that transportation systems deliver.

This multi-goal, multi-benefit approach aligns with the early approach labeled as co-benefits or ancillary benefits in the literature. It requires that a transport system is not only devised with the aim of maximizing mobility, but is also concerned with reaching other goals simultaneously. The concept of co-benefits has been pushed mostly in combination with climate change mitigation goals (Krupnick et al., 2000; Aunan et al., 2004; Bollen et al., 2009, Nazelle et. al., 2011), and has been applied particularly to urban transport (Creutzig and He, 2009; Bongardt et al., 2010; Creutzig et al., 2011b; UNEP, 2011), serving as the foundation for the systematic assessment of future scenarios and policy instruments.

Climate change mitigation is an important driver of envisaged improvements to transport systems. Fortunately, appropriate policies can be designed such that actions to reduce greenhouse gas (GHG) emissions also deliver other environmental and social benefits (EEA, 2008a). In addition to climate change mitigation, sustainable transportation solutions must also consider the multiple goals listed in Table 9.1. This perspective is also presented in other studies (EEA, 2008a, EEA, 2008b; Creutzig and He, 2009; Bongardt et al., 2010). The multi-goal, multi benefit approach maintains that meeting the social needs of growing urban populations requires affordable transportation services that efficiently facilitate accessibility to work, study, and leisure activities, and suggests that this can be designed with attention to operational efficiency to support economic development, low-carbon, energy security and environmental goals and for improving social and healthy living.

9.1.2 Overview of Energy use in Transportation

The concurrent fast expansion of population, urbanization, and global mobility has multiplied the world's demand for fuels for transportation and city-wide energy services. As shown in Figure 9.1, energy use in the transport sector in 2007 was high, 28% of total final energy use.

During the last several decades, the energy use of transport sectors in both Organisation for Economic Co-operation and Development (OECD) and non-OECD countries have increased substantially, as shown in Figure 9.2. In developing countries, the increase in recent years has become more prominent due to rapid urbanization and motorization. And, although a major increase in energy use was caused by road

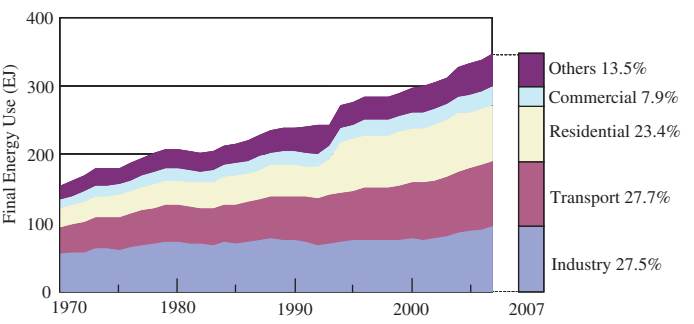

Figure 9.1 | Global energy use in various end-use sectors (others include agriculture/forestry, fishing, and non-energy use). Source: based on IEA, 2009b.

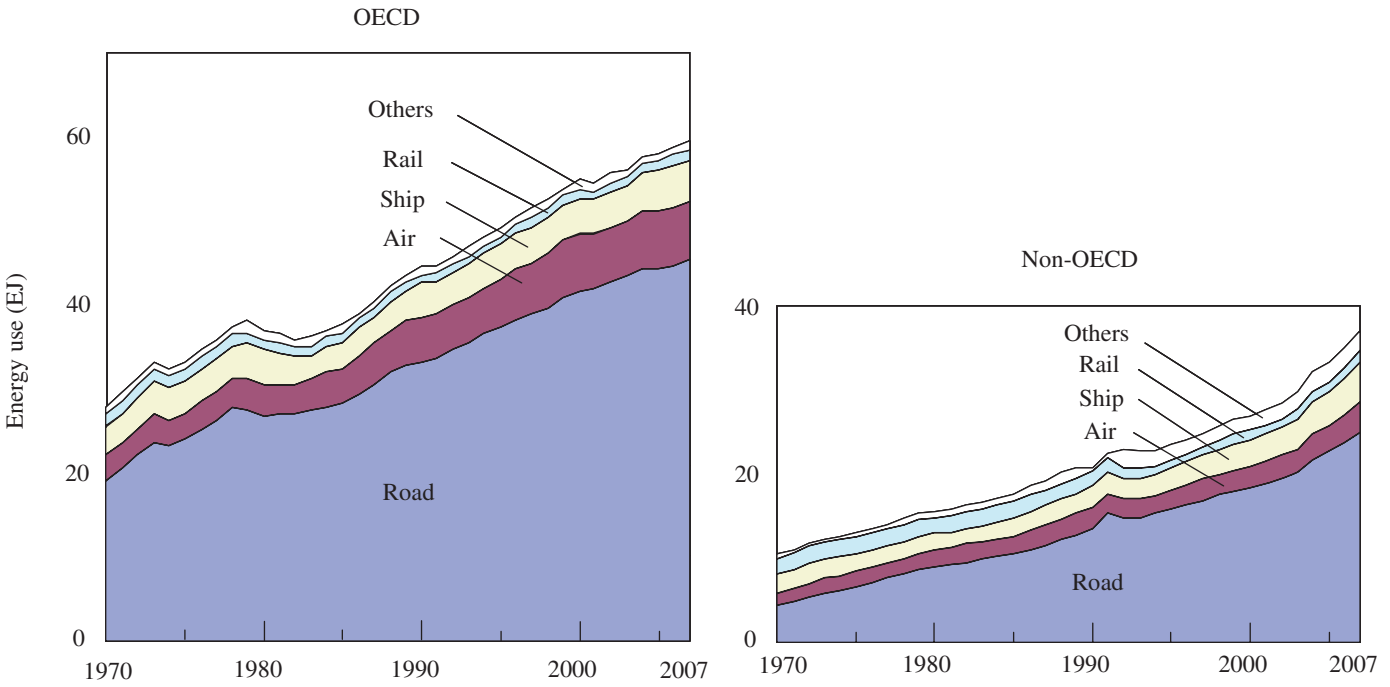

Figure 9.2 | Transport energy use in OECD and non-OECD countries by mode (others include pipeline and non-specified). Source: based on IEA, 2009b.

transport, the actual phenomenon of motorization is quite different between OECD and non-OECD countries. Non-OECD countries started later and still show motorization rates significantly below OECD countries. However, the speed of their concurrent urbanization and motorization is unrivalled, especially in China, and puts significant demands on adapting transport infrastructures.

A single fossil resource- petroleum- supplies 95% of the total energy used by world transport. This dependence results in two major areas of global concern: the long-term security of energy supplies and the fast-rising contribution of the transport sector to greenhouse gas (GHG) emissions (IEA 2009a; Stern, 2007). The carbon dioxide (CO_2) emissions and energy use of different transport sub-sectors are proportional (see Figure 9.3.).

The transport sector has the highest rate of growth in energy use and related CO_2 emissions of all final end-user sectors. This rate is expected to increase up to 1.7% a year between 2004 and 2030 (IEA 2009a).[1] In 2007, the global transport sector produced 6.6 $GtCO_2$ emissions, corresponding to 23% of world energy-related CO_2 emissions and, road transport, mostly passenger transport, accounts for 73% of this total.

A much higher rate of growth of 3.7%/year (between 1990–2003) corresponds to freight transport, this trend is expected to continue (see Figure 9.4) (McKinsey Global Institute, 2009).

1 Transport appears to be the highest energy-using sector in Figure 9.1 because the buildings sector is divided into residential and commercial.

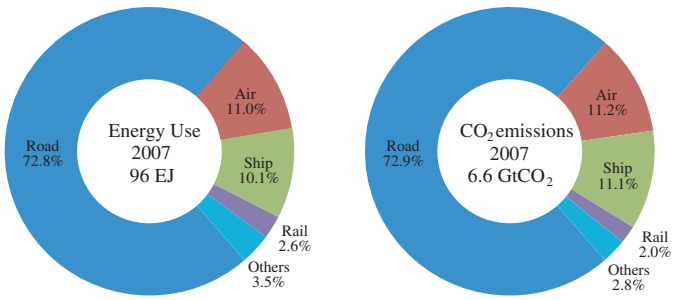

Figure 9.3 | Modal share of global energy use and CO_2 emission in transport sector (2007). Others include pipeline transport and non-specified use. Source: based on IEA, 2009a; 2009b.

Urbanization has been extremely rapid in the past 60 years, with a 2.6% annual average growth rate (UN, 2009). More than half of the world now lives in urban areas (UN, 2007; UN, 2008). In 2010, twenty one cities reported having a population over 10 million compared with two cities in 1950 (UNDP, 2010). Rapid growth in suburban areas and the rise of "edge cities" in the outer suburbs has been a common form of development facilitated by the rise of personalized motor transportation (see Chapter 18). The greater distances replicated through the low-density development discourage walking and bicycling as a share of total travel and are not easily served by public transport (WBCSD, 2002; 2009). A growing demand for travel and a declining share in the use and quality of public transportation services have been the observed result across developed and developing cities alike (Gwilliam, 2005; Tiwari, 2006, Hidalgo and Carrigan, 2010; Buehler and Pucher, 2011).

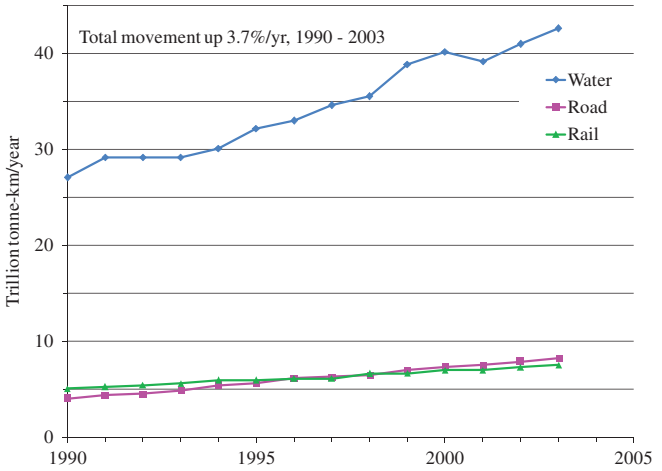

Figure 9.4 | Global freight movement in trillion tonne-km/year (t-km/yr). Source: Gilbert and Pearl, 2007.

The rapid motorization of many of the world cities has not been a global phenomenon. Many low-income urban areas in developing countries do not even have access to motorized public transport services of any sort (Tiwari, 2006; Vasconcellos, 2010). In developing country rural areas in sub-Saharan Africa, but also in parts of Asia and Latin America, walking more than 10 km/day each way to collect water or fuels, work on farms, and attend schools and health services is not unusual. Walking can be also prevalent for the urban poor, when commuting by public transport becomes very costly. For example, commuting accounts for 14% of the income of a poor family in Manila compared with 7% of the income of a higher income family in the same city (World Bank, 1996; Gwilliam, 2002).

The extent of global motorization explains only part of the increasing trends in energy use and carbon emissions from transport worldwide. Other contributing factors relate to consumer preferences for larger, heavier and more powerful passenger vehicles, particularly in the industrialized world, which have resulted in larger energy use for transport, despite the sustained technological improvement on car fuel efficiency attained on new passenger vehicles during the last decades. By 2008, more than half of all vehicles purchased in the United States were SUVs (sport utility vehicles) or light trucks. A weight reduction of the average car sold in the United States to European levels would bring about a 30% reduction in fuel intensity (Schipper, 2007). The average fuel economy of the new light-duty vehicle (LDV) fleet[2] in the United States in 2005 would have been 24% higher had the fleet remained at the weight and performance distribution it had in 1987 (Khan Ribeiro, et al., 2007). In addition a drop of fuel consumption rates of more than 1%/year would have resulted during that same period, contrary to the fast rate of increase that has continued until today. (Heavenrich, 2005; Sperling and Gordon, 2009).

Another contributing factor is the switch to relatively faster speed modes of travel, particularly motorized vehicles and air transportation, which has led to an increase in the total yearly distance travelled (Schäfer, 2000). The switch to faster speed modes has been facilitated by a considerable decline in the share of income spent in transportation during the last decades (Berri et al., 2010). Faster modes and larger transport infrastructural investments enabled the expansion of urban areas and the process of suburbanization, allowing people to maintain the average time budget for their daily travel roughly constant (van Wee et al., 2006). Simultaneously, increasing income allowed commuters to choose the more expensive modes, e.g., motorized vehicles. In developing countries, where income increases have been less significant, a relative decrease in car purchase cost in the early 1990s, and a relaxation of restrictions or even the imposition of minimal restrictions on imports of second-hand cars has sustained a progressive diffusion of motorized modes of transport (Berri et al., 2010). Countries with different land use and transportation policies, including fuel prices, have different rates of auto mobility per unit of GDP per capita (Millard-Ball and Schipper, 2011; see Figure 9.5). Vehicle use (km per capita) differ for example between the United States and Japan by a factor of about 3 (Shipper, 2009).

If these historic trends continue, there will be a vast worldwide expansion of motorization and a resulting increase in fossil fuel use and GHG emissions from transport. The local impacts of congestion, noise, air pollution, health, safety, and energy security are of immediate concern. Globally, climate change – the atmosphere's sink capacity – and limited resources pose huge inter-temporal challenges. However, as the least developed areas become economically mature and their populations' incomes rise, the evidence suggests that individuals will tend to favor private motorized vehicles. This is in part because these vehicles promise to provide a faster and more flexible, convenient, and reliable form of travel than the available local and intercity public transport, but it is also because the car's

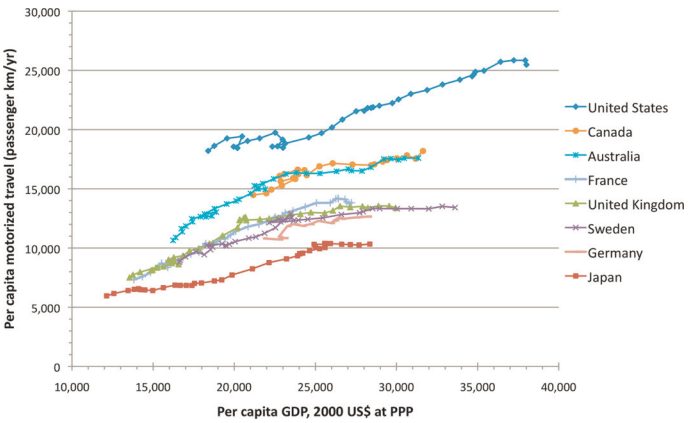

Figure 9.5 | Passenger motorized travel in some OECD countries. Passenger travel levels off with income. Developing countries, such as China and India (see Figure 9.8) start from low levels but are rapidly motorizing. Source: Millard-Ball and Schipper, 2011.

2 In the United States, fuel economy refers to the number of miles (distance) travelled/gallon of fuel (miles/gallon). The expected trend is for fuel economy to increase. In Europe, and elsewhere, the equivalent metric is the fuel intensity measured in liters of fuel used/100 km (liters/100 km); the expected trend is for the fuel intensity of the vehicle fleet to decrease over time.

attractiveness and seductiveness is deeply embodied in the culture and psychology of modernity (Whitelegg, 1997; Thomsen, et al., 2005; Urry, 2007). The car industry is strategically positioned in quickly emerging markets, notably in China and India, to tempt these new potential customers with simpler and affordable models (Sperling and Gordon, 2009).

In addition, the largely unregulated massive scale importation of used vehicles to developing countries, and the fact that these vehicles are kept running with great ingenuity for longer than the manufacturer's estimated lifetime, aggravates the energy requirements, local environmental problems, and carbon emissions contributions from the sector. Finally, a number of influential converging factors such as economic policies that maintain fuel subsidies and planning practices that incentivize suburban residential developments, large malls, and retail centers with extensive free parking all can play an important role in increasing motorization and energy use in transport.

The world auto fleet increased from about 50 million vehicles in 1950 to 580 million vehicles in 1997 (WBSCD, 2002). China's vehicle sales have already overtaken car sales in the United States by a huge margin increasing from 2.4 million in 2001 to around 17 million by 2010 (ADB, 2009). Two-wheeled scooters and motorcycles are important in the developing world and in parts of Europe. (WBSCD, 2002; Tiwari, 2006; Zegras and Gakenhaimer, 2006; ADB, 2009).

Non-motorized transportations (NMTs) are dominant in developing countries. Walking accounts for 20–40% of all trips in many cities (WBCSD, 2002), while bicycles are important means of transportation in Asia and also in industrialized cities like Amsterdam and Copenhagen. Research and data for walking and cycling pale in comparison to research on motorized transport (Methorst et al., 2010).

Public transportation, especially buses, though declining in share in favor of private cars in the industrialized world and some emerging economies, have a high modal share elsewhere. For example, it is estimated that buses make up 61% of the motorized trips in Santiago, Chile (Estache and Gómez-Lobo, 2005). The public transportation share in 2007 in 15 cities in Latin America is 43% of the total trips, and 60% of the motorized trips. Of total public transport, 15% is by rail, 52% in formal buses, and 33% in informal microbuses and jitneys[3] (CAF, 2010). Public transport in many developing cities is characterized by hundreds of separate bus companies. For instance, it is estimated there are 200 operators on average for a single minibus route in Lagos, Nigeria (Gwilliam, 2005).

Intercity and international travel is growing rapidly and is dominated by auto and air modes. In Europe, Japan and in China intercity passenger travel is combined with fast rail travel. Worldwide passenger air travel is growing by 5% annually, a faster rate of growth than any other travel mode (WBCSD, 2002).

3 Jitneys are vans or small buses that transport passengers on a route for a small fare, follow somewhat regular routes (but generally not on a published schedule), and often allow for ad hoc route deviations to accommodate passenger needs (Small and Verhoef, 2007).

Industrialization and globalization have also stimulated freight transport, which now uses 35% of all transport energy (WBCSD, 2004a). The truck-transport sector has a continuously high demand for petroleum, particularly diesel. Truck-transport accounted for 12.5% of global petroleum demand and 45% of global diesel demand in 2006 (McKinsey Global Institute, 2009). Freight transport is more conscious of energy efficiency considerations than passenger travel because of pressure on shippers to cut costs (Larsen and Peterson, 2009). However, the historic rapid growth of truck-transport energy use reflects in large part that the truck sector has limited efficiency improvements opportunities for diesel engines (McKinsey Global Institute, 2009). The increasing demand for fast, reliable, smaller, "just-in-time" and door-to-door shipments contributes to the rapid growth of energy use for freight transport. The result has been similar to the case of passenger vehicles in that, although the energy efficiency of specific modes has been increasing, the movement to the faster and more energy-intensive modes translates into faster rates of energy use. The opportunities for switching from truck to rail apply to only a small number of truck shipments (those involving sufficiently large volumes and long distances), which represent a small percentage of truck-transport volume; for example, this will be an option for only 4% of shipments in Europe (McKinsey Global Institute, 2009). Worldwide the trends show rail and domestic waterways' shares of total freight movement declining, and highways' shares increasing, while air freight, though remaining a small share, growing rapidly. Furthermore, environmental harm continues to increase as fuel efficiency improvements are offset by increased freight kilometers.

Freight transport can be summarized as follows:

- the majority of international freight transported worldwide comes from a few countries. In 2008, more than three-quarters of exported freight were from only 25 countries (US DOT, 2010);
- international freight is dominated by ocean shipping; the bulk of international freight is carried aboard extremely large ships carrying bulk dry cargo (e.g., iron ore), container freight, or fuel and chemicals (i.e., tankers);
- regional freight is dominated by large trucks, with bulk commodities carried by rail and pipelines, and some water transport;
- national or continental freight is carried by a combination of large trucks on higher speed roads, rail, and ship;
- urban freight is dominated by trucks of all sizes (Khan Ribeiro, et al, 2007); and
- from mid-2008 to mid-2009, as global economic activities slowed, goods transported worldwide by ocean carriers and airlines fell (US DOT, 2010).

Transporting freight around the world depends on geography, available infrastructure, and economic development. All modes participate

in the United States' freight transport system, which has the highest total traffic in the world. Russia's freight system is dominated by rail and pipelines. Europe's freight systems are dominated by trucking and shipping with a market share of 47% and 42% (in tonne-kilometers [t-km]), respectively, in European Union-27 countries, while rail's market share is only 11%, despite its extensive network (EC, 2008; EC, 2010). This rather small share of freight on rail in Europe is the result of priority given to passenger transport, divergent requirements for operability of urban rail systems, and market fragmentation between rival national rail systems, affecting the overall intermodality and a consolidation for rail freight in the European market (EC, 2008). China's freight system uses shipping as its largest carrier, with substantial contributions from rail (UNESCAP, 2004). Figure 9.6 shows the share of modes for passenger and freight.

9.2 Energy Use in Different Modes of Transportation

9.2.1 Road Transportation

From 1971 to 2007, global transport energy use rose steadily, with an average growth rate of 2.5%/year, which closely paralleled growth in economic activity around the world. The road transport sector (including both LDVs and trucks) used the most energy and grew most in absolute terms (IEA, 2009b).

For passengers, road transport represents the most important mode (see Figure 9.7). The sums of passenger kilometers (p-km) for two- and three-wheelers, cars, minibuses, and buses are much higher than other modes in every single region of the world. For freight, trucking used about 23% of total energy used by the transport sector in 2005. Data on surface freight movement in many countries is poor, but most freight transport moved by road and rail appears to be domestic rather than international. In the European Union, for example, available data for 2005 indicates that only around 30% of all road freight (in terms of tonne kilometers) crossed an international border. The corresponding figure for rail freight, which accounted for 19% of all surface freight in the same year, was 51%.

Travel surveys and fuel use statistics indicate that passenger car travel per capita is approaching saturation[4] levels in most OECD countries (Cresswell, 2006; Dennis and Urry, 2009; Millard-Ball and Schipper, 2011), and that distances traveled by each vehicle each year may be declining as the total number of vehicles on the road and levels of congestion increase. Car ownership rates have risen above one LDV for every two people on average in OECD countries, nearly 1.5 vehicles for every two people in the United States, and an increasing number

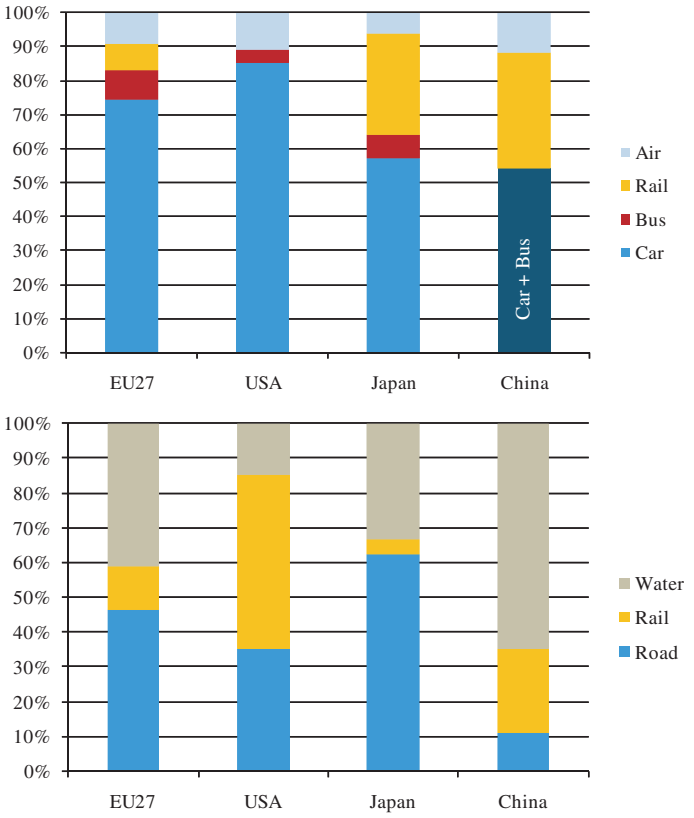

Figure 9.6 | Modal split of passenger (top) and freight transport (bottom; air freight transport not included) in terms of passenger-km (p-km) and t-km, respectively (2005). Source: based on EU, 2010.

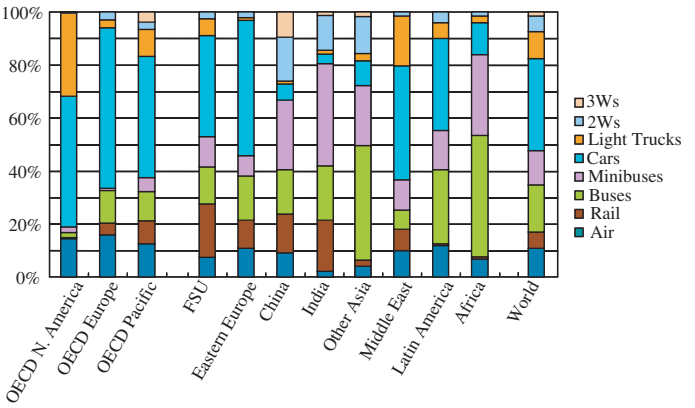

Figure 9.7 | Estimated motorized passenger travel split by mode (2005). Source: IEA, 2009c. ©OECD/International Energy Agency 2009.

4 Saturation here refers to several observed trends: a) a slow turnover and penetration of vehicles due to low population growth in OECD countries. An equivalent slow turnover in developing countries can be attributed to long vehicle life plus extensive market penetration of second-hand vehicles; b) little or no variation in the number of trips and the time people use for travel daily. The value across travel surveys in OECD countries over time has been remarkably stable – between 2, 7 and 3 trips per day. Similarly, the per capita "time budget" shows a stable trend at about one hour/day (Lyons and Urry, 2005; van Wee et al., 2006). Comparatively, in developing countries, time series travel survey statistics are lacking, but the reported values vary within a similar range from 2.2 trips/day (Padam and Singh, 2001) to 4.0 trips/day and an average time between 70–90 minutes/day (Hu and Reuscher, 2004); c) Finally, the average distance travelled/day/ person (work related) has also remained unchanged, around 10–60 km/day globally (see Chapter 18 for a similar discussion).

of households own two or more vehicles. This leads to a flattening of, or even a decrease in, the average distance travelled by each vehicle each year (IEA, 2009c). For long-distance travel, faster modes such as air travel are growing more rapidly than passenger car travel, accounting for the majority of the increase in total distance travelled per year (Axhausen et al., 2003).

There is a close, bidirectional interaction between urban transport, land use, and urban form (Gordon et al., 1989; Anas et al., 1998; Wegener and Fürst, 1999; Small and Verhoef, 2007). Cities of similar wealth often have very different levels of motorization, reflecting the effect of other factors such as urban form, design, and density on transportation modes (Næss, 2006; Merriman, 2009; for more see Chapter 18 on urbanization). Modal shares vary dramatically across cities. The share of trips by walking, cycling, and public transport is 50% or higher in most Asian, African, and Latin American cities, and even in Japan and Western Europe. The use of bicycles in cities like Amsterdam and Copenhagen demonstrate that coordination of land use and transport planning can be key to maintaining high levels of safe use of NMT (Beatley, 2000; Spinney 2009).

The prevalence of NMT in most developing country regions and in Eastern Europe is partially the result of low levels of economic growth and infrastructure investment. Data for Africa, Asia, and Latin America shows walking to be the major transport mode among the poorest city residents (World Bank, 1996; Gwilliam, 2002; Tiwari, 2006; Vasconcellos, 2010). Starting in the 1970s, Western Europe has made a conscious effort, to restrict urban sprawl and motorization, and to invest in improved NMT infrastructure (Banister, 2005).

Motorization does not necessarily imply the increase of passenger four-wheeled automobiles. Motorized two- and three-wheelers are among the most popular means of transport in Asian countries and are important elements of motorization in parts of Africa (Nagai et al., 2003). Most cities in India have a rate of private motor vehicle ownership similar to the wealthier cities of Latin America, where motorized four-wheeled vehicles are predominant. By this same account, cities like Kuala Lumpur and Bangkok are already exhibiting motorization levels close to those of Western European countries (ADB, 2006; see Figure 9.8).

The increase in the number of two- and three-wheeled vehicles in developing countries is much more accelerated as compared with the increase of four-wheeled vehicles (Gwilliam, 2003; Zegras and Gakenhaimer, 2006). Once individuals have gained mobility with a two- or three-wheeler motorized vehicle, it is likely that many will shift to four-wheeled vehicles when they attain higher levels of income. If this condition is fulfilled, it can be expected that the ownership and number of four-wheeled vehicles in developing countries, particularly in China and great parts of Asia, will increase dramatically (Nagai et al., 2003; Wang et al., 2006; ADB, 2009). Reasons cited by these authors for the motorcycle motorization phenomenon in many countries include lower capital and operating costs than automobiles coupled with lower levels of real purchasing power; superiority in time and door-to-door convenience relative to automobiles in congestion; and superiority to an often deteriorating public transport system. Despite their prevalence, rapid growth and safety considerations, until recently motorcycles have been ignored both in planning and infrastructure implementation, including traffic counts and pollution control efforts, but this is changing (see, i.e., the Clean Air Initiative for Asian Cities, 2011). As motorcycles and three-wheelers are light vehicles, their overall fossil fuel consumption is not as large as conventional cars. Furthermore, new technologies such as electric and hybrid engines are being introduced, further reducing their fossil fuel consumption. Nevertheless, traffic safety concerns need to be thoroughly addressed.

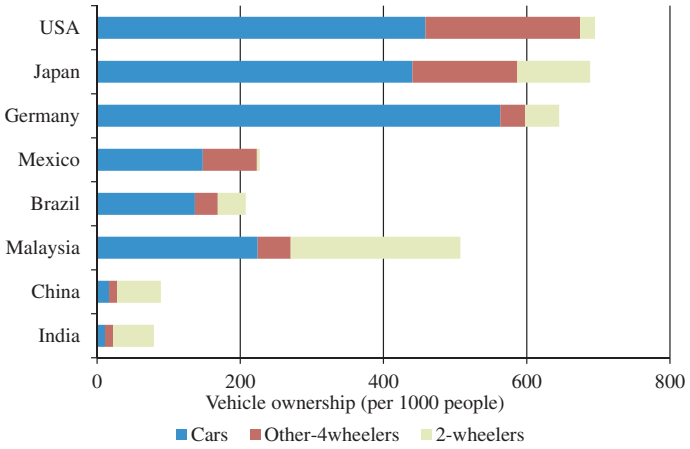

Figure 9.8 | Vehicular penetration in 2006 of several developed and developing countries (other four-wheelers include busses and trucks). Source: based on MoRTH, 2009.

For example, electric bikes (e-bikes) in China emerged from virtual non-existence in the 1990s to achieve annual domestic sales of 13.1 million in 2006, which is equal to the sales of gasoline two-wheelers (ADB, 2009). As it is likely that electric two-wheelers will continue to substitute for bicycles and public transport as incomes rise in China, appropriate policy initiatives may lead to wider electrification of the Chinese transport system (ADB, 2009). The rapid parallel development of new traffic safety rules and regulations to accommodate e-bikes is necessary, and it can serve as inspiration for other Asian cities experiencing the same trends.

9.2.2 Railways

Railway traffic systems are unique in terms of location and technology. Railway traffic systems are highly concentrated in a few world regions. Approximately 90% of all freight and passenger railway traffic can be found in North America, Russia (freight oriented), Japan (passengers), China, India, and Europe (see Figure 9.10). In total, in 2007 there were slightly over 960,000 km of rail lines globally, carrying over 28 billion passengers (2495 billion p-km) and 11.4 billion tonnes (8845 billion t-km) of freight (Thompson, 2010).The top five passenger rail systems

Box 9.1 | Case Study of Urban Mobility in Developing Countries

The World Business Council for Sustainable Development (WBCSD) Mobility for Development project has researched the state of mobility in rapidly growing cities at various stages of economic development (WBCSD, 2009). With three billion people surviving on less than US$2/day and not adequately served by existing mobility systems, the urgent challenge is to expand transport benefits to those currently excluded from urban transport systems and reduce transport's environmental impact. The project set out on a process of research, dialogue, and learning in four cities: Bangalore in India, Dar es Salaam in Tanzania, Sao Paulo in Brazil, and Shanghai in China.

Each of the cities has experienced rapid urban and economic growth, accompanied by growth in transportation, both passenger and freight, public and private – but in quite different ways. Public transport remains a major and sometimes overwhelmingly dominant provider of personal mobility. In these cities, the public transport share of all motorized trips ranged from 45% in Sao Paulo to 71% in Dar es Salaam. In Bangalore and Dar es Salaam, informal paratransit is an important provider of access (see Figure 9.9). Indeed, in the latter, public transport is currently being provided almost exclusively by approximately 9,000 privately-owned and operated minibuses known as *dala dalas*. It is also apparent that non-motorized modes still provide a major share of personal mobility in each city. In Shanghai in 2004, trips by foot and by bicycle accounted for 31% and 25% of the daily total, compared to 31% and 33%, respectively, in 1995. In Sao Paulo in 2002, 37% of daily trips were by foot and 1% was classified as "other" (it is assumed that this category includes trips by bicycle).

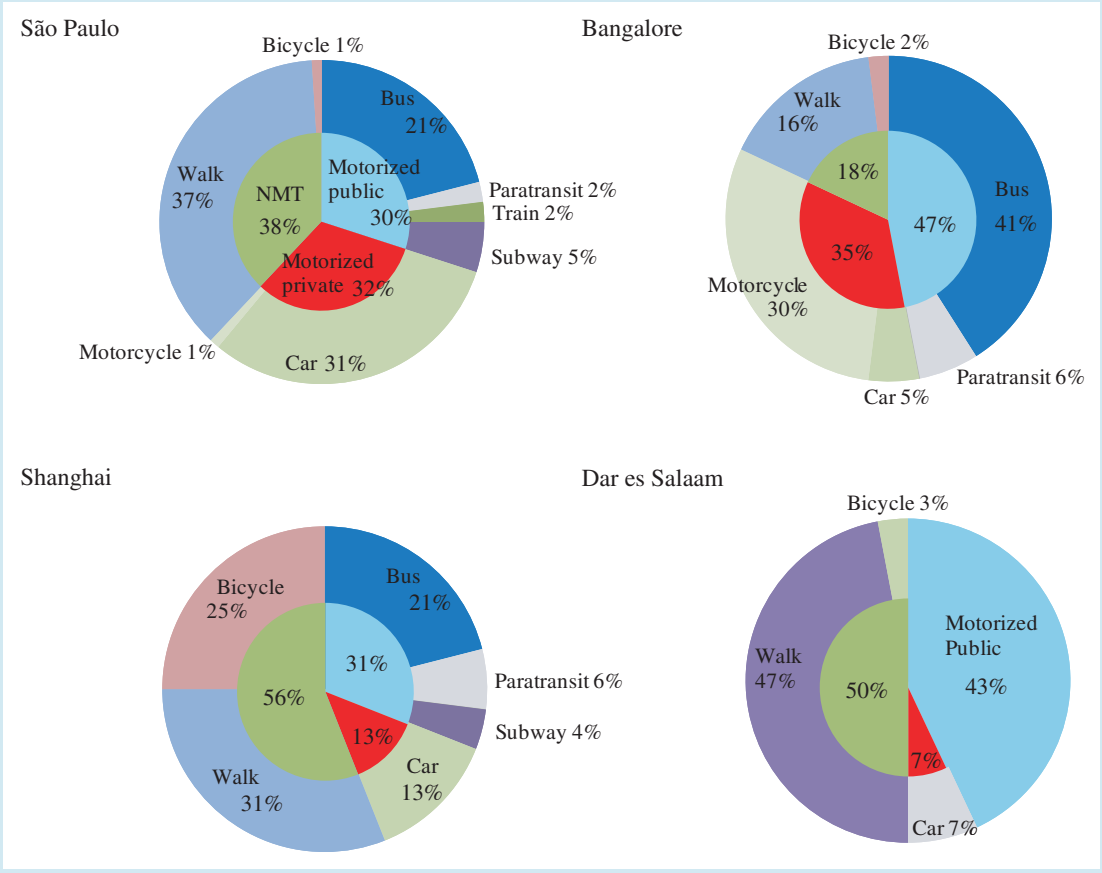

Figure 9.9 | Passenger transport modal shares of several cities in developing countries. Source: based on WBCSD, 2009.

carry 85% of the world's rail passenger traffic. Only three railway systems account for 79% of the world's railway t-km (Statistics Bureau of Japan, 2010).

Rail's main activities are high speed passenger transport between large cities, high-density commuter transport in the city, and freight transport over long distances. Heavy rail transit systems are generally

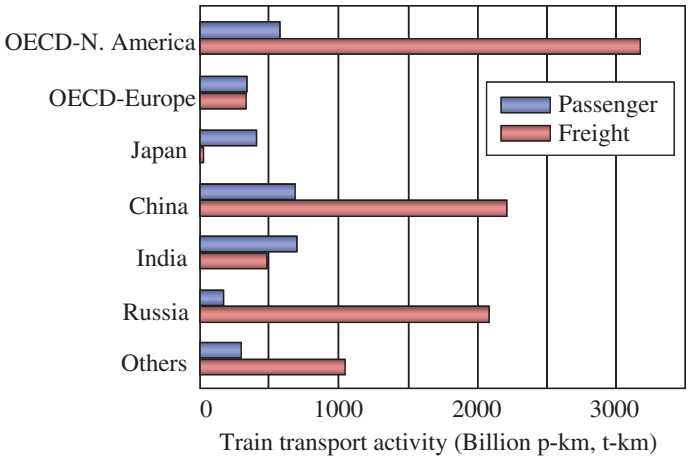

Figure 9.10 | Railway traffic in the major regions. Source: based on Statistics Bureau of Japan, 2010.

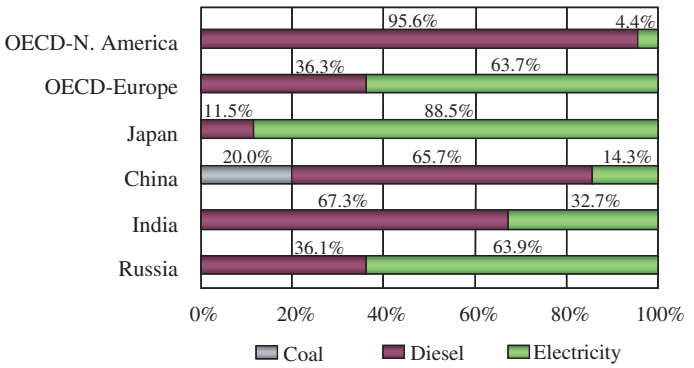

Figure 9.11 | Energy use in railway transport systems in the major regions. Source: based on IEA, 2009b.

found only in the largest, densest cities of the industrialized world and a few developing-world cities, like Beijing, Delhi, Mexico City, and Sao Paulo, among others (Kahn, Ribeiro et al, 2007).

In Europe, Japan, and Russia, electricity is a major energy source for rail, while diesel dominates in North America, China, and India (see Figure 9.11). Electric power for rail systems comes from a variety of sources, predominantly from coal. Coal is also directly used as locomotive fuel in some developing countries.

Trains are more efficient when compared with trucks, and the same applies for passenger trips when compared to all other motorized options (Figure 9.12). Efficiency is strongly dependent on the loading factor. Hence, the economic and environmental viability of public transport crucially depends on urban density.

9.2.3 Aviation

Since 1960, passenger air traffic grew 2.4 times faster than the global GDP growth rate, enabling unprecedented global mobility and causing total aircraft GHG emissions to rise (IPCC, 1999). From 1985–2005, total scheduled traffic, measured in terms of tonne-km, grew at an average annual rate of 5.5% (see Table 9.2).

In 2005, over 3940 billion domestic and international passenger-km were logged by the world's scheduled airlines (Figure 9.13). In the same year, nearly 150 billion t-km of domestic and international freight were transported by scheduled airline services (Figure 9.14). It is estimated that in 2005, the world's airlines carried over 2.1 billion passengers and some 40 million tonnes (Mt) of freight on scheduled services. During the same year, airlines performed on scheduled services 3940 billion p-km (equivalent to 365 billion t-km), some 150 billion freight t-km and 4.6 billion mail t-km (ICAO, 2007).

Today, international air traffic represents just over 60% of the total scheduled passenger air traffic and about 85% of global freight air traffic (ICAO, 2010). The demand for international flights has increased almost four times from 1985 to 2005, while domestic demand has only doubled (see Figure 9.15). The lower growth of domestic demand when compared to international demand can be attributed to competition with other modes by land.

The regional share of international air passenger traffic changed in the period 1985–2005. Europe, Asia/Pacific, and the Middle East increased their shares in total air passenger-km while North America, Latin America, and Africa have decreased (see Figure 9.15).

The share by region of international freight traffic changed in the period between 1985 and 2005 (see Figure 9.16). Asia/Pacific and the Middle East increased their shares in total freight-t-km considerably. North America did not vary much. Latin America, Africa, and Europe decreased (see Figure 9.17).

Aviation contributes to climate change in a number of different ways, and in more complex ways than most other sectors (IPCC, 1999). Aviation

Table 9.2 | Trends in total scheduled air traffic. World (1975–2005).

Scheduled Services	Average annual growth (%)		
	1975–1985	1985–1995	1995–2005
Passenger-km	7.0	5.1	5.2
Freight tonne-km	7.5	7.6	5.5
Mail tonne-km	4.3	2.5	-1.9
Total tonne-km	7.1	5.8	5.2

used 252 Mtoe of energy in 2007, mostly jet fuel, which is around 11% of all transport energy used. International travel accounts for 62% of aviation, and is continuously increasing (IEA, 2009b). The total energy demand is expected to triple to about 750 Mtoe in 2050 in the IEA 2009 baseline scenario (IEA, 2009c). In the same study's high baseline scenario, this reaches nearly 1000 Mtoe (IEA, 2009c). Estimating the impact of aviation's GHG emissions is complicated by a number of uncertainties.

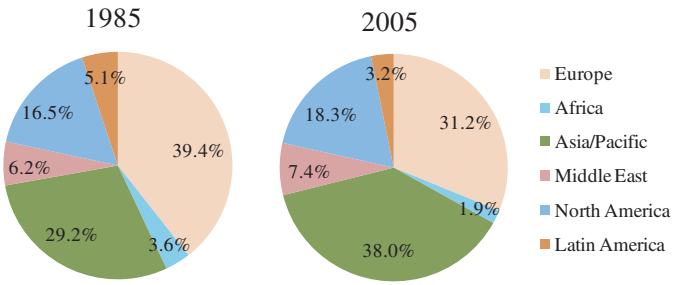

Figure 9.16 | Regional distribution of air transport – freight t-km. Source: ICAO, 2007. ©ICAO, reproduced with permission.

Total aircraft fuel consumption is expected to grow at a rate of 3 and 3.5 %/year, as shown in Figure 9.17. This is far less than the predicted 4.8%/year growth rate in air traffic. During the 37th Session of the Assembly in October 2010, the International Civil Aviation Organization (ICAO) adopted the first globally harmonized Resolution on international aviation and climate change. The resolution was adopted with some States expressing reservations and calling upon the ICAO Council to continue its work on specific aspects of the agreement. The resolution aims to collectively achieve global aspirational goals of improving fuel efficiency by 2% per year and stabilizing CO_2 emissions at 2020 levels. The Assembly also agreed on the guiding principles for market-based measures and decided to explore a global scheme for international aviation. A global CO_2 certification Standard for aircraft is being developed aiming for 2013.

Some measures, such as reducing overall airplane travel volumes, may reduce emissions across the board. But other measures, such as improving aircraft engine efficiencies, may result in trade-offs between different pollutants; for example, a reduction in CO_2 emissions might be

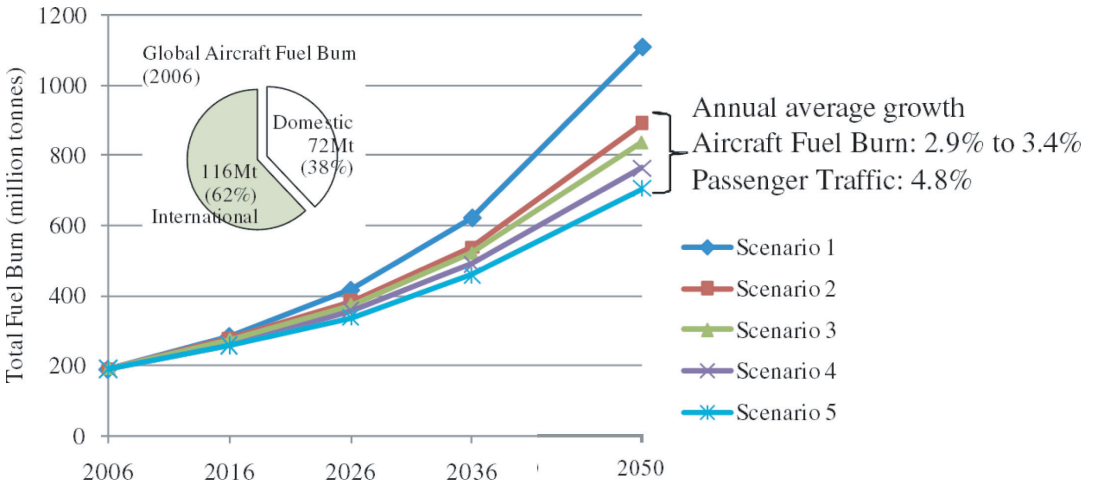

Figure 9.17 | Global aircraft fuel burn, international and domestic traffic combined (2006–2050) (Details of scenario; see Box 9.2). Source: modified from ICAO, 2010.

achieved at the cost of higher NO_x emissions. The levels of scientific understanding of the impacts of each of the contributors to radioactive force from aviation varies, and research is urgently needed to better understand and quantify the potential impacts of aviation emissions and the net effects of various mitigation strategies (IEA, 2009c). Box 9.2 details technology-specific scenarios developed by the ICAO (ICAO, 2010). Policies that also affect total air traffic demand and address air transport externalities are explained in Section 9.6.

9.2.4 Shipping

According to the United Nations Conference on Trade and Development (UNCTAD), more than 80% of global trade by volume is carried by sea (IMO, 2009; UNCTAD, 2010). Throughout the last century, the shipping industry has seen a general trend of increases in total trade volume. Increasing industrialization and the liberalization of national economies have fuelled free trade and a growing

Box 9.2 | The Future of Aviation

The ICAO (2010) estimated average annual passenger traffic growth of between 4.0–5.2 % through 2036. In order to accommodate this growth, the size of the global commercial aircraft fleet would need to grow by nearly 250% by 2036. The complete forecast is presented in the table below.

A range of potential technology and operational scenarios were considered in order to estimate global aviation fuel consumption through 2036, and they were then extrapolated to 2050. Described below as in ICAO (2010), these scenarios include a business-as-usual (BAU) sensitivity case, which was not considered to be likely, given the investments currently being made in operational improvements and the increasingly aggressive levels of operational and technological improvement.

Description of ICAO/CAEP (2010) Future Scenarios

- *Scenario 1 (Sensitivity)*: This scenario includes the operational improvements necessary to maintain current operational efficiency levels, but does not include any technology improvements beyond those available in current (2006) production aircraft.
- *Scenario 2 (Low Aircraft Technology and Moderate Operational Improvement)*: In addition to including improvements associated with migration of the latest operational initiatives, e.g., those planned in NextGen and Single European Sky ATM Research (SESAR) (Scenario 1), this scenario includes fuel burn improvements of 0.96 %/year for all aircraft entering the fleet after 2006 and prior to 2015, and 0.57 %/year for all aircraft entering the fleet beginning in 2015 out to 2036. It also includes additional fleet-wide moderate operational improvements by region.

- *Scenario 3 (Moderate Aircraft Technology and Operational Improvement)*: In addition to including improvements associated with migration of the latest operational initiatives, e.g., those planned in NextGen and SESAR (Scenario 1), this scenario includes fuel burn improvements of 0.96 %/year for all aircraft entering the fleet after 2006 out to 2036, and additional fleet-wide moderate operational improvements by region.

- *Scenario 4 (Advanced Aircraft Technology and Operational Improvement)*: In addition to including improvements associated with migration of the latest operational initiatives, e.g., those planned in NextGen and SESAR (Scenario 1), this scenario includes fuel burn improvements of 1.16 %/year for all aircraft entering the fleet after 2006 out to 2036, and additional fleet-wide advanced operational improvements by region.

- *Scenario 5 (Optimistic Aircraft Technology and Advanced Operational Improvement)*: In addition to including improvements associated with migration of the latest operational initiatives, e.g., those planned in NextGen and SESAR (Scenario 1), this scenario includes an optimistic fuel burn improvement of 1.5 %/year for all aircraft entering the fleet after 2006 out to 2036, and additional fleet-wide advanced operational improvements by region, as shown in Table 9.3 under "upper bound." This scenario goes beyond the improvements based on industry recommendations.

Table 9.3 | CAEP/8 passenger traffic growth rate forecast – Most Likely, High, and Low Scenarios.

Scenario/Sector	Average annual growth rate of passenger traffic (%)				
	2006–2016	2016–2026	2026–2036	2006–2026	2006–2036
High Scenario (Optimistic)					
International	5.9	5.5	5.0	5.7	5.5
Domestic	5.0	4.7	4.4	4.9	4.7
Global [Int. + Domestic]	5.5	5.2	4.8	5.4	5.2
Most Likely Scenario (Central Forecast)					
International	5.4	5.0	4.6	5.2	5.0
Domestic	4.5	4.3	4.1	4.4	4.3
Global [Int. + Domestic]	5.1	4.8	4.4	4.9	4.8
Low Scenario (Pessimistic)					
International	4.8	4.4	4.0	4.6	4.4
Domestic	3.6	3.2	2.8	3.4	3.2
Global [Int. + Domestic]	4.3	4.0	3.6	4.2	4.0

Source: ICAO, 2010.

The results of this analysis are shown in Figure 9.17, which estimates that global fuel consumption will increase from approximately 200 Mt in 2006 to between 711 and 897 Mt in 2050. This translates to between a 2.9 % and 3.4 % annual average growth rate in fuel consumption over the period. On a per flight basis, efficiency is expected to improve over the period; however, in absolute terms, GHG emissions are expected to rise significantly relative to 2006 emissions. Further, market-based policy instruments may possibly be required to achieve a notable contribution from the aviation sector to achieve 2050 climate mitigation goals (see Section 9.6).

demand for consumer products. In 2006, seaborne trade reached over 48 trillion t-km; this represents an increase of 49% compared to trade in 1996, as shown in Figure 9.18 (Singapore Maritime Careers, 2011)

Also according to the Singapore Maritime Careers (2011), the three main types of goods transported by sea are dry bulk, oil, and containerized cargo. Dry bulk (iron ore, grain, coal, bauxite/alumina, phosphate, etc.) accounted for 38% of the world's seaborne trade in 2006. The

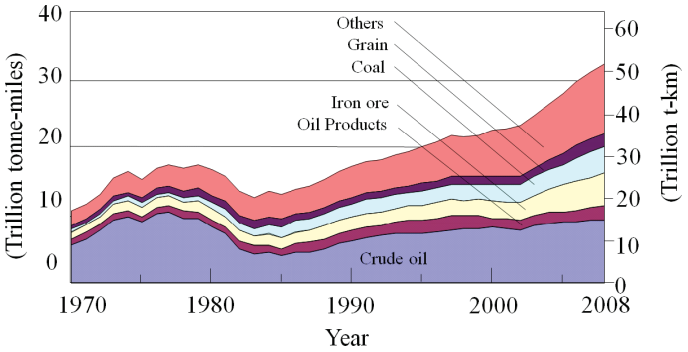

Figure 9.18 | World seaborne trade. Source: based on UNCTAD, 2010.

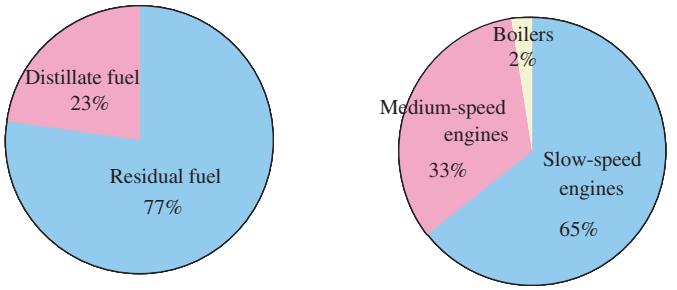

Figure 9.19 | Share of seaborne shipping fuel consumption by fuel type and engines in 2007. Source: data based on IMO, 2009.

second largest share of cargo was oil trade, which accounted for 36%, and containerized cargo contributed 15%. These trades are carried by more than 20,000 merchant ships to various ports around the world, leading to a global cargo throughput of 14.8 Gt and container throughput of 440 million twenty-foot equivalent units (TEUs).[5]

Ships transport food (grains, rice, maize, meat, fish, sugar, vegetables, vegetable oils, etc., and also fertilizers to increase crop productivity), energy (crude oil, refined oil products, ethanol, coal, and gas), raw materials (iron ore, scrap iron, minerals, lumber, wool, rubber, cotton, etc.) and finished products of all sorts. Besides this regular transportation, special ships perform other tasks like offshore service activities, cable laying, pipe laying and dredging, fishing, and exploration and research, among others.

Shipping fuel consumption is mainly residual fuel. Residual fuels are the cheapest fuels with the highest boiling points. They usually contain relatively high amounts of pollutants, in particular sulphur, and they contaminate water and air along coastlines. Estimates for 2007 show total fuel consumption was 333 Mt, as shown in Figure 9.19. The greatest demand for fuel (83%) comes from international routes.

Emissions from fuel in seaborne transport were estimated to amount to 1065 $MtCO_2$-eq in 2007, more than that of rail and aviation combined. However, black carbon emissions are not measured. Also, this figure does not include hydrofluorocarbon emissions from refrigerating systems and fugitive emissions of CH_4 from oil transport (IMO, 2009). Advances in technology have increased shipping's efficiency. For example, cargo vessels are estimated to emit 2–30 gCO_2/t-km, compared to a range of ca. 200 to 800 gCO_2/t-km for trucks with trailers (IMO, 2009; IEA, 2009d). However, efficiency gains are outweighed by significantly higher increases in overall volume.

5 TEU is a unit of cargo capacity used to describe the capacity of container ships and container terminals. It is based on the volume of a 20-foot-long (6.1 m) intermodal container.

Shipping activity is driven by the world economy. Understanding this mechanism for seaborne transport and other shipping activities is vital to estimate future energy demand and emissions from this mode. The huge growth rates of world seaborne trade figures were mostly driven by international trade, and the globalization of supply chains. Shipping is not immune to economic downturns – a notable fall in trade occurred, for example, during the worldwide economic recession of the early 1980s, during the Asian financial crisis of the late 1990s and, more recently, the financial crisis of 2008/2009 led to a small reduction in seaborne transport in 2009 that was already more than compensated for in 2010 (estimate by UNCTAD, 2010).

9.3 Transportation Trends and their Relation to Major Global Issues

Transport has a strong two-way interaction with the major global issues addressed by the Global Energy Assessment: urbanization, equity, climate, energy security, health, and environmental protection. This section explores this interaction, stressing that the results of implementation of transportation policies and investments can be favorable or detrimental to the attainment of goals in any of these areas. Therefore, gaining further understanding of these opportunities, challenges and potential co-benefits is necessary. Goals for sustainable transportation consider reducing the need to travel (to have fewer and shorter trips), encouraging a shift to more energy-efficient and safer modes of travel, and improving the technologies and operations of different transport modes (Banister, 2008; Dalkmann and Sakamoto, 2011). The last five years have seen the emergence of climate concerns as a flag point with the reporting by IPCC on the role of transport in CO_2 emissions (IPCC, 1999; Kahn Ribeiro et al., 2007; Stern, 2007; Bakker and Huizenga, 2010).

The GEA proposes combining the goals regarding global and local issues and those for sustainable transportation into a multi-goal framework approach that highlights normative goals and creates the opportunity of multiple entry points for decision makers (Chapters 2–6). In this way it envisions the synergy of effective action toward selected goals producing a catalyzing effect of change toward a larger systemic transport and energy transformation. The ability to impact

transportation activity and trends is paramount to achieving goals in any of the major global and energy issues that GEA addresses; this requires the assessment of the purpose and goals of specific transport interventions and their impact on larger goals. The methodological approach followed in this assessment begins with a review of the relationship between current transport trends and their impact on major global issues. Understanding the specific terms of this relationship can help to pinpoint the variables that serve to measure progress toward these goals. Transport sustainability is matched in this assessment with goals linking transport, urbanization, and equity, as well as those that link health and environmental protection (e.g., quality of life, reduced air pollution, noise). Climate mitigation focuses on emissions reduction goals, while energy security relates to fossil fuel independence (fuel diversification and net reduction of fossil fuels use for transportation).

Enabling conditions for change include increasing the level of investment, capacity building, technology transfer, institutional building, and general public awareness and education. The assessment of potential approaches at regional, national, and local levels are comprehensive but different approaches are necessary by region and locality, appropriate pricing policies for fuels, vehicles, and congestion will be needed across the globe and are further discussed in Section 9.6.

9.3.1 Economic Growth and Equity

Transportation systems are the backbone of urban social and economic development and are a determinant of the quality of urban life. As global urban populations are rapidly increasing, land-use planning and technologies and practices for smart urban transport become essential for urban development. Technological advances and motorization have brought major improvements in our ability to cover longer distances, become flexible, and make use of available space.

However, in most cities, urban travel and mobility has deteriorated over time. For instance, the yearly delay in urban areas in the United States with more than three million inhabitants has increased from 31 hours per auto commuter in 1982 to 50 hours in 2010 (Schrank et al., 2010). In most cities in developing countries, rapid urbanization and motorization are coupled with the inability of local governments to respond adequately to the demand for growth in infrastructure and public transport services (Vasconcellos, 2001; World Bank, 2008a). Simultaneously, the rate of car ownership growth supersedes the extension of road capacity. The combined rapid population and motorization growth and slower pace of economic development results in urban spatial impoverishment (see Chapter 18), making the provision of an adequate level of safe, reliable, and efficient transport services almost impossible. Further, as vehicle ownership and road use increase, traffic congestion, noise, and air pollution worsen (Vasconcellos, 2010).

Urbanization and urban form, or the spatial shapes of cities, have a complicated and interwoven bidirectional relationship with transportation (Small and Verhoef, 2007). Large-scale urbanization is only feasible with reduced transport costs (Krugman, 1991). Urbanization produces economics of agglomeration, a precondition to global integration. This generally leads to rising incomes and greater service provision, which, in turn, usually increases rates of ownership of motorized forms of transportation. Urban form, on the other hand, determines transportation needs (Næss, 2006). For example, dense cities and mixed land-use patterns create short distance destinations enabling walking and non-motorized transport options, whereas sprawling cities perpetuate dependence on motorized modes. In turn, highway infrastructure and inexpensive cars and fuels contribute to sprawled, auto-oriented urban development (Newman and Kenworthy, 1999; Banister, 2005). [6]

Accessibility is a useful measure to evaluate the quality of urban transport for users. It can be defined as ease of reaching opportunities throughout the urban area, such as jobs, shopping, medical services, and social activities (Cervero, 2005). Poor accessibility, quality of transportation services, and the question of transport service affordability are strong indicators of the links between transportation, urbanization, and social equity. Improving accessibility levels depends upon the urban form, distribution of land uses, transportation infrastructure, and the transport service level measured in travel time. Accessibility can be improved by proximity or mobility. Proximity is a function of urban form and land-use mix (i.e., dense, mixed-use development with a good jobs-housing balance) and mobility is determined by the level of transportation services, system operations, and vehicle performance characteristics within a particular urban area.

Cities with low auto-mobility could have high levels of accessibility due to the proximity of the urban opportunities in the city core if sustainable transport modes are used (Cherry, 2007). Cities with high auto-mobility might have low levels of accessibility due to the distance of decentralized activities in sprawling suburban communities. Lack of job accessibility, especially for vulnerable populations – those with low income, women, the elderly, and persons with disabilities – has been identified as a major contributor to poverty in developing countries and is an essential consideration in the development of any transportation policy (Gwilliam, 2002; Vasconcellos, 2001; 2010).

The provision of sustainable transport services, including low-carbon vehicles, can be hampered by lack of affordability. Affordability of transport means the ability to purchase access to basic goods and activities (e.g., medical care, basic shopping, school, work, other social services and socializing), usually expressed as the percentage of monthly income devoted to transport by poor families compared to a

6 For more information on the urban energy system see Chapter 18.

benchmark considered "affordable" for households (Serebrisky, et al, 2009). According to Litman (2007), this benchmark is achieved when households spend less than 20% of their income on transport and less than 45% on transport and housing combined. However, other authors (Serebrisky, et al, 2009) have observed that transport expenditures may be low in poor households due to a suppression of trips or a prevalence of walking and non-motorized modes; therefore subsidies for public transport, a common policy, may not reach the targeted population. These authors consider that the percentage of income used in transport can be seen as a good approximation of the hardship faced by certain population groups and an indication that deeper analyses are necessary.

A more effective use of resources within cities to aid affordability may be investing to increase accessibility improving sidewalks, crossing bridges and other non-motorized infrastructure (Serebisky, et al, 2009). Urban planners and decision makers can target improving accessibility through integrated transport and urban design favoring mixed use, short distances, and modal integration, and by planning and implementing safe infrastructure for a number of low-cost, low-tech, non-motorized modes of transport (see further discussion in Section 9.6).

Transportation affordability is also affected by the number of vehicles that a household possess, the costs of using each vehicle, indirect costs such as residential parking, and the quality and costs of using alternative modes such as transit, rail, ridesharing, car-sharing, taxi services, cycling, and walking (Litman, 2007). The goal of introducing more efficient vehicles and low-carbon fuel technologies in developing countries will raise other dimensions to the concept of transport affordability at national and regional levels.

Finally, public acceptability is essential to transport sustainability, as it creates the conditions for implementation and improvement. The concept of acceptability will be further elaborated as part of the enabling conditions for sustainable transport implementation in Section 9.6.8. Improving the balance between transportation-urbanization and equity issues requires policies for enhancing the three A's: accessibility, acceptability, and affordability.

9.3.2 Public Health and Local Ecosystem Impacts

Transportation activity, particularly in cities, has specific impacts on public health and local ecosystems. According to Dora (2011), health risks from transport come from outdoor urban air pollution (1.2 million deaths in 2005), physical inactivity (3.2 million deaths and 19 million healthy life years lost in 2005), traffic injuries (1.3 million deaths in 2005), traffic noise (e.g., stress, memory loss, and analytical impairment), climate change (150,000 deaths), and lack of access to vital goods and services, social networks, equity, and cohesion, which is profound and under-reported. [7]

Road traffic injuries have become a global health and developmental problem (WHO, 2009). Higher road fatalities and air pollution are common in developing countries, while health problems associated with lack of physical activity are more common in industrialized nations. Over 90% of the world's fatalities on the roads occur in low- and middle-income countries, and almost half of those who die in road traffic crashes are pedestrians, cyclists, or users of motorized two-wheelers. These individuals are collectively known as vulnerable road users, and this proportion is higher in the poorer economies of the world (WHO, 2009). The death rates caused by road traffic accidents have been declining over the last decades in many high-income countries due to the adoption and proper enforcement of traffic laws, as well as persistent allocation of human and financial resources to build up effective and sustainable enforcement activities. However, even in these countries, road traffic injuries remain an important cause of death, injury and disability (WHO, 2009).

Dependence on car mobility and lack of physical activity foster obesity (Woodcock et al., 2009, 2011). The effects of physical inactivity and obesity on population health are more detrimental than those produced by traffic injuries and deaths when comparing the leading causes of death (heart attacks, heart diseases) and Burden of Disease studies by the WHO (WHO, 2009; Dora, 2011). The cost of urban road transport and air pollution on public health can be in the order of 3% of GDP (Creutzig and He, 2009).

Other significant indirect effects on health from transport are related to stress (e.g., noise-induced), which compound the dramatic effects that lack of exercise and car dependence have had in developed countries and result in other potentially debilitating health conditions. Both short- and long-term exposure to air pollution affects human health adversely. Air pollution is caused by emissions from mobile (vehicles) and stationary sources and can have significant local effects during stagnant weather conditions (WHO, 2006; see Box 9.3 and Figure 9.20). Even low concentrations increase the risk of adverse health impacts. The air quality guidelines of the WHO recommend 20 µg/m3 annual mean (indicated in Figure 9.24 by a dashed line), which is exceeded even for most cities in OECD countries. Limit values that are in force in several countries are typically 40–60 µg/m3 (the EU limit value is also indicated in the Figure 9.20 by a dashed line) (WHO, 2006). Air pollutant emissions can be directly linked to the fuel combustion, energy production, and industrial activities taking place in a particular urban environment. However, air pollution is also trans-boundary, as air pollutants can travel considerable distances from their sources.

A sustainable transport agenda needs to understand transportation as a key component of health in urban development. It thus requires considerable further research, particularly in non-OECD countries where most data or reliable statistics on traffic safety, air pollution, and noise are still lacking (WHO, 2006).

7 For more information on energy and health, see Chapter 4.

Box 9.3 | PM_{10} and $PM_{2.5}$ as Indicators for Suspended Particulate Matter and Typical Values Worldwide

Globally, the most frequently used indicator for suspended particles in the air has been PM_{10} – particles with an aerodynamic diameter <10 µm, but recent reviews by WHO, the USEPA, and European health agencies have pinpointed $PM_{2.5}$ as a better indicator of health risk as it penetrates more deeply into the respiratory tract. **Studies show correlation of health outcomes with either PM_{10}, $PM_{2.5}$ or both, although $PM_{2.5}$ better represents combustion sources, which are of the greatest concern in this report.** Here we present data for PM_{10} only; however, since $PM_{2.5}$ is not yet measured routinely in many parts of the world. **$PM_{2.5}$ levels are typically about 10–60% lower than PM_{10} depending on the location and season, however its temporal and geographical variations are often well correlated with PM_{10}** as shown for example in the recent global modeling study for the Global Burden of Disease project (Brauer et al., 2011).

An overview of typical annual average PM_{10} concentrations in selected cities around the world is presented in Figure 9.20. The data selected for this presentation demonstrate that the general levels of suspended particles in Asia and Latin America are higher than those in Europe and North America. About 70% of the cities selected from these regions have annual average PM_{10} concentrations above 50 µg/m³.

In general, the highest concentrations of PM_{10} were reported in Asia. This region also experiences relatively high background concentrations owing to forest fires and local emissions of particles from use of poor-quality fuels. A well-known springtime meteorological phenomenon throughout East Asia is the Asian Dust cloud, which originates from windblown dust from the deserts of Mongolia and China and adds to the general level of PM in the region.

Chinese cities experience very high airborne particle concentrations due to primary particles emitted from coal and biomass combustion and motor vehicle exhaust, as well as secondary sulphates formed by atmospheric chemical reactions from the sulphur dioxide emitted when coal is burned. Typical annual average PM_{10} concentrations were reported to be as high as 140 µg/m3 in Beijing. In many areas of the world, massive and prolonged forest fires have caused significant increases in PM concentrations.

For a discussion of air pollution, including particulates, in the GEA pathways, see chapter 17, Section 17.5.2.

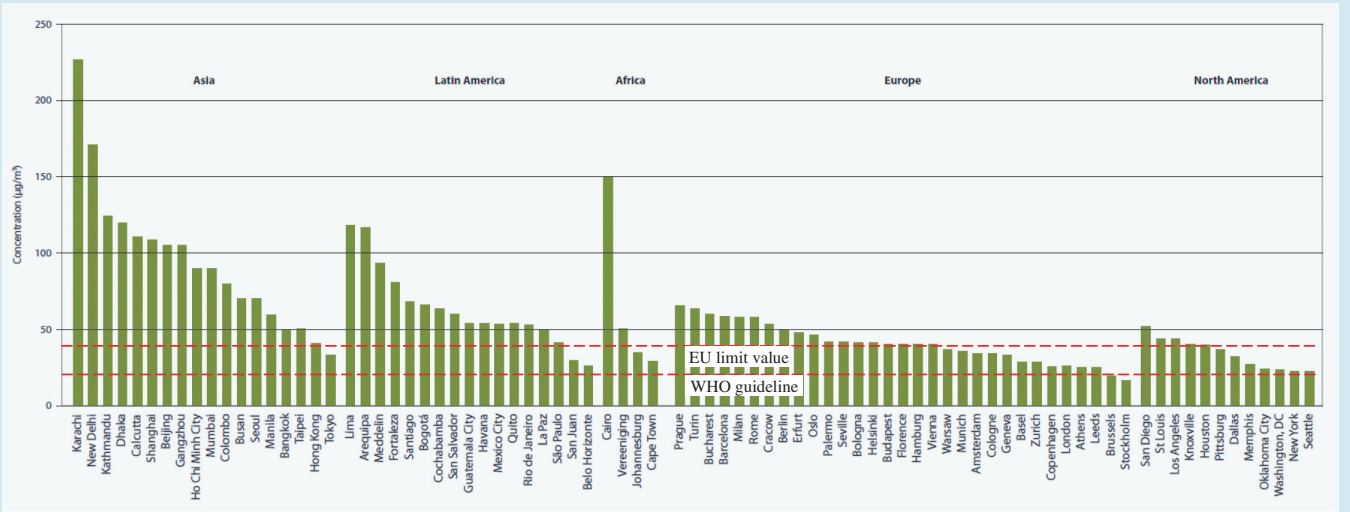

Figure 9.20 | Annual average PM_{10} concentrations observed in selected cities worldwide. Even low concentrations increase chances of adverse health impact. The air quality guidelines of the WHO recommend 20 µg/m³ annual mean, below levels of even most cities in OECD countries. Source: WHO, 2006.

Source: WHO, 2006; Brauer et al., 2011.

In addition, local and regional pollutants (e.g., acidifying substances, ozone precursors, and particulate matter) damage ecosystems. Releases of oil or chemical substances into the environment by trucks and tankers during routine work or accidents adds to the pollution of soils, rivers, and the sea. The expanse of land area covered by transportation infrastructure excludes it from other uses, cutting through ecosystems and impacting fauna and flora.

9.3.3 Climate Change

The reduction of GHG emissions in all sectors, including transportation, is of paramount importance to reduce the effects of climate change (IPCC, 2007; IEA 2008). While international climate negotiations and treaties (i.e., Kyoto in 1997) were mostly quiet on the transport sector, policy makers at local, national, and regional levels, as well as manufacturers of transport vehicles and systems, have recognized the climate challenge related to transportation.[8]

GHG emissions from transport can be calculated through decomposition of transport demand, energy intensity, and carbon intensity, using a similar approach to the Kaya identity (Creutzig and Edenhofer, 2010; Creutzig et al., 2011a). Transport demand can be divided into activity (trips) and modal share. Energy and carbon intensity are associated with particular modes of travel, as indicated in the ASIF model (Schipper and Marie-Lilliu, 1999).

Of all transport modes, LDVs contribute the highest percentage of GHG emissions (see Figure 9.21), followed by significant contributions by freight trucks, air traffic, and water-borne. Transport activity, and particularly the use of LDVs, generally increases with economic growth; hence the trends indicate increasing emissions if no action is taken. The recent 2008/2009 recession in OECD countries had the effect of reducing the total amount traveled in all transport modes, especially for international shipping; however, overall global transport activity, and hence transport-related emissions, continued increasing.

In terms of GHG intensity, or grams of CO_2 equivalent emitted per unit of freight or passenger transport (tank-to-wheel vehicle emissions during operation), there is a large difference between modes. Rail and shipping are the most efficient modes for both passenger and freight transport (see Figure 9.22).

With respect to CO_2 emissions, IEA estimates that, driven by increases in all modes of travel, but especially in passenger LDVs and aviation, the baseline projection[9] of GHG emissions in transport increases by nearly 50% by 2030 and 80% by 2050 (IEA 2009; see Figure 9.22). In a high

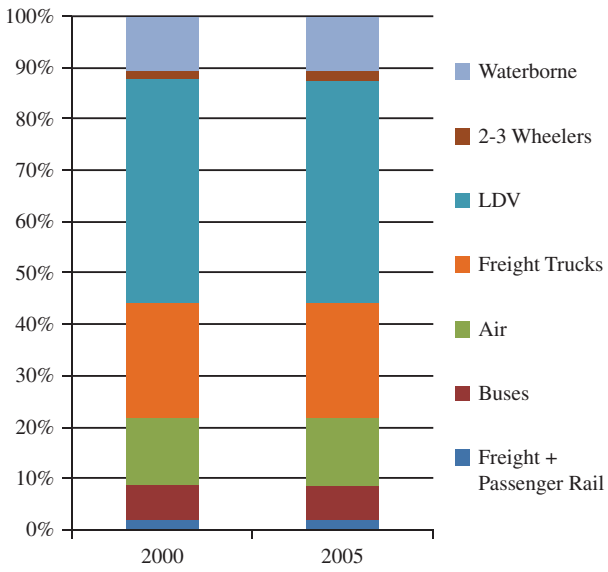

Figure 9.21 | Modal shares in world vehicles in CO_2 emissions (%). Source: based on ITF, 2008.

baseline scenario,[10] it increases by 130%. CO_2-eq emissions increase at even faster rates, due to increased use of high carbon fuels such as coal-to-liquids after 2030. GHG emissions from transport nearly double from about 7.5 Gt in 2006 to about 14 Gt in 2050 in the baseline scenario and to 18 Gt in the high baseline scenario.

Figure 9.23 shows a comparison of CO_2 emissions from various combinations of powertrain and fuel on a well-to-wheels (WTW) basis for LDVs. It is interesting to note that from a climate change mitigation perspective, it may be better to have an internal combustion engine-hybrid electric vehicle (ICE-HEV) than an electric vehicle in areas where the electricity is produced mainly in coal-powered plants. This is an example of why a life-cycle analysis is a crucial approach to inform policymaking.

9.3.4 Energy Security

Transportation demand is expected to grow at a rapid pace for the foreseeable future (IEA, 2009d). However, the way transport needs will be served depends on several factors that are directly related to energy security[11].

First, it is in every nations interest to promote and support transportation activity but as transport is dominated by one feedstock, petroleum, supply disruptions can jeopardize the essential continuity of transport activity (for a further discussion, see Chapters 7 and 17). Second, the primary driver of transport activity is economic

8 See also Chapter 3.

9 Baseline: follows the IEA World Energy Outlook 2008 Reference Case to 2030 and then extends it to 2050. It reflects current and expected future trends in the absence of new policies. These values represent expert opinions and are subject to high uncertainties.

10 High baseline: this scenario considers the possibility of higher growth rates in car ownership, aviation, and freight travel over the period to 2050 than occur in the baseline.

development, as global economic conditions fluctuate and financial capitals move from regions to regions so will the flows of passengers and goods globally. High economic development in industrialized countries, and also in China, India, Brazil guarantees that transport demand levels will remain high. If the rest of Asia, Latin America and Africa fulfill their economic potential, a fast growth of transport demand may take place over the next several decades. Finally, current trends in developing countries point toward an increasing dependence on private cars. This will require substantial increases in petroleum use even when transportation technology, the energy efficiency of different vehicles and fuels, as well as their cost and desirability, is expected to continue improving.

In the aggregate, these trends indicate that energy use in transport will continue to increase and that fossil fuels are expected to continue to be the dominant propulsion source. Nevertheless, countries have choices in policy and infrastructure that may affect the key drivers of energy use and propulsion fuels: transport activity, modal choice, and technologies.

Most projections of transportation energy use and GHG emissions have developed reference cases that project future conditions in the case of governments continuing current policies, which mainly favor automobile use powered by fossil fuels. These reference cases establish a baseline that can be used to compare the implications of different policies and programs.

Widely-cited projections of world transportation energy use include reference cases by the International Energy Agency (IEA, 2008; 2009a; 2009c) and the WBCSD (2004b), whose forecast was undertaken by the IEA.

In contrast with the GEA pathways—which does not include a business as usual (BAU) path, the transportation projections from the mentioned scenario studies include business-as-usual forecasts under the assumptions that world oil supplies will be sufficient to accommodate the large projected increases in oil demand, and that world economies will continue to grow without significant disruptions. Attending to these fundamental assumptions, the BAU scenarios of each of the cited studies forecast robust growth in world transportation energy use over the next few decades, at a rate of around 2%/year. If these projections are correct, it will mean that transportation energy use in 2030 will be about 80% higher than in 2002 (see Figure 9.24 for the most recent estimates available). In addition for these studies, most of the new energy use

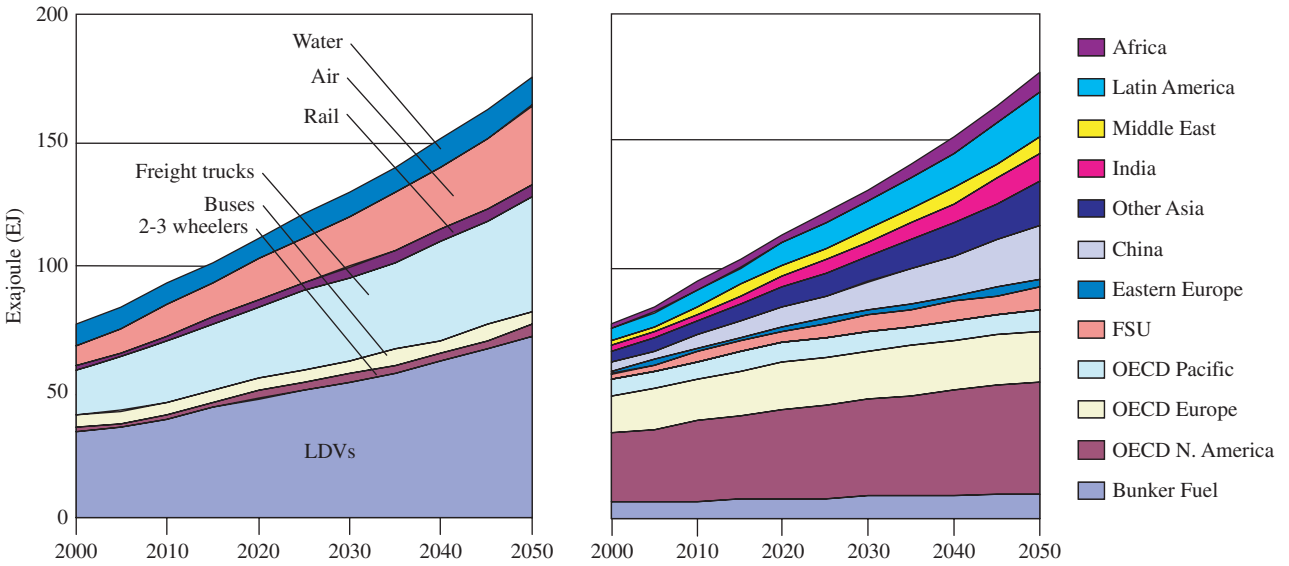

Figure 9.24 | Projection of transport world energy use by mode and region. Source: based on IEA, 2008.

is projected to be in petroleum fuels at 93–95% of transport fuel use over the period (see Figure 9.25). Nevertheless, the BAU scenarios imply increasing prices of oil; and the IEA predicts an average cost above US$130/barrel in 2030 (IEA, 2010a). All these estimates and assumptions are in danger of encountering further difficulties due to disruptive changes in resource supply (Bundeswehr Transformation Center, 2010), which would amplify energy security concerns. The GEA pathways (discussed in Chapter 17) and the GEA-Transport scenarios in this chapter include assumptions and considerations from a global energy security analysis.

With respect to energy security, it is important to point that the rise of consumption in emerging economies will lead to a shift in transport energy use. For example, in China, where the number of cars is growing at a rate of 20%/year, even under a slower projected growth of 6%/year, China's transportation energy use would increase by a factor of four between 2002 and 2025, from 4.3 EJ in 2002 to 16.4 EJ. India's transportation energy use is projected to grow at 4.7%/year during this period, and in countries such as Thailand, Indonesia, Malaysia, and Singapore, growth would be above 3%/year. The same path would be observed in the Middle East, Africa, and Central and South America, with growth rates at or near 3%/year. The current share of non-OECD countries in global transport energy use is 36% and would increase to 46% by 2030 (Kahn Ribeiro et al., 2007).

Developed countries transportation energy use is expected to grow at lower rates of 1.3%/year. This modest figure is attributable to more efficient engines and to the use of alternative fuels as a result of current policies. In North America, growth would be even lower, with a rate of 1%/year due to moderate growth in population and travel but only modest gains in energy efficiency. In Western Europe, transportation energy use would have an increase of 0.6%/year as a consequence of

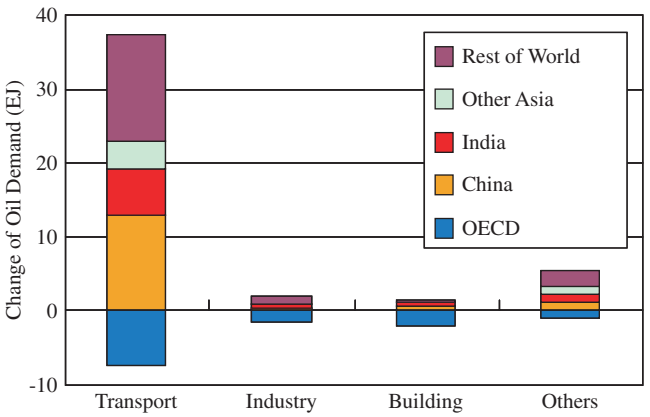

Figure 9.25 | Reference scenario: projected changes in oil demand, 2006–2030. Source: adapted from IEA, 2010a.

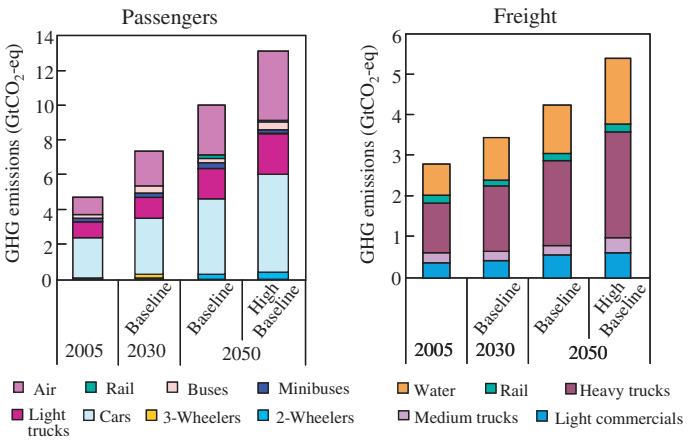

Figure 9.26 | Passenger and freight transport GHG emissions baselines by mode. Source: adapted from IEA, 2009d.

slower population growth, high fuel taxes and improvement in vehicle energy efficiency. Pacific OECD is also expected to grow at a rate of 0.6%/year. In total, developed economies' share of world transportation energy would be reduced from 40% to 31% from 2005 to 2030 (Kahn Ribeiro et al., 2007).

Worldwide expected growth of transport energy use means only that diversification of fuels for transportation is a key component of transport sustainability in terms of energy security. To reduce oil prices, strong policies to reduce demand for fossil fuels are required. IEA (2010a) projects prices in the range of US$110/oil barrel if new policies are in place and US$90/oil barrel in 2035 for policies that achieve the goal of keeping carbon concentration in the atmosphere below 450 parts per million (ppm). In the long term, global transportation systems will need to rely on greatly diversified and non-fossil sources of energy. The provision of a high level of transportation services with less dependence on fossil fuel and progressively more reliance on alternative sources of energy (i.e., electricity produced from renewable or non-fossil sources) is feasible worldwide, in combination with the implementation of avoid-shift-improve policies, as indicated by the United Nations Environment Programme (UNEP, 2011).

9.4 Assessing Energy Resources and Technology Options

The need for energy security, avoiding dangerous climate change, and other sustainability concerns, such as better air quality in cities, requires a combined approach (see UNEP, 2011 for more on the avoid-shift-improve framework). This section concentrates on assessing alternative and cleaner fuels and technologies for sustainable transport. Fuels that currently dominate are gasoline and diesel for road transport, electricity for rail, bunker fuels for shipping, and kerosene for air traffic. All modes could benefit from lower carbon technologies, including electric-powered rail, which needs decarbonization of electricity (as discussed in Chapter 11). As road and air are the dominant modes of transport, and are a major source of transport sector GHG emissions, the focus below is on alternative fuels for these modes.

Alternative fuels, including electricity, hydrogen, biofuels, and natural gas, are expected to gain increasing market shares in the coming decades (IEA, 2009d). An important indicator of fuel environmental quality is provided by global warming potential, i.e., GHG content per unit of energy, as estimated by full lifecycle analysis. Crucially, global warming potential can vary enormously for all fuel categories, depending on upstream production process. Hence, electricity, hydrogen, and biofuels constitute low-carbon fuels only if their respective supply chains are low carbon.

Fuel supply chain lifecycle is also important for fossil fuels. For example, upstream emissions of extraction increase significantly for oil tar sands and deep water resources, now entering the market due to increased oil prices (IEA, 2010a). From this perspective, Arabian oil resources perform better than unconventional fossil fuel resources.

Beyond their environmental footprint, novel fuels may have infrastructure constraints, at least initially. While some fuels, such as biofuels and biomethane, can rely on existing distribution infrastructures, electric, hydrogen and hybrid concept cars need completely new or partially new infrastructures. Conversely, from an energy generation standpoint, electric cars can use the capacity existing in current and planned power plants, whereas biofuels and hydrogen would have to scale up production facilities. Building new facilities and approving infrastructure investments necessary to support the market expansion of specific alternative fuels entail making complex decisions. Alternative fuels may function with a certain degree of complementarity, such as when biomass is used to produce electricity. But the most likely case involves trade-offs between alternative sources. Once a decision to create and develop a market for one source is made, it is likely that the chain of decisions and investments will lead to path dependency. Research and development of conventional fuels and powertrains represent sunken investments, as they build on a century of experience, learning curves, and economics of scale. Barriers to the entry of alternative fuels and technologies that hinder their widespread adoption include huge up-front costs for infrastructure and affordable vehicle technologies. This is particularly true for hydrogen, for which investments in infrastructure are considered to be in the range of US$200–500 billion for its use to be feasible in the United States (Hammerschlag and Mazza, 2005). Another uncertainty regarding future benefits and costs, these investments could constitute another technological lock-in. The issue has a lesser impact for electric cars, as the existing electric grid already provides a crucial part of the infrastructure requirement.

Multiple equilibria, corresponding to different fuels, are possible. Some of them could be far from the global optimum. In fact, several authors indicate that a hydrogen economy could result in a suboptimal equilibrium (Keith and Farrell, 2003; Odgen et al., 2004; Hammerschlag and Mazza, 2005). Taking this into consideration, it is useful to evaluate different fuels based on current knowledge of their respective lifecycle analyses. For more discussion on infrastructures, see Chapter 24.

9.4.1 Alternative Fuels for Road Transportation

9.4.1.1 Natural Gas and Biomethane[12]

Natural gas could rely on the existing internal combustion engine platform of vehicles and existing distribution infrastructures, subject to minor changes. While whole-scale infrastructure investments are not needed, a new pump system for gas fuel is required. Natural gas appears as compressed natural gas (CNG, 200–1500 psi) and liquid natural gas (LNG, liquefied at -160°C). Natural gas and biomethane are methane-based (CH_4) fuels and have about 20% lower carbon content than other fossil-based liquid fuels. As such, they are candidates for lowering the

12 See also Chapters 12 and 13

carbon intensity of transportation. Natural gas vehicles emit very low levels of particulate matter (PM) – NO_X, and carbon monoxide (CO) – and can reduce carbon emissions by up to 25% for heavy-duty vehicles (US DOE AFAVDC, 2009).

LNG is more than twice as energy dense as CNG, but has only 60% of the energy density of diesel. Vehicle technology, which uses large compressed gas storage tanks and spark ignition ICEs (internal combustion engines), is particularly mature for heavy-duty applications, which are less constrained by the low energy density of natural gas.

Biomethane is a biofuel refined from biogas, a natural byproduct of organic decay. Major sources of biogas include landfills, manure lagoons, and other agricultural systems. For end-use purpose, biomethane can be treated as natural gas. Fuel-graded biomethane can be directly injected into CNG pipelines or liquefied with LNG and be used in all the same applications. Using biomethane provides the opportunity to reduce GHG emissions, especially if it is sequestered from existing facilities such as landfills, manure lagoons, and rice paddies (unsequestered biomethane has 20 times the global warming potential of CO_2). Methane comprises over 10% of all GHG emissions for Annex I countries in terms of CO_2 equivalence, and around 26% for non-Annex I countries (IPCC, 2007). Harnessing and utilizing biogas is a key strategy for reducing these emissions.

9.4.1.2 Biofuels

Biofuels have been seen as a promising way forward to energy security and climate change mitigation. In some world regions, they are also regarded as a new form of revenue for farmers. However, market-mediated deforestation – and other so-called indirect land-use effects – can negate any GHG abatement and add pressure on global food security and biodiversity. The two major biofuel-producing countries are the United States and Brazil; 46% of global production occurs in the United States, 42% in Brazil, 4% in Europe, and 8% in the rest of the world (World Bank, 2008b). The European Union and the United States have ambitious relative or absolute targets for biofuel market shares by 2020 (see Section 9.6). Key questions for biofuels are their climate mitigation potential, and their (indirect) effects on competitive land uses, such as food production and ecosystem functioning (see also Chapter 20).

Biofuels were originally regarded as zero- or low-carbon fuels. This is based on the fact that biofuels release only CO_2 upon combustion that plants previously absorbed from the atmosphere via photosynthesis. However, GHG gases are also emitted during cultivation (by fertilizer and nitrate application) and harvest of the feedstocks, as well as subsequent processing, refining, distribution, or the various transportation requirements throughout the production stages. Moreover, direct and indirect land-use changes associated with growing the feedstock often change the carbon stored above or below ground.

The lifecycle GHG emissions of biofuels have been studied comprehensively, with emphasis usually placed on bioethanol (Quirin et al., 2004; Niven, 2005; Farrell et al., 2006; von Blottnitz and Curran, 2007; see also Chapter 11). The earlier literature suggests that biofuel systems show moderate to strong fossil fuel substitution potential and GHG savings when compared with conventional petroleum-based fuels. GHG savings vary for different biofuel systems, based on differences in growing methods, climate, and feedstock characteristics. Tropical sugar crops, in particular ethanol from Brazilian sugar cane, were shown to be the most productive feedstocks (e.g., Goldemberg, 2009) – a result that is disputed in the more recent literature (Lapola et al., 2010). Second generation biofuels from lignocelluloses are usually suggested to be the most abundant and potentially most sustainable feedstocks (von Blottnitz and Curran, 2007). A number of studies find GHG performance is worse for current biofuels than for fossil fuel systems (Patzek, 2004; Patzek and Pimentel, 2005; Hertel et al., 2010). Some variation is due to model assumptions regarding the system boundaries, the way co-products are accounted for, and the differences in input parameters and secondary data sources used (Farrell et al., 2006). More recently, three crucial qualifications of GHG benefits of biofuels have pointed out that:

- CO_2 emissions from direct and indirect land-use change are often neglected, tend to worsen GHG benefits, and add considerable uncertainties over the net GHG benefits of biofuels (e.g., Searchinger et al., 2008; Creutzig and Kammen, 2009a; Plevin et al., 2010).

- If land-use change is involved, emissions are better accounted for by temporally explicit lifecycle analysis that addresses upfront land-use emissions, long-term GHG savings from biofuels, and potential soil sequestration (O'Hare et al., 2009).

- Nitrous oxide emissions are estimated simplistically in most studies and have high uncertainties, which can have strong negative effects on the GHG emission balance of biofuels. For example, the IPCC default emission factor for nitrous oxides related to biofuels may underestimate emissions by a factor of 3–5 (Crutzen et al., 2008).

Uncertainties are a major issue, in particular with respect to indirect land-use emissions and nitrous oxide emissions. For example, US corn ethanol reduces GHG emissions per kilometer driven by 20% compared to conventional gasoline, as long as land-use change-related emissions are excluded from the calculations. However, once land-use emissions are accounted for, corn ethanol has twice as high lifecycle emissions as gasoline accounted over a 30-year production period (Searchinger et al., 2008). Within a 95% confidence margin, indirect land-use charge emissions from US corn ethanol expansion range from 21–142 gCO_2-eq/MJ, i.e., from small, but not negligible, to several times greater than the lifecycle emissions of gasoline (Plevin et al., 2010).

In Europe, there is mainly permanent grassland that could be diverted to biofuel feedstock production. If this conversion takes

place, it may take 20 to 110 years (+/- 50%) to recover the soil carbon through GHG emission savings from using the biofuel grown on the same land (de Santi et al., 2008). The same detailed bottom-up study reveals that emissions from nitrous oxides may vary by a factor of 100 depending on the site-specific conditions, notably soil organic content.

A summary of estimates for a variety of different biofuels is given in Figure 9.27. Note that these estimates are subject to major uncertainties (e.g., Plevin et al., 2010). In summary, indirect land-use change-related emissions can worsen the effect of biofuels significantly. For further discussion of the uncertainty of direct and indirect land-use emissions, see Chapter 11.

The performance of biofuels from different feedstock is very mixed across other environmental impact categories (von Blottnitz and Curran, 2007). Biofuel impact is often more harmful compared to conventional fossil fuels (Quirin et al., 2004). A comprehensive LCA of a broad variety of biofuel feedstocks suggests a trade-off between fewer GHG emissions and higher environmental disadvantages of different kinds compared to conventional petroleum-based fuels (Zah et al., 2007). Biofuels might be a greater overall public health risk than conventional petroleum-based fuels due to ozone effects. For a more comprehensive assessment on issues such as water use and biofuel production, see Chapter 20.

Crucially, agricultural crop production for biofuels competes with food production. The current production of biofuels based on conventional crops – first generation biofuels – has already put pressure on global food prices. While the World Bank estimates that biofuel production has been responsible for roughly 75% of the increase in food prices between 2002 and 2008, the overall literature is ambiguous on the magnitude of the biofuel-induced price hike (see Chapter 20 for a complete discussion). Food price hikes and induced food insecurity have severe consequences for the livelihoods of people in poor countries. The Food and Agricultural Organization of the United Nations (FAO, 2008) suggests that an additional 75 million people were pushed into undernourishment during the global food price crisis in 2007, bringing the total to nearly one billion hungry people in the world. Achieving the aggressive biofuel targets in the United States and Europe could potentially have much larger impacts, which justifies the need for questioning current biofuels strategies.

Second and third generation biofuels have been put forward as biofuels with low lifecycle emissions. Second generation biofuels are derived from non-food crops, and important variants such as cellulosic bioethanol are suggested to have very low lifecycle GHG emissions (Farrell et al., 2006). Third generation biofuels are produced from algae and have much lower land demand. However, more recent studies question the economic viability of second generation biofuels and point out that these biofuels compete with food production, too (Sanderson, 2009). For further discussion, see Chapter 11, Section 11.2.

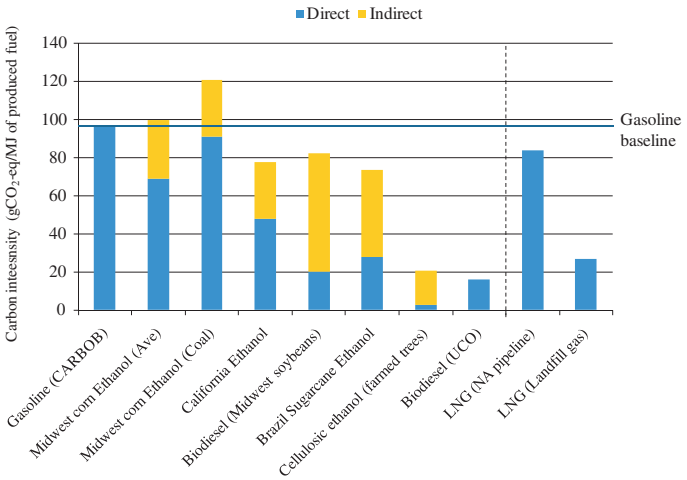

Figure 9.27 | Carbon intensity of different biofuels as compared to gasoline. UCO refers to used cooking oil which is generally assumed to have no indirect effects, and hence, has relatively low carbon intensity. Source: based on CARB, 2009; Creutzig et al., 2011a.

In summary, with a few exceptions[13] biofuels currently available in the market place have questionable impact on GHG emissions, food security, and other land-related issues, such as deforestation and biodiversity. Large uncertainty on indirect land-use changes and third level impact requires further research. Meanwhile, further large-scale biofuel production must be considered with caution. The accumulation of niche-based solutions, however, may be promising (Tilman et al., 2009). Chapter 11 and 20 suggest that the deployment of advanced biofuels with low GHG footprint is possible and can be recommended if managed in the strict context of sustainable development and if food security remains uncompromised.

9.4.1.3 Electricity and Hydrogen

Electricity and hydrogen as fuels for road transport both represent intermediate energy storage mediums that need to be produced by other sources of energy (e.g., coal, nuclear, or wind in the case of electricity, and natural gas or electricity itself in the case of hydrogen). Hence, they are discussed together. First, common features are presented and both fuels are compared. Then specific issues for each fuel are raised.

The limiting factor for battery electric cars is the total energy that can be delivered and the limited driving range, whereas the constraint for hydrogen fuel cell vehicles is the amount of power they can produce and whether this will be sufficient to meet vehicle acceleration requirements (Eaves and Eaves, 2004). Battery storage has higher WTW efficiency (75–85%) than hydrogen (30–50%) and lesser known variants such as compressed-air storage (<30%) (Schaber et al., 2004; Eaves and Eaves, 2004; Creutzig et al., 2009), translating into the more efficient

13 Such as Brazil Sugarcane Ethanol, cellulosic ethanol, Biodiesel from used cooked oil (UCO), and advanced biofuels.

economic and environmental performance of electric cars than hydrogen cars (Hammerschlag and Mazza, 2005). For electric cars, costs scale according to battery capacity. As most trips would be short distances, plug-in hybrid electric vehicles (PHEVs) provide the best cost-benefit ratio in the medium term (APS, 2008). Research and development (R&D) also needs to comprise demand-side technologies, as the current electric grid capacity is sufficient to fuel 20–50% of the European Union or the United States' fleets when demand-side technologies and policies are deployed (Denholm and Short, 2006; Kintner-Meyer et al., 2007; EC DGJRC, 2009).

Electricity

For electric mobility, electricity production and the required vehicle technology and recharging infrastructure need to be assessed. Since electricity generation and its distribution infrastructure are already widely used in most countries, there is no significant barrier to its use for road transport. Efficiency is discussed in Chapter 9, Section 9.3.2. Hence, the focus here is on electricity production. The key factor determining the life-cycle emissions of electric vehicles (EV) is the carbon intensity of the electricity generation.

Renewably produced electricity comprised 18% of global electrical consumption in 2007 and is projected to rise further (EIA, 2010, see also Chapter 11). The difference is mainly due to uncertainty in ambition of global climate change mitigation policies. In 2008, renewables comprised over 50% of all newly added electrical capacity in the United States and Europe combined, or 276.7 GW (Martinot and Sawin, 2009). With the current electricity mix in countries such as the United States and Germany, electric cars can have about the same global warming impact as conventional cars with otherwise the same characteristics (e.g., Creutzig et al., 2009). With an increasing share of renewable energies, the global warming impact of electrics is expected to decrease.

EVs do not necessarily reduce net emissions, but they remove them from inner cities where air pollution has the highest public health impact (i.e., intake fraction is highest). Hence, an electrification of current car fleets would produce public health advantages in most cities.

Electric mobility requires a new infrastructure. Electric vehicles face barriers to market entry, mostly related to range anxiety. The challenges that remain for all-electric vehicles (e.g., BEVs, PHEVs) are technological and logistical.

First, the requirements of fueling infrastructure and capacity of the electric grid to recharge EV batteries are important considerations. The fueling infrastructure for EVs is less costly to deploy than for hydrogen, requiring only recharging stations with conventional outlets connected to the existing electrical grid, which are estimated to cost around US$2000 per commercial charging station (Morrow et al., 2008). Another option would be to have fueling stations remove depleted batteries from vehicles and provide fully charged batteries to drivers, thereby helping them avoid lengthy recharging times. A study in the United States showed there is sufficient off-peak electrical capacity to charge 185 million EVs overnight, or 75% of the current US passenger vehicle fleet (Schneider et al., 2008). Policies and smart infrastructures are required to make use of off-peak capacity. While using off-peak electricity will result in overall increased grid efficiencies, it will still result in greater wear and tear of the grid, especially for transformers, resulting in higher maintenance costs (Blumsack et al., 2008).

Second, the batteries themselves are problematic components of EVs. The weight, size, cost, and lifetime of batteries must be optimized to improve the marketability and all-electric range (AER) of EVs. Larger batteries provide longer AERs and weigh from 23 kg (50 lbs) for limited-AER PHEVs to 450 kg (1000 lbs) for highway capable 320 km (200mile) AER BEVs (Shiau et al., 2009). Given the trade-off between battery weight and vehicle fuel efficiency, researchers are trying to reduce battery weight while maintaining desired AER. Most of today's EV models use nickel-metal hydride (NiMH) batteries, but the next generation will use Li-ion batteries, which are more compact and lightweight but also more expensive.

Third, the incremental cost of EVs compared to gasoline ICEs and Gs is significant. In the long term, PHEVs with an AER of 64 km (40 miles) are estimated to be at least US$11,000 more expensive than gasoline ICE vehicles (Simpson, 2006). The battery is the most expensive component of EVs, with a cost of US$30,000 or more for BEVs (US BTS 2001). Lower battery costs and higher petroleum costs will make them more competitive, along with other government incentives such as tax rebates and subsidies (Simpson, 2006). When taking into account the fuel cost savings, PHEVs could be up to US$11,000 cheaper than conventional ICE vehicles over their lifetime. However, the high sticker price for highway capable BEVs, as much as US$100,000 for some current models, requires substantial reduction before they can be mass-marketed (Tesla Motors, 2009).

Hydrogen

Hydrogen has been used in ICEs of cars, trains, ships, and other applications prior to the 1930s. Hydrogen gas burns cleanly in an ICE with minimal PM, NO_x, and CO_2 emissions. As a second possible technology, hydrogen-fuel cell vehicles emit only water as a byproduct.

Using hydrogen as a transportation fuel enables decentralized fuel production and refueling. Similar to electric vehicles, hydrogen vehicles allow for the displacing of fossil fuels if the hydrogen is produced from renewable energy. Hydrogen vehicles can also act as renewable energy storage devices. As an advantage over electric vehicles, hydrogen has higher energy density, and hence long-range driving is possible. However, WTW efficiency is lower than for electric cars. If not produced by electrolysis where the electricity is provided by renewable energies, hydrogen cars tend to have higher GHG emissions than electric cars.

The largest barrier to hydrogen vehicle use is the present economic infeasibility of mass-marketing the technology. Fuel cells, hydrogen

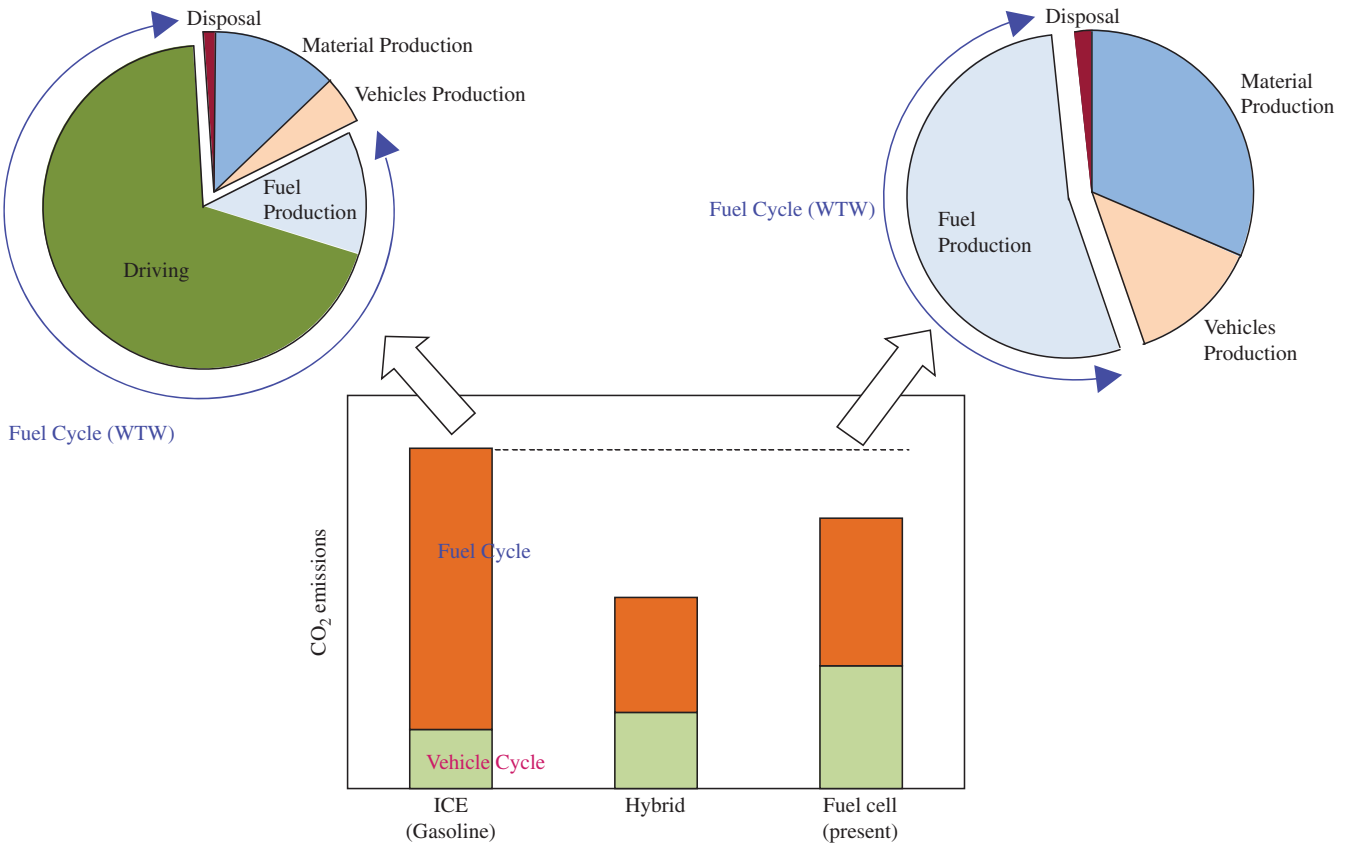

Figure 9.28 | LCA for passenger vehicles. (Pie charts show the details of CO_2 emissions from both fuel and vehicle cycles. Pie chart for HEV is not shown, but general features are between ICE and FCV.) Source: based on Toyota, 2004.

storage devices, fueling infrastructure, and hydrogen production are all currently very costly. Overcoming these kinds of economic and logistical barriers will require substantial political will and public funding into the foreseeable future, another impediment in its own right. However, should hydrogen transportation become economically viable, it provides an opportunity for significantly reducing GHG emissions.

9.4.2 Improving the Efficiency of Road Vehicles

Fuel use is a function of vehicle use (km/yr) and fuel economy (fuel/km). This section addresses potential for improvement for fuel economy.

9.4.2.1 Lifecycle Analysis of Motorized Vehicles

For automobiles, lifecycle analysis can be divided into the two parts; fuel cycle (extraction of crude oil, fuel processing, fuel distribution, and fuel use during vehicle operation) and vehicle cycle (material production, vehicle manufacturing, vehicle distribution, and disposal at the end of life). For a typical ICE vehicle, 70–90% of energy use and GHG emissions take place during the fuel cycle, depending on vehicle efficiency, driving mode, and lifetime driving distance, as shown in Figure 9.28 (Toyota, 2004).[14] This indicates that the most effective CO_2 reduction measures would target the fuel cycle, making vehicle fuel economy an important aspect of vehicle technologies.

Although the vehicle cycle contributes 10–30% to the overall emissions in conventional cars, fuel cell and hybrid cars have higher levels of vehicle cycle emissions because more energy is needed to make battery, fuel cell stack, and electronic parts, such as motors and power control units (Toyota, 2004).

Recent research has summarized results of fuel cycle analyses (e.g., IPCC, 2007; CARB 2009; Creutzig et al., 2011a), especially in relation to biofuel and hydrogen production. Regional studies of the WTW CO_2 emissions of conventional and alternative fuels and vehicle propulsion concepts include a General Motors/Argonne National Laboratory (GM/ANL, 2005) analysis for North America, EU-CAR/CONCAWE/JRC (2006) for Europe, and Toyota/

14 For other transportation modes such as train and ship, very similar pictures can be observed where the CO_2 emission is dominant during operation, as shown in Figure 9.33 (Aihara and Tsujimura, 2002; Kameyama et al., 2005). CO_2 emissions during operation are very sensitive to total length, frequency of travel and other operational conditions.

Mizuho (2004) for Japan. These LCAs display small but significant differences for ICE-gasoline and ICE-D (diesel), reflecting the difference in oil producing regions and regional differences in gasoline and diesel fuel requirements and processing equipment in refineries (Khan Ribeiro, et al., 2007).

The WTW CO_2 emissions shown in Figure 9.30 are for the following four groups of vehicle/fuel combinations; ICE/fossil fuel, ICE/CNG, EV, FCVs and a number of hybrids. The full WTW CO_2 emissions depend on not only the drive train efficiency (tank-to-wheel or TTW) but also the emissions during fuel processing (well-to-tank, or WTT). ICE-D has 16–24% lower emissions due to the high efficiency of the diesel engine. The results for hybrids vary among the analyses due to different assumptions of vehicle efficiency and different driving cycles. Toyota's analysis of the Prius, using a Japanese 10–15 driving cycle, demonstrates a potential for CO_2 reductions of 30–50% (Khan Ribeiro, et al, 2007).

The lifecycle emissions of ICE vehicles using biofuels and fuel cell vehicles are extremely dependent on the fuel pathways. For ICE-Biofuel, the CO_2 reduction potential is often assumed to be very large (30–90%) (e.g., IPCC, 2007). As the discussion in Section 9.3.1 demonstrated, recent research estimates that current biofuels possibly have a higher global warming potential than gasoline, mostly due to taking indirect land use change into account (see Figure 9.23).

The potential of EV is strongly dependent on the CO_2 emission factor of power generation. In regions where coal-fired plants dominate, switching to EV increases CO_2 emissions. The GHG reduction potential for natural gas-sourced hydrogen FCV is moderate, but lifecycle emissions could be dramatically reduced by using CCS (carbon capture and storage) technology during H_2 production. Using renewable energy such as C-neutral biomass as a feedstock or electricity from renewables as an energy source also will yield very low emissions (Khan Ribeiro, et al, 2007).

9.4.2.2 Fuel Economy: Minimizing Energy Losses

There are significant opportunities to improve energy efficiency of road transport. Only about 20% of the energy from the fuel put into passenger vehicles gets used to operate the vehicle. The rest of the energy is lost in the engine and drive train and during idling (OTA, 1995; US DOE, 2010) as seen in Figure 9.31.

There is great potential to improve vehicle energy efficiency through improvements in vehicle technology. Fuel use of road transportation can be reduced by increasing the conversion efficiency of the fuel energy to work by improving drivetrain efficiency and recapturing energy losses; and reducing vehicle loads such as weight, rolling, air resistance, and accessory loads, thus reducing the work needed to operate it.

Engine losses
In gasoline-powered vehicles, more than 60% of the fuel energy is lost in the engine due to engine friction, pumping air into and out of the engine, and wasted heat. These losses can be reduced by advanced engine technologies such as variable valve timing and lift, turbocharging, direct fuel injection, and cylinder deactivation. Also, diesel engines have about 15–25% higher efficiency than gasoline engines. As will be discussed later, fuel cell vehicles and electric vehicles are future options for substantial improvement in powertrain efficiency.

Idling losses
During urban driving, idling at stop lights or in traffic causes significant energy loss. These losses can be reduced by automatically turning the engine off when the vehicle comes to a stop and restarting it instantaneously when the accelerator is pressed. This is a standard technology in current hybrid vehicles.

Drivetrain losses
Energy is also lost in the drivetrain and it is improved by technologies such as automated manual transmission and continuously variable transmission.

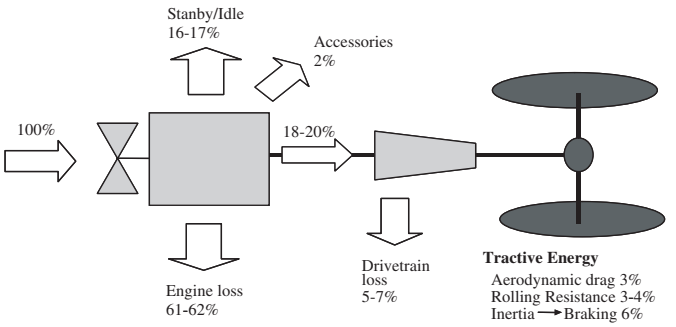

Figure 9.31 | Energy use in a typical gasoline passenger vehicle (mid-size, urban driving mode). Source: based on Kobayashi et al., 2009.

9.4.2.3 Fuel Economy: Reducing Vehicle Loads and Weight

Rolling resistance
Rolling resistance is the resistive forces between the tires and the road, and is directly proportional to weight. It amounts to up to about 30% of total tractive force. It can be reduced by tire design (tread and shoulder designs) and tire materials, and redesigning wheel bearings and seals. For passenger cars, a 5–7% reduction in rolling resistance leads to a 1% improvement of fuel efficiency. However, there are trade-off such as traction, durability, and noise.

Aerodynamic drag
About 30% of total tractive forces is lost by aerodynamic drag, and it become higher during fast highway driving, since drag is directly proportional to the square of speed. Drag forces are reduced by reducing the frontal area of the vehicle, smoothing out body surfaces and adjusting the body's basic shape and so on.

Accessories
Accessories such as air conditioning, power steering, windshield wipers, and audio systems use energy generated from the engine. This becomes substantial in battery-powered vehicles during hot or cold weather.

Braking losses
Upon braking, kinetic energy of vehicles is lost. The regenerative braking system can capture the energy as electricity or a kinetic force.

Vehicle weight
Energy to overcome the vehicle's inertia is directly related to its weight. The less a vehicle weighs, the less energy required to start and drive it. Weight can be reduced by lightweight materials and vehicle design. Lightweight materials in BEVs can increase the driving range – one of the crucial constraints of electric vehicles. For example, carbon fiber materials will be used for BMW's 2013 Mega City Vehicle, but with a penalty of cost.

9.4.2.4 Vehicle Efficiency through Hybrid Technology and Alternative Fuel Engines

Hybrid drivetrains
Typical hybrid-electric drive trains is a combination of a fuel-driven power source, such as a conventional internal combustion engine with an electric drivetrain – electric motor/generator and battery (or ultracapacitor) – in various combinations. In most current hybrids, the battery is recharged only by regenerative braking and engine charging, without external charging system from the grid. Since the 1997 introduction of the Toyota Prius hybrid in the Japanese market, hybrid electric drivetrain technology has advanced substantially. The markets for hybrid vehicles have expanded, presently providing a variety of improved systems in alternative forms and different combinations of costs and benefits.

Hybrid systems now cover a range of technologies from simple belt-drive alternator-starter systems, offering perhaps 7–8% fuel economy benefit under US driving conditions, to "full hybrids" such as the Prius, offering up to perhaps 40–50% fuel economy benefits (IPCC, 2007). Hybrids recover the kinetic energy by regenerative braking system and also save energy by idle-stop, therefore they can improve fuel efficiency in congested urban driving conditions. This might be particularly useful for taxis and vehicles dedicated to urban use as well as for some heavier-duty applications, including urban buses and urban delivery vehicles (IPCC, 2007). FedEx has claimed a 57% fuel economy improvement for its E700 diesel hybrid delivery vehicles (FedEx, 2004). Hybrid sales have expanded rapidly. In the United States, sales were about 7,800 in 2000 but rose to 350,000 in 2007. Worldwide cumulative Prius sales alone hit 500,000 by the end of April 2006, 1,000,000 by the end of April 2008, and 2,000,000 by the end of September 2010.

Plug-in hybrids, or PHEVs, are conventional hybrids with a capability of charging from the grid, and can be seen as a merging of hybrid electric and battery electric vehicles. PHEVs get some of their energy from the electricity grid. Plug-in hybrid technology could be useful for both LDVs and for a variety of medium-duty vehicles, including urban buses and delivery vehicles. Substantial market success of PHEV technology is, however, likely to depend strongly on further battery development, in particular on reducing battery cost and specific energy, as well as increasing battery lifetimes.

By using electricity to "fuel" a substantial portion of distance driven the potential of PHEVs to reduce oil use is clear (IPCC, 2007). The US Electric Power Research Institute (EPRI, 2001) estimates that 30 km hybrids (those that have the capability to operate up to 30 km solely on electricity from the battery) can substitute electricity for gasoline for approximately 30–40% of miles distance driven in the United States. With larger batteries and motors, the vehicles could replace even more mileage. However, their potential to reduce GHG emissions compared with more than that achieved by current hybrids depends on their sources of electricity. For regions that rely on relatively low-carbon electricity for off-peak power, e.g., natural gas combined cycle power, GHG reductions over the PHEV's lifecycle will be substantial. In contrast, PHEVs in areas that rely on coal-fired power could have increased lifecycle carbon emissions. In the long-term perspectives, transition to a low-carbon electricity sector could allow PHEVs to play a major role in reducing transport sector GHG emissions (IPCC, 2007). Technically, the development of high-performance batteries for PHEVs remains a big challenge.

Hydrogen/fuel cells

During the last decade, FCVs have attracted growing attention and made significant technological progress. Hydrogen fuel cells decouple carbon from power generation and emit only water vapor. Growing urban air pollution, climate impacts and energy security and the potential to provide new desirable attributes for vehicles (low noise, new designs) are main drivers for development of FCVs. Hydrogen can be produced from a wide range of sources including fossil, nuclear and renewable. However, the chicken-and-egg challenge to provide vehicles and required infrastructure at the same time is more pronounced for hydrogen vehicles than it is for electric vehicles, reducing the short-term likelihood of large-scale deployment. However, a study about the US Hydrogen Initiative states that hydrogen can be produced in a "distributed" fashion at the refueling station by reforming natural gas and renewable fuels like ethanol utilizing existing delivery infrastructure to meet initial lower volume needs with the least capital investments, therefore fuel reformers would not require a substantial hydrogen transport and delivery infrastructure (Chalk, et al., 2008). While production is workable, hydrogen must be compressed, stored and dispensed at refueling stations or stationary power facilities. The same study considers that "hydrogen costs and availability and fuel-cell durability and cost are still formidable challenges to be solved" (Chalk, et al., 2008). Although there are several types of FCVs, such as direct-drive and hybrid powertrain architectures and fuelled by pure hydrogen, methanol, and hydrocarbons (gasoline, naphtha), nearly all auto manufacturers are now focused on the pure hydrogen FCV. Significant technological progress has been made for these several years, including improved fuel cell efficiency and durability, cold start (sub-freezing) operation, increased range of operation, and dramatically reduced costs. (Although FCV drive train costs remain at least an order of magnitude greater than ICE drivetrain costs).

A recent US National Research Council assessment (NRC, 2008) concludes:

- Concentrated efforts by private companies, together with governments around the world, have resulted in significant progress toward a commercially viable hydrogen fuel cell vehicle.
- Fuel cell costs have been reduced significantly over the past 4–5 years. Costs projected for high-volume (500,000 units/year) automotive fuel cell production are approximately US$100/kW for relatively proven technologies and US$67/kW for newer laboratory-based technologies.
- A significant market transition to FCVs could start around 2015 if supported by strong government policies to drive early growth.

The GHG reduction potential of FCVs strongly depends on the hydrogen production pathways and the efficiency of vehicles. At the present technology level, with FCV TTW efficiency of about 60%, and where hydrogen can be produced from natural gas at 60–80% efficiency, WTW CO_2 emissions can be reduced by 40–65% compared to current conventional gasoline vehicles. In the future, if hydrogen is produced by water electrolysis using renewable electricity such as solar and wind, or nuclear energy, the entire system from fuel production to end-use in the vehicle has the potential to be a true zero emissions system. The same is almost true for hydrogen derived from fossil sources with CCS system, in which as much as 90% of the CO_2 produced during hydrogen manufacture is captured and stored.

Table 9.4 | Increase of fuel efficiency due to various vehicle technologies.

Engine Technologies	Increase (%)	Transmission Technologies	Increase (%)
Variable Valve Timing & Lift	1–9	Continuously Variable Transmissions (CVT)	3–8
Cylinder Deactivation	7–7.5	Automated Manual Transmissions (AMT)	7–9
Turbochargers	2–7.5		
Idle Stop	0.5–8

Electric vehicles

Battery-powered electric vehicles operating today are powered by electricity acquired from the grid and stored on board in batteries. Electric vehicles have high efficiencies of more than 90%, but the big challenges are left to be overcome; short driving range and short battery life. Although the potential for CO_2 reduction strongly depends on the power mix, WTW CO_2 emission can be reduced by more than 50% compared to a conventional gasoline ICE (JHFC, 2006).

Vehicle electrification requires a more powerful, sophisticated, and reliable energy-storage component than lead-acid batteries. NiMH batteries currently dominate the hybrid market and Li ion batteries are expected to replace the market. The energy density has been increased to 170 Wh/kg and 500 Wh/L for small-size commercial Li ion batteries and 130 Wh/kg and 310 Wh/L for large-size EV batteries. The major hurdle left for Li ion batteries is high cost (IPCC, 2007).

Ultracapacitors offer long life and high power but have low energy density and a high current cost. The energy density of ultracapacitors has increased to 15–20 Wh/kg (Power System, 2005), compared with 40–60 Wh/kg for Ni-MH batteries. The cost of these advanced capacitors is in the range of several 10s of dollars/Wh, about one order of magnitude higher than Li batteries (IPCC, 2007).

9.4.2.5 Quantifying the Efficiency Improvement of Technologies

Table 9.4 summarizes the impact of vehicle technologies on vehicle fuel efficiency (Kobayashi et al., 2009). Most of these technologies are already commercially utilized, and the range of improvement by the use of these technologies is still relatively large. There are some trade-offs, such as emission control and safety issues. Employment of these technologies in new vehicles leads to an increase of vehicle production costs, although part (and, in some cases, all) of this cost increment is offset by fuel savings. Car manufacturers will select unique packages of technologies, based on the level of improvement required, economy viewpoint, and also their expertise.

Based on these technology developments, vehicle efficiency presented here is estimated along the timeline from 2010–2050 (Kobayashi et al., 2009). Since base vehicles, and assumptions about the employment of technologies and their effectiveness are different, the range of estimates among the studies are rather large, and the estimates of MIT (Ref. No. 5–8 in Table 9.7) are in the higher range compared with others. This is partly due to a more optimistic view, but also due to the fact that the potentials for improvement of vehicle efficiency in the US market is larger. As can be seen in Table 9.5, baseline gasoline ICE vehicles with conventional drivetrains could be continuously improved up to 2050, and achieve close to a 50% increase in fuel efficiency with advanced technologies. At the same time, diesel ICEs will gain higher efficiency, but their margin over gasoline vehicles will shrink (Kobayashi et al., 2009)

Several technical hurdles remain to be overcome for wide marketplace acceptance of hybrids, fuel cells, and electric vehicles. As mentioned above, the cost increase due to new technology is very important when gauging potential market penetration (Kobayashi et al., 2009). As in the case of efficiency improvement, there are large differences among studies. In particular, cost estimates for HEVs in EUCAR/CONCAWE/JRC (2004) are significantly higher than other studies. This may be explained by their assumption of very high HEV battery requirement with 6kWh, which allows the 20 km of full EV operation.

In Figure 9.32, most of the data lies below US$6000. Calculating how many years customers need to pay off the increment of vehicle price by saving the fuel cost provides some implication for the market (Kobayashi et al., 2009). Starting with a typical situation in the United States, that a vehicle has a fuel efficiency of 10 km/L (24 MPG) and travels 19,000 km (12,000 miles) yearly, results in an annual fuel consumption of 1900 L (500 gallons). If fuel costs US$0.80/l (US$3/gallon), the annual fuel cost is US$1500. If the fuel efficiency improvement is 50%, customers need 12 years to pay off the price increment. In Japan, where fuel prices are almost twice as high, but distance traveled per year is around 14,000 km, only six years are needed to pay off the price increment. Although this does not necessarily mean that customers will be willing to buy

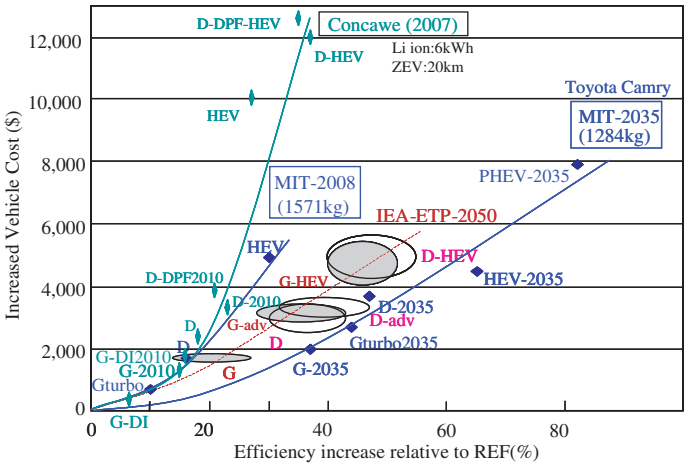

Figure 9.32 | Price increase of vehicle due to efficiency increase. Data for IEA are shown as ellipses indicating the range of data. (G: gasoline, D: diesel, DI: direct-injection, DPF: particulate filter) Source: based on data from EUCAR/CONCAWE/JRC, 2006; Bandivadekar, 2008; IEA, 2008.

the vehicle with such an increased price, this fuel savings/vehicle cost trade-off may be commercially allowable if future consumers are highly concerned about fuel economy.

9.4.3 Aviation

9.4.3.1 Alternative Fuels for Aviation

Sustainable alternative fuels produced from biomass or renewable oils offer the potential to reduce lifecycle GHG emissions from aviation. As these fuels contain significantly lower fuel sulphur, they may also help to reduce emissions of particulate matter and lessen aviation's impact on air quality. Aviation is heavily dependent over the short- and medium-term on drop-in liquid fuels. Sustainable alternative aviation fuels are not available today in significant quantities, and considerable doubts remain on their lifecycle GHG emissions. In fact, the lifecycle GHG emissions of biofuels may be higher than previously estimated when indirect effects are included (see Section 9.3), putting doubts on the straight-forward realization of win-win opportunities.

In the short term,[15] sustainable alternative fuels for aircraft may be available in limited quantities and have a lifecycle CO_2 footprint equal to, or less than, conventional jet fuel. It will be necessary to blend these alternative fuels with conventional jet fuel at up to a maximum of 50% to produce a drop-in fuel. Drop-in jet fuels are completely interchangeable with conventional jet fuel, and so will not require the modification of fuel handling and distribution systems.

In the medium term, it is possible that sustainable alternative fuels for aircraft will be available in much larger quantities. Given sufficient demand or incentive, significant supplies of jet fuel that offer a significant reduction in lifecycle CO_2 emissions could be available in the mid-term. Significant research and development activities currently underway are expected to lead to a number of commercial scale production facilities. Also, the development of new sustainable alternative fuels for aircraft could be able to reduce costs of fuels to compete with conventional jet fuel in the mid-term.

In the long term, the aviation industry may explore more radical fuels that require redesigned engines and airframes. Fuels such as liquid hydrogen and liquid methane might be used to significantly reduce GHG emissions.

The following goals for alternative fuels are relevant for aviation:

- The US Consortium for Continuous Low Energy, Emissions, and Noise (CLEEN) has set a goal that 20% of jet fuel available for purchase by US commercial airlines and cargo carriers will be alternative fuels by 2016.
- The European Union has established a requirement that lifecycle GHG emission savings from the use of biofuels shall be at least 50% by 2017 and at least 60% by 2018 (however, indirect land-use emissions are not included in this accounting so far, as of April 2011).
- The European Union set a target of 10% use of renewable energy sources in transport by 2020.

Alternative aviation fuels are discussed individually below.

Natural gas and electricity
For ground operations in ground power units (GPUs) and energy backup systems, natural gas and electricity are already being used in some airports, mainly as substitutes for diesel. These measures are for short term implementation. Even though the cost of retrofit or equipment replacement can be expensive, these fuels still may be practicable to use in the aviation industry.

Fuel cells
There are ongoing studies on the use of fuel cells to power small generators and aircraft auxiliary power units when on the ground. The cost of these cells remains very high, and they are seen as a long-term measure for reducing emissions at airports.

Hydrogen
For aircraft operations, the most difficult option from a technological point of view is hydrogen. Great changes in aircraft design will be necessary for using this fuel that releases water vapor and NO_x (which also have radiative forcing) when burned. As it is a radical change of paradigm, this is considered a long-term solution. Since it requires changes in structures for fuel storage and transport, as well as new design technology and aircraft building, the economic impacts must be significant for the aviation industry, and society as a whole, to accept such a radical change.

Synthetic liquid fuel
Synthetic liquid fuels are obtained from different kinds of sources such as coal, natural gas, biomass, oil shale, or tar sand. One problem related to

15 Short term is approximately 5–10 years; medium term is 11–20 years; long term is over 20 years.

Box 9.4 | Alternative Fuels for Aviation Demonstration Cases

The international aviation industry has successfully demonstrated the technological feasibility of using sustainable alternative jet fuel blends in flight tests without affecting safety. The following test flights using alternative aviation fuels have been conducted during the past two years, which supported the approval of the ASTM D-7566 Standard Specification for Aviation Turbine Fuel Containing Synthesized Hydrocarbons, the first new jet fuel specification in more than 20 years.

Examples of aviation alternative fuel demonstrations:

- Airbus flew its A380 test aircraft with one of its four engines running on a 40% blend of Gas-To-Liquid (GTL) fuel with conventional jet fuel on 1 February 2008.
- Virgin Atlantic flew a Boeing 747–400 on 23 February 2008 with one engine operating on a 20% biofuel mix produced from babassu oil and coconut oil.
- Air New Zealand flew a Boeing 747–400 with one engine on 50% jatropha-derived hydro-treated renewable jet (HRJ) biofuel and 50% kerosene on 30 December 2008.
- Continental Airlines flew a Boeing 737–800 with one engine using 50% jet fuel and 50% algae and jatropha mix on 7 January 2009.
- JAL flew a Boeing 747–300 with 50% HRJ biofuel (derived from camelina, jatropha, and algae) and 50% kerosene mix on 30 January 2009.
- Qatar Airways performed the first revenue flight with alternative fuel on 12 October 2009. An A340–600 flew from London to Doha with its four engines running on a 48.5% blend of GTL with conventional jet fuel.
- KLM flew a Boeing 747–400 using a mix of 50% HRJ biofuel (derived from camelina) and 50% conventional Jet A1 on 23 November 2009.

Source: UNFCCC, 2010.

this type of fuel is its low lubricity due to the absence of sulphur in its composition. A second problem is the high cost of production, because it is still predominantly based on the Fischer and Tropsch process (coal-, gas-, or biomass-to-liquids), which requires an intense use of energy for precursor gasification and CO polymerization in the presence of water. Therefore, synthetic fuels are energy and CO_2 intensive. In spite of that, they are broadly compatible with current fuel systems, can produce a clean burn, and tend to produce less particulate matter. There are little technological barriers towards the introduction of synthetic liquid fuel technology

Biofuels

In the aviation industry, biofuels are seen as the most promising candidate. Biofuels are being tested by several companies. However, biofuels perform unfavorably in terms of global warming potential, as seen from a lifecycle perspective. For lifecycle accounting of biofuels, see Section 9.3.1.1.

There is an important difference between biofuels for road transport and biofuels for aviation. Because aviation fuels must have a high energy density and chemical stability as well as a low freezing point, conventional biofuels are not suitable. Therefore, biofuels for aviation must be drop-in (hydrocarbon) fuels that can be produced by hydro-treating the bio oil, gasification/F-T process and other new biochemical pathways, such as sugar-to-diesel process. These production processes are still in the R&D phase.

9.4.3.2 Improving Energy Efficiency in Aviation

The aviation sector's efficiency track record is solid. Aircraft being built today are greater than four times more efficient than those built 40 years ago. According to Greener by Design (2011), "fuel efficiency in aviation improved by 70% between 1960 and 2000 – a better record than any other transport mode. Between 1990 and 2000 alone, aviation fuel efficiency improved by 20%. Improvements of an additional 20% are projected by 2015 and 40–50% by 2050, relative to today's aircraft. Current research programs have goals of reducing landing and take-off NO_x emissions by up to 70% over today's regulatory standards, while also improving fuel consumption by 8–10% over the most recent production engines by about 2010."

ICAO's Assembly Resolution A37–19 is aimed at improving the outlook for aviation's future climate footprint. The resolution recognizes the potential of technological and operational improvements,

market-based measures, and the use of sustainable alternative fuels to reduce aviation's climate impact. The resolution aims to collectively achieve global aspirational goals of improving fuel efficiency by 2% per year and stabilizing CO_2 emissions at 2020 levels. However, with respect to projected growth rate in aviation (Schäfer et al., 2009), GHG emissions from aviation will challenge ambitious GHG mitigation targets.

ICAO (2009) has identified a basket of measures for addressing GHG emissions from international aviation:

- *Aircraft related technology development (including alternative fuels)*: Measures in this category include purchase of new aircraft, retrofitting and upgrade improvements on existing aircraft, new designs in aircraft/engines, fuel efficiency standards, and alternative fuels. Some of these measures have the potential for very high gains in fuel efficiency/emissions reduction, but the costs are likely to be high and there will be a long timeframe for implementation.

- *Improved air traffic management and infrastructure use*: More efficient air traffic management planning, ground operations, terminal operations (departure and arrivals), en route operations, airspace design and usage, and air navigation capabilities. These are measures with the potential for relatively short- to medium-term gains, although the scale of potential relative gains is low to medium. More efficient planning and use of airport capacities, construction of additional runways and enhanced terminal facilities, and clean fuel-operated ground support equipment. These can be implemented in the short to medium term, but potential emission reduction gains are likely to be low. Increased airport capacity may also encourage increased emissions from aircraft unless appropriate actions are taken to address the emissions.

- *More efficient operations*: Measures include minimizing weight, improving load factors, reducing speed, optimizing maintenance schedules, and tailoring aircraft selection to use on particular routes or services. This area is essentially a matter for aircraft operators and can be further incentivized by market-based instruments.

9.4.4 Shipping and Railways

9.4.4.1 Improving Energy Efficiency in Shipping

Giving the global volume of seaborne trade, the shipping industry is increasingly expected to share the burden of reducing global emissions of CO_2. Shipping is already a very efficient form of transport in terms of CO_2 emissions per tonne-km of goods moved. It compares favorably with rail transport, is more efficient than road transport, and is considerably more efficient than air freight (see Figure 9.12). Bunker fuels used in shipping are highly polluting for international seas and coasts and they challenge marine ecological systems.

In the past increases in fuel oil prices have encouraged improvements in ships fuel efficiency. During 2008, many ship operators, particularly of container ships, adopted a policy of "slow steaming," i.e., reducing the speed at which a ship operates. Reduction in a ship's speed from 26 knots to 23 knots can result in a 30% fuel savings.

Marine diesel engines are already highly efficient, operating near the theoretical maximum thermal efficiency. Almost 50% of the energy

in the fuel is converted into mechanical work in a large marine diesel engine. Effective recovery of waste heat from the engine can further raise the efficiency to nearly 55%.

Because there is currently little or no scope for improving the efficiency of the marine diesel engine itself, improvements will have to come from other elements of ship design and operation. The International Maritime Organization (IMO) is currently debating which measures could be introduced to limit or reduce shipping's CO_2 emissions. Measures can be divided into operational measures, i.e., those that deal with how the world fleet is managed and operated, and technology/design measures. The latter can be further subdivided: some measures can be introduced only at the design/building stage for a ship, whereas others can be retrofitted to existing ships. Tables 9.6, 9.7, and 9.8 list some of the measures considered by IMO, giving an indication of what might be achievable.

9.4.4.2 Improving Energy Efficiency in Railways

Rail is more energy efficient than most other transport modes, For example, in Germany, rail-based passenger transport has about one-third of the GHG emissions per passenger of air traffic, and half of car transport (IFEU, 2010). Despite this, enhancement of energy efficiency is an important issue in order for railways to reap cost savings and to enlarge competition advantages, as well as to reduce railway's contributions to climate change.

One key means of improving energy efficiency in railways is to deploy advanced technologies. The International Union of Railways funded a project in which all relevant railway energy-saving technologies have been analyzed and evaluated. These evaluated technologies are summarized in Table 9.9. For electric railways, decarbonization can be achieved by switching from fossil fuels (e.g., coal fired power plants) to renewable energies.

9.5 Alternative Images of Future Transport Scenarios

9.5.1 GEA-Transport Model Overview

To conduct projections and policy analysis for GEA-Transport[16], we utilized the IEA's global transport spreadsheet model, which was developed for the WBCSD's Sustainable Mobility Project (SMP) (WBCSD, 2004a). The IEA model has the capability of making a scenario through 2050, which was expanded up to 2100 for this GEA transport study, which is a bottom-up model and differs from the one in Chapter 17. The WBCSD/SMP transport spreadsheet model is designed to handle all transport modes and most vehicle types. It produces projections of vehicle stocks, travel, energy use, and other indicators through 2050 for a reference case and for various policy cases and scenarios. It is designed to have some technology-oriented detail and to allow for fairly detailed bottom-up modeling. The model does not include any representation of economic relationships (e.g., elasticities), nor does it track costs. Rather, it is an accounting model, anchored by the ASIF identity:

- Activity (passenger and freight travel)
- Structure (travel shares by mode and vehicle type)
- Intensity (fuel efficiency)
- Fuel type – fuel use by fuel type (and CO_2 emissions per unit fuel use).

For these factors in road transport, vehicle sales and stocks are most important variables to affect the final results. As shown in Figure 9.33, historical vehicle ownership is closely related with growth of income level per capita. Around the threshold of US$5000/person, vehicle ownership grows very rapidly, but the growth rate for specific regions is quite different and is affected by various factors, such as geographic conditions, infrastructures, policies, and so on.

As outlined from the long-term historical data for the United States and Japan, this growth pathway is important to determine vehicle stock at a certain economy level. If this growth rate remains at the lower level by some measures in the future, the vehicle stock in developing countries can be kept low compared with those in developed countries.

In the GEA transport model, the future level of vehicle ownership in developing countries is assumed to be lower compared to those for most of

16 The GEA-Transport model differs from the GEA model in Chapter 17 in that it is a bottom-up model. The departing approaches resulted in differences that were considered acceptable within the range of allowance.

Box 9.5 | Storyline of the Bottom-up Scenarios for Energy and Transport Development

Under the reference scenario, which is produced with the WBCSD/SMP model, energy use of the transport sector increases significantly when it is associated with economic development, especially in developing countries. Car ownership rate, use of more energy-intensive and faster modes of transport, and freight activity increase with an increase in economic level (see Section 9.5 where the transport model is discussed).

At the same time, more efficient powertrain technologies and more efficient operation reduce relative fuel consumption, and more use of low carbon fuel reduces CO_2 emissions from the transport sector. However, as demand increases with economic development, reductions due to technological advancement are offset, leading to an absolute increase in CO_2 emissions from the transport sector.

There are many potential technologies and measures to reduce energy use and CO_2 emissions from the transport sector. CO_2 emissions can be reduced significantly under three CO_2 constraint pathways: GEA-mix, GEA-supply, and GEA-efficiency. In Chapter 17, each pathway has a transport-specific branching point between liquid and advanced transportation fuels. In contrast, the pathways presented in Chapter 9 all assume the introduction of advanced technologies, but with different compositions and to varying degrees.

Under the GEA-mix pathways, the share of biofuels[17] increases in every transport sector using gasoline, diesel and jet fuel, and energy intensity of aviation and shipping are also improved over the reference scenario. While the share of hybrids in passenger and freight vehicles increases, new vehicle types such as electric vehicles and fuel cell vehicles are progressively put into the market. Efficient operation of trucks reduces the fuel consumption of freight transport. The characteristic of this pathway is a balanced use of all possible reduction options.

In the GEA-supply pathways, the negative emission of power generation through CCS, as discussed in Chapter 12, further reduces CO_2 emissions, especially from road transport. The modal shift from personal vehicle to public transport in passenger transport is enhanced by policy measures in both GEA-efficiency and GEA-mix pathways. The efficiency of vehicles is improved progressively toward 2100, but the rate of improvement is highest in the GEA-efficiency set of pathways. At the same time, electric vehicles, including Plug-in HEVs, are aggressively introduced into the market under the GEA-efficiency pathways.

developed countries. This could be caused by a number of factors, including inhomogeneous structure of countries due to greater urbanization and lower suburbanization, greater income disparities between the wealthy and the poor, and limits on the infrastructure needed to support large numbers of vehicles, as well as future policies to reduce the need for motorized transport. Good examples of the role of policy measures to reduce personal vehicle ownership are discussed in the policy section. Based on GDP per capita, most countries presently classified as developing countries are not classified as developing countries in 2100.

9.5.2 Assumptions

9.5.2.1 Assumptions for Population and GDP

In Figure 9.34, global population reaches 10 billion in 2100, which is close to the level of SRES B2 scenario. Most of the growth occurs in

17 The values of emission factor for each biofuel are taken from the various studies, such as shown in Figure 9.27.

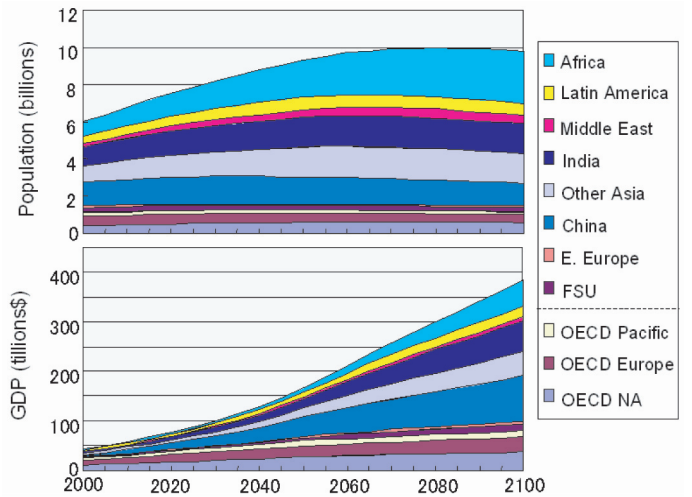

Figure 9.34 | Growth of population and GDP by region.

developing countries. Global GDP grows significantly up to around US$400 trillion toward the end of the century,[18] and GDP per capita also increases in most developing countries. As GDP is the strongest driver of car ownership, transport activities, and car ownership are expected to increase accordingly (see also Schäfer et al., 2009).

9.5.2.2 Assumptions for Vehicle Stock by Region and Fuel Economy

Three sectors are primarily propelling worldwide transport energy growth: LDVs, freight trucks, and air travel (IPCC, 2007). The Mobility 2030 study projects that these three sectors will be responsible for 38%, 27%, and 23%, respectively, of the total 100 EJ growth in transport energy that it foresees in the 2000–2050 period. The WBCSD/SMP reference case projection indicates the number of LDVs will grow to about 1.3 billion by 2030 and to just over 2 billion by 2050, almost three times higher than the present level (see Figure 9.35). Nearly all of this increase will be in the developing world (WBCSD, 2004b).

The present trend reveals a dominance of road transport and private cars, as well as an increase in aviation. As a consequence, it will be hard to curb fuel demand in any scenario timeline. LDVs and OECD countries will continue to dominate transport energy use for a long time, even with the growing participation of developing countries, mainly China.

One important factor affecting levels of car ownership is vehicle life, which determines the rate of replacement of older cars with new ones. As shown in Figure 9.36, the vehicle life is quite different from country to country. In terms of CO_2 reduction, vehicle efficiency is progressively improved, so the total level of CO_2 reduction is not strongly affected by the difference of longer tail at lower survival rate. However, this

18 The assumptions for population and GDP growth are slightly higher than those of Chapter 17, but GDP per capita data, which are only used for the scenario analysis, are consistent with each other.

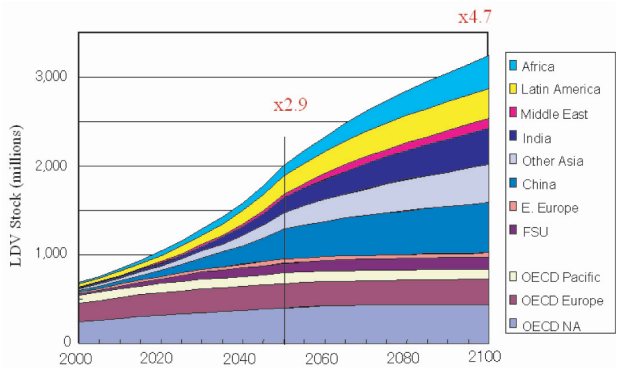

Figure 9.35 | Total stock of LDVs by region. They will grow 2.9, and 4.7 times higher than the present level by 2030, and 2050 respectively. Source: based on WBCSD, 2004b.

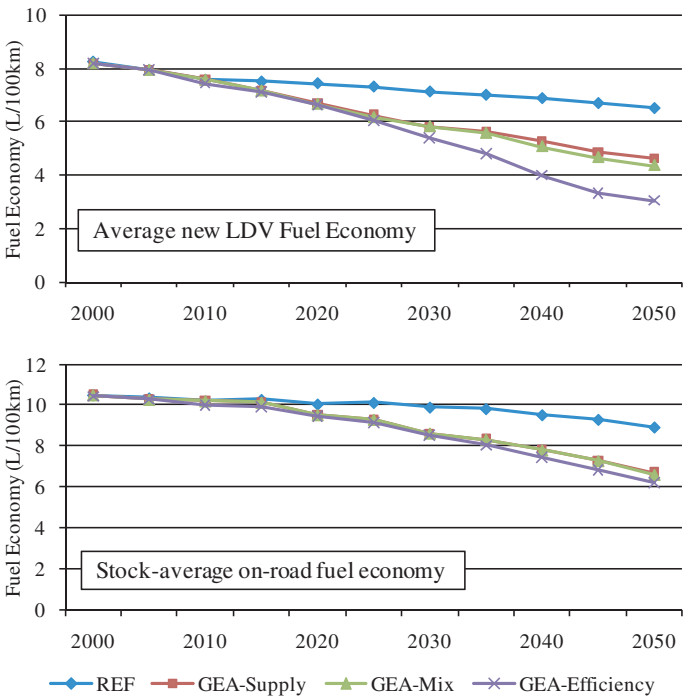

Figure 9.37 | Trend of new vehicle and stock-average on-road fuel economy.

becomes very important when tail pipe emissions are considered. Very few, but very old cars could be responsible for a large part of local air pollution, because these few cars might emit orders of magnitude more pollutants.[19]

Figure 9.37 shows the trend of new vehicle and stock-average on-road fuel economy values. Fuel economy values for three GEA scenarios show 40–50% improvement of new car fuel economy over 50 years, while stock-average fuel economy is improved by only 30% or so, because of the delay in replacement by older existing vehicles.

9.5.3 Key Results

9.5.3.1 Fuel Use Projection in the Reference and Pathways to Realize the GEA Scenario[20]

Along with an increase in population and GDP, as shown in Figure 9.34, vehicle stocks will increase significantly by a factor of 2.9 and 1.6 between 2000/2050 and 2050/2100, respectively, in the reference and GEA-supply scenarios (see Figure 9.35). LDV stocks in 2100 are 4.7 times larger than that in 2000. In 2050, the stocks in Asia are already bigger than that in the United States now, and are almost twice as large as that in all OECD countries in 2100. At the same time, truck stocks increase as fast as those for LDVs. The modal shift from passenger cars to trains will reduce ownership in passenger cars (LDV) by 40% and 20% in 2100, in the GEA-mix and GEA-efficiency pathways, respectively (see Figure 9.38). Truck stocks are reduced by 20% in 2100 in GEA-efficiency pathways due to a modal shift from trucks to freight train.

As the economy and population grow, other subsector activities also increase, as shown in Figures 9.39 and 9.40. Among passenger transport, the growth rate of aviation is largest. Aviation in 2100 is more than ten times larger than in 2000 in the reference scenario[21] and the GEA-supply and GEA-mix pathways. In the GEA-efficiency pathway, growth rate in aviation is slightly smaller.

In the GEA-efficiency and GEA-mix pathways, passenger train activity grows largely in 2100 because of modal shift from passenger cars. On the other hand, passenger car activity stays almost the same after 2050. In terms of magnitude, the share of LDV and aviation is significant and this is also true in terms of fuel consumption as shown in Figure 9.41.

In order to reduce fuel consumption and CO_2 emissions simultaneously, a variety of options for LDV can lead to the same goal (e.g., Figure 9.23),

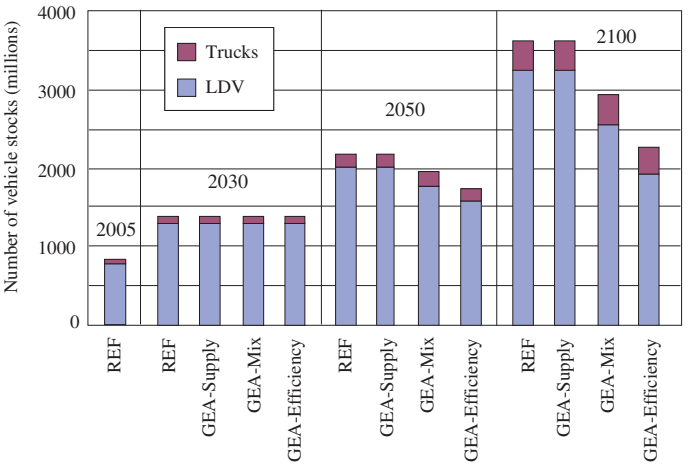

Figure 9.38 | Growth of stocks of LDVs and trucks.

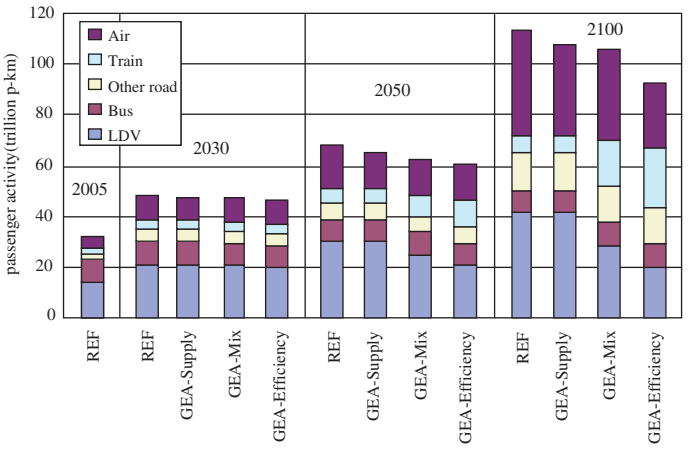

Figure 9.39 | Growth of passenger transport activity.

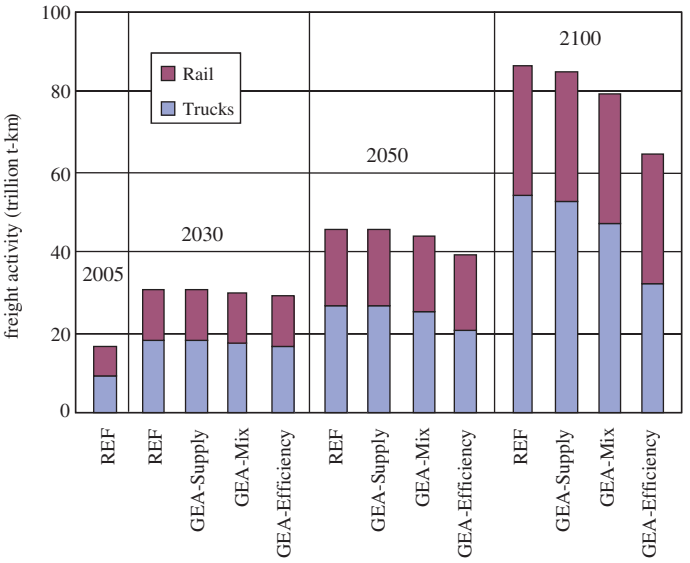

Figure 9.40 | Growth of freight transport activity.

19 These high-emitter vehicles were a hot issue in California in the 1990s.

20 See also Chapter 17.

21 Reference scenario is produced based on the WBCSD/SMP model and extended from 2050 to 2100. See Box 9.5.

but measures for aviation are limited. The most promising measures are efficiency improvements and biofuel; but there are many issues to overcome to utilize the benefit of biofuels, including the sustainability concern (see Section 9.3.1.1).

In modeling freight transport to project fuel consumption, the starting point was activity data for both trucks and freight trains. But for shipping, the growth rate of fuel consumption is directly projected from the first place of modeling because of its insignificant contribution to overall freight transport.

As shown in Figure 9.40, the growth of truck and freight train activity is significant and their activities in 2100 are four to seven times, and five times larger, than 2000, respectively. In terms of fuel consumption, the share used by trucks is most important, but the actual amount of fuel consumption differs very much depending on the pathways (see Figure 9.41).

In the reference scenario projection, global transportation fuel use increases by a factor of nearly 2.3 between 2000 and 2050 and slows down slightly afterwards, leading to an increase of a factor of around 1.5 between 2050 and 2100 (see Figure 9.42). Use of gasoline, diesel fuel, and jet fuel grows substantially, while other fuels retain a tiny share. Alternative fuels and advanced vehicles do not penetrate significantly in the reference scenario. Total fuel use by mode will grow significantly for all modes but buses, with the biggest growth occurring for LDVs, freight trucks, and air travel. It should be noted that most of the increase in fuel use occurs in developing countries.

Fuel efficiency improvement and introduction of new technologies significantly reduce fuel use by 35%, 40%, and 60% in 2100 for pathways GEA-supply, GEA-mix, and GEA-efficiency, respectively, compared with the reference scenario (see Figure 9.46). Reduction is most prominent in the LDV subsector, while air and trucks remain major players, along with LDVs (see Figures 9.41 and 9.42).

As shown in Figure 9.42, energy use decreases in the order of GEA-supply, GEA-mix, and GEA-efficiency pathways. This is mainly caused by different improvement rates of fuel efficiency and reduction rates of vehicle driving distance per year.

In the reference scenario, conventional fuels make up the major part of fuel consumed. In the GEA pathways, usage of biofuels, especially advanced biofuels, such as cellulosic ethanol and BTL diesel and jet fuel, increase with time. In 2100, the share of biofuels becomes 20–45%, depending on the pathway. Having assumed that advanced biodiesel is widely used in all vehicles with diesel engines, including trucks and buses, the share of advanced biodiesel becomes relatively large compared with that of advanced ethanol in 2100. Preconditions for wide-scale application of advanced biofuels are stringent policy instruments that discriminate against the mostly environmentally

harmful, high-carbon but more price-efficient agrofuels that are currently produced, notably US corn ethanol. Lifecycle analysis of these biofuels is discussed earlier in this chapter, and appropriate policy instruments will be discussed later.

9.5.3.2 Light-Duty Vehicles

In the reference and GEA-supply pathways, new vehicle sales increase by a factor of 2.7 and 1.5 between 2000/2050 and 2050/2100, respectively. Although the new car market in OECD countries is almost saturated, the market in developing countries, especially in Asia (including China and India), will grow significantly (see Figure 9.43).

In the GEA-efficiency and GEA-mix pathways, new car sales decrease significantly because of a modal shift to trains. In 2100, new car sales in the GEA-efficiency and GEA-mix pathways are 44% and 22% lower, respectively, than that for the reference and GEA-supply pathways.

As shown in Figure 9.44, the share of HEVs increases with time, but these are replaced with fuel cell vehicles and electric vehicles in 2050 and 2100. In 2100, the share of FCVs and EVs is around 70%. Since there is a large uncertainty about the evolution of new vehicle technologies, FCV shares over EVs varied significantly among the GEA pathways.

9.5.3.3 CO_2 Projections

Global transport CO_2 emissions from vehicles tank-to-wheel (TTW) are projected to increase by a factor of 2.3, from about 5.4 Gt in 2000 to 12.4 Gt in 2050 and by 3.5 to 18.9 Gt in 2100 in the reference scenario. Also, like fuel use, the vast majority of CO_2 increase will be in non-OECD (i.e., developing) regions. In the GEA pathways, those emissions are significantly reduced to around 6–7 Gt in 2100. As shown in Figure 9.45, the well-to-wheel (WTW) emissions increase up to 21.6 Gt in 2100 in the reference scenario, but are reduced to 6–7 Gt due to the large use of alternative fuels, such as biofuels, electricity, and hydrogen in the GEA pathways.

As shown in Figure 9.45, the contribution of the TTW and WTT (well-to-tank) component to the reduction of CO_2 emissions is different among the three GEA pathways. In GEA-supply and GEA-mix pathways, the reduction of the WTT component is more important, because the negative emission from power generation, biofuels, and H_2 production is effectively utilized. In the GEA-efficiency pathway, the TTW component contributes more to the reduction of CO_2 emissions through the greater improvement of vehicle fuel efficiency.

Large fuel efficiency improvements and introduction of alternative fuels in LDVs and trucks in the GEA pathways contribute to the greater reduction of CO_2 emissions compared to the reference scenario. In aviation, the large growth of activity offsets CO_2 emission reductions due to efficiency improvement and biofuel use.

Analysis of the contribution of major measures on emission reduction in the LDV subsector is seen in Figure 9.46. It clearly shows that net reduction of CO_2 emissions from the current level can be achieved by the introduction of new technologies, such as EVs and fuel cell (FC) vehicles, although improvement of fuel efficiency in conventional vehicles (FE) and hybrid vehicles (HV) also contribute significantly to the reduction. It should be noted that for market penetration of these new emerging technologies, strong, continuous support from governments is needed from the R&D phase through to the commercialization phase. In the GEA-efficiency and GEA-mix pathways, the contribution of modal shift to trains is also important.

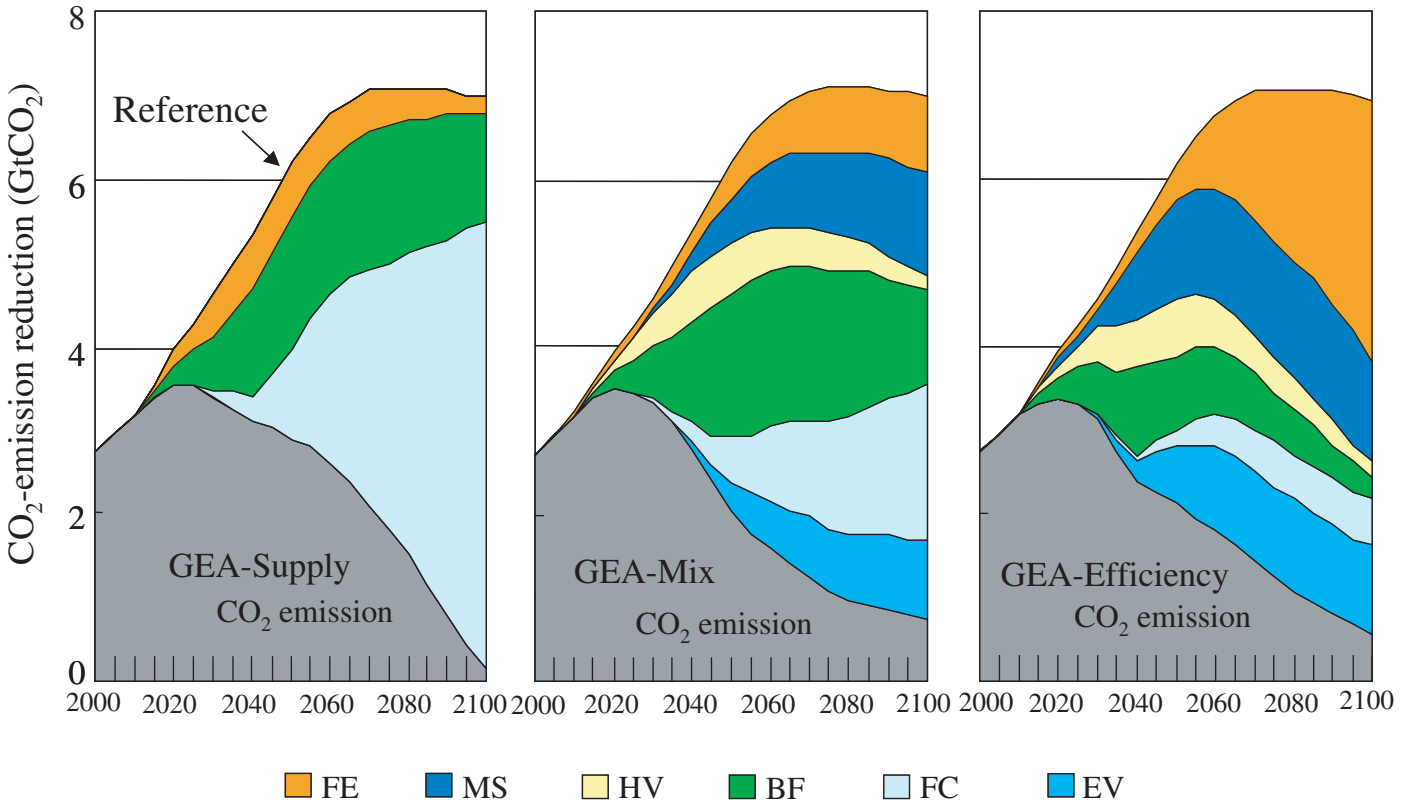

Figure 9.46 | Reduction of well-to-wheel CO_2 emissions for LDVs from reference scenario in GEA (FE: Fuel efficiency, MS: Modal shift, HV: Hybridization, BF: Biofuel, FC: Fuel cell, EV: Electric vehicle).

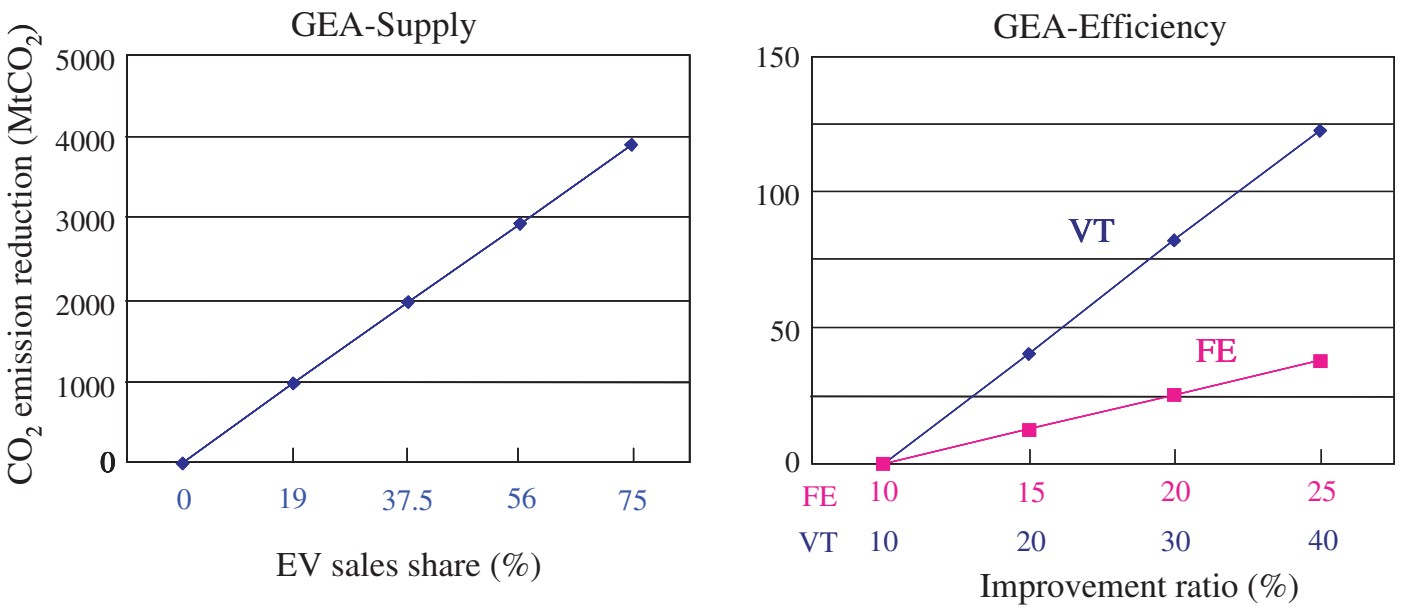

Figure 9.47 | Sensitivity analyses for the EV share in the GEA-supply pathway, and the reduction rate of vehicle driving distance per vehicle (VT) and fuel efficiency (FE) in the GEA-efficiency pathways.

Since perspectives of technology evolution are highly uncertain, especially toward 2100, some sensitivity analyses were performed for the LDV subsector, including the share of EVs, improvement of the fuel consumption rate, or fuel efficiency (FE), and reduction of the vehicle driving distance per vehicle (VT). In the GEA-Efficiency scenario, the share of EV and FCV sales is fixed to be around 75%, and CO_2 emissions from electricity generation factors for FCVs and EVs are nearly zero-emission and negative-emission, respectively. As shown in Figure 9.47, EV share in the GEA-Supply scenario was changed from 0 to 75%; accordingly, FCV share was changed from 75 to 0%. With the increase of EV share, the contribution of reduced emission of electricity generation using fossil fuels becomes larger and CO_2 reduction increases up to 4 Gt, which can be compared with the default emission level of the GEA-supply pathway – about 6 Gt (Figure 9.49).

In the reference scenario, LDV annual VT is assumed to be constant up to 2100, while in the GEA-efficiency scenario, it decreases after 2050 and is 13–17% lower than the reference scenario in 2100. The FE is assumed to be improved 2–3%/year in the reference scenario. In the GEA-efficiency pathway, this is further decreased after 2050 up to 13–17% in 2100, compared with the reference scenario.

The impact of these parameters on the reduction to CO_2 emissions is much smaller than that of the EV share mentioned above. However, this does not mean that the improvement of these parameters is not important, because they strongly affect the total amount of the fuel use in the transport sector. Figure 9.47 shows how a reasonable range of variation of these factors affect the estimated variations quite significantly.

9.5.4 Interpretations of How the Pathways Meet the GEA Goals

Measures to achieve the GEA goals should be distinguished by the timeframe on which one is focusing. Priorities among the many options may change over time. In the short and mid-term, most developing countries will still be in the transition stage of motorization, and available technological measures to meet the goals may be limited. In the long term, some developing countries will be in the middle of motorization, and various advanced technologies, such as advanced biofuels, fuel cell vehicles, and electric vehicles might be widely available in the market.

9.5.4.1 Fuel Efficiency

Improving efficiency is the primary option to reduce energy use and CO_2 emissions simultaneously from now until 2100. Many countries have imposed fuel economy standards. They have shown that these are very effective policy instruments, requiring car manufacturers to make more efficient cars. Additional measures, such as taxes and incentives, are required to encourage customers to buy these more efficient cars.

Fuel efficiency improvement itself is not good enough to reduce tail pipe emissions, such as NO_x, CO, and hydrocarbons. After-treatment devices for exhaust gases are required to significantly reduce pollutants being expelled from the tail pipe, which can be enhanced by emission standards.

9.5.4.2 Modal Shift

Switching passenger transport from LDVs to trains, buses, and non-motorized means can be very effective for reducing energy use. For dispersed suburban living, such as in many parts of the United States, this may not be an easy task. Infrastructure investment, integrated land use and transport planning, and sustainable transport policies are needed to shift personal travel to more energy-efficient modes such as walking, cycling, and public transportation.

A co-benefit of such a modal shift is reduction of traffic volumes, especially in urban areas, which contributes to a reduction in congestion and local air pollution. Since increased traffic volumes correlate to an increase in road traffic fatalities, reducing congestion through a modal shift has another co-benefit of improving road safety.

9.5.4.3 Advanced Biofuels

The merit of biofuels is their additive natures to other improvement measures in conventional vehicles, such as fuel efficiency, and therefore quick effects can be expected. With a careful choice of production pathways, biofuels can reduce CO_2 emissions significantly, as well as some tail pipe emissions.

9.5.4.4 Fuel-Cell Vehicles

FCVs can reduce energy use and drastically reduce emissions with the proper choice of pathways. The biggest barriers to FCV introduction are high costs and infrastructure issues. To build up infrastructure takes a long time and strong government support is needed.

9.5.4.5 Electric Vehicles

Hybrid vehicles and plug-in hybrid electric vehicles offer a cost-effective and smooth transition to electric mobility. PHEV, could expand the sale share to compromise the high cost of batteries. However, since only a small fraction of consumers may accept the limited driving range and high cost of a pure battery electric vehicle, battery electric vehicles may be limited to a small market in urban areas.

One of the major merits of FCVs and EVs is zero emissions from tail pipes. This is especially beneficial in highly-populated urban areas.

However, the GHG reduction potential of electric vehicles depends significantly on the carbon intensity of the electricity generation process. Since hydrogen and electricity can be produced by various energy sources, use of a secondary energy can reduce oil use and increase energy security.

Although advanced technologies have some barriers to overcome, new technologies are needed to reduce CO_2 emissions below the current level (Figure 9.46).

9.6 Policies and Measures to Meet Multiple Goals for Sustainability and toward a Global Energy Transition[22]

The transport pathways described in the previous section illustrate alternative paths and aspirations for a progressive transformation of the global transport sector in line with the GEA goals toward attaining a sustainable global energy transition within the next 50 to 100 years. The pathways presented are technologically optimistic but still display insufficient potential to decarbonize the transport sector. GEA emphasizes that the sustainable global energy transition needs to be anchored in socially equitable, environmentally sustainable, and economically effective development goals. The scale and scope of the transition indicates that nothing less than a sustainable systemic change is required. Hence, we also include shifts to non-motorized transport and public transport modes, and integrated land use and transport planning in our analysis of suitable policies towards a desired transition.

The world is now predominantly urban, and most future population increases will be absorbed by urban areas (see Chapter 18). Transport plays a fundamental role in the development and economic prosperity of urban areas because commercial organization, the location of industry, housing, and all other general services are transport dependent. At the present rate of world urbanization, cities will require increased transport services to make accessible the supplies needed for their physical expansion and to support economic development. The challenge of developing sustainable low-carbon transport systems will define the possibility of guaranteeing life in urban places as economically viable, socially constructive, environmentally safe, and, in general, qualitatively enjoyable spatial configurations. Hence, a large part of the policies and measures discussed in this section focus on urban areas.

From a climate change mitigation perspective, one can categorize emissions from transport into carbon intensity of energy, energy intensity of transport, and total transport demand (Schipper and Marie-Lilliu, 1999; Creutzig et al., 2011a). Both the decision to travel or not and the modal choice for this travel affects fuel consumption, and therefore carbon emissions. With a focus on urban road transport, a transition to sustainable transport can follow the "Avoid, Shift, Improve" framework (GTZ, 2007; Bongardt et al., 2010). This framework considers three major principles under which diverse policy instruments (Planning, Regulatory, Economic, Information, Technological) are grouped interventions to mitigate GHG emissions from transport, assuming different emphases for developed and developing countries (Dalkmann and Brannigan, 2009). "Avoid" and "Shift" influence the level of activity and structural components that link transport to carbon emissions. "Improve" focuses on technological options, not only with respect to climate mitigation but also taking into account local environmental conditions and social concerns.

9.6.1 Reduce the Need to Travel

A transition toward sustainable transport goes beyond technology. In fact, the quality of transport can be improved in a broader sense by a multitude of individual measures and combined policy packages, particularly in urban areas. Reducing or avoiding the need to travel can be achieved through encouragement of greater use of transit systems and non-motorized transport, as well as through increasing urban density, mixed-use urban spaces, and greater emphasis on communications technologies.

While technological pathways and scenarios allow us to envisage large-scale changes that can help decarbonize the transportation sector, measures such as those mentioned above that reduce congestion, air pollution, and motor noise and that increase the accessibility of shopping and local services for pedestrians and cyclists ultimately increase quality of life in a very tangible manner.

9.6.1.1 Enhancing Accessibility

Enhancing accessibility for transport users often reduces overall transport demand in terms of distance while improving the quality of movements. Analysis focuses on aspects of mixed land use and density, modal interconnectedness, and transit-oriented development. The relation between mobility and urban structure is interdependent. While cities generate the transportation systems they require in the development process, mobility demands and transport system responses also shape urban form.

GEA has developed a full module on urbanization and energy use in Chapter 18 that explores the relationships between patterns of spatial, population, and economic growth of cities. It looks at interactions with the patterns generated by urban transport systems, and the resulting effects on total energy use. This section will only focus on general public policies for managing and shaping transport and land use urban activities, and recommend interested readers to take full advantage of the thorough review provided in Chapter 18.

The best opportunities for directing transportation, land-use planning, and urban development toward sustainability may reside in urban

22 See also Chapter 22.

centers of small and medium sizes, where most of the future population and economic growth are expected. Urban populations continue to expand at more than 6%/year in many developing countries. In some of these countries, per capita motor vehicle ownership and use continue to grow by up to 15–20%/year. Sprawling cities make the journey to work excessively long and costly for the very poor. This is overwhelming the operational sustainability of urban transport systems and is one of the causes of social, economic, and environmental imbalances and social inequities. The challenge for towns and cities everywhere is to enhance accessibility and reduce congestion, accidents, and pollution.

Traditional transportation planning developed largely in parallel with a post-WWII explosion of individual motorization in the United States, in an already wealthy society going through a period of sustained economic growth. The initial policy response in the United States, based on a predict-and-provide planning framework, was to accommodate the private car to the maximum extent possible, while retaining public transport modes for the dwindling market of those without cars.

An entirely different strategic approach was taken in the former communist countries, opting for public transport as the primary urban mode and developing cities accordingly. In both these cases, the common element has been the strength of institutions and the importance of public policies for the provision of infrastructure, the supply of services, and, consequently, the modal choices.

9.6.1.2 Enhancing Modal Interconnectedness

Smart Growth (also called New Community Design) is a general term for policies that integrate transportation and land use decisions, as an alternative to urban sprawl. Smart growth and mixed land use is closely related by multimodal interconnectivity. For example, public transit ridership crucially depends on design of pedestrian facilities, enabling smooth and rapid access to stations. Park-and-ride is ambivalent. On the one hand, park-and-ride facilities allow car-dependent commuters to participate in public transit in inner city areas. On the other hand, park-and-ride may encourage further urban sprawl and medium-length commuting to park-and-ride facilities. To increase ridership and improve the economic viability of transit systems, transit stations need to be accompanied with mixed-use development, i.e., including both employment opportunity and housing, and market-rate parking charges (Cervero, 1994). In contrast, large-scale free parking makes the area surrounding transit stations unattractive and increases insecurity. Easy access to car sharing can also have two effects. On the one hand, it can deter car purchase, and by this reduce overall car ownership. On the other hand, it may encourage car driving by those that usually rely exclusively on environmentally friendly modes. However, it is estimated that the overall effect of car sharing is beneficial for mobility and the environment.

9.6.1.3 Enhancing Regional Transit-Oriented Developments

The most consistent approach, which is by now state-of-the art in progressive cities, is to integrate land use and transportation planning to achieve a low-carbon infrastructure, reduce travel distances and travel time and increase accessibility to jobs, shops, and leisure facilities (Bongardt et al., 2010). The bottom line is that new mixed-use, high density developments must be close to public transit, and vice versa, and that the cost of using a car must be relatively increased in terms of money and time, to avoid high levels of motorization. Transit-oriented developments enable people to access housing, jobs, services by walking, biking, or riding transit, thus avoiding the necessity of driving to meet these needs and increasing the accessibility of goods and services. The case of Curitiba in Brazil offers a good example of how a coherent set of policies linking urban density, and a highly efficient bus rapid transit public transport system can transform a city (Bongardt et al., 2010)

9.6.1.4 Enhancing Mobility Management

Reducing the need to travel by car can be approached by implementing mobility management practices. The goal is to enhance and create transport services that promote a safe interconnection of modes and infrastructure for the use of sustainable modes such as walking, cycling, and public transport. Mobility management is a targeted approach that focuses directly on changing behavior at the individual or group level (e.g., company employees). It requires information, organization, coordination, and effective marketing and promotion to complement traditional traffic system management and infrastructure-orientated transport planning.

Mobility management can be seen as a new way of managing urban transport as a whole. It pulls together traditional approaches with public transport improvements and traffic management measures (including congestion charging and traffic calming). The main aims of mobility management are to:

- improve accessibility for all users and the conditions (social attractiveness, safety, economic efficiency) for an effective use of sustainable travel modes;
- improve the integration of activities and new land uses with sustainable travel modes and services covering the entire urban transport system;
- reduce traffic growth by limiting the number, length, and need for motorized vehicle trips; and
- improve interchange between transport modes and facilitate the interconnection of existing transport networks.

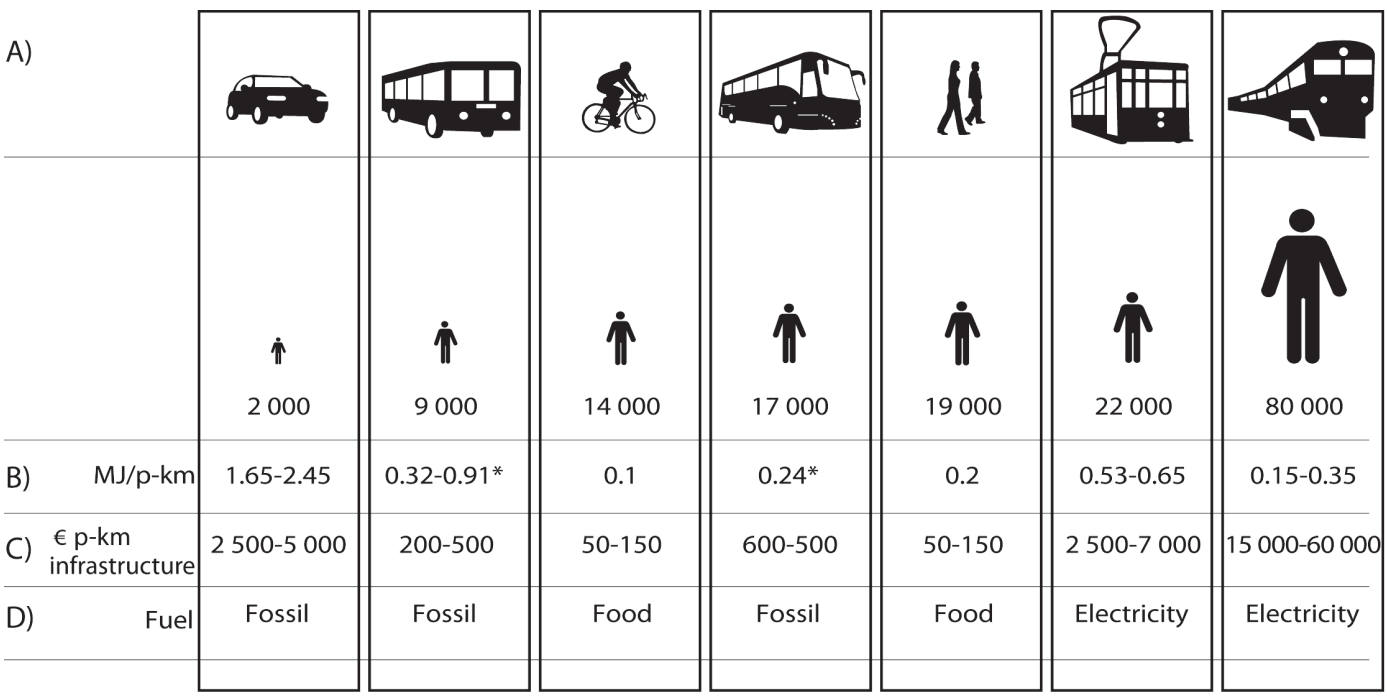
Mobility management has a demand-orientated approach that considers alternative transport modes – public transport, collective transport, car-pooling, cycling, walking, etc. – as "products" that have to be marketed. It works with specific "clients" or "client groups," defined according to trip nature and purpose (home-school, home-work, shopping, leisure), and 'traffic generators' or the sites or activities that attract the traffic (city centers, companies, schools, tourist attractions, events, shopping centers, residential areas, etc.). Because each site is different, mobility management generally works with site-specific mobility plans.

Good marketing is necessary to convey and promote the positive results and benefits on the use of sustainable modes. Changing travel behavior is often associated with restrictions and sacrifices, or with critiques for placing unfair restrictions on car use. A well-planned mobility management plan ultimately enhances mobility opportunities for everybody, those who accept to shift to alternative modes and those who continue to drive.

9.6.2 Develop Alternatives to Car Use

9.6.2.1 Enhance Public Transportation

Public transportation carries a large proportion of passenger trips in most of the heavily populated urban areas of industrialized and developing regions in the world. Many developing cities, where the modal share for bus transit alone can be in upper range of 65–80%, are



*Lower values correspond to Austrian busses, upper values correspond to diesel busses in Mexico city before introduction of BRT system.

Key:

A) Values are indicative for European and Asian cities and can vary significantly across cities, world regions, and particular situations. For example, BRT capacity can more than double with a second lane. Suburban rails in India can transport up to 100,000 passengers per hour.

B) Energy intensity in MJ per passenger km. SUVs can exceed depicted values for cars. Energy values for bus in the US are generally higher due to low ridership (Chester and Horvath, 2010). While BRT systems have similar energy efficiencies as normal busses, they provide signficant systemic energy savings via modal shift, small bus substitution, and reduction in parallel traffic (Schipper et al., 2009). BRT systems can also be converted from oil based fuels to electricity and hydrogen.

C) Estimated infrastructure costs in euros per passenger kilometer are highest for subway systems and heavy rail. Costs for bus system can be significantly lower than for individual motorized transport. Infrastructure costs for non-motorized transport are very cost competitive and can realize significant social benefits.

D) Dominant fuels are given for each mode.

Figure 9.48 | Corridor capacity of different modes of transportation (people/hr on a 3.5 mile-wide lane). Source: Modified from Breithaupt, 2010.

characterized by hundreds of separate bus companies. For example, a single minibus route in Lagos, Nigeria is estimated to be served by 200 mini enterprises (Gwilliam, 2005; Small and Verhoef, 2007). The provision of high-quality public transport connecting urban and suburban centers, with integrated fare systems and efficient intermodal/interface linkages, is paramount to enhancing the public transport services, equal accessibility, and other social aspects related to the provision of equitable services of these transport systems.

Bus Rapid Transit (BRT)

Bus Rapid Transit (BRT) is a high-quality bus-based transit system that delivers fast, comfortable, and cost-effective urban mobility (Wright, 2006). It is one of the most important transportation initiatives today and is increasingly being used by cities looking for cost-effective mass transport solutions.

BRT systems can enhance bus efficiency through segregated bus lanes, designs that make boarding and exiting buses quicker, bus priority at intersections, and effective coordination at stations and terminals. Political backing is a key ingredient for success in all BRT systems (Wright, 2006). However, dedicating road space to exclusive use by public transport can be politically difficult, especially given the relative political strength of private motorists. BRT systems can achieve higher speeds than conventional buses[23] and capacities that equal or exceed rail transit at lower costs as they usually take over an existing road lane (about 35,000 passengers can be carried in each direction; see Figure 9.48) (Hidalgo and Carrigan, 2010; ITDP, 2007). BRT has the flexibility to provide limited stop and express services.

There are currently 47 BRT systems operating worldwide and 16 more under construction. Most systems are in Europe (17, of which 10 are in France), while widely visible systems are in Latin America – in Curitiba, Brazil and Bogota, Colombia (Wright, 2006). By providing high-capacity and high-speed service, BRT systems attract more riders and provide service more efficiently than conventional bus services operating in mixed traffic (ITDP, 2010). BRT systems have achieved a certain amount of success in providing reasonable fare levels without the intervention of operating subsidies. Fares in the range of US$0.25–0.70 are typical with the subsidy-free systems in Latin America (Hidalgo and Carrigan, 2010).

Not all BRT strategies, technical and operational elements are transferable from one city to another. Availability of institutional, technical and management skills are vital to whether a BRT system will work effectively in its operations (handling of passenger boarding and alighting efficiently, with little delay); system signal prioritization (avoiding disruptions to traffic flow on major cross streets); vehicle designs (affecting system performance, cost, and appearance, both external and internal). These aspects are contributors to the overall success of any BRT system.

23 Conventional buses usually operate under significant levels of congestion. For example while conventional buses were operating at 10 km/h, the BRT Transmilenio System in Bogota operates at an average commercial speed of 27 km/h (ITDP, 2010)

Light Rail Transit (LRT)

LRT uses electric rail cars operating along a dedicated lane or track, separated from other traffic most typically for density reasons in city centers, or in the case of trams, they often operate in mixed traffic without an exclusive lane. Light rail systems can carry 10–20000 passengers per hour down one corridor (Wright and Fjellstrom, 2005).

There are currently over 400 light rail systems operating worldwide, of which around 300 are tram systems. Most are in Europe, with a few in developing countries. Advances in electronics, software, and materials are playing a major role in making LRT systems more attractive to operators. This has been a major factor in the expansion of existing systems and the construction of entirely new systems during the past several decades (Wright and Fjellstrom, 2005).

LRT is seen as an extremely diversified mode that can be used for short urban lines, as well as long regional lines with various levels of speed and capacity, using alignments that vary from streets to fully separated tunnels, viaducts, and intercity railway tracks. LRT is also seen as an element of urban economic development; in fact, economic theory suggests that the increased value of land close to LRT is best used to finance public transit. Improvements in track and car design have reduced noise levels to a point where LRT protagonists consider LRT systems quieter than diesel buses (Wright and Fjellstrom, 2005).

Increasingly, BRT is challenging the development of new LRT systems on the grounds of cost. BRT systems are becoming more and more sophisticated and capable of emulating the service levels of LRT at much lower investment and operating costs.

There is considerable debate over the capacity of LRT systems compared with BRT systems. With the use of articulated and bi-articulated buses in Curitiba and Bogota, the capacity of BRT has equaled – and exceeded – that of comparable LRT systems. The development of LRT systems is therefore likely to be limited to cities where tram operations exist, and where they can be cost-effectively upgraded and enhanced.

A negative development limiting applications of LRT has sometimes been over-design. Instead of economical designs that allow for the construction of large networks, a number of projects have been upgraded step by step, resulting in very high costs.

BRT and LRT should be considered as complementary modes. LRT is seen as being suitable for situations demanding heavy passenger volumes, use of tunnels in high-density urban centers, and direct service in pedestrian zones.

Heavy Rail Transit

Heavy rail transit systems comprise Metro and Commuter Rail systems operating in exclusive rights-of-way without grade crossings, with high platform stations.

Metro is the term for mostly underground (subway) heavy rail transit, which are the most expensive form of MRT/km, but have the highest theoretical capacity 50,000 passenger per hour in one direction (even 80,000) (Wright and Fjellstrom, 2005, Salter, et.al, 2011). The option of constructing an underground capital-intensive Metro transport system has been supported by many elected officials and voters with promises that it will help reduce congestion, pollution, transform social culture and even become the gem of a cosmopolitan city (Figueroa, 2010; Global Mass Transit, 2010). This despite evidence of extremely high costs compared to buses and a record of under-predicting the cost on this type of project (Flyvbjerg et al., 2004; Flyvbjerg et al., 2009).

Heavy rail transit systems are primarily found in large, dense cities of the industrialized world. However, there are also quite a few in upper-tier developing world cities, such as Tehran, Mexico City, Guangzhou, and Santiago. Bangkok has a new train system that reaches 60 km/hr, averaging 25–45 km/hr compared with the Bangkok traffic speed of 14 km/hr (Salter, et. al, 2011).

Intraurban – long distance – transport is most efficiently served by railways than it is today when car transport and aviation are the prevalent choices. High-speed railways trips are competitive in time with car and plane trips. Notably in some European countries and Japan, for up to 1000 km (Madrid-Barcelona, Paris-Marseille, Hannover-Munich, Kyoto-Tokyo). China puts efforts into replicating and even superseding this success story. Forty-two high-speed, mass transit train lines have been operationalized in China in the last years. The Chinese bullet train connects Ghangzhou to Wuhan, traveling 1036 km (664 miles) in a little more than three hours. The new superfast trains introduced in China are economically competitive and create economies of large-scale production for another big export industry.

9.6.2.2 Enhance Other Means of Transportation

There are many other alternatives to private car use that can be researched and considered.[24]

Enhance and Facilitate the Use of Non-Motorized Modes

The vast majority of all trips made daily worldwide are on foot. In the United States, for example, according to the 2001 US National Household Survey, 48% of trips were 3–4 km or less, and 24% were 1.4 km or less. These trips are the most suitable to the use of non-motorized modes. Many people rely on NMT, i.e., trips made on foot or by wheelchair, bicycle, tricycle, skateboard, handcart, cycle rickshaw, or other non-motorized vehicles, to meet their daily transportation and mobility needs. Facilitating the use of NMT is important because they are the least carbon-intensive mode of transport available and have been shown to have health benefits. Most people worldwide have the potential to use NMT.

The presence of pedestrians and safe cyclists are a commonly-used gauge of a successful, vibrant urban space. Pedestrian environments provide safe and salubrious public spaces where people can meet and interact. Active NMT can be part of the solution to increasing public health and confront obesity concerns, particularly in developed countries.

Planning for NMT extends beyond the physical infrastructure to include psychological factors and institutional stasis hindering the adoption of non-motorized modes, variability in the facility needs of each of mode, safety, equity concerns, and land-use practices conducive to NMT. Below a brief discussion on the ramifications of these concerns, planning strategies applicable to non-motorized vehicles (NMV) and to pedestrians are presented.

Equity

In many places, NMT is viewed as the option of last resort if it is not for recreation. Low-income and transportation-disadvantaged persons (elderly, youth, people with disabilities) often rely and gain independent access to services from improvements on NMT facilities, and so does the community at large. The presence of sidewalks and curb ramps, free from surface irregularities and of adequate width, not only give people with disabilities a way of travelling independently but also benefits all pedestrians. Such infrastructure also benefits parents with prams, tourists with luggage, the old, the young, the pregnant, the visually impaired, wheelchair users, users with crutches, etc. Such universal and equitable access principals promote designs that accommodate the widest range of users possible.

NMT can also provide economic benefits for the poor. For many poor, private vehicle ownership of a bicycle, animal carts, or cycle rickshaws actually indicates a considerable economic achievement or a sign for upward economic mobility.

In urban areas, NMTs are not only relevant for the movement of people, but also for the transport of goods. NMVs such as cycle rickshaws and handcarts are an essential means of transporting people and goods in cities and towns in Asia and Africa. In many African towns, sellers or small-scale service providers use handcarts to transport goods to and from markets. In Asian cities, rickshaws designed for passengers often transport goods. NMT also facilitates indirect economic benefits sparked by the demand for NMTs, spare parts, and services such as repair, vehicle rent, and paid parking.

Safety

Road safety is a critical issue. Increased NMT can beget economic mobility and other equity benefits, but it is irresponsible to promote NMT without addressing various safety concerns associated with these relatively vulnerable road users. The speed and volume of cars, trucks, and buses are particularly threatening to cyclists and pedestrians. Data from several cities shows a "safety in numbers" phenomenon – that increasing the

24 For further references regarding other private providers of public services such as digital hitchhiking, hitchhiking, jitney, share taxis, shuttle services, slugging, taxis, vanpooling, see GTZ, 2002; ITDP, 2010.

number of bicyclists reduces the rate of accidents or injuries of bicyclists (accidents per 1000 bicyclists, for instance). This suggests that without changing the volume of vehicular traffic, introducing more cyclists to the road makes bicycling safer. There are several reasons and theories, including the argument that drivers become more familiar with seeing bikes on the road, and thus come to expect and look for them (Brandt, 2011).

Proper infrastructure for pedestrians and bicyclists is critically important for supporting increased NMT mode share. Sidewalks, pedestrian crossings, and bicycle lanes are only the most basic provisions needed. At a minimum, basic, unobstructed, and safe infrastructure is needed to accommodate and promote NMT. Desirable infrastructure would include secure bicycle parking at transit stations, physically segregated bike paths, bike boxes, dedicated bicycle turning signals, and audible and tactile pedestrian crossing signals. The quality of NMT infrastructure will largely determine the NMT mode share.

The presence of so-called "eyes on the street" NMT tends to increase perceptions of safety and can help pedestrians feel safer on less-frequented streets. Adequate light levels at night are important, particularly for women, to enhance safety. Separate facilities and proper lighting are also essential because NMVs and pedestrians may be difficult for drivers to see, particularly when traffic speeds are moderate or high. A concerted effort to increase safety for NMT users is crucial in its own right, but as an ancillary benefit, an attractive and safe pedestrian environment creates more livable communities.

Overcoming Barriers

Even if safe, extensive, convenient facilities for NMT were available, there remain various psychological, educational, geographic, and institutional barriers.

There is a widespread lack of respect for non-motorized users even in developing countries where NMT are dominant. In general, NMT tends to be stigmatized. Some people consider walking and cycling outdated, unsophisticated, and unexciting compared with motorized modes. Some even consider them as symbols of poverty and failure. These are one of the biggest psychological impediments for a modal shift away from motorized modes (UNEP, 2011; Salter, et al., 2011).

Constraints placed by physical barriers and excessive detours to overcome these barriers also impede use of NMT. In many cities, the environment is seen as unattractive for NMT and pedestrian use due to pollution, traffic volumes, and poor quality walkable areas.

Bicyclists report many reasons why they are encouraged to cycle, chiefly among them are cost-effectiveness, health, status. (Alliance for Biking and Walking, 2010). Potential cycle commuters can be however discouraged by a lack of shower and parking facilities at work. NMVs in general, and bicycles in particular, can be easy to steal. Provision of safe and secure bicycle and other NMV parking, in integration with public transportation stations and stop places are therefore essential ingredients to promote NMV use. Creation of safe routes and parking facilities and simple education and training for people to gain confidence or road skills to cycle contribute to the widespread adoption of NMT (Alliance for Biking and Walking, 2010). Geography can be a factor that constrains NMV in many places.

There are institutional barriers and lack of technical staff to plan NMT facilities and manage a large increase of their use. It is often difficult to agree on prioritizing and secure funding for infrastructure and non-infrastructure projects for NMT due to finite funds, other transportation priorities, and underestimation of the magnitude of NMT. Travel surveys and traffic counts usually ignore or under-count short trips, non-work travel, travel by children, recreational travel, and non-motorized links. Many conventional user surveys attribute the entire trip to a single mode, regardless of the extent to which additional modes are involved and ignoring the fact that virtually every trip begins and ends with walking.

Increasing Non-motorized Transport Mode Share

There are many specific ways to encourage mode shift from other modes to NMT. A short list of suggestions is presented here modified from (Litman, 2010):[25]

- Planning for NMT is an important part of transport planning. An integrated transport policy is required that defines the role of NMT and NMVs within the total transport system and in relationship to other modes, such as private cars, public transport, and walking. Action plans need to include measures that will help overcome the barriers to NMT outlined above and better integrate NMT. Policies to encourage NMT usually form part of the mobility management and transport demand management measures.

- Improve pavements (sidewalks, cycle tracks), crossings (crosswalks), paths, and bicycle lanes and correct specific road hazards (sometimes called "spot improvement" programs).

- Improve the management and maintenance of NMT facilities, including reducing conflicts between users and maintaining cleanliness and enhancing safety.

- Accommodate people with disabilities and other special needs (universal design).

- Develop pedestrian-oriented land use and building design (new urbanism or transit-oriented development) and increase road and path connectivity, with special NMT shortcuts, such as paths between cul-de-sacs and mid-block pedestrian links.

- Introduce and maintain NMT related street furniture (e.g., benches) and design features (e.g., human-scale streetlights).

25 For a full overview on walking and cycling encouragement, see Victoria Transport Policy Institute, 2011.

- Use traffic calming, speed reductions, vehicle restrictions, and road space reallocation.
- Introduce safety education, law enforcement, and encouragement programs.
- Integrate NMT and public transport facilities (bike/transit integration).
- Provide adequate and secure bicycle parking and address security concerns of pedestrians and cyclists. Create multi-modal access guides, including maps and other information, on how to walk and cycle to particular destinations.

Municipalities and sustainable transport agents can market and promote activities to provide people with information, skills, and positive examples or role models that will promote the popularity of non-motorized vehicles.

Improve Pedestrian Infrastructure

While all the recommendations above also apply to pedestrians, pedestrians are inherently different from NMVs. Pedestrians generally travel more slowly than any other mode – about 4.5 km/hr. Many people will only walk about one kilometer, leaving pedestrians particularly sensitive to detours, roadway conditions, street aesthetics, and perceptions of street crime.

There are many ways to improve facilities, depending on existing infrastructure for pedestrians. A needs assessment can measure indicators of walkability, including factors such as land use mix, street connectivity, residential density, street and building design, scale and nature of place near homes, retail floor area ration, access to public transport, availability and quality of sidewalks, degree of separation from moving traffic and the degree to which moving traffic constitutes a barrier, pedestrian crossings, accessible and direct routes, and air quality.

Additionally, walkability can be evaluated at various scales (Litman, 2010):

- *Site level*: walkability is affected by the quality of pathways, access to buildings, and related facilities.
- *Street or neighborhood level*: the existence of footpaths (pavements or sidewalks) and pedestrian crossings (crosswalks), as well as roadway conditions (road widths, traffic volumes and speeds).
- *Community level*: accessibility, such as the relative location of common destinations and the quality of connections between them.

9.6.2.3 Enhance use of Telecommuting and Communication Technology

Technological change has fundamentally influenced the function and forms of cities and the way people and goods can travel in the city. The convergence of computing and information communications technologies allows a user-friendly interface for many actors and transactions, for information, education, business and a wide range of daily life social activities (Banister, et al., 2004). Communication networks and applications can improve mobility systems in several ways for example: by substituting some types of physical movement with Information Technology based solutions (for example: e-health & e-care; e-learning, e-working, e-culture & e-media, e-economy, e-mobility, e-government & e-democracy); by unleashing significant traffic efficiency via urban traffic managing systems that increase logistic opportunities and safety, and by facilitating opportunities to create a better connected and integrated array of public transport services.

There is a potential for telecommuting to substitute some work trips, particularly for jobs in which greater work flexibility is possible or where rules are made more flexible. Access to information and communication technologies may also have a dual effect where readily available information on new and exciting destinations and shopping-related entertainment stimulate travel and limit the scope of the substitution of virtual and physical travel. For the most part a synergistic relationship can be expected. That is, the more one or another form of telecommunication takes place, the more all forms of communication and travel are stimulated, while some types of travel are substituted (Mokhtarian, 1990; Banister, et.al., 2004). The full impacts of this dual relationship are still being determined. Some studies report that there is no clear certainty that activities such as online-shopping can result in environmental gains from a reduction in passenger transport (Cullinane, 2009). Similar evidence can be found regarding the effects on freight transport indicating that "internet shopping requires carriers to deliver goods to end users rather than to intermediaries, resulting in overall growth in direct shipments to customers. Together, these trends have increased the number of shipments, particularly small shipments, that carriers handle, and expanded the number of links in the freight supply chain that are needed to deliver goods to their final destination" (US DOT 2010).

9.6.3 Improve Use of Existing Infrastructure

Road traffic growth outpaces population and economic growth in most urban areas of the world. In developing countries, motorization can be as low as ten cars per thousand people (parts of China, India) and rarely exceeds 200 cars/1000 people, while two-wheeler ownership can be high. Motorization is higher than 600 cars/1000 people in the United States. Even with the current low levels of motorization in many developing countries, major challenges are associated with the unprecedentedly fast pace of urbanization, which imposes a high demand for adequate transport and the provision of other urban services and infrastructure. As more than one-half of the developing world's population and between one-third and one-half of its poor will be living in cities within the course of one generation, a substantial increase in the demand for energy services can be expected from most urban areas (Gwillian, 2002).

Further construction of major road infrastructure has done little to tame congestion or to reduce overall travel time. High-profile examples in large metropolitan areas of developing countries are Beijing, Bangkok, and Mumbai, where a decade of unprecedented investment in transport transformed an entire urban landscape with congestion becoming ever more problematic.

Institutions and policies that either accommodate the car or favor public transport have not been adequate, which resulting in greater congestion and poor accessibility and mobility. With well-known exceptions like Curitiba, Brazil and Hong Kong, China neither urban nor state-based institutions in developing countries have been strong and/or funded enough to accommodate rapid rates of population and motorization growth, exacerbated by the presence of sharp income inequalities.

The World Bank is actively working to carry out a retrospective/prospective study on urban transport policies and activities and is financially supporting construction of several urban transport systems. In addition, several initiatives of a global scale like the global Transport Knowledge Partnership, the Sustainable Urban Transport Project and the Partnership for Sustainable Low Carbon Transport are providing the best available international experience and expertise to help develop sustainable and efficient transport in developing and transition countries.

9.6.3.1 Parking Management Policies

Every car on the road needs a place to be parked; it is a key issue in almost all urban areas (GTZ, 2009). For an average of 23 hours of the day cars are parked, and if used for all journeys they would need a parking space at both ends of every trip – meaning that many spaces are required for every car. A parked car takes up around eight square meters when parked and often the same again in maneuvering space; this is a huge amount of space in dense urban areas where land is limited and expensive.

In many cities around the world, parking is unregulated, in great supply, and provided free of charge. Abundant parking makes it easier and cheaper to drive, and pandemic parking lots increase the distance between development, making cars more necessary (Shoup, 2005).

While drivers may pay very little to park a car, the actual cost of the parking spaces can be quite high. The cost of surface parking (on street or off-street in parking lots) depends on the price of the land and therefore varies significantly by location. Each space in a parking structure costs at least US$125/month (Shoup, 2005). Despite the high cost of providing parking spaces, in 1995, 95% of US automobile commuters parked free at work (Shoup, 2005).

Free or heavily subsidized parking reduces the costs borne by drivers, biasing individuals' travel choices toward more driving (Shoup, 2005). Shoup estimates that free parking reduces the cost of automobile commuting in the United States by 71%. Since many commuters base travel choices on the relative direct costs of each mode, charging for parking would make a substantial difference in travel behavior (Small and Vehoef, 2007). Removing subsidies for workplace parking in the United States would be equivalent to increasing the price of gasoline to US$4.44/ gallon (Shoup, 2005).

An environmental impact report for a new parking structure built at University of California, Los Angeles in 2003 estimated that each parking space would generate 1170 vehicle-km (727 vehicle-miles travelled) per month, and have associated external costs from increased congestion and emissions of nearly US$117/month (Shoup, 2005). Parking should be priced so that the people utilizing the parking internalize its costs.

On street, curb parking is often similarly underpriced. Where there is a parking meter, the price does not cover the actual costs of the parking. Economic theory says that under-pricing curbside parking creates a shortage. This shortage of curbside parking leads to "cruising" – drivers circling the block in search of available spaces. Studies have demonstrated that in some New York City neighborhoods, 30–45% of traffic is from cruising (Transportation Alternatives, 2006; 2007). A study by Transportation Alternatives (2008) estimated that each year, drivers circling for parking on a 15-block section of Columbus Avenue in New York City's Upper West Side drove 589,000 km (366,000 miles) and emitted 325 tonnes of CO_2.

A GTZ report reviews crucial parking effects and policies worldwide (GTZ, 2009), recommending, among others, the following:

- Recognize the role of parking in creating or limiting car demand in transport policy documents and actions.
- Implement maximum parking standards for new developments, paying careful attention to limit parking provision near public transit.
- Legislation is needed to set a framework for parking charges and fines, and to put liability for any fine with the owner of the car.
- Legislation should give local authorities the power to enforce parking regulations and use the parking revenue to improve a sustainable transport system.
- Manage parking demand by introducing paid parking; consider dynamic parking pricing that varies by time of day and parking availability.
- Parking tariffs should be higher for on-street than off-street, to encourage people to use the latter.

- All changes to parking must be communicated well in advance; a positive approach toward working with the public may increase compliance with parking regulations.

9.6.3.2 Intelligent Traffic/Infrastructure Systems

Traffic management via computerized control of traffic signals and traffic segregation is an important urban transport strategy for increasing the movement of people and goods with higher quality and a safer way as well as to enhance urban environment conditions. Segregation in the form of dedicated bus lanes, bicycle lanes and pedestrians also favors safety and attractiveness of public transport and it contributes even more to a healthy environment and to poverty alleviation.

Traffic management requires expertise and a strong local management agency (with strong regulatory and enforcement capacities) to be implemented, maintained and improved. The lack of these requirements might explain why many cities have not yet introduced such measures or benefited from them. According to the global Transport Knowledge Partnership fragmentation of responsibilities between agencies and lack of inter-agency coordination, coupled with a lack of staff and resources, reduces the effectiveness of many traffic management schemes."

9.6.3.3 Traffic Calming

Traffic calming strategies aim to reduce the speed and volume of traffic to improve safety for pedestrians and cyclists, as well as to improve environmental conditions. Similar to other sustainable transport policies, this involves more than just physical changes; it represents a process of social change requiring extensive community participation. Traffic calming measures are comprised of volume control measures that reduce through traffic by blocking certain movements and diverting traffic to other streets, as well as speed control measures that slow down traffic by changing vertical or horizontal alignment or narrowing the roadway.

Traffic calming measures range from relatively affordable (simple speed humps) to very expensive (designs that affect drainage patterns, utility pole locations or underground services).

Although largely beneficial, traffic calming measures can have drawbacks. Traffic calming measures such as speed humps or raised crosswalks are unsuitable on bus routes or streets that are used frequently by emergency vehicles. Such measures can cause delays up to 10 seconds per measure. Slow traffic on one street can displace vehicles onto adjacent streets, creating unwanted spillover that impacts inhabitants of neighboring streets. Measures that prohibit through traffic can make it more difficult for residents to reach their homes and for visitors to reach local businesses and institutions.

9.6.4 Policies for Alternative Fuels and Efficient Vehicles

9.6.4.1 New Vehicle and Fuel Economy Standards

Fuel economy standards are an effective and efficient policy instrument to reduce GHG emissions in the road transport sector. Fuel economy standards are mandated in many important world regions in order to curb fuel consumption and GHG emissions in new vehicles (An et al., 2007; IEA, 2009d; Creutzig et al., 2011a). Fuel economy standards, however, do not apply for the used vehicles that are often exported to developing countries. Fuel efficiency standards can also complement price instruments, such as carbon taxes and emission trading, that are not fully effective due to dynamic market failures (see also Plotkin, 2008; Flachsland et al., 2011). The European Union and Japan have the most ambitious fuel efficiency standards, with fleet-averaged targets of around 130 gCO_2-eq/km. Although still to be enforced, the European Union adopted an even more ambitious long-term target of 95 gCO_2-eq/km for 2020. China requires ca. 129 gCO_2-eq/km for new vehicles in 2015. The United States implemented a 153 gCO_2-eq/km target for 2016.

The development of fuel efficiency standards in different world regions is summarized in Figure 9.49. This figure is an update from An et al., (2007) with new significant European Union, US, and Chinese regulations (2007). The data is displayed in MJ/km – a suitable measure of energy efficiency, as it applies to all fuels (including electricity/biofuels) and is irrespective of supply-chain GHG emissions (Creutzig et al., 2011a).

An intensity reduction in terms of lower CO_2-eq/MJ is not necessarily equivalent to an absolute reduction in GHG emissions. Two different rebound effects could compromise the desired outcome. First, car

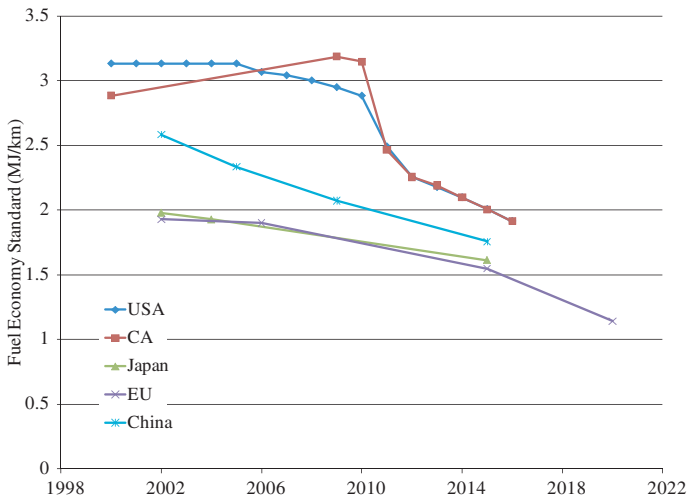


Figure 9.49 | Energy intensity standards of passenger cars extrapolated from current fuel efficiency standards (1 liter gasoline = 32 MJ). Source: An et al., 2007; Creutzig et al., 2011a.

Table 9.11 | Overview of fuel efficiency standards in some world regions.

European Union	CO_2 emissions	gCO_2/km	weight-based fleet standard	NEDC
California	GHG emissions	gCO_2-eq/mile	Absolute fleet standard for LDT1/LDT2	FTP 75
United States	Fuel economy and GHG	mpg and gCO_2-eq/mile	Footprint-based fleet standards for cars/ light trucks	FTP 75
Japan	Fuel economy	km/l	Weight-based fleet standard	Japan 10–15
China	Fuel economy	l/100km	Weight-based fleet standard	NEDC

Source: Creutzig et al., 2011a.

drivers could use the reduction in marginal cost from lower fuel use to increase total travel distance. Based on a review of 22 studies, Greening et al., (2000) suggest a potential rebound effect in the transport sector of between 10–30%. But they highlight the existence of unmeasured components, such as changes in automotive attributes related to shifts toward increases in weight, horse power, and acceleration of cars purchased. The rebound effect generally decreases with income and level of congestion and increases with fuel costs, suggesting a short- and long-run rebound effect of 4.5% and 22.2%. (Small and Van Dender, 2007; Hymel et al., 2010). The sharp rise in oil prices in 2008 might therefore have led to stronger rebound effects than previously observed. A review suggests that total travel volume in OECD countries started to level off between 2000 and 2010 (Millard-Ball and Schipper, 2011). As another kind of rebound effect, market forces could induce a higher production of fuel efficient cars without inducing a simultaneous reduction in gas guzzlers. Despite moderate rebound effects, total expected GHG abatement by fuel efficiency standards is significant and may be – as part of a broad policy mix – the single most effective climate policy in the transport sector (Creutzig et al., 2011a).

Furthermore, fuel efficiency standards are also considered to be relatively cost effective. Their relative contribution to climate change mitigation corresponds to that of other sectors, and costs are approximately in the same price range (e.g., Blom et al., 2007). One should ask, then, which specific design of fuel efficiency standards is most efficient? For example, some world regions have fleet average requirements (e.g., the European Union), whereas other world regions have targets for each car of a specific weight class (e.g., China; see Table 9.8). Given the same level of overall ambition, the first rule is more cost-efficient, as it gives flexibility to car manufacturers in determining where to invest in fuel efficiency. Effectiveness is not impacted if the fleet average target remains the same. Attribute-based standards redistribute the abatement burden among car manufacturers and consumers, and usually follow political rationale, while decreasing overall efficiency.

The unit of fuel efficiency deserves particular attention. Currently, the most common unit of fuel efficiency is volume per distance or its inverse. With alternative fuels and vehicles taking an increasing share of the market, additional units of fuel efficiency (TTW measures) are suggested to convert to energy or GHG emission per distance, e.g., MJ/km (Creutzig et al., 2011a). This choice of unit would provide a level playing field in a more diverse fuel and vehicle market.

The IEA recommended 25 different efficiency measures, including mandatory fuel economy standards, for LDVs and trucks (IEA, 2008). Four measures are recommended for worldwide implementation:

- Introduce, strengthen, and harmonize, where appropriate, mandatory fuel efficiency standards for LDVs.
- Introduce fuel efficiency standards and related policies, such as labeling and financial incentives, for heavy-duty vehicles.
- Introduce measures that promote proper inflation of tires and adequate tire maintenance and adoption of labeling and other efficient vehicle accessories such as headlights, internal lighting, and air conditioning systems.
- Provide incentives to encourage drivers to adopt safe driving techniques, the promotion of eco-driving, including driver training and deployment of in-car feedback instruments.

9.6.4.2 Used Vehicle Emissions Standards

Imports of used vehicles from developed countries contribute significantly to the vehicle fleet in developing countries. In 2005 alone, Mexico imported 1.3 million vehicles from the United States that were more than 10 years old (Johnson et al., 2009). Strict new vehicle fuel economy standards that increase vehicle prices further encourages the import and sale of older used cars in Mexico and other developing countries. Any fuel economy improvements achieved with new vehicle restrictions could be diminished or negated if older polluting vehicles introduced into the fleet reduce the overall on-road fuel economy.

It is therefore important for any new vehicle fuel economy standards to be accompanied by measures that discourage the purchase and ownership of fuel-inefficient used vehicles, such as inspection and maintenance requirements and border inspection interventions (Johnson et al., 2009).

The World Bank's *Low Carbon Development for Mexico* (Johnson et al., 2009) suggested that border vehicle inspections require imported vehicles to meet minimum environmental standards in order to indirectly regulate the efficiency of used imported vehicles. For instance, vehicles exceeding a certain emissions threshold would be banned from the

country. Similarly, municipal or statewide vehicle inspection programs could restrict vehicle registration or licensing to those vehicles meeting certain tailpipe emissions standards.

9.6.4.3 Reducing the Carbon Intensity of Fuels

Biofuels have been discussed, and partially misunderstood, as low- or zero-carbon sources of energy for transportation, and as a suitable strategy for reducing oil dependency. Hence, the development of biofuels has been supported by a range of policy instruments, including volumetric targets or blending mandates, tax incentives or penalties, preferential government purchasing, government-funded research, development, and deployment (RD&D), and local business incentives for biofuel companies. For example, biodiesel production in Germany jumped with the introduction of a tax break, and slumped again with introduction of a new tax rate.

Another powerful tool that has been introduced into the policy arena over the past decade is renewable fuel mandates. Renewable fuel mandates require fuel producers to produce a pre-defined amount, or share, of biofuels and blend them with gasoline. The mandates aim to reduce the carbon intensity of transportation fuels by entering larger amounts of low-carbon fuels into the market without setting particular intensity targets. Some renewable fuel mandates are non-discriminatory in that they do not differentiate between different types of biofuels. From an environmental perspective, this assumes that any renewable fuel source is less carbon-intensive than conventional gasoline. However, recent evidence shows that this might not be the case (see Crutzen et al., 2008; Searchinger et al., 2008). Discriminatory renewable fuel mandates, on the other hand, apply to only a selection of biofuels or introduce quotas for the least carbon-intensive biofuels.

In its directive on the promotion of the use of energy from renewable sources (EC, 2009a), the European Union mandates 10% renewable fuels used in transportation by 2020. In the United States, the Renewable Fuel Standard 2 (RFS2) program will increase the volume of renewable fuel required to be blended into transportation fuel from 9 billion gallons in 2008 to 36 billion gallons by 2022, corresponding to around 9–13% of total fuels (EPA, 2010a).

However, renewable fuel standards are insufficient for a number of reasons (Creutzig et al., 2011a):

- Only biofuels, and no other alternative fuels, can contribute to achieve this goal. Hence, this is a technology-specific regulation.
- Only some, but not all, biofuels are subject to meeting threshold values. Regulation should be proportional to carbon content to be effective.
- In the current regulation, lifecycle accounting is not accurate as it is performed by relying on hypothetical technologies. It underestimates indirect land-use emissions and ignores epistemic and highly relevant uncertainties related to land-use change (e.g., Plevin et al., 2010).

A Low Carbon Fuel Standard (LCFS) is different from renewable fuel standards in that it: a) mandates a specific overall decrease in the average carbon intensity of all fuels; and b) accounts for the carbon emissions of each individual fuel, including non-conventional fossil fuels. The primary purpose of a LCFS is to reduce the carbon intensity of fuels for LDVs. As such, a LCFS provides a level playing field across all fuels, rather than mandating specific fuels of the RFS. A LCFS has been implemented in California that requires a 10% reduction in fuel carbon intensity by 2020 (Schwarzenegger, 2007; CARB, 2009). In the European Union the Fuel Quality Directive COM-2007–18 requires a 6% reduction in CO_2-eq of transportation fuels from 2010 to 2020 (EC, 2009a). The US RSF2 indicated threshold values (EPA, 2010a), and a LCFS-like instrument is under discussion in China.

LCFS can remedy some of the insufficiencies in renewable fuel standards. However, a LCFS is also criticized for leakage and shuffling (Stoft, 2009). As an intensity-based instrument, a LCFS suffers from perverse incentives that may, in effect, increase emissions (Holland et al., 2009). Furthermore, the epistemic uncertainty in lifecycle analysis is pervasive, and is not only a matter of research accuracy but is of systemic nature (Plevin et al., 2010). Addressing transport biofuel emissions in a context of a total cap of GHG emissions by introducing fuel and feedstock accounting standards has been suggested to avoid perverse incentives and to decrease the reliance on subjective and unreliable lifecycle accounting to some degree (deCicco, 2009; Creutzig et al., 2011a).

9.6.5 Creating Economic Incentives or Disincentives

Price instruments in transport can cover several purposes. First, price instruments can be understood as user charges to recover investments in infrastructures. Second, price instruments can potentially aim to internalize the huge social costs of transportation (e.g., EEA, 2008b). Third, price instruments have a steering effect, and can reduce or shift demand that produces high social costs. Economic theory predicts that price instruments that address social costs comprehensively are immune to rebound effects. However, if only one category of social costs is priced (e.g., GHG emissions), other social costs of transport will not necessarily improve (e.g., congestion and space consumption of motorized transport in inner cities).

9.6.5.1 Fuel Taxation and Carbon Pricing

In many countries, fuel taxes are an important source of revenue for financing the transport sector. Fuel taxes reclaim the costs of transport infrastructure from road users. As a crude benchmark, US$0.10/liter may

yield the financial resources necessary to maintain the road system, and an additional US$0.03–0.05/liter can be a source of finance for urban transport (GTZ, 2009).

Fuel taxes can be evaluated according to four categories of cost recovery and taxation purposes (GTZ, 2009), and countries can be sorted according to these four categories:

- In the first category, fuel prices do not reflect the costs of production and distribution. Some countries, notably Iran and Saudi Arabia, subsidize road users so strongly that not even the costs of oil production and distribution are covered. IEA estimated global fossil fuel consumption subsidies in 2008 alone at about US$557 billion (IEA, 2010b).[26]

- The second category recovers road infrastructure costs. Here, the relatively low fuel taxes of the United States are suggested as a conservative benchmark, i.e., the minimum level of fuel taxes to recover road construction and maintenance costs.

- The third category comprises the countries that attempt to internalize the external costs of road transport, i.e., tentatively including issues like consumption of urban space and air pollution.[27] Usually, countries that explicitly try to internalize the external costs of road transport have the highest fuel taxes (e.g. European Union countries, Hong Kong).

- In the fourth category, fuel taxes are used as a general source of revenue. Fuel taxes are easier to collect than income taxes or value-added taxes, and can constitute a major source of income for core state functions such as health services and education. This is particularly relevant in countries where tax code enforcement is limited by weak institutional capacity.

Fuel taxation is a straightforward instrument and a good proxy to achieve a number of objectives. However, it is crude with respect to localized externalities, such as congestion and air pollution. Localized road user charges (e.g., congestion charges) can remedy this gap (see below). For the current fleet of vehicles, because GHG emissions are proportional to gasoline and diesel consumption, fuel taxes can address GHG emissions of transport sufficiently accurately. However, with increasing shares of alternative fuels and technologies, fuel supply chains diversify, by this shifting GHG emission upstream in varying supply chains (Creutzig et al, 2011a). GHG emissions of transport are better addressed by upstream emission trading or carbon taxes (Flachsland et al., 2011).

26 www.iea.org/files/energy_subsidies.pdf.

27 Data suggests (e.g., EEA, 2008b) that even the relatively high fuel tax levels in the European Union insufficiently address external costs of road transport. The European Union intends to raise specific road user charges (e.g., EC, 2006).

9.6.5.2 Vehicle Taxation and Subsidies

Vehicle taxation can be used to regulate total car ownership. As most infrastructure and social costs are related to car usage, but not car ownership, vehicle taxation is commonly seen as a sub-optimal price instrument. However, a well designed vehicle tax can successfully mimic non-available first-best pricing instruments (Fullerton and West, 2000). High vehicle taxation limits motor vehicle penetration. For example, Denmark has higher vehicle taxes and lower car ownership than the United States. As another example, cities with dense urban agglomeration, such as Singapore or Shanghai, regulate vehicle ownership by auctioning licenses.

9.6.5.3 Road User Charging

Road user charging, or road pricing, means charging for the use of roads in a way that reflects the actual costs of using them, i.e., paying more when roads are congested and less when traffic is light. Congestion charging is a form of demand management that aims to reduce motor vehicle travel, or shift it to the most sustainable modes, for passenger or freight in peak hour traffic in order to reduce congestion, improve travel times, and reduce emissions (Pigou, 1920; Prud'homme and Bojacero, 2005). A city toll would use road pricing in cities not only for reducing congestion, but also to be an efficient measure to account for other externalities, including air pollution, noise pollution, accidents, and GHG emissions (Creutzig and He, 2009). Road pricing works best when applied in parallel with other measures, such as public transport improvements and provisions for cyclists and pedestrians, to support mode shifts. Technically, the joint application of push (pricing) and pull (investments into NMT and public transit) produces synergies via reduced demand elasticities, reduces opportunity costs for car drivers, and increases public welfare gains (Creutzig and He, 2009). Communication and the involvement of key stakeholders are vital to the success of a pricing scheme, and must be consulted effectively to raise the level of awareness and support.

Key examples of road pricing schemes are found in London, Singapore, Milan, and Stockholm. The London Congestion Charging Scheme, in place since 2003, led to a reduction of vehicle-km traveled of about 20%, significant travel time savings, 16% reduction in CO_2 emissions, substantial reduction of air pollution, and altogether higher life quality in London (Transport for London, 2007). The Singapore Area Licensing Scheme, introduced in 1975, is part of a comprehensive policy package that makes Singapore a leading city in urban transportation worldwide. The updated scheme, Singapore Electronic Road Pricing, is adaptive in pricing so that traffic is always fluid, maintaining speeds of 45–65 km/hr on expressways and 20–30 km/hr on arterial roads. The ECO-PASS scheme in Milan, in place since 2008, is relatively young and has better air quality as one of its primary objectives. Money raised will go toward buses, cycle paths, and green vehicles. The Stockholm congestion pricing scheme is particularly interesting for its political implementation. A trial period was

introduced to persuade road users of the congestion relief benefits of this instrument. Following the trial period, in September 2006, a referendum was held in which a majority of voters, comprising city inhabitants but not outer districts, voted in favor of the congestion charging scheme. Carbon dioxide emissions dropped by 10–14%, which is very significant for a single policy instrument. Smaller cities, such as Durham, England and Valetta, Malta, have also had positive experiences with congestion charging.

Both design and distribution effects play a major role in the political success of road pricing and city tolls. A congestion charging scheme in Hong Kong was abandoned partly because people thought their movements might be tracked. Congestion charging is likely to be more accepted if the revenues subsidize alternative modes of transport, including public transit and NMT, and by this reduce opportunity costs for transport users. In contrast to Stockholm, a congestion charge referendum was rejected in Edinburgh. Car users were vehemently opposed and emphasized the costs to them, and neither car users nor public transit users were strong proponents of future benefits (loss aversion). A solid communication strategy with clear objectives was missing. Other crucial success criteria include a single implementation agency and a political champion and figurehead of the process. Design should correspond to the spatial scope of authority and voters. Both consultation and promotion of the project are required and, accordingly, the project must be kept simple (e.g., Gaunt et al., 2006).

9.6.6 Establish Policies Targeting Freight and Long-Distance Transport: Shipping, Trucks, Rail, and Air

Freight transportation continues to show growth rates that mirror development in an economy or exhibit even a slightly faster growth. It is likely that the recent economic downturn will have a short-term impact on the pace of growth, but this will not change the general trend toward long-term growth of freight transport.

9.6.6.1 Heavy-Duty Vehicles

The demand for freight transportation is driven by economic considerations and the development of logistics in the private sector (EEA, 2008b). Road transport dominates the inland freight transport market. Heavy-duty vehicles dominate inland freight transport at the expenses of rail and inland waterway transport, even in countries where a well-developed and extensive rail and water transport network exists, such as in Europe. Policies and measures to reduce the energy use of road freight are therefore focused on the short to medium term.

Three measures with energy saving potential that can also improve the fuel energy efficiency of the road freight sector include: "training of drivers in energy-efficient or eco-driving techniques, allowing larger vehicles, and reducing average driving speed" (McKinsey Global Institute, 2009). Lowering the speed of trucks has to be assessed vis-à-vis overall traffic safety considerations.

Measures such as the internalization of freight transport external costs (i.e., traffic-based air pollution, noise, and congestion), even if not directly aimed at reducing climate emissions, will contribute to that end goal.

A combination of regulatory policies, such as mandated fuel efficiency improvements for trucks, combined with a steadily increasing carbon tax, could achieve significant reductions in energy use per tonne-km of transport. Shifting freight and passenger transport to rail can be encouraged through government support for R&D of new technologies combined with a steadily increasing carbon tax. At present, neither aviation nor international shipping fuel is subject to any tax or regulation and is not subject to any restrictions under the Kyoto Protocol.

9.6.6.2 Rail

Encouraging a modal shift from road freight transport to rail and inland water transport and short-sea shipping are important measures, as the latter are less polluting modes for freight transportation. However, there are limits to how much a rail network can be expanded and this limits the potential for a substantial shift from trucks to rail.

9.6.6.3 Shipping

Inclusion of international transport emissions, or more generally, all sorts of environmental pollution attributable to international shipping, within a global climate policy framework has proven to be difficult, primarily because the responsibility for reducing emissions does not fall directly within the jurisdiction of any single country. Due to the global nature of shipping and aviation, sectoral approaches may be more appropriate for tackling emissions reductions in international transport. In fact, the shipping industry favors a global treatment of GHG emissions to avoid a multitude of regional regulations (UNCTAD, 2010). There are currently two main types of policy for GHG reduction considered by the IMO: market-based instruments and efficiency requirements. Market-based instruments include emissions trading schemes, fuel levies, energy efficiency credit trading schemes, and other hybrid schemes. Regulating emissions from maritime and air transport could potentially generate resources to finance climate change adaptation and mitigation measures in developing countries (Monkelbaan, 2010).

9.6.6.4 Aviation

A wide variety of economic, market-based measures have been identified for the aviation industry to make progress in reducing net emissions.

These include voluntary carbon offsetting, emissions trading schemes, emissions charges, and positive economic incentives.

The most advanced policy is the inclusion of aviation into the European Union emission trading scheme (ETS) (Directive 2008/101/EC; see European Commission, 2006), understood to be the most cost-efficient and environmentally effective option for controlling aviation emissions. Like industries, airlines will receive tradable allowances covering a certain level of CO_2 emissions per year. After each year, airline operators must surrender a number of allowances equal to their actual emissions in that year. From the start of 2012, emissions from all domestic and international flights – from or to anywhere in the world – that arrive at or depart from a European Union airport will be covered by the European Union ETS. The European Union ETS can thus form the basis for global action. Airline operators are expected to buy certificates from non-aviation abatement options. Due to the relatively weak cap of the European Union ETS, expected low carbon prices until 2020, and limited demand price elasticity of passengers, the overall reduction in demand growth and carbon emissions is expected to be insignificant (Anger and Köhler, 2010). Nonetheless, the European Union ETS directs attention to the growing emissions of the aviation sector and is expected to serve as a role model for other countries and world regions considering similar national or regional schemes, and to link these to the European Union scheme over time.

Possible regulatory and other measures include aircraft movement caps/slot management, enhanced weather forecasting, transparent carbon reporting, and education and training programs. Each of these can contribute to an overall action plan by individual Contracting States.

9.6.7 Assessment of Policy Contributions to Meeting the Multiple GEA and Transport Sustainability Goals

No single policy, actor, or technology has the silver bullet for an energy and sustainability transition in transportation. Achieving multiple goals within a relatively limited time frame requires action on all spatial scales in order to address technologies, urban design, and demand management alike. Governments of nations and cities around the world have different reasons for acting on transport energy sustainability. Appropriate policies will vary according to city, country, and circumstances but should be integrated across scales (Corfee-Morlot et al., 2011). The role of government is pivotal for an energy sustainability transition. The GEA approach considers a multiple-goal approach that requires multiple policies to be implemented simultaneously as policy packages.

Forming multi-policy packages as a way to frame transport policy is a strategy that is receiving increasing attention by researchers and policy makers (OPTIC, 2010). The motivation is the realization that traditional approaches based on single-goal policies have limitations when trying to resolve complex transport problems related to environment and climate. A multi-policy package has been defined as: "a combination of individual policy measures, aimed at addressing one or more policy goals with the objective of improving the impacts of the individual policy measures, minimizing possible negative side effects, and/or facilitating the measure's implementation and acceptability" (OPTIC, 2010).

Transportation is a sector bound by multiple direction causalities with land use and behavioral parameters that lead to major policy paradoxes. These multi-direction causalities affect transport policy implementation. One crucial example is "induced or latent traffic demand," in which building new road infrastructures induces additional traffic (e.g., Goodwin, 1996; Cervero, 2008).

The rebound effect states that efficient vehicle technologies make driving cheaper, and hence will increase the amount of driving and the external costs associated with it. The effectiveness of a fuel economy standard in reducing aggregate fuel consumption then is undermined if the rebound effect is large (Small and Van Dender, 2007; Van Dender, 2009). Two arguments contend that while the rebound effect is real, it should not deter advances in energy efficiency. First, trends clearly indicate that people favor a move toward faster modes of travel, and total distance travelled continues to grow globally. Given these preferences, efficiency improvements will mitigate but not limit the rise in fuel use that would be occurring anyway as trends unfold. Improving efficiency is necessary but not sufficient to meet climate, environmental protection, and energy security goals in transport. Second, the demand for driving and the distances driven are increasing because they generate net benefits to the driver, meaning there are benefits and not just external costs that need to be considered. Finally, while better fuel economy does lead to more driving, it appears to increase less when there is congestion, because congestion itself is a deterrent to driving (Van Dender, 2009).

The rebound effect and overall rising demand is difficult to tackle with fuel efficiency regulations and technological improvements alone and requires appropriate and encompassing demand policies, such as pricing, to be in place. In the absence of pricing policies, consumer preferences for faster, heavier, and stronger performance LDVs, induced and latent demand, and the rebound effect will result in total travel demand such that social benefits are heavily outweighed by social costs, such as congestion at the local level and climate change on a global scale. To effectively and efficiently deal with sub-optimally high demand, focused demand management (e.g., based on pricing policies) is a necessary complement to technological advancement.

A qualitative assessment pairs the sustainable goals outlined in this chapter with policies grouped according to the following categories: Planning, Regulatory, Economic, Information, and Technology. The contribution is rated as essential when policy implementation is a step toward the attainment of a particular goal and when this is well documented in the literature. The contribution is rated as uncertain when no conclusive study has proven the effectiveness between policy implementation and the goal. Finally, the

contribution is categorized as complementary when the expected effect can indirectly or in addition to other policies contribute to creating some synergy to the attainment of that goal.

9.6.7.1 Planning Policies (Table 9.12)

- Two essential planning instruments can be adopted in all countries and cities to meet sustainability goals. First, design urban spaces to improve walkability and facilitate the use of non-motorized modes of transportation. This, in addition to parking policies (pricing, location, etc.) and all other policies to reduce car use and accommodate human-powered modes, are policies that serve most goals. Second, increase the speed, frequency, and coverage of public transport to improve the use of public transportation.
- The role of urban densification is essential to improving accessibility to services and jobs, while impact on congestion can be ambivalent. Increasing density is a planning policy that needs to be seen in a city-wide, or even regional, context when transportation corridors are designed (Cervero, 2008). Density needs to be a complementary policy to other land-use and transport planning policies, such as mixed use zoning, walkability, non-motorized modes, housing policies, etc. (Banister, 2008; Wheeler, 2004).

9.6.7.2 Regulatory Policies (Table 9.13)

- Regulatory policies have a clear role regarding traffic safety, air pollution, noise, climate mitigation, and diversification of energy sources.
- Gaps in regulatory implementation can diminish the effect of otherwise effective instruments. Therefore, capacity for implementation is also essential.

- Regulatory policies affecting one transport subsector may have little impact on other subsectors, demonstrating the need for instruments or sets of instruments creating comprehensive coverage.

- Although the impact of regulations on urbanization and equity goals related to transport as they are presented here can be seen as uncertain, the positive benefits of the stringent enforcement of safety, noise, and air pollution rules are without a doubt beneficial to the quality of life in a city for all its inhabitants.

9.6.7.3 Economic Policies (Table 9.14)

- Pricing policies are essential to address environmental, climate, and energy security goals. They play a complementary role in terms of sustainability and equity goals. Pricing policies can create incentives for the introduction of new transportation technologies and the use of new infrastructure. Depending on the design and revenue recirculation scheme, they can have regressive or progressive distributional effects.

- Pricing policies are considered in many respects to be more flexible and effective than regulatory and planning instruments, the latter of which are often viewed as "command and control measures." However, pricing policies may receive little or no acceptability by society and have high political, transaction, implementation, and enforcement costs.

- Economic policies are essential to achieve climate mitigation and diversification of energy sources and have mostly a complementary effect on achieving the other goals.

- Road pricing effectiveness depends on the alternatives. If drivers are induced to divert their journeys to non-toll roads, there is only a very localized reduction in air pollution. If trips are taken with other modes of transportation that are more energy efficient, the effects are larger.
- Feebates for fuel economy standards may induce people to drive more (rebound effect), as the marginal cost is cheaper.
- Alternative fuels may not improve air pollution or climate mitigation if they are produced using fossil fuels.

9.6.7.4 Policies to Improve Information (Table 9.15)

Improving information is essential for a low-carbon transition and to contribute to larger goals for transport and urbanization, health, environmental protection, and climate change mitigation (Banister, 2008).

9.6.7.5 Contribution of New/Improved Technologies (Table 9.16)

Measures improving technology and inducing technological shifts contribute to energy security, climate, and environmental goals.

9.6.8 Enabling Conditions to Facilitating a Sustainable, Low-carbon Transition

9.6.8.1 Improving Institutional Capacity

A tension exists between the need for policy and decision makers to commit to a full systemic change and the need to get things done using existing policies, institutions, capacities, and decision-making frameworks. Institutional and human resource capacity is a prerequisite for the implementation of sustainable transport policies. As a rule of thumb, an unregulated transport sector tends to produce a number of inefficient environmental and social externalities. One important factor is

institutional integration and coordination (Banister 1998, 2005; May et al., 2006).

9.6.8.2 Improving Acceptability and Public Information

Sustainable transport is not only characterized by a number of goals or co-benefits, but also by procedures such as participation and open communication. In fact, improving the acceptability of changes of the transport system often is a precondition for successful implementation. Such is its importance, that information itself has been identified as a key component of sustainable transport (Banister, 2008). In Table 9.17 key insights of information for transport transitions are identified.

9.7 Conclusion

Achieving sustainability goals in transport that help induce economic growth, energy security, equitable access and better health, and contribute to poverty alleviation and to meeting low emissions goals,within the limited time frame of a few decades requires transformative actions and political commitment from the local communities to the supra-national and global level. Actions must be taken to change the landscape of cities to favor multiple short-distance destinations, to enhance accessibility by foot and non-motorized modes, and to enhance and extend a variety of smart-integrated public transport services. These kinds of structural and demand-side policies are necessary complements to technological innovation for energy efficiency and alternative fuel deployment.

Table 9.16 | Potential contribution of new/improved technologies to transport and GEA goals.

Globally, transportation policy makers, technicians, and manufacturers must purposefully participate in climate change mitigation and actively contribute to reduce energy security concerns. Locally, the livability of human settlements, environmental pollution, health, and spatial equity can be dramatically improved by sustainable transport practices.

Achieving this vital transition requires extensive investment in high-quality public transportation and non-motorized transport that encourages a shift to these modes from private automobiles. There needs to be an overall reduction in VMT, a radical shift in urban development from car-centric to people-centric models that prioritize walkable, dense, mixed-use urban spaces. Also required is the decarbonization of transportation fuels, mainstreaming of near-zero GHG emissions vehicle technologies, such as plug-in hybrid vehicles, full battery electric vehicles, and hydrogen fuel cell vehicles. Altogether, this comprehensive set of policies will affect not only transport use but also societal interaction, e.g., via land-use patterns and personal choices and preferences.

The task of transforming transportation will not be possible without sustained effort and deep involvement over the upcoming years and decades by industry, governments, and consumers (Lutsey and Sperling, 2007). Achieving a multitude of local transitions for sustainable urban transport is a key challenge as cities for some additional 3 billion urban dwellers will need to be constructed by 2050. As discussed in Chapter 18 most of this urban growth will take place in medium size cities. This represents a window of opportunity to use many of the approaches covered in this Chapter, in particular, for giving a renewed focus on addressing issues of accessibility, density, land use and urban design to favor walking and bicycling, public transport service affordability, local equity and environmental concerns. The future sustainability of cities requires solid policy actions essential to decrease barriers for slow-mode traffic, reduce air pollution and noise nuisances, and to make cities safe and comfortable places for transport and living.

The required planning practices, policies, and technological innovation for this transition cannot be limited to improving the energy efficiency of personal vehicles (LDVs) and fuels. It must aim to upgrade the energy efficiency of all subsectors within all transport systems – including heavy-duty vehicles, buses and trucks, trains, airplanes, ships, agricultural vehicles, and off-road transport – on a scale from the local to the national to the international.

This transformation must embrace a long-term vision. It presents challenges that need to be overcome. Chief among them are societal barriers, limited institutional capacities, and status (e.g., Urry, 2007; Creutzig et al., 2011b). Another challenge is that fuel technologies that may be

Table 9.17 | Key elements for promoting public acceptability for a transport transition.

Information	• Education, awareness campaigns, and promotion through media and social pressure are an essential starting point • Explanation of the need for a transition toward sustainable, low-carbon mobility, emphasizing positive economic, social, and health benefits to individuals and businesses
Involvement and communication	• The process must be inclusive, with clear aims and an understanding of the consequences by those who the strategy will impact • Design to gain support and understanding, so that stakeholders can buy into proposals • Raise levels of consistency between expectations and outcomes
Packaging	• Push and pull policies measures need to be combined in mutually supporting packages • Policies restricting car use or raising its costs should be accompanied by well-publicized programs to improve availability and attractiveness of alternatives to driving alone, including car pooling, public transport, cycling and walking, all financed by dedicated revenues from car pricing measures
Selling the benefits	• It is necessary to widely publicize the benefits, even if there are costs, inconvenience, and sacrifice • Car drivers support funding of alternative modes to reduce congestion on the roads they drive on • Overweight or obese individuals would directly benefit from better walking and cycling conditions • Everyone benefits from cleaner air and safer traffic conditions • More walking, cycling, and public transport use would help relieve parking shortages. These are important and direct impacts that all individuals can support
Adopt controversial policies in stages	• Support needs to be built up in terms of positive outcomes and measurable improvements in the quality of life • Politics is about reflecting prevailing preferences and also forming opinions • Acceptance of responsibilities and commitment to change through actions is the key to success
Consistency between different measures and policy sectors	• Some measures (e.g., pricing) are common to all futures, and such measures need to be implemented now, even though the impacts may not be immediate • Regulations, standards, subsidies, and tax incentives should all be used to encourage manufacturers and other transport suppliers to develop and adopt the most energy-efficient and environmentally friendly technology possible • The precautionary principle should be followed, particularly on the global warming effects of transport emissions, and actions should be consistent over the longer term • Many problems created for the transport system do not emanate from the transport sector, but from other sectors. Thus, a more holistic perspective is needed that integrates decision making across sectors and widens public discourse
Adaptability	• Decisions today should not unnecessarily restrict the scope for future decisions, so that the adaptive behavior of individuals and agencies can be assessed • There is no prescription or blueprint for the correct procedures to follow. Each situation requires separate analysis and implementation, including flexibility to change policy measures if intentions and outcomes do not match. Assessment of risk and reversibility are both strong components of sustainable mobility • Adaptability is not an excuse for inaction or weak action. It is an argument for clear decision making and leadership, supported by analysis and monitoring to check the effectiveness of policy action

Source: adapted from Banister, 2008.

best suited to help with the transition are not presently at the commercialization stage. Furthermore, current marginal improvement in technologies can constitute further long-term technological lock-in, and may constitute a barrier for the deployment of transformational technologies.

Transforming transportation toward sustainability requires the implementation of a portfolio or aggregated bundle of policies and hybrids of regulations and market mechanisms directly linked to targets that enhance mobility while protecting the environment. This includes considerations of air pollution, GHG emission reduction, carbon tax policies, quality of accessibility, affordability of urban mobility, safety, and acceptance from urban residents. A transition must build in long-term signals to fuel producers, and needs to incentivize the development and dissemination of new, cleaner, and affordable technologies. To be successful, a transition must be accompanied by the effective communication of sustainable transport goals (Jaccard, 2006). Pioneer regions and cities in sustainable transport can provide benchmark policies and lower the behavioral barriers in other regions and cities.

It is necessary to immediately start intelligently designing low-carbon transportation systems in developing countries that can also bring co-benefits, such as clean air or a reduction of congestion, that are necessary for sustainable development (Bongardt et al., 2010). Such measures could be supported by international climate mitigation efforts as administered by the UNFCCC, an intervention fostered by the Partnership on Sustainable Low Carbon Transport.

An important near-term approach is to identify strategies for decarbonizing key subsectors like aviation, marine transport, and heavy-duty vehicles. Transport intensity needs to be addressed in all road transport subsectors through urban planning and transportation demand management. The strategy for dealing with automakers is to bring highly efficient, alternative-fuel vehicles to the market with policies that focus on the link between new product commercialization and

the mass dissemination necessary to realize substantial cost reductions from economies of scale and economies of learning (Jaccard, 2006).

Finally, with the multiplicities of sustainable transportation goals and different spatial scales involved, the cost of transforming transportation can vary dramatically across industries, countries, and regions. With this in mind, it is imperative that local governments gain experience and expertise even before national and global initiatives are in place. Lower-level government policy structures need not preclude – and can even advance – multiple goals toward transforming transportation and sustainability, integrating policy measures across goals while differentiating between geographic settings (Lutsey and Sperling, 2008; Creutzig and Kammen, 2009b).

Executive Summary

Buildings are key to a sustainable future because their design, construction, operation, and the activities in buildings are significant contributors to energy-related sustainability challenges – reducing energy demand in buildings can play one of the most important roles in solving these challenges. More specifically:

- The buildings sector[1] and people's activities in buildings are responsible for approximately 31% of global final energy demand, approximately one-third of energy-related CO_2 emissions, approximately two-thirds of halocarbon, and approximately 25–33% of black carbon emissions.

- Several energy-related problems affecting human health and productivity take place in buildings, including mortality and morbidity due to poor indoor air quality or inadequate indoor temperatures. Therefore, improving buildings and their equipment offers one of the entry points to addressing these challenges.

- More efficient energy and material use, as well as sustainable energy supply in buildings, are critical to tackling the sustainability-related challenges outlined in the GEA. Recent major advances in building design, know-how, technology, and policy have made it possible for global building energy use to decline significantly. A number of low-energy and passive buildings, both retrofitted and newly constructed, already exist, demonstrating that low level of building energy performance is achievable. With the application of on-site and community-scale renewable energy sources, several buildings and communities could become zero-net-energy users and zero-greenhouse gas (GHG) emitters, or net energy suppliers.

Recent advances in materials and know-how make new buildings that use 10–40% of the final heating and cooling energy of conventional new buildings cost-effective in all world regions and climate zones. Holistic retrofits[2] can achieve 50–90% final energy savings in thermal energy use in existing buildings, with the cost savings typically exceeding investments. The remaining energy needs can be met at the building- and community-level from distributed energy sources or by imported sustainable energy supply. The mix of energy-demand reductions, on-site renewable energy generation, and off-site renewable energy supply that corresponds to the most sustainable solution and minimizes the total cost needs to be evaluated case by case, applying a full system life cycle assessment. Net zero-energy buildings and communities[3] are possible only for select building types and settlement patterns, mainly low-rise buildings and less densely populated residential areas. However, their economics are presently typically unfavorable, as opposed to high-efficiency buildings. Meanwhile, compact medium-rise and high-rise developments offer many advantages, such as reduced surface-to-volume ratios and typically lower energy service demands due to the higher density and concentration of building uses.

The scenarios constructed by the GEA buildings expert team, in concert with the GEA main pathways, demonstrate that a reduction of approximately 46% of the global final heating and cooling energy use in 2005 is possible by 2050 (see Figure 10.1). This is attainable through the proliferation of today's best practices in building design, construction, and operation, as well as accelerated state-of-the-art retrofits. This is achievable while increasing amenity and comfort and without interceding in economic and population growth trends and the applicable thermal comfort and living space increase. It goes hand in hand with the eradication of fuel poverty – i.e., supplying everyone with sufficient thermal

1 The GEA refers to energy use in the buildings sector as all direct energy use in buildings, including appliances and other plug loads, and accounting for all electricity consumption for which activities in buildings are responsible. Embodied energy use, emissions of the production of building materials, and their transport to the construction site, and other equipment are not included.

2 Holistic retrofit refers to a major renovation of a building involving a complex of various energy efficiency measures. It is the opposite to a stepwise renovation, when, first, some parts of the building are renovated (e.g., windows), later other parts (e.g., insulation), etc.

3 Net zero energy buildings (communities) are buildings (communities) that consume as much energy as they produce from renewable energy sources within a certain period of time (usually one year)

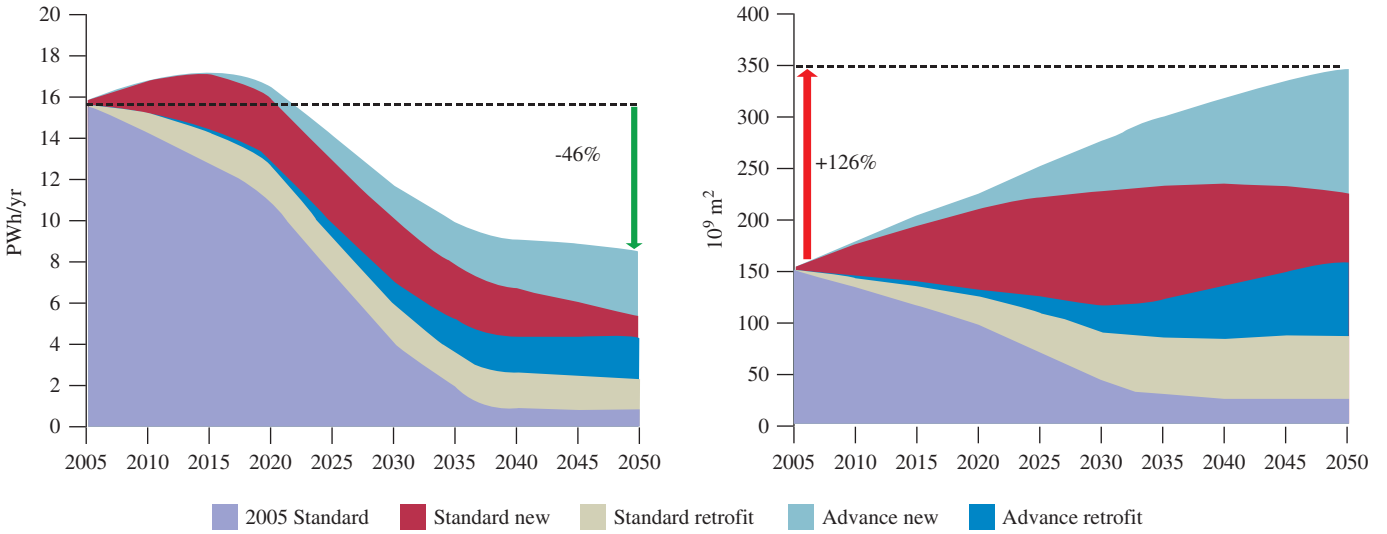

Figure 10.1 | Global final building heating and cooling energy use[4] until 2050 in the state-of-the-art scenario (corresponding roughly to the "GEA Efficiency" set of pathways) (left), contrasted to global floor area (on the right) projections.

comfort. Reaching these state-of-the-art energy efficiency levels in buildings requires approximately US$14.2 trillion in undiscounted additional cumulative investments (US$18.6 trillion with no technology learning) until 2050. However, these investments return substantially higher benefits, e.g., approximately US$58 trillion in undiscounted energy cost savings alone during the same period.

Present and foreseen cutting-edge technologies can reduce energy use of new appliances, information and communication technology (ICT), and other electricity-using equipment in buildings by 65% by 2020, as compared to the baseline. Longer-term projections of technology improvements are speculative, but likely to provide significant additional improvement. Through lifestyle, cultural, and behavioral changes, further significant reductions could be possible.

However, the scenario work also demonstrates that there is a significant lock-in risk. If building codes are introduced universally and energy retrofits accelerate, but policies do not mandate state-of-the-art efficiency levels, substantial energy use and corresponding GHG emissions will be "locked in" for many decades. Such a scenario results in an approximately 33% increase in global building energy use by 2050 compared to 2005, as opposed to a 46% decrease – i.e., an approximately 79% lock-in effect relative to 2005. This points to the importance of building shell-related policies being ambitious about the efficiency levels they mandate (or encourage). Figure 10.2 illustrates opportunities offered by a state-of-the-art scenario as well as the lock-in risk for the 11 GEA regions.

A future involving highly energy-efficient buildings can result in significant associated benefits, typically with monetizable benefits at least twice the operating cost savings, in addition to non-quantifiable or non-monetizable benefits now and avoided impacts of climatic change in the future. One of the most important future benefits is mitigation of the building sector's contribution to climate change. Other benefits include: improvements in energy security and sovereignty; net job creation; elimination of or reduction in indoor air pollution-related mortality and

4 In Chapter 10 energy use is measured in kWh, as it is the most commonly used metrics for the buildings sector. In order to convert kWh to kJ, please, follow the rule: 1 kWh = 3600 kJ.

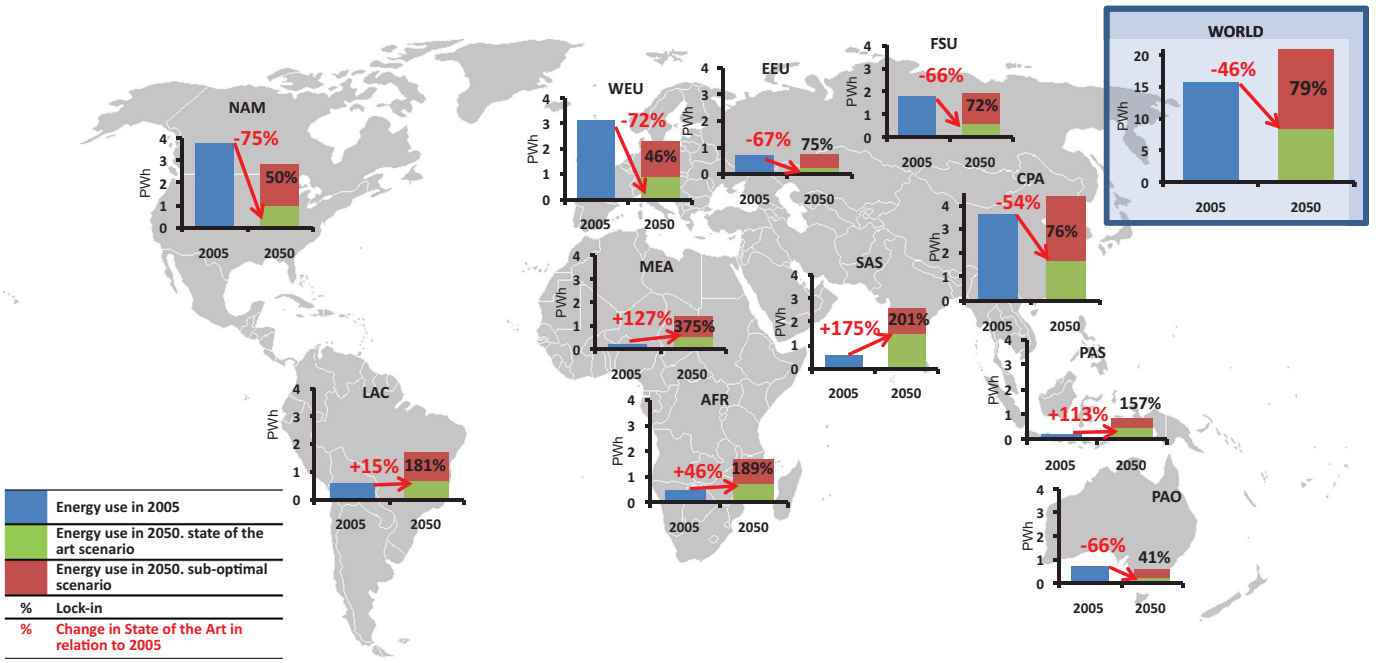

Figure 10.2 | Final building heating and cooling energy demand scenarios until 2050: state-of-the-art (~corresponding roughly to the GEA Efficiency set of pathways) and sub-optimal (~corresponding roughly to the GEA Supply set of pathways) scenarios, with the lock-in risk (difference).

Note: *Green bars, indicated by red arrows and numbers*, represent the opportunities through the state-of-the-art scenario, while the red bars with black numbers show the size of the lock-in risk (difference between the two scenarios). Percent figures are relative to 2005 values.

morbidity; other health improvements and benefits; alleviation of energy poverty and improvement of social welfare; new business opportunities, mostly at the local level; stimulation of higher skill levels in building professions and trades; improved values for real estate and enhanced ability to rent; and increased comfort, well-being, and productivity.

A survey of quantitative evaluations of such multiple benefits shows that even a single energy efficiency initiative in buildings in individual countries or regions has resulted in benefits with values ranging in the billions of dollars annually, such as health improvement-related productivity gains and cost aversions. At the same time, the market-based realization of significant, mostly cost-effective efficiency opportunities in buildings is hampered by a wide range of strong barriers. These barriers are highly variable by location, building type, and culture, as well as by stakeholder groups, such as planners, architects, craftsmen, investors, house and building users, and supervisors. Technological and human capacities of change need to be considered together, as it is through individual and organizational decisions that technologies are provided, adopted, and used. Analysis and examples in this chapter show that most of these barriers can be overcome or mitigated through policies, measures, and innovative financing schemes. A broad portfolio of instruments is available and has been increasingly applied worldwide to capture cost-effective efficiency and conservation potential and to tap other sustainable energy opportunities. Due to the large number and diversity of barriers, single instruments such as a carbon price will not unlock the large efficiency potential, but policy portfolios, tailored to different target groups and tailored to a specific set of barriers, are necessary to optimize results.

Among policy instruments, stringent, continuously updated, and well-enforced building and appliance standards, codes, and labeling – applied also to retrofits – are particularly effective in achieving large energy savings, mostly highly cost-effectively. In order to achieve the major building energy use reductions that have been shown to be possible in this chapter, an urgent introduction of strong building codes mandating near-zero-energy performance levels and progressively improving appliance standards, as well as the strong promotion of state-of-the-art efficiency levels in

accelerated retrofits in existing building stocks, are crucial. In contrast, net-zero-energy building mandates are not the most sustainable, cost-effective, or even feasible solutions in many cases, such as dense urban zones or large commercial buildings, and may only encourage urban sprawl. Thus the introduction of such mandates and commitments should be carefully analyzed and, in some cases, re-examined.

For ICT and entertainment appliances, regulation also needs to tackle the durability of the equipment in addition to its operational energy use due to the high-embodied GHG emissions. Appropriate energy pricing is fundamental, and taxation provides the impetus for a more rational use of energy sources. In poor regions or population segments, subsidies enabling a highly energy efficient capital stock can be more effective in tackling energy poverty than energy price subsidies. Carefully designed subsidies enabling investments may be needed to bridge the discount rate gap between society and private decision-makers, and the availability of financing for building owners and users is often a crucial precondition. Innovative financing schemes, such as performance contracting, are paramount for groups with limited access to financing. Carbon prices need to be very high (above US\$60/tCO_2) and sustained over a long period to achieve noticeable demand effects in the buildings sector. However, in order for energy price signals to be effective and sensible, energy price subsidies need to be removed so that the technology and fuel pricing environment provides a level playing field for sustainable energy options to be feasible. Awareness campaigns, education, and the provision of more detailed and direct information, including smart metering, enhance the effectiveness of other policies and enable behavioral changes.

A combination of sticks (regulations), carrots (incentives), and tambourines (measures to attract attention such as information or public leadership programs) has the greatest potential to increase energy efficiency in buildings by addressing a broader set of barriers. Achieving a transformation in the buildings sector that is in concert with ambitious climate stabilization targets by the mid-century entails massive capacity building efforts to retrain all trades involved in the design and construction process, as well as consumers, building owners, operators, and dwellers.

A transition into a very low building energy future requires a shift in focus of energy sector investment from the supply-side to end-use capital stocks, as well as the cultivation of new innovative business models, such as performance contracting and Energy Service Companies.

Novelties in this chapter, as compared to previous assessments, include (1) a focus on energy services, as well as life cycle approaches accounting for trade-offs in embodied vs. operational energy and emissions; (2) applying a holistic framework toward building energy use that recognizes buildings as complex, integrated systems; (3) presenting new global and regional building energy use scenarios until 2050, using a novel performance-based global building thermal energy model; (4) recognizing the importance of the lock-in effect and quantifying it; (5) in-depth attention to non-technological opportunities and challenges; (6) a large database on quantified and monetized co-benefits; and (7) a critical assessment of zero-energy buildings and related policies.

10.1 Setting the Scene: Energy Use in Buildings

10.1.1 Key Messages

Almost 60% of the world's electricity is consumed in residential and commercial buildings. At the national level, energy use in buildings typically accounts for 20–40% of individual country total final energy use, with the world average being around 30%. Per capita final energy use in buildings in a cold or temperate climate in an affluent country, such as the United States and Canada, can be 5–10 times higher than in warm, low-income regions, such as Africa or Latin America.

10.1.2 The Role of Buildings in Global and National Energy Use

Energy services in buildings – the provision of thermal comfort, refrigeration, illumination, communication and entertainment, sanitation and hygiene, and nutrition, as well as other amenities – are responsible for a significant share of energy use worldwide. The exact figure depends on where system boundaries are drawn. The global direct total final energy use in buildings was 108 EJ in 2007 and resulted in emitting 8.6 $GtCO_2e$ (IPCC, 2007), 33% of global energy-related CO_2 emissions (IEA, 2008a). Globally, biomass is the most important energy carrier for energy use in buildings, followed by electricity, natural gas, and petroleum products. Almost 60% of the world's electricity is consumed in residential and commercial buildings (IEA 2008a). In addition to the energy consumed directly in buildings, primary energy is lost in the conversion to electricity and heat and petroleum products, and the transport and transmission of energy carriers cost energy. In addition, the construction, maintenance and demolition of buildings requires energy, as do the manufacturing of furniture, appliances, and the provision of infrastructure services such as water and sanitation. The use of this indirect or embodied energy is influenced by the level and design of energy service provision in buildings. While comprehensive global statistics on indirect energy cost of buildings do not exist, regional data are presented below.

At the national level, direct energy use in buildings typically accounts for 20–40% of individual country's total final energy use (see Table 10.1), with the world average being 31%. In terms of absolute amounts, there is a significant variance among different world regions. Per capita final energy use in buildings in a cold or temperate climate in affluent countries, such as the United States and Canada, can be 5–10 times higher than in warm, low-income regions, such as Africa or Latin America (Table 10.1). Figure 10.A.1 in the online appendix and Figure 10.3 provide further information on the characteristics of building energy use by region or representative countries. Figure 10.4 shows total final energy use in buildings per capita in different world regions, according to the International Energy Agency (IEA) statistics. Figure 10.5 shows final energy use per square meter for thermal comfort by world region and building type, according to input data collected from different sources for the model presented in Section 10.6. Because sources of building energy vary greatly, e.g., significant amounts of coal and biomass burned on site in China and India and a much higher share of electricity in other countries, this results in large differences in primary energy use because of the additional energy demands of power generation and distribution.

However, policies to address sustainability challenges of energy services rendered in buildings can often only be designed optimally if a life cycle approach is used for energy accounting and not only the direct energy use is optimized. For instance, there are trade-offs between minimizing operational energy use and embodied energy in building materials; these trade-offs in greenhouse gas emissions can be even larger. For example, reducing CO_2 emissions through increased Styrofoam insulation increases hydrochlorofluorocarbon (HCFC) emissions, potentially resulting in increased rather than decreased overall greenhouse gas emissions when measured in CO_2 equivalents. Further trade-offs exist in cooking energy use and embodied energy in foodstuffs. Reduction in certain energy service demands in buildings results in the reduction of energy use of other sectors, such as electricity transformation losses, transportation (such as for building materials, water, food, etc.), or industrial energy use (needed for products and appliances in buildings). Therefore, building-related energy services can only be optimized if a systemic, life cycle approach is used to reduce associated total primary energy use and associated environmental impacts. Unfortunately, global building energy use and emission data using a life cycle approach do not exist, but smaller-scale data on life cycle building energy use is presented below. As buildings are the end-point of a large share of our energy using activities – for example, a large share of products manufactured in industry are ultimately for the purpose of providing various services in buildings and many goods being transported are being used in buildings – reducing service needs requiring energy input in buildings is key to achieve a reduction in overall primary energy use. When a life cycle approach is applied to understand the energy services demanded, the importance of buildings grows substantially.

10.1.3 The Demand For Different Energy Services In Buildings And Their Drivers

10.1.3.1 Key Messages

Energy is used in buildings to provide a variety of services, including comfort and hygiene, food preparation and preservation, entertainment, and communications. The type and level of service and the quantity and type of energy required depend on the level of development, culture, technologies, and individual behavior. Global trends are toward electrification and urbanization, including toward multi-family from single-family dwellings. At all levels, large variations in cultural attitudes, individual behaviors, and the selection of construction materials and practices, fuels, and technologies contribute to a wide range of energy services and energy use.

Table 10.1 | Contribution of the buildings sector to the total final energy demand globally and in selected regions in 2007.

World regions	Share of the residential sector in %	Share of the commercial sector in %	Share of the total buildings sector in %	Residential and commercial energy demand per capita, MWh/capita-yr.
USA and Canada	17%	13%	31%	18.6
Middle East	21%	6%	27%	5.75
Latin America	17%	5%	22%	2.32
Former Soviet Union	26%	7%	33%	8.92
European Union-27	23%	11%	34%	9.64
China	25%	4%	29%	3.20
Asia excluding China	36%	4%	40%	2.07
Africa	54%	3%	57%	3.19
World	**23%**	**8%**	**31%**	**4.57**

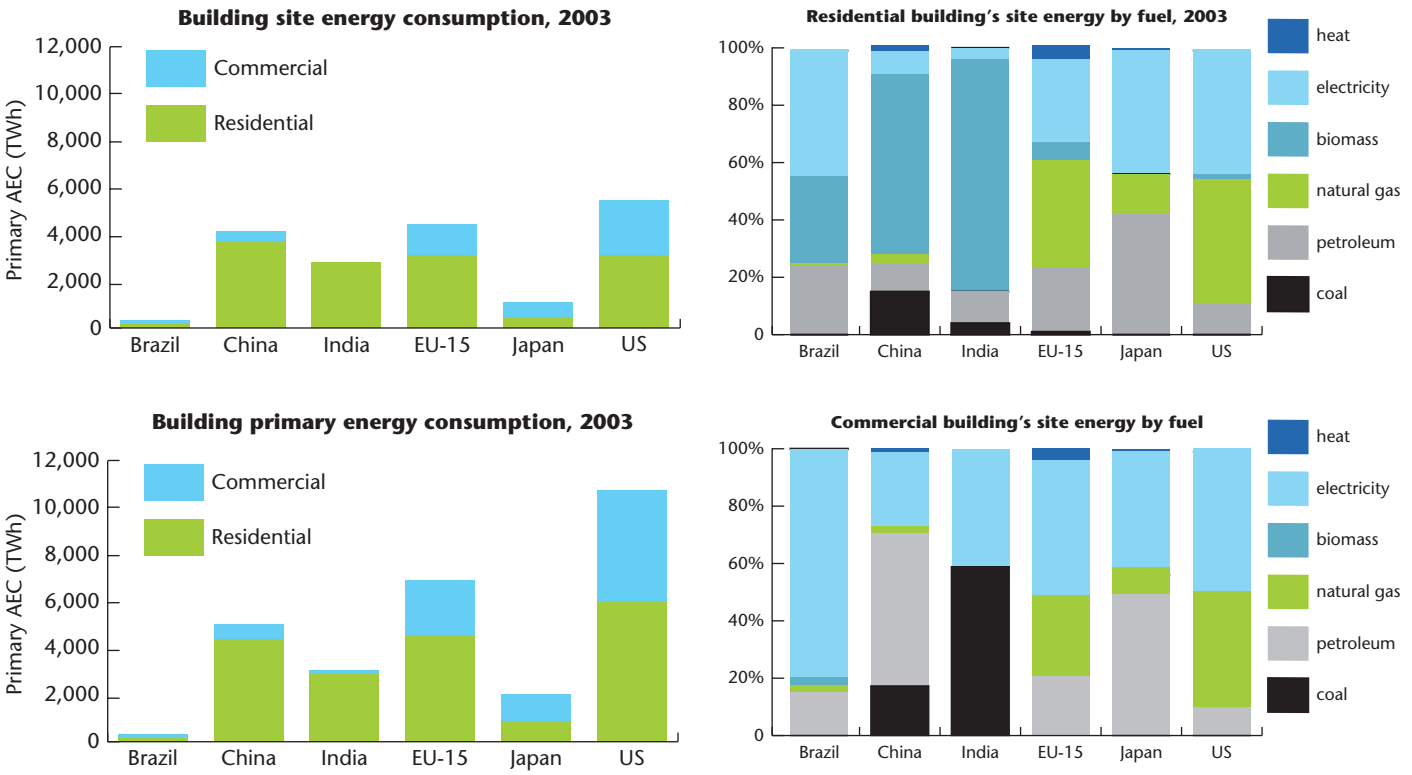

Figure 10.3 | Building final and primary energy use in selected countries in 2003; AEC = annual energy consumption. Source: WBCSD, 2008.

10.1.3.2 Building Energy Demand by Service Type

The type and level of service and quantity and type of energy required depend on a large number of factors, including culture, technologies, and individual behavior. This section includes a review of national and regional assessments conducted to understand the importance of different energy services in buildings. No global systematic studies have been performed to understand the importance of different energy services in buildings or other sectors, and therefore this section covers a selection of national and regional assessments. Figure 10.6 shows the breakdown of primary energy use in commercial and residential buildings by end-use services in the United States. The figure demonstrates that five energy services accounted for 86% of primary energy use in buildings in 2006. These were: (1) thermal comfort – space conditioning that includes space heating, cooling and ventilation – 36%; (2) illumination – 18%; (3) sanitation and hygiene, including water heating, washing and drying clothes, and dishwashing – 13%; (4) communication and entertainment – electronics including televisions, computers, and office equipment – 10%;

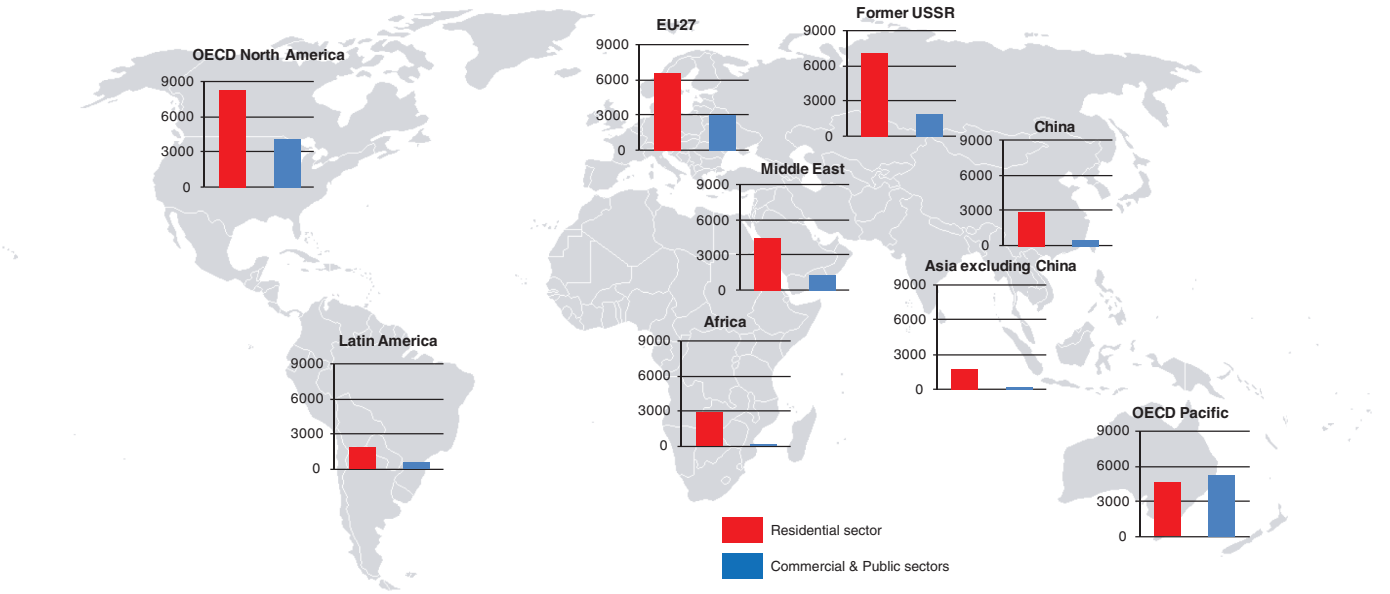

Figure 10.4 | Total annual final energy use in the residential and commercial/public sectors, building energy use per capita by region and building type in 2007 (kWh/capita/yr). Source: data from IEA Online Statistics, 2007.

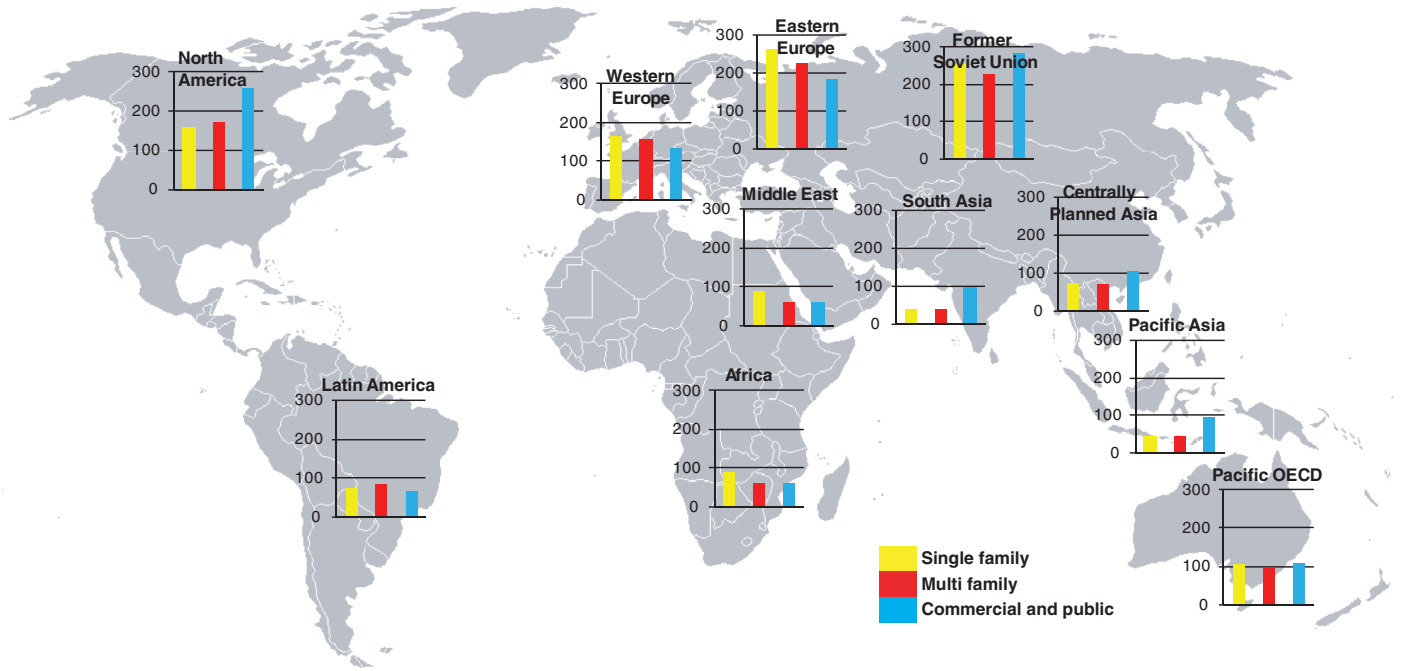

Figure 10.5 | Final heating and cooling specific energy consumption by region and building type in 2005 (kWh/m²/yr). Source: Model estimations (see Section 10.7).

and (5) provision of food, refrigeration and cooking – 9% (US DOE, 2008). The remaining 14% includes residential small electric devices, heating elements, motors, natural gas outdoor lighting, and commercial service station equipment, telecommunications equipment, medical equipment, pumps, and combined heat and power in commercial buildings.

Recently, McNeil et al. (2008) made an estimate of the current and projected end-use energy demand in buildings for ten separate regions covering the world. In the OECD member states, it was found that the five energy services listed above use 76% of the electricity and 69% of the fuel final energy[5] in buildings. In developing countries (non-OECD member states), they account for 93% of site electricity and 78% of fuel use, respectively. According to the best available figures (IEA, 2006), household energy use in developing countries contribute almost 10% of the world primary energy demand. Household use of biomass in developing countries alone accounts for almost 7% of world primary energy demand.

5 Includes natural gas, bottled gas (LPG), and fuel oil. Does not include coal or biomass, and excludes district heating, which is significant in China, Europe, and the Former Soviet Union.

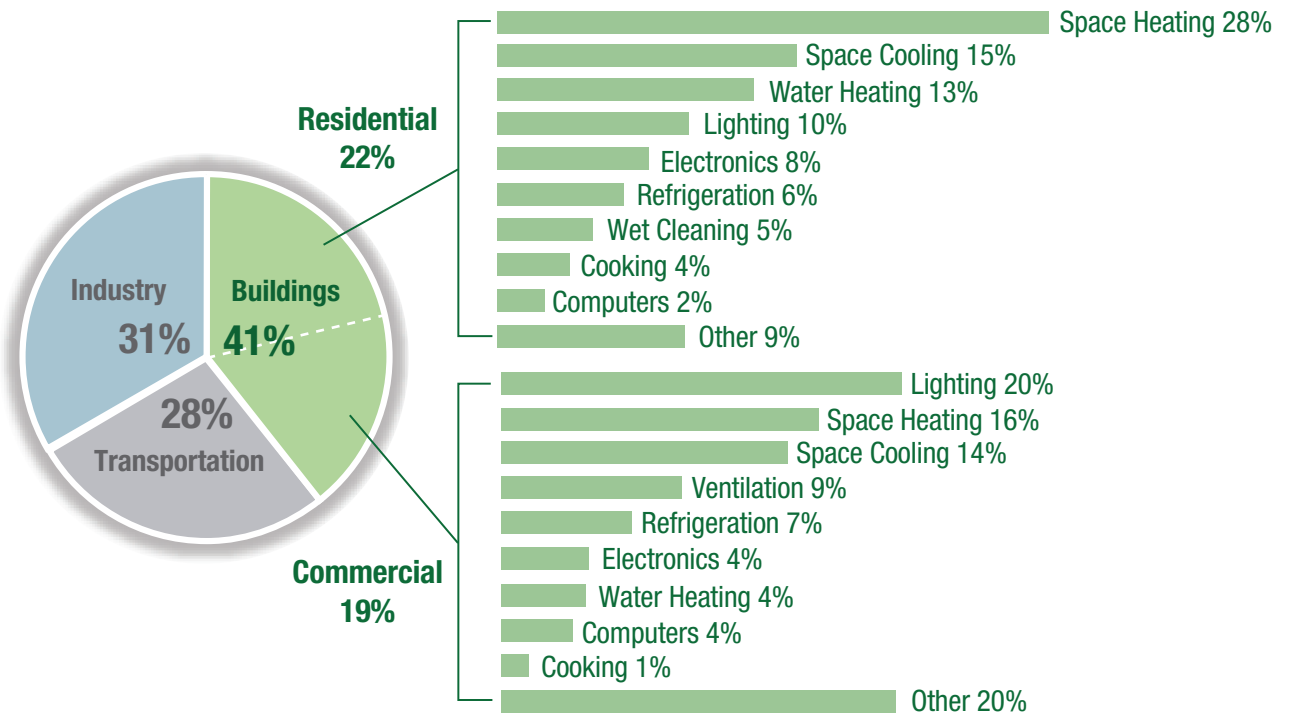

Figure 10.6 | Primary energy use in US commercial and residential buildings in 2010. Source: US EIA, 2011; 2012.

Valuable time and effort are devoted to fuel collection instead of education or income generation. While a precise breakdown is difficult, the main use of energy in households in developing countries is for cooking, followed by heating and lighting. Because of geography and climate, household space- and water-heating needs are small in these countries.

A review of national level studies of household energy services, analyzed on a life cycle basis, is presented in Figure 10.7. Buildings-related energy use contributes 60–70% of the total household energy use in OECD countries (Hertwich, 2005b) and up to 90% in India (Pachauri and Spreng, 2002; see also Box 10.1 and Figure 10.8). The remainder of household energy use is mostly related to mobility. On average across studies for a selected number of countries where data was available, buildings-related energy use, including the primary energy required to produce the energy carriers used in the household, accounts for 32% of the total household energy requirements. "Other shelter," which includes water and waste treatment utilities and construction and maintenance of buildings and furniture, accounts for 11%. Mobility accounts for 24%, food for 14%, recreation for 7%, clothing for 4%, and other for 9%. Variation in the importance of different categories, however, is substantial. Additional life cycle effects of building energy use are considered in Section 10.1.4.

10.1.3.3 Variations in Energy Service Needs and Key Drivers

The following factors are major contributors to changing energy service demands: (1) population growth; (2) urbanization; (3) shift from biomass to commercially available energy carriers, especially electrification (percent of population having access to electricity); and (4) income, which is a strong determinant of the set of services and end-uses for which commercial energy is used and the quantity and size of energy-using equipment; (5) level of development; (6) cultural features; (7) level of technological development; and (8) individual behavior. Availability and financial aspects of technologies and energy carriers are also important.

The demand for energy services in buildings varies among regions according to geography, culture, lifestyle, climate, and the level of economic development. It also varies by the type of use, type of ownership, age, and location of buildings (e.g., residential or commercial, new or existing buildings, private or public, rural or urban, leased or owner-occupied) (Chakravarty et al., 2009). There are also significant differences in energy services among commercial subsectors – such as offices, retail, restaurants, hotels, and schools – and between single- and multifamily residential buildings. Different approaches, standards and technologies to how the buildings are sited, designed, constructed, operated, and utilized strongly affect the amount of energy used within buildings.

The level of economic development is a main driver of the global differences in energy use in buildings as set out in the previous sections. Table 10.1 shows that energy use per capita in buildings is up to an order of magnitude higher in North America than in most of Asia, Africa, and Latin America. This section sets out some more detailed differences, and their drivers, among countries as well as within individual countries.

Figure 10.9 shows there are differences in per capita energy use among six developed countries, at similar affluence levels (IEA, 2007b). The data

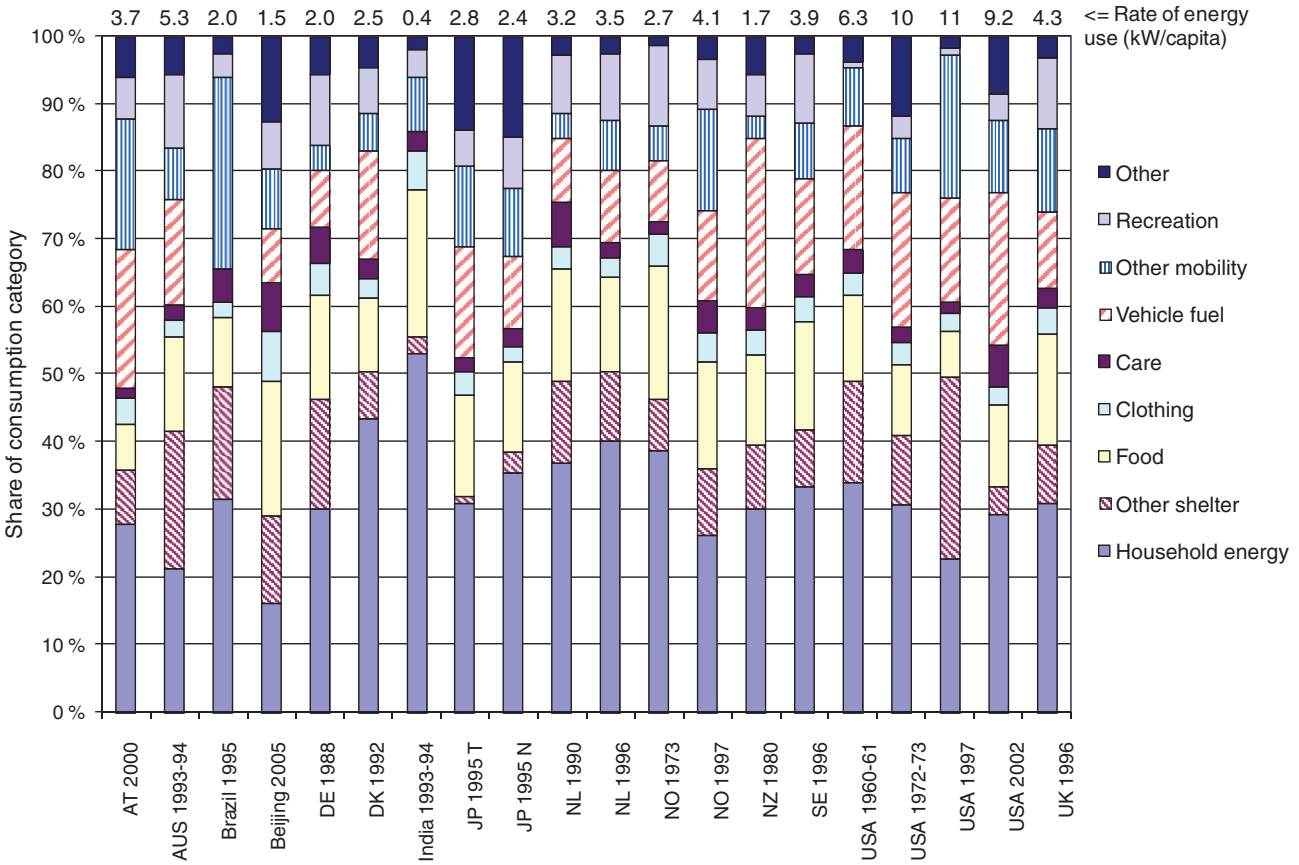

Figure 10.7 | Share of consumption categories in total energy use based on life-cycle analysis or input-output calculation and rate of annual energy use in kilowatt per capita (numbers on top of the columns). Source: Hertwich, 2011.

are "degree day normalized," i.e., corrected for the key climatic driver of heating demand. The overall energy use is higher in the United States, even by developed country standards, but lower in Japan, and intermediate in Europe and Canada. The variation between end-uses is large. For instance, space-heating demand follows the same broad pattern as the total use and is driven largely by per capita floor area and building internal temperatures (IEA, 2007b). Other end-uses are relatively less important, but there are substantial differences, notably the higher energy use in lighting and appliances in North America. The figure also illustrates the role of culture in determining energy efficiency. Japan uses less than a third of the energy used in the United States for space heating, even when normalized for climate. This is due to more compact living, as well as focusing on providing thermal comfort through alternative means rather than universal heating of all living space. The Japanese *kotatsu*, a table frame heat source which is combined with blankets and adaptive clothing, is still a common alternative despite high affluence levels.

10.1.3.4 Cultural, Social and Behavioral Drivers

Culture, values, and individual habits significantly influence consumption, as does the choice of technologies. The section above provided an example for heating energy use determined by culture in Japan. This section provides more examples and highlights further issues. For instance, cooking energy demand varies largely with dietary choices. The use of refrigerated, packed, and tinned food is very limited in developing countries which leads to larger energy use for cooking. In rural China, similar to many other developing countries, cooking is the largest energy demand item for 60% of families.

A major source of variation in energy services and energy use is the impact of habits and behavior (see Section 10.4.8), irrespective of level of development. Within all countries, high-income groups contribute disproportionately to energy demand (Chakravarty et al., 2009). However, income is not the only factor. Lenzen et al. (2006) investigated the variation of energy use with household income and size, type of house, urban versus rural location, education, employment status, and age of the householder in several countries. Higher income social groups use more energy per capita, with the elasticity of energy expenditure ranging from 0.64 in Japan to 1.0 in Brazil. Lenzen et al. (2006) also found that energy use differs across countries even after controlling for the main socioeconomic and demographic variables, including income. This result confirms previous findings that the characteristics of personal energy use are partly determined by distinctive features such as historical events – for example, energy supply shortages or the introduction of taxes, socio-cultural norms, behavior, and present market conditions, as well as energy and environmental policy measures.

Box 10.1 | Energy Use in Buildings in India

In India, energy end use in buildings varies largely across income groups, building construction typology, climate, and several other factors. The energy sources utilized by the residential sector in India mainly include electricity, kerosene, liquefied petroleum gas (LPG or propane), firewood, crop residue, dung, and other renewable sources such as solar energy. The per capita energy use in the residential sector is as low as 2560 kWh/yr for India.

Traditional fuels are predominantly used for cooking. In the rural areas of the country, the three primary sources of energy for cooking are firewood and chips, dung cake, and LPG. In urban areas, cooking energy sources are primarily LPG and piped natural gas in select cities. Figure 10.9 shows seasonal differences in energy demand for Delhi, India (Manisha et al., 2007). In summer months, air-conditioners and refrigerators each account for about 28% of total monthly electricity consumption, while lighting accounts for about 8–14% of annual electricity consumption. In winter, major uses of electricity are refrigerators (44%), water heating ("Geyser" 18%), and lighting (14%).

Based on CPWD (2004), in India's commercial sector 60% of the total electricity is consumed for lighting, 32% for space conditioning, and 8% for refrigeration. End use consumption varies largely with space conditioning needs. In a fully air conditioned office building, about 60% of the total electricity consumption is accounted for by air conditioning followed by 20% for lighting.

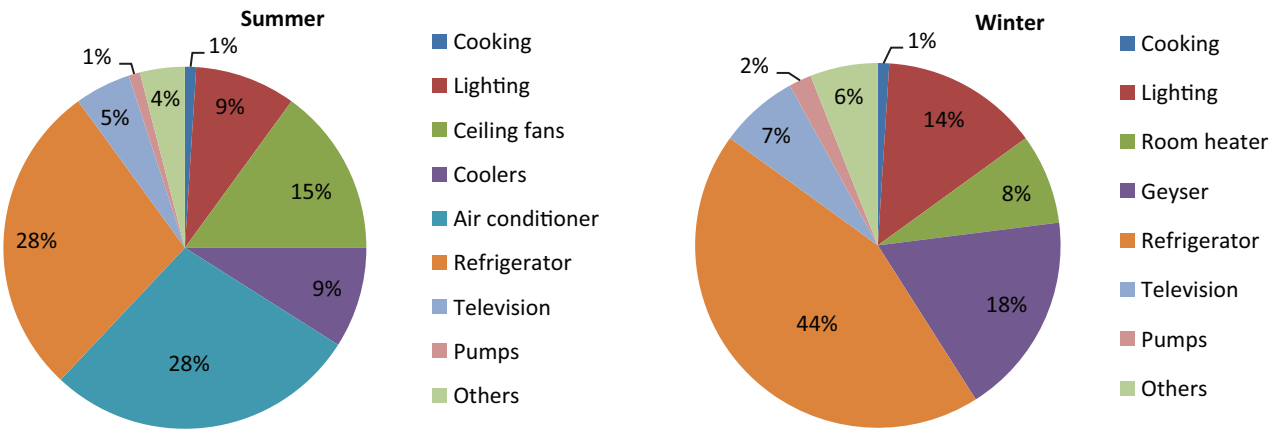

Figure 10.8 | Share of end-uses (by appliance) in electricity consumption in Delhi, India. Source: Manisha et al., 2007.

Note: "Others" include washing machine, computer and irons.

A study carried out by Socolow (1978) demonstrated energy use variations of more than a factor of two between houses that were identical but had different occupants. Gram-Hanssen (2004) found a similar variation of household electricity use in much larger sample of identical flats in Denmark. This is consistent with the findings of the World Business Council for Sustainable Development/Energy Efficiency in Buildings (WBCSD/EEB) that show that people can improve energy efficiency in buildings by around 30% by behavioral changes without any extra costs, or they can compromise a building's performance by up to 60% by behavioral effects (WBCSD, 2009).

A similar result is illustrated by a study of energy use for home air conditioning in a residential building in Beijing (Zhang et al., 2010). The building consists of 25 home units, all with similar income characteristics. Although each flat is fully occupied, the difference in energy use can be as large as a factor of 40 (see Figure 10.10). While the average is 2.3kWh/m^2, the range is from near zero to over 14 kWh/m^2. The real income of the high-energy users is lower than those of the low-energy users.

Social choices about cooling technology will prove increasingly important. For instance, a very large stock of residential, institutional, and commercial buildings in India is still designed to be non-air-conditioned and to use only ceiling fans to provide thermal comfort during hotter periods, while in other countries electric chilling is the standard in commercial buildings. Occupants of Indian buildings are acclimatized to higher temperature and humidity conditions without feeling uncomfortable. This translates to very low energy usage in such buildings, with a very limited scope for enhancing energy efficiency, but with a high potential for reducing future air conditioning needs.

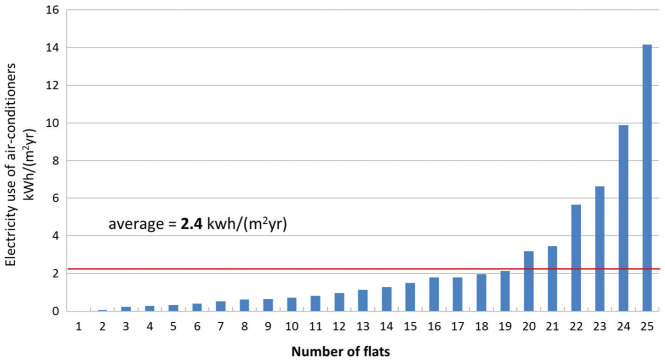

Figure 10.10 | Electricity consumption of air-conditioning in 25 flats of a residential building in Beijing. Source: based on Zhang et al., 2010.

10.1.3.5 The Drivers of Changing Demand for Building Energy Services

The share of energy use in buildings in the total energy use increases with the level of economic development. In India, with a near-consistent 8% annual rise in annual energy demand in the residential and commercial sectors, building energy use has seen an increase from 14% in the 1970s to nearly 33% of total primary energy use in 2004–2005 (authors' calculation based on the data from IndiaStat, 2010).

In addition to the determinants of building energy services discussed above, additional factors are major contributors to changing energy service demands: (1) population growth; (2) urbanization; (3) shift from biomass to commercially available energy carriers, especially electrification (percent of population having access to electricity); and (4) income, which is a strong determinant of the set of services and end-uses for which commercial energy is used and the quantity and size of energy-using equipment; (5) level of development; (6) cultural features; (7) level of technological development; and (8) individual behavior. Availability and financial aspects of technologies and energy carriers are also important.

While energy use in buildings is influenced by income, specific energy use does not necessarily continue growing at an equal rate at higher income levels. For instance, Figure 10.11 shows the trend of specific building energy use in the United States during the second half of the twentieth century, for Japan since 1970, and the trend for China since the mid-1990s. The most significant increase can be observed during the first two decades in this period. While gross domestic product (GDP) continued to increase in the second part of the period, improvements in technological efficiency have kept energy growth trends at bay. Chinese-specific building energy demand figures currently are in the same range as the United States in the 1950s. Whether China will follow trends of the United States or will be able to decouple the increase in wealth from specific building energy use at an earlier stage is an important determinant of global future energy use.

Building location, form, and orientation are integrally related to urban/rural design, which, in turn, also influences energy use necessary for transporting people and products to buildings, as well as the feasibility of certain sustainable energy supply options such as district heating and cooling, and community-scale renewable energy generation. Therefore, urban design, building energy use, and urban transport energy use are integrally related (see Chapter 9 and Chapter 18).

In India and China, urban households tend to have higher energy requirements than rural households (Lenzen et al., 2006; Peters et al., 2007). In China, moving from a rural to an urban life currently increases household demand for energy by about a factor of three (Table 10.2), while in developed countries, urban households tend to have lower energy requirements. By 2020, both rural and urban demand for energy will increase due to a combination of urbanization, a shift from biomass to commercial energy carriers, and increased income. Thus, Chinese urban energy use per household in 2020 is expected to be five times the amount of rural energy per household today.

Building size and building floor space per person are also important factors that depend upon income and demographics. Households with more occupants tend to have lower per capita energy use. Older and wealthier individuals are more likely to occupy larger dwellings with fewer occupants. Often, improved energy efficiency is offset over time by bigger floor space per person or per household.

In sum, population growth, urbanization, the shift from biomass to commercial fuel carriers including electricity, and income growth are contributing to increasing demand for energy services. Technologies, practices, and policies toward increasing energy efficiency are offsetting growth in some locations and offer large future potential for reducing the quantity of energy required for energy services. Individual choices of lifestyle and specific behavior may greatly increase or decrease the demand for energy services.

Table 10.2 | Increasing energy intensities when moving from rural to urban life in China.

	China annual energy per household in the North China (kWh)						
	Year 2000		Year 2020		Ratio as percent		
	Rural	Urban	Rural	Urban	Urban/Rural 2000	Urban/Rural 2020	2020 Urban/ 2000 Rural
Space heating	631	4990	4638	9027	791%	195%	1431%

10.1.3.6 Energy Carriers Used to Satisfy Energy Service Needs in Buildings

In developing countries, biomass, coal, oil products, and natural gas are mostly used to satisfy energy service needs in buildings because in rural areas people have easier access to biomass compared to people living in cities, and because even many urban building occupants do not have access to electricity, (Shepherd and Zacharakis, 2001; Melichar et al., 2004; see also Chapter 2). The progression from traditional biomass fuels to more convenient and cleaner fuels has traditionally been explained by the "energy ladder" model, suggesting that increasing affluence is the key to the transition.

More recently, the multiple fuel model was developed to explain household decision making in developing countries under conditions of resource scarcity or uncertainty taking into account the following factors: (1) economics of fuel and stove type and access to fuels; (2) technical characteristics of cookstoves and cooking practices; (3) cultural preferences; and (4) health impacts (Masera et al., 2000). In addition to urbanization, Pachauri and Jiang have identified income, energy prices, energy access, and local fuel availability as key drivers of the transition from traditional to modern fuels in China and India (Pachauri and Jiang, 2008).

In developed countries, electricity and natural gas are the most frequently used energy carriers, with electricity taking an increasing share. For instance, while buildings in the United States use only 39% of the country's primary energy, they use 71% of electricity and 54% of the natural gas supply.

Figure 10.12 presents the distribution of fuels in total final energy use in the residential and commercial sectors worldwide. Note that residential energy use (81.3 EJ) exceeds commercial and public sector energy use (27.5 EJ) by a factor of three.

10.1.4 Indirect Energy Use from Activities in Buildings in Detail Using the Life Cycle Assessment Approach

10.1.4.1 Key Messages

The life cycle approach is necessary to optimize the total energy required to provide energy services in buildings because the importance of indirect energy use can increase as more energy efficient technologies are applied. Depending on climate and energy efficiency, the construction of a building contributes as much as 25% to total indirect energy use, with

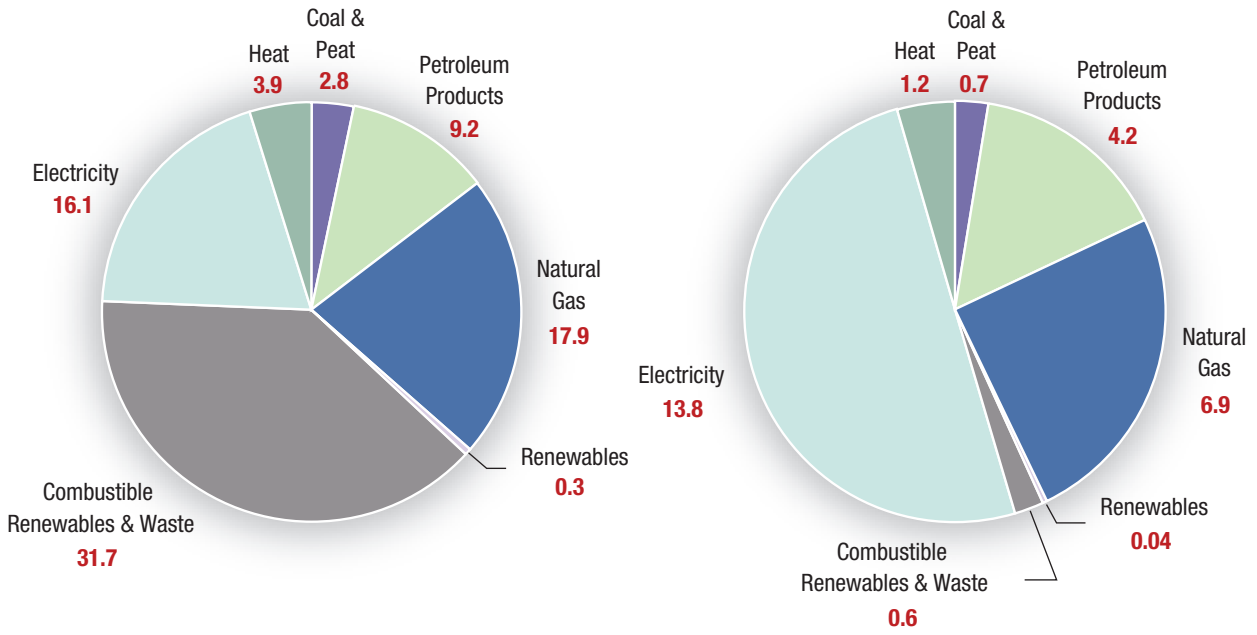

Figure 10.12 | World total final energy consumption by fuel in the residential (left) and commercial and public (right) sectors in 2007 (EJ). Source: IEA Online Statistics, 2007.

higher values for very high efficiency or energy self-sufficient buildings. Even though commonly pursued efficiency strategies increase the energy embodied in the building, in cold and temperate climates this invested energy is typically recovered with an energy payback time below one year. Building-integrated PV systems, however, require at least five years to recover the energy invested in their construction and may, from a life cycle perspective, not be the cleanest option of supplying electricity. The environmental impacts of different building materials and designs depend on a number of factors with wood offering an advantage in terms of carbon storage and potential energy recovery after demolition. A refurbishment of existing buildings to increase efficiency can offer savings in total life cycle energy use compared to demolition and new construction. While optimal solutions will be site- and case-dependent, in general significant reductions in environmental impacts can be obtained with energy efficient building designs, a wise choice of building materials, and renewable energy sources integrated in buildings.

10.1.4.2 Introduction to the Life Cycle Approach

A life cycle approach is necessary to optimize the total energy use required to provide energy services in buildings, because, for instance, the importance of indirect energy use can increase as more energy-efficient technologies are applied (see also earlier sections). In addition to direct energy use, a life cycle approach takes into account the energy used to produce the materials for constructing the buildings, energy losses associated with the provision of electricity and fuels to the buildings, energy used in the construction and maintenance of a building, and energy used in manufacturing and supplying building equipment – ranging from lighting and TV sets to heating and cooling equipment (Treloar et al., 2000). This indirect energy use has been variously referred to as embodied, grey, or upstream energy.

This section provides an overview of embodied energy, including the trade-offs between embodied and operational energy, and examines it in detail for important cases: construction, heating, and energy embodied in water consumption in buildings. Indirect energy use is strongly affected by choices made during building construction, operation and/or use, as well as dietary choices.[6]

10.1.4.3 Embodied Energy

This section provides some general insights from life cycle assessment (LCA), and presents results of life cycle studies for building materials and buildings. Section 10.1.3 presented the direct use of energy for different energy services in the US residential sector. Figure 10.13 provides an overview of the direct and indirect energy use of the average household in the United States in 2002, from the life cycle perspective. Indirect energy use is split into energy losses and indirect energy connected to the purchase of all other goods and services. The largest category is private transport. The second largest category is "utilities," which includes direct energy use and the provision of water and wastewater treatment. The third largest category is the indirect energy embodied in food purchased by households.

6 Embodied GHG emissions cover a broader set of issues than just embodied energy. They also include process-based CO_2 emissions from clinker production, carbon storage in wood, and the non-CO_2 GHGs (mainly fluorinated gases) used in the production of certain construction materials and in the operation of some equipment, such as chillers. IPCC (2007) discussed non-CO_2 emissions related to buildings in detail, and thus this section focuses on indirect energy use.

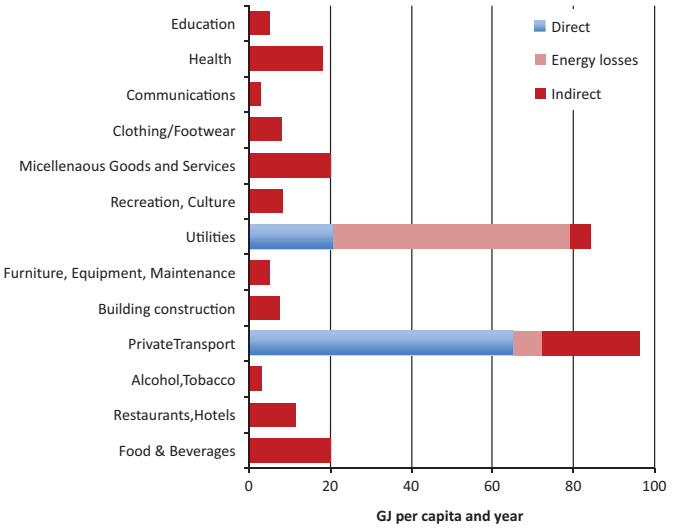

Figure 10.13 | Direct and indirect primary energy use of the average US citizen in 2002 for different consumption purposes. Source: based on Weber, 2009.

There is a trade-off between direct and indirect energy use in a number of areas, for example in thermal comfort and handling of foods. In the United States about 50% of direct energy use in buildings goes to ensuring thermal comfort (see section 10.1.3). While the building structure itself has other functions as well, its main energetic function is to provide thermal comfort. Clothing also functions partially to provide thermal comfort. Overall, however, the energy use in buildings and the cost of providing that energy dominate the total energy cost of providing thermal comfort in the United States. This issue is revisited in the remainder of Section 10.1.4.

Refrigeration and cooking requires about 10% of the direct household energy use, which is clearly less than the indirect energy required to grow and process the food. The importance of indirect energy used for manufactured goods used in buildings increases with increasing wealth, and hence overtime (Lenzen et al., 2006).

10.1.4.4 The Life Cycle Impact of Building Materials and Design

There is a distinction between the construction, operations and maintenance, and demolition of buildings. For most buildings, the bulk of energy use is in the operations phase, and energy conservation efforts have appropriately focused on reducing this energy use through smarter design, better insulation material, and improved building technology. However, for short-lived or highly efficient buildings, construction is responsible for a substantial share of the total energy use. Demolition offers an opportunity to recover some of the energy, either by combusting elements with high heating value or by reusing building materials and components, thus avoiding energy-intensive primary production of new materials. In construction, and especially demolition, energy for transport is an important consideration, constraining remanufacturing and recycling of building components and materials.

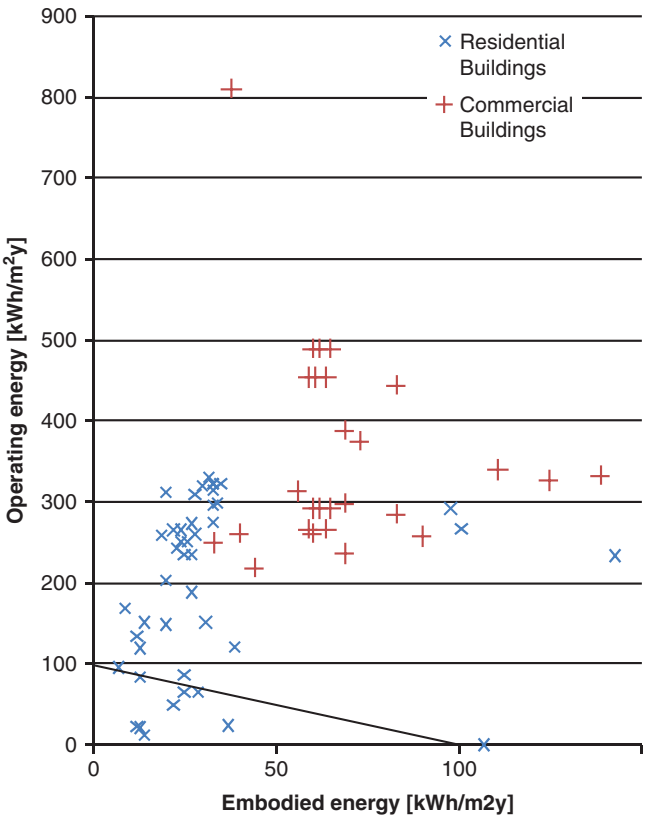

Figure 10.14 | Primary embodied and operating energy of buildings from a review of case studies mostly from northern/central Europe and Asia, including most efficient designs. Source: Sartori and Hestnes, 2007; Ramesh et al., 2010.

Note: the lines indicate points of equal life-cycle primary energy use.

Ramesh et al. (2010) reviewed life cycle energy studies of 73 buildings, including 60 buildings in OECD countries from Sartori and Hestnes (2007). The operating and embodied energy are presented in Figure 10.14. The embodied energy dominates only in three cases, two in climates not requiring heating or cooling and the other a self-sufficient solar home in a Nordic country. In most cases, the embodied energy contributes to 5–25% of the total energy over the lifecycle. The embodied energy, however, varies between 9 and 140 kWh/m^{2}y, given building lifetimes of 30–100 years. Similar results have been obtained for the United Kingdom (Monahan and Powell, 2011).

An analysis of different alternatives for the main building material in Sweden demonstrated that wood is preferable over concrete, especially if the wood is used as fuel after demolition or reused in buildings (Borjesson and Gustavsson, 2000; Lenzen and Treloar, 2002; Gustavsson and Sathre, 2006). Using a detailed input-output analysis of the entire Swedish construction sector, Nässen et al. (2007) show that building materials account for a little more than half of the energy use in the production of new detached and multifamily buildings. The energy use for excavation of the site and transport is important, as is the sum of construction and service inputs. This sector-wide study estimates energy use in the production phase of buildings for Sweden at about 25% of the total energy used for buildings (Nässen et al., 2007). Studies usually only account for energy, not

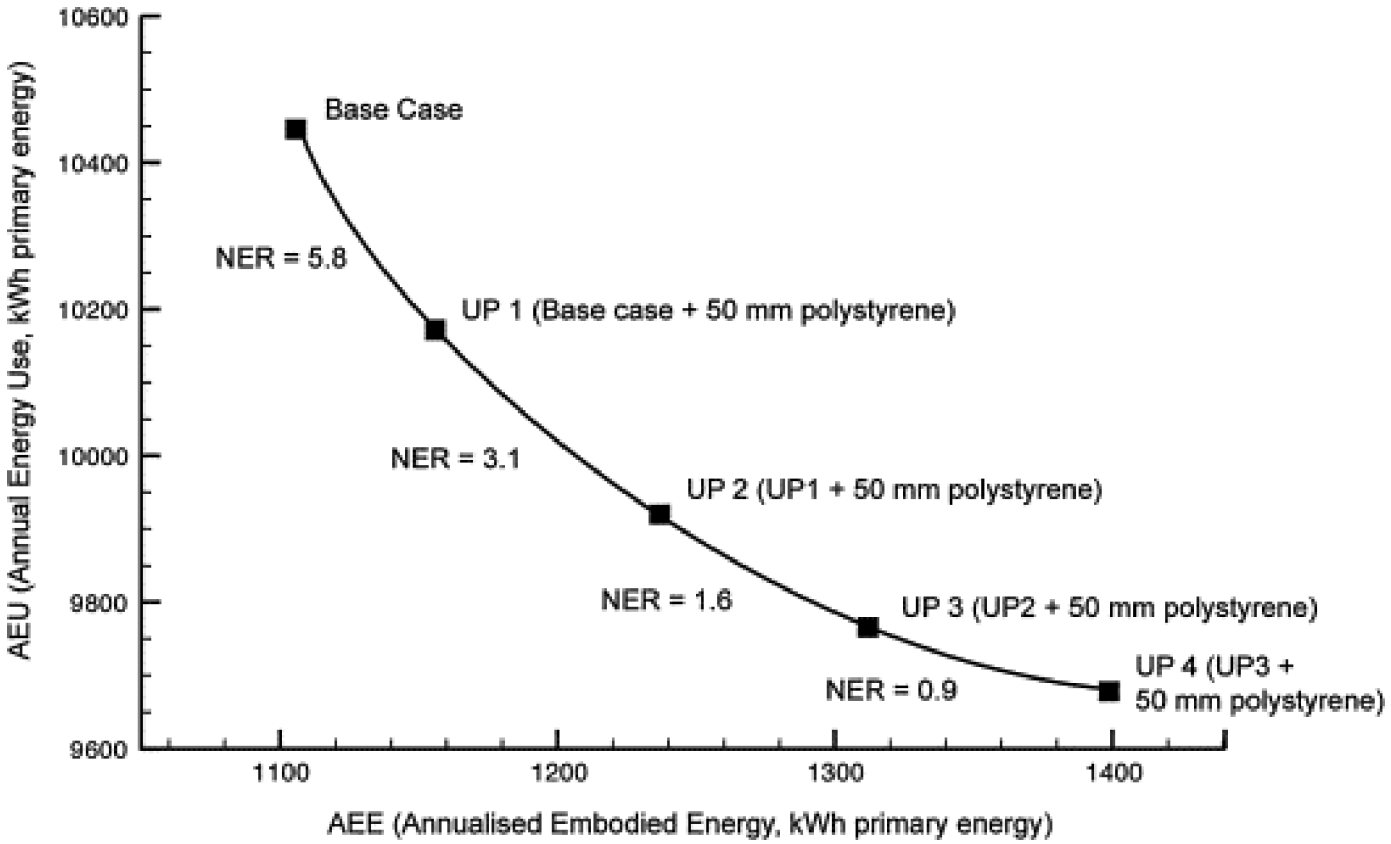

Figure 10.15 | Annualized operational energy use vs. annualized embodied energy use for polystyrene insulation of differing thickness for a case study of low-energy residential building in a maritime climate. Source: Hernandez and Kenny, 2010.

Note: The Net Energy Ratio (NER; also called the return on energy investment) indicates the benefit of each step of additional insulation.

environmental impacts. Depending on the energy mix chosen by various actors along the life cycle, a lower life cycle energy use does not necessarily result in lower environmental impacts (Brunklaus et al., 2010).

10.1.4.5 Highly Efficient Buildings and Active Components

For highly energy efficient buildings and the use of active[7] building technology, the trade-offs between embodied energy and environmental impacts and operational energy and environmental impacts becomes critical and requires a life cycle assessment to ensure that measures are not counterproductive.

Figure 10.15 illustrates an investigation of the trade-off between embodied energy and operating energy. Increasing the thickness of a fairly energy-intensive insulation material (polystyrene) in a house that already has a passive design (15 kWh/m^{2}y) reduces energy use up to a point. The last step, from UP3 to UP4, leads to an increase of life cycle energy use, because the net energy ratio (energy return on investment) is smaller than one (Hernandez and Kenny, 2010).

Reviewed case studies of highly efficient buildings indicate that efficient design depends on higher initial investments of embodied energy. The embodied energy cost of efficiency, however, is small and the energy payback period is on the order of months (Feist, 1996; Winther and Hestnes, 1999). Similar gains can be made by retrofitting existing buildings in a cold climate (Dodoo et al., 2010). An environmental assessment of a passive house in France indicates that the passive design leads to a reduction in environmental impacts in 10 out of 12 impact categories investigated, by 28% on average over a conventional design (Thiers and Peuportier, 2008). Blengini and Di Carlo (2010) report similar results for a passive house in Italy. Environmental gains, however, significantly depend on the energy source and conversion technology for heat and electricity. A study in Sweden indicates that a passive house supplied entirely by electricity can lead to higher environmental impacts than a standard building supplied by district heat (Brunklaus et al., 2010). No comparable studies for hot and dry or hot and humid climates were found.

The introduction of active energy-generating components such as solar collectors and photovoltaic (PV) modules leads to a substantial increase in embodied energy and environmental impacts (Winther and Hestnes, 1999). Published net energy analyses indicate an energy payback time of solar hot water heaters from half a year to two years (Crawford and

7 By active building technology this section refers to components that generate energy, mostly power.

Treloar, 2004), while the energy payback time of building-integrated PV systems is five years and up (Lu and Yang, 2010; Leckner and Zmeureanu, 2011). Local circumstances, such as insolation at the site and orientation of the cells, as well as electric grid properties, determine whether building-integrated PV cells are beneficial from an environmental perspective. A solar building in Spain featuring solar collectors, an absorption cooling tower, and PV arrays was found to lead to substantial reductions in emissions of greenhouse gases, acidifying gases, and ozone precursors, while causing substantial increases in water use and the emissions of human toxicants and no change in other life cycle impacts (Batlles et al., 2010).

10.1.4.6 Demolition vs. Retrofitting

The question often arises about how far it is worth pursuing the retrofitting of existing poor quality buildings from a sustainable energy perspective rather than demolishing them and replacing them with state-of-the-art new construction. There is no single answer. Various aspects of building renovation, replacement, and demolition have been investigated. Building lifetime and the choice of demolition technique are important for the life cycle energy use of different building materials. If the building structure can be made to fit new purposes, retrofitting is often the more environmentally friendly option, because it preserves material and reduces transport needs. Itard and Klunder (2007) have investigated the case of two larger residential projects using life cycle assessment. According to their results, maintenance or transformation of the existing stock has lower impacts in both cases than demolition and new construction. These results are confirmed by studies of individual building components. Retrofitting to high energy efficiency standards is fully possible and often environmentally desirable (Dodoo et al., 2010). If a demolition is necessary, the embodied energy in the building material can be preserved through the reuse of building components or recycling of the material, or it may be recovered through incineration. The environmentally preferable option depends on local circumstances, and transportation required for alternative solutions is an important factor (Bohne et al., 2008).

10.1.4.7 Life Cycle Energy and Emissions of Residential Appliances

The electricity used by electric and electronic products used in buildings is ultimately converted to heat and either contributes to heating the building or needs to be removed through a cooling system, depending on the climate, building, and heat load. Such energy use in office buildings can be up to several 100kWh/m^2/yr, while appliance-related electricity consumption in residential buildings in OECD countries is typically around 50kWh/m^2/yr.

Life cycle assessments of large appliances indicate that operations-phase electricity use is the dominant source of environmental impacts (Cullen and Allwood, 2009). For personal computers, however, the production causes significant impacts (Williams, 2004). In what is to our knowledge the first study of life cycle impacts of household appliances and

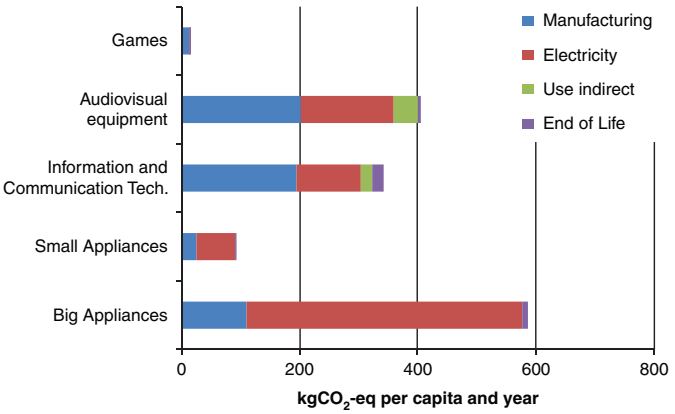

Figure 10.16 | GHG emissions associated with the purchase, use and disposal of electric and electronic equipment in Norwegian households, assuming 0.56 kgCO_2-eq/kWh for use-phase electricity (EU average). Source: Roux, 2010.

Note: Big appliances comprise cold appliances, wet appliances and big cooking appliances; small appliances include vacuum cleaners and microwaves; ICT includes computers, phones and peripherals; and audiovisual equipment include TVs, video equipment and audio equipment.

electronic equipment, Roux (2010) shows that the greenhouse gas emissions caused by the production of information and communication technology and audiovisual equipment purchased by Norwegian households is larger than the emissions caused by the electricity this equipment uses, even assuming a relatively polluting electricity mix (Figure 10.16). Taking the manufacturing of the equipment and the use of networks and content of ICT and audiovisual equipment into account, the GHG emissions caused by this equipment are equal to or larger than those caused by washing machines, driers, refrigerators, and freezers taken together. While these research results cannot be generalized, they indicate that the growing, rapid turnover of household electronics is an emerging problem that comes on top of the energy use of traditional household appliances. It may also stress the importance of regulating the durability of such equipment as a key energy- and GHG-saving strategy for residential emissions, potentially with comparable reductions as direct energy-saving policies.

10.1.4.8 Energy Embodied in Buildings-Related Water Use

Another commodity through which energy is embodied in buildings is water. The trade-offs between energy and the environment are discussed in detail in Chapter 20; however, this section narrows its focus only to the significant interactions of water and energy associated with their usage in buildings. These interactions are (1) water use for energy supply that is later used in buildings; (2) energy use to produce water consumed later in buildings; and (3) water used in energy consuming equipment and appliances installed in buildings as a special subcategory of interaction number two.

First, energy supply requires water. For instance, in the United States around 40% of freshwater withdrawals are used as cooling water for thermal power plants that are generating electricity (Huston et al., 2004).

Thus, reducing electricity demand in buildings has the potential to reduce freshwater withdrawals and associated environmental impacts. Second, water used in buildings[8] requires energy to extract, pump, transport, treat, and dispose the potable water and wastewater and to heat water for the final domestic and commercial use. For example, in California, these water-related energy uses for all sectors (buildings, industry, and agriculture) account for about 19% of the state's electricity, 32% of its natural gas, and 88 million gallons (3%) of diesel fuel every year (John et al., 2005). Barry (2007) estimated that 2–3% of the world's energy use is used only on pumping and treating water for civil and industrial supply. Water losses increase the amount of energy required to deliver water to the consumer. Barry (2007) provides case studies from Mexico, Brazil, and South Africa that exemplify that water loss ranges from one-third to one-half of the volume of water produced due to leaks and system inefficiencies.

Energy can be saved through water consumed in buildings by technologically reducing water demand at the point of its final use – such as through efficient washing machines, low flow faucets, toilets, and shower heads, increasing efficiency of water heating (see Section 10.4 for details), and eliminating water losses during the process of water extraction, treatment, transportation, distribution, and wastewater cleaning. Another cost-effective opportunity is the promotion of water-saving habits and lifestyles. Use of treated wastewater for other applications, such as for landscaping and flushing, is also predominant and even mandatory in India for several building typologies under environmental clearance norms. This, in turn, saves energy for pumping and transportation of water. The Alliance to Save Energy (2008) estimated that municipalities can cost-effectively save at least 25% of energy and money through water systems alone.

Finally, a special subcategory of energy saving measures is associated with water use in energy-using appliances, such as water heaters, cooking devices, and dish- and clothes-washing machines and in cooling and chilling applications. Energy savings can occur by means of water saving considerations in this equipment. Evaporative cooling is still largely used in India, for example, and provides a low-energy means of providing cool air in many parts of the world. For air conditioning applications, water-cooled chillers are more energy efficient than air-cooled ones. There is a dichotomy of choice between the use of water-efficient vis-à-vis energy-efficient chilling machines. Use of potable fresh water for space conditioning is prohibited in several states of India, especially where fresh water supplies are constrained. Also, existing environmental clearance norms for large-scale building projects in India encourage the use of recycled and treated wastewater or harvested rain water for space conditioning purposes. These measures not only address an environmental challenge – clean water conservation – but also reduce water-related energy use in connection with cooling.

8 According to UNEP, the global environmental footprint of the building sector represents 25% of total water use (UNEP SBCI, 2009).

10.1.5 The Impact of a Changing Climate on Building Energy Service Demand

A warming and changing climate has a strong influence on energy use in the building sector worldwide. While cooling demand increases as the climate warms, passive cooling approaches (e.g., overnight ventilation, shadowing) become less effective or do not achieve acceptable indoor temperatures. On the other hand, heating demand decreases in cold zones and allows acceptable winter comfort to be achieved more easily. In temperate climate areas such as much of Europe, Japan, South Africa, or the United States, both impacts on winter heating and summer cooling demand can be observed.

The net impact of warming depends on a complex set of factors. These include the choice of fuel and conversion efficiencies for heating fuels and power generation, building design, efficiency, and operation. Cooling loads will depend strongly on the market penetration of air conditioning, which itself will be dependent on income, building design, culture, and increasing internal loads of buildings by office automation, as well as external temperature. In addition, the cooling demand is exacerbated by the urban heat island effect (see Section 10.2.6) and the escalation of service demand for cooling. In some moderate climate regions, by contrast, heating loads may decrease substantially, or may even become unnecessary due to the combined effect of advanced know-how in building construction, building insulation performance, and an increase in internal heat loads. In contrast, the load on refrigeration equipment increases and its efficiency decreases with rising internal temperatures. The overall global effect is very likely to be an increase in electricity use, due to additional cooling demand in warmer continents and regions, despite a reduction in direct heating fuel use, with a net impact on primary energy that depends on a range of factors (Hunt and Watkiss 2011).

Changes in summer temperatures will also tend to increase the maximum load on electricity systems that already have summer peak demand, and therefore increase the need for power generation capacity. There are also implications for cooling strategies in buildings in some regions. In those regions with cold moderate climates where residential building over-heating is currently not a significant issue, it may become so, and passive cooling techniques currently associated with warmer climates will need to be incorporated into building design. On the other hand, in some arid climates, as diurnal average temperatures rise, existing passive cooling techniques may become inadequate, leading to greater reliance on active cooling. In general, buildings will need to be designed to allow comfortable conditions to be maintained in the range of climates they are expected to face over a building's lifetime. To the extent this is not done, there are increased mortality and morbidity risks from heat stress, although health impacts of cold will fall.

For much of Europe, increases in electricity demand for air conditioning and cooling will be outweighed by reductions in the need for heating energy up to 2050 (Jochem et al., 2009) while warming is moderate

and no thermally advanced buildings are considered. The individual changes may be quite large: for example, 10% per degree change in winter temperature for residential space heating in the United Kingdom (Summerfield, 2010). The aggregate impact of the different effects is smaller. The net result in a 4°C scenario[9], for instance, is a reduction in final energy demand by 2050 of 3.3% (Jochem et al., 2009) for the European Union-27 plus Norway and Switzerland. However, electricity used in space cooling is presently more carbon intensive in many countries than energy used for heating (e.g., gas, heating oil, wood fuels) in Europe and other countries in moderate climates. Depending on the final energy mix for heating and cooling, and the mix of primary energy for electricity supply, net CO_2 emissions in quite a few countries could still slightly increase even though overall energy demand decreases (Cartalsi et al., 2001; Frank, 2005; Aebischer et al., 2007; Rivière et al.; 2008).

The total electricity demand in the buildings sector is projected to slightly decrease in Nordic and Baltic countries (0.5%) by 2050. However, a 7% increase in the electricity demand by 2050 is expected in southern Greece, Malta, Cyprus, Southern Italy, Spain, Bulgaria, and Romania in a 4°C Scenario (Mirasgedis et al., 2007; Jochem et al, 2009). This points to distributional issues regarding adaptation or mitigation policies between northern and southern European countries. It may also lead to a greater need to balance summer electricity flows via the trans-European electricity grid, particularly during extreme heat waves. Similar effects can also be assumed for northern and southern states in the United States, Russia, or provinces in China.

According to Mansur et al. (2005), the combination of climate warming and fuel switching – from fuels to electricity – in buildings in the United States results in increases in the overall primary energy demand. There is likely to be a significant growth in the installation of air conditioning, but, with low utilization, additional energy demand may remain modest (Henderson, 2005), as confirmed by Jochem et al. (2009) for European countries north of the Alps.

There will be smaller impacts on other uses of energy in buildings. While the energy required to supply the same amount of hot water slightly decreases in a warmer climate, any increased demand for showers and bathing in warmer weather and additional heat waves will offset this reduction.

Climate change will increase electricity and primary energy demand in most emerging and developing countries, in contrast to a small or even beneficial effect in more temperate industrialized countries of the developed world such as Scandinavian countries, Russia, or Canada.

If left to the market alone, i.e., in the absence of specific government interventions, the responses to these climate changes are likely to be based on incremental short-term considerations – for example, the purchase of inefficient types of room air conditioning during hot summers. This may lock in the existing set of inefficient technologies (Unruh, 2000) in situations where innovative solutions would be more desirable (e.g., passive ventilation, passive buildings, cooling by absorption technology, shadowing by building elements and trees, white roofs and surfaces, vegetation in urban areas). Given the long life of building stock, it is clearly a priority that policies consider climate mitigation and adaptation of the building stock together.

10.2 Specific Sustainability Challenges Related to Energy Services in Buildings

10.2.1 Key Messages

This section focuses on major cross-cutting, building-specific issues that often present challenges and require trade-offs when pursuing sustainable energy goals; additional to those covered by other chapters in GEA. The key message that is valid across various subsections is that most of such challenges can be overcome by a high-efficiency, state-of-the-art building (from new and retrofits) and energy using equipment stock. The section on fuel poverty shows that high-efficiency buildings may eradicate fuel poverty and through this can also improve general social welfare.

10.2.2 Indoor Air Quality and Health Impacts of Air Tightness

Improving air tightness is an important method to reduce heating and cooling energy demand. However, it is also important to secure adequate ventilation, so as to maintain a healthy indoor environment due to the variety of chemicals used in interior materials, furniture, and daily goods. While this is not an issue with advanced buildings described in this chapter, since by design they operate with ventilation rates that result in very high indoor air quality, this is still an issue with existing or sub-optimally designed, inefficient future buildings.

One way to improve indoor air quality in increasingly airtight buildings is to reduce the use of materials emitting high levels of volatile organic compounds and ensure adequate ventilation. Health problems caused by airtight buildings without adequate ventilation, the so-called sick building syndrome,[10] were first identified as a result of reducing air change rate as an energy conservation measure. In order to ensure proper air quality, the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) proposed a range of allowable CO_2 concentrations from 1000 ppm to 2500 ppm, as well as ventilation requirements of 10 liters/sec per person for office spaces. In addition,

9 The 4°C scenario assumes that global average temperature will rise by 4°C compared to pre-industrial levels (van Vuuren et al., 2008).

10 Sick building syndrome describes the situations in which building occupants experience health and comfort effects that appear to be linked to time spent in a building, but no specific illness or cause can be identified (US EPA, 1991).

case control studies of allergy symptoms in 390 Swedish households (Bornehag et al., 2004) showed that the air change rate of the case group that had allergy symptoms was lower than 0.5/h[11], the same value under which the sick building syndrome and other air infectious diseases have also been shown to increase (Seppanen et al., 1999). In Japan, measurement of the concentration of chemicals in 2800 households (Osawa and Hayashi, 2009) showed that concentrations of formaldehyde in 27.3% of the households were higher than the guideline value. As a result, the revised Building Standard Law stipulates that air change rate in the living rooms of new constructed buildings must be secured at at least 0.5/h.

10.2.3 Household Fuels vs. Environmental Health

As discussed in Chapter 4 and other Chapters of the GEA, indoor air pollution arising from poor quality fuels burnt in inefficient devices has a health toll of mortality and morbidity measured by hundreds of millions each year. Since the issue is treated in detail throughout this document (including, but not limited to, Chapters 2, 3, 4, 11, and 19), this section only brings the importance of the issue to the fore and highlights some key relevant aspects.

Traditional biomass fuels have been the single most important energy source in buildings for centuries. They still account for approximately 10% of global total primary energy use concentrated primarily in developing countries. Approximately 60% of all biomass is used in solid unprocessed forms such as firewood, agricultural waste, and dried animal dung burnt in crude and inefficient stoves and open fires for cooking and heating (IEA, 2008b). Chronic Obstructive Pulmonary Diseases, to which pollution from poor combustion of biofuels indoors contribute, are predicted to become the world's third largest cause of death by 2030 (WHO Statistics, 2008).

Women and children in rural and urban areas of developing countries are most at risk due to their daily, close proximity exposure. Providing chimneys and efficient wood-burning stoves have been shown to reduce health risks by up to 50% in some areas (Romieu et al., 2009). Facilitating access to clean fuels such as biogas, solar thermal energy, liquefied petroleum gas, or electricity could reduce health risks, particularly in urban areas where commercial energy is more widely available. Facilitating a "multiple fuel and clean technology" by simultaneously making a more efficient and cleaner use of biomass for cooking and increasing access to other modern fuels has wider potential ecological and economic benefits due to reduced forest degradation and the time spent, mostly by women, in collecting fuel (García-Frapolli et al., 2010). This challenge is explored in more detail in Section 10.7.3 and new developments on advanced stoves are reported in Section 10.4.3.

11 Exchange rate of the total room air volume per hour.

10.2.4 Fuel and Energy Poverty

Even if access to modern energy carriers has been enabled, many population segments still may not be able to afford sufficient amounts of energy to meet their basic needs. The problem exists even in the most affluent countries, in many of which significant shares of the population cannot afford adequate heating, or are forced to spend disproportionate shares of their income on meeting basic thermal comfort needs. Since, as the section below argues in detail, this is often not due to generic poverty; or is in cases cause of other poverty, this problem is intimately related to the sustainable development goals of GEA.

While there are several definitions of fuel poverty, this document's use of the term is broader than that in many other sources. According to Tirado Herrero (in preparation), "A household is in fuel/energy poverty when it is unable to afford an adequate amount of energy services to satisfy its basic domestic needs – particularly sufficient thermal comfort – or is forced to spend a disproportionate share of its income on them". This phenomenon, called "energy poverty" and "fuel poverty," was introduced in Chapter 2, and its health impacts were discussed in Chapter 4. This chapter elaborates further on these health and social consequences, and discusses how the solution to the problem goes hand in hand with sustainable energy goals in buildings.

Fuel poverty originates from a combination of three main causes: household income, energy prices, and domestic energy efficiency. In many cases the problem can be substantially alleviated, sometimes even eliminated, by significantly improved efficiency – thus providing a strong synergy with sustainable energy goals. Box 10.A.1(see the GEA Chapter 10 online appendix) provides a case study in India of a project to provide solar lighting for approximately 886 million rural residents.

Fuel poverty is often the long-term consequence of measures that were introduced to provide sufficient access: i.e., subsidized energy prices for the poor. Artificially low energy tariffs provide the wrong economic signals and thus result in the acquisition of inefficient equipment and occupation of energetically poor buildings. When consumers are weaned from the subsidized prices, they find themselves locked into disproportionally high energy expenditures. An example of this is the formerly communist countries of Central and Eastern Europe and the former Soviet Union, where highly subsidized energy pricing policies have resulted in a very poor efficiency building stock and highly inefficient infrastructure. After the fall of communism, the introduction of market-based energy pricing resulted in significant shares of the population now living in fuel poverty and not being able to afford adequate heating. Since they can especially not afford investments in improving the efficiency of their energy using stock or buildings, poor population segments may turn out to pay significantly more for lower levels of energy services than the more affluent who can afford higher levels of efficiency.

Fuel poverty is an insufficiently researched and reported problem, especially in certain regions like the former Soviet Union and Central and

Table 10.3 | Incidence of fuel poverty in selected countries and regions.

Country/Region	Main estimates	Reference
UK	- Number of fuel poverty households in the UK ranging between 2 and 6.5 million (1996/2007)	DECC (2009a)
Ireland	- 17.4% of households unable to adequately heat the home (2001)	Healy and Clinch (2002)
EU	- Average percentage of households unable to heat home adequately (1994/97) in EU14: 16.9% [max: 74.4% in Portugal; min. 1.6% in Germany]	Healy (2004)
CzechRepublic	- Less than 10% of households suffering from domestic energy deprivation	Buzar (2007)
Macedonia	- More than 50% of households suffering from domestic energy deprivation	Buzar (2007)
New Zealand	- Between 10% and 14% of households in fuel poverty using the UK definition of adequate indoor temperatures (2001).	Lloyd (2006)
Hungary	- The average Hungarian household allocated 9.7% of its net income to energy expenses (2000/07) - 15% of the population (1.5 million) declared to be unable to afford to keep their homes adequately warm (2005/07)	Tirado Herrero and Ürge-Vorsatz (2010)

Eastern Europe, where it is suspected to be widespread (Buzar, 2007; Boardman, 2010). Though slowly gaining priority in some policy and research agendas (Friel, 2007), it is still far from being a common issue of concern (see Table 10.3). Even in economically and socially advanced regions like the European Union, few Member States have come up with specific strategies or policy frameworks to address the issue. In fact, few countries – only the United Kingdom (BERR, 2001; DEFRA/BERR, 2008), Ireland (MacAvoy, 1997), the United States (Power, 2006) and New Zealand (Chapman et al., 2009) – have started any significant action to tackle fuel poverty. In the United Kingdom, the government has set as a goal that by 2018 no British household should be spending more than 10% of its income on energy (DEFRA/BERR, 2008). The likely failure in meeting this target in the United Kingdom, as foreseen by Boardman (2010), evidences the scale of the challenge and provides arguments for jointly tackling fuel poverty, climate change mitigation, and energy security challenges. In fact, since domestic energy efficiency solutions allow bringing households out of fuel poverty while capping or reducing their energy use levels (Milne and Boardman, 2000), eradicating fuel poverty will certainly have positive effects on those related challenges.

There is evidence that inadequate indoor temperatures cause excess winter mortality (EWM) (Eurowinter Group, 1997), with most western countries reporting relative EWM rates ranging from 5% to 30% (Healy, 2004) (see Table 10.4). Based on a cross-country comparison, taking Norway as a control case, it is estimated that 44% of the cardiovascular- and respiratory-disease excess winter deaths registered in Ireland in 1986–1995 can be associated with poor housing standards (Clinch and Healy, 1999). Fuel poverty is also linked to certain illnesses (Morrison and Shortt, 2008; Roberts, 2008), with particularly negative physical and mental health effects being recorded for vulnerable populations, such as the elderly and children (de Garbino, 2004; Howieson, 2005; Liddell and Morris, 2010).

A common policy tool for alleviating fuel poverty has been subsidies aimed at reducing the energy bills or increasing the disposable income of low income households (DEFRA/BERR, 2008; Scott et al., 2008; Tirado Herrero and Ürge-Vorsatz, 2010). Such support schemes have, however, been criticized because, even though they succeed in reducing fuel poverty temporarily, in the long run they lock these households into fuel poverty by creating disincentives to improving the efficiency of energy using equipment and buildings. Healy (2004) has argued that the saved income most likely will be spent on more energy rather than invested in improving the quality of the dwellings. In addition, direct support schemes are often poorly targeted, distort the market, and constrain government budgets (Scott, 1996; IEA, 2007b; Fülöp, 2009).

A more sustainable and long-term solution is the retrofitting or replacement of inefficient equipment and building stock of these populations by high-efficiency ones. As this requires substantial investments that those experiencing fuel poverty themselves will not be able to afford, it may be necessary to (re)allocate public funds and financing to such purposes. For instance, since large sums of public funds, comparable to the investment costs of high energy efficiency retrofit programs that may fully eliminate the fuel poverty problem are devoted yearly to social energy price subsidies and temporary fuel poverty alleviation measures, a progressive substitution of the latter by the former can substantially contribute to the solution of the problem.

In addition, since a high-efficiency building and appliance stock contributes to the solution of many other problems – such as GHG and other environmental emissions, energy security, and employment – policy integration can result in the availability of funds that can more effectively reach those goals through improved efficiency, especially if sources from these several fields are combined. For instance, Ürge-Vorsatz et al.

Table 10.4 | Incidence of excess winter mortality (EWM) in selected countries.

Notes: 1) Percentage of additional deaths in the cold season in comparison with the warm season

(2010) have suggested that Hungary could cover the bill of deep renovation of its entire inefficient building stock, and thus the complete elimination of its fuel poverty, from the redirection of existing budgets, while still reaching the objectives of those budget items.

10.2.5 Health Problems Caused by Intermittent Local Heating

Household heating in some cold regions, including Japan and parts of Europe, is often limited to the occupied space, causing large temperature differences between heated and unheated spaces.

In Japan, measurements of indoor air temperatures in residential buildings located in cold regions indicate that indoor air temperatures are maintained around 20ºC in the heated rooms, while the temperatures of bedrooms, bathrooms, and toilets without heating can be as low as outdoor air temperatures (Yoshino et al., 1985). The average temperature difference between heated rooms and not heated rooms is often about 20ºC. It is thought that blood pressure overshoots caused by such large temperature differences are one of the causes of high death rates from apoplexy in these districts. Moreover, a large percentage of deaths from accidental drowning in bathtubs in Japan is due to the low temperatures in unheated bathrooms (Tochihara, 1999): the sudden change in blood pressure before and after bath might also be the cause of death from apoplexy or anemia. High-efficiency, state-of-the-art buildings advocated in this chapter could help overcome this problem. With minimal or no energy investments, they can provide full thermal comfort and thus reduce such mortality and morbidity.

10.2.6 Urban Heat Islands vs. Resilient Buildings

The outdoor air temperature in hot weather in thermally massive built environments with surfaces of low albedo is increasing due to the urban heat island phenomenon (Oke, 1982; Akbari et al., 1990; inter alia). It is becoming a major reason for the increase in energy use, and is exacerbated by the measure that is supposed to reduce the impact: the air conditioning of buildings. Air conditioners transport indoor heat to the outdoors, adding to the heat generated by air conditioners themselves, thereby contributing to the urban heat island effect in areas with mechanical cooling. The heat island effect occurs when surfaces of the built environment absorb sunlight, which is released as heat during cooler periods, such as nighttime, and keeps the air temperature warm. It can raise a city's temperature by up to 3–4°C and catalyzes smog formation and other health hazards (US EPA, 2007).

Table 10.5 | Energy saving for HVAC loads due to green roofs in different regions[12].

Percentage Energy Savings for HVAC loads (rounded to the nearest integer)	Number of Floors	City, Country, Latitude
73%	1	Toronto, Canada, Latitude: 43°41′ N
29%	2	
18%	3

Chapter 4 reviews some health impacts of heat stress. This section presents a few further examples. Narumi et al. (2007) carried out investigations on the relationship between infection and air temperature in Osaka, Japan. The number of daily reports of disease increased when the average outdoor temperature was higher than 22°C. Six out of fifteen types of infections: (1) hand-foot-and-mouth disease; (2) herpangina; (3) pharyngoconjunctival fever; (4) enterohemorrhagic escherichia coli; (5) infectious gastroenteritis; and (6) epidemic keratoconjunctivitis – showed a positive correlation with temperature.

Genchi et al. (2007) studied the increase of tropical nighttime temperatures caused by the urban heat island phenomenon, and quantified the impact on sleep disorders. The results show that when the temperature is higher than 26.7°C, about 10% of residents suffer from sleep disorders, with 1°C increase of air temperature at midnight. It was estimated that the economic losses due to insomnia was about 305 billion yen (US$ 3.53 billion).

Among the strategies to address the urban heat island effect are "cool roofs" and roof and vertical "greening." Cool roofs are solar reflective roofs that absorb less sunlight than conventional roofs. The greater reflectivity is achieved by utilizing a light color of roof surface and special highly reflective[13] and emissive[14] materials, which can reflect at least 60% of sunlight instead of 10–20%, reflected by traditional dark-colored roofs (US EPA, 2007). Standard black asphalt roofs can reach 74–85°C at midday during the summer. The surface temperature of bare metal or metallic roofs can increase up to 66–77°C. Cool roofs reach peak temperatures of only 43–46°C, even in full summer. Conventional roofs can be 31–47°C hotter than the air on any given day, while cool roofs tend to stay within 6–11°C of the background temperature.

Cool roofing materials cost 5–20% more than conventional ones, but in the long run they can provide considerable cost and energy savings, reduce GHG emissions, and improve human health. Human health improvements include reducing heat-related illnesses and reducing deaths in buildings without air conditioning (US EPA, 2007). Energy savings vary greatly from one building to another between 10 and 70% of total cooling energy use (Wang, 2008). Preliminary estimates of the global emitted CO_2 offset potentials for cool roofs and cool pavements by Akbari et al. (2008) are in the range of 24 Gt of CO_2 and 20 Gt of CO_2, respectively, giving a total global emitted CO_2 offset potential range of 44 Gt of CO_2.

Green roofs and walls also mitigate the heat island effect, improve urban air quality (Yang et al., 2008), reduce CO_2 concentrations, and reduce the need for winter heating (Takebayashi and Moriyama, 2007; Li et al., 2010). Green roofs have also been shown to provide thermal insulation to buildings through a combination of the reduced thermal conductivity of the roof structure, and the evapotranspiration of the plants (Martens et al., 2008). A number of studies have shown that insulation provided by green roofs can reduce energy use of heating, ventilation, and air conditioning (HVAC) systems. However, the energy savings reported in the literature are usually the results of simulations rather than real measured data, therefore, the range of presented values is very wide. For example Sailor (2008) finds that for a 2-story office building in Chicago and Houston a green roof with 0.2m thick soil reduces total electricity use by 2% in both cities and reduces natural gas use by about 9% in Chicago and by about 11% in Houston compared to a conventional membrane roof. Table 10.5 demonstrates the results from several studies and shows that modeling results of HVAC energy saving from green roofs vary between 6–72% depending on the climate zone and number of floors affected.

12 All energy savings presented in the Table are the results of simulations and not measured data

13 Solar reflectance, or albedo, is the percentage of solar energy reflected by a surface.

14 Thermal emittance is the amount of heat a surface material radiates per unit area at given temperature, i.e., how readily a surface gives up heat.

As the urban and global climate changes – and warms – the ability of buildings to continue to provide healthy and thermally-comfortable environments for inhabitants will be further challenged. A combination of efficiency (via passive solar design), bio-climatic design (where buildings are greened and integrated into their natural settings rather than set apart from them) (Yeang, 1994), and design for adaptability (when buildings are designed for simple retrofitting to enhance resilience to environmental climatic extremes) (Graham, 2005) is necessary to cope with climatic challenges (Bornstein and Lin, 1999). Designers, developers, regulators, and financiers – both government and private – urgently need to be made aware of this deteriorating situation. Occupants also need to be provided with a greater choice of strategies, including energy feedback and occupancy monitoring systems, in order to tune buildings to changing climatic conditions.

Among the primary purposes of buildings is the provision of thermal comfort. Thermal comfort is a dynamic quality based on the interaction of people's metabolism, sensory perceptions, expectations, and acclimatization experiences, as well as the human body's interaction with the surrounding interior building materials. The material nature of the urban environment is in a constant dynamic relationship with the urban climate (Santamouris, 2001), which is in turn embedded in the regional and ultimately the global climate – a relationship still little understood and appreciated. A change in any of these parameters can change perceptions and experiences of comfort, which exacerbates the demand for energy for heating or cooling. Integrating into a building the potential to naturally resist climatic extremes and especially temperature excesses in urban settings is a fundamental advantage of bio-climatically appropriate design. Both sustainability and livability are enhanced as a consequence.

10.3 Strategies Toward Energy-sustainable Buildings

This section briefly reviews the key strategies that can be applied to move towards buildings that use energy in more sustainable way. The sections to follow "unpack" these strategies, and translate them into concrete technological and non-technological options.

The key to achieving sustainability in the building stock is to reduce the energy requirements in operating buildings to the point where building energy needs can be met entirely through renewable and non-greenhouse gas emitting energy sources, while maintaining indoor air quality and avoiding hazardous chemicals. The extent to which present building energy requirements need to be lowered in order to be satiable by renewable energy depends on the overall energy demand in society and hence on the success of measures to reduce energy demands in other sectors of the economy. It also depends on the achievable and sustainable energy supply from renewable energy sources which, in the case of biomass energy, depends on a number of still uncertain biophysical and climatic factors, as well as on diet through its impact on the availability of land for bio-energy crops (see Chapter 20). The building energy intensity (annual energy use per unit of floor area) that can be regarded as sustainable depends on the human population and the floor area per person, which together determine the total building floor area. Given limits – either physical, economic, or practical – to the renewable energy supply, a larger global building floor area will require lower energy use per unit of floor area. In the GEA pathways (Chapter 17) where future energy systems meet the key environmental, social, and economic objectives, energy intensity is reduced by the factor of three to four (and even larger in some regions).

A hierarchy of options for achieving reductions in the energy intensity of buildings of this magnitude is presented in Section 10.4, beginning with urban-scale energy systems, building-scale energy systems, and finally, individual energy using devices in buildings. A least-cost approach to achieving sustainable energy use in buildings will be to implement energy saving measures – either in the construction of new buildings or the retrofitting of existing buildings – up to the point where the cost of the next measure exceeds the cost of the least expensive renewable energy supply option. The least expensive renewable energy supply option might involve the on-site generation of electricity and thermal energy, or it might entail the provision of locally produced biomass or the provision of C-free electricity from distant but high quality wind, solar, or other renewable electricity sites. The relative costs of achieving a given low building energy intensity, of on-site generation of renewable energy, and of off-site supply of renewable energy will vary regionally, over time, and with the type of building under consideration. Some forms of renewable energy supply, such as passive heating, ventilation and daylighting, can be regarded as energy demand reduction measures rather than energy supply measures, but in any case, they tend to be low cost and so will be early choices in a hierarchy of increasingly stringent demand or supply measures.

10.4 Options to Reduce Energy Use in Buildings

10.4.1 Key Messages

Deep – 75% or more – reductions in the gross energy requirements of new buildings compared to the performance of most types of recent new buildings can be achieved in most or all jurisdictions in the world through application of the Integrated Design Process and of the principles discussed here. It is also possible to achieve significant – 50% or more – reductions in the energy use of existing buildings. Once gross energy requirements have been reduced by a factor of two to four, it is sometimes possible to supply most or all of the remaining energy requirements with on-site renewable energy generation such as active solar technologies (photovoltaic, solar thermal) mounted on or integrated into the building envelope, thereby reducing the net energy requirements to zero or achieving net energy generation.

Through drastic reductions in the net energy requirements of buildings, it will be significantly easier than otherwise to eventually supply all of the remaining energy requirements from off-site renewable energy sources (such as wind, solar and biomass), whether local or distant but of high quality.

10.4.2 Urban-Scale Energy Systems, Urban Design, and Building Form, Orientation, and Size[15]

10.4.2.1 Key Messages

Urban design influences energy use by buildings in several ways. Shape, height and orientation significantly affect heating and cooling loads and opportunities for passive ventilation. The density of urban developments influences the economic viability of district heating and cooling systems.

10.4.2.2 Role of Street Orientation and Width

Traditional houses and streets in many parts of the world used to be laid out so as to provide a significant amount of self-shading. The spacing of buildings close enough to provide significant self-shading will diminish wind strength near the ground, reducing the potential for ventilation, although daytime ventilation is not always useful. Close spacing also reduces solar access in winter, but such access will not be needed in those hot-summer regions with mild winters. Bourbia and Awbi (2004) measured temperatures at the 1.5 m height in traditional (narrow) and contemporary (wide) streets in a city in Algeria. Traditional streets are about five degrees cooler than contemporary streets, whether oriented north-south or east-west. This is due both to greater shading of traditional streets, which reduces direct solar irradiance, and the smaller sky viewing angles, which reduces diffuse solar irradiance. In hot-dry desert climates of India, the urban scape is defined by narrow roads banked by tall and compact houses with thick walls and small openings – all of these strategies help keep heat out of buildings.

10.4.2.3 Role of Building Shape, Form, and Orientation

Building shape (the relative length, width, and depth), form (small-scale variations in the shape of a building), and orientation are architectural decisions that have significant impacts on heating and cooling loads, as well as on daylighting and opportunities for passive ventilation, passive solar heating and cooling, and for active solar energy systems. For instance, in temperate climates, the optimal orientation for rectangular buildings is the long axis running east-west, as this simultaneously maximizes passive solar heating in the cold season and minimizes solar heating in the warm season. Traditional houses in warm climates in India were mostly designed around courtyards and front courts (Aangan) that served as congregation spaces for families and for sleeping during nighttime, as these are naturally cool outdoor spaces. Developing countries, such as India, have a rich legacy of architecture that uses traditional low- or no-energy techniques to ensure thermal and visual comfort. Old forts and havelis (mansions) had deployed several innovative techniques of natural lighting, ventilation, and natural cooling to achieve desired comfort levels.

Roof design is another feature that can influence energy use. An unconditioned space between inhabited rooms and the roof is a traditional insulating technique, and one that allows significant improvements in thermal performance without loss of useful space, by installing additional insulation. An overhanging roof also provides passive cooling via shading, as well as protecting walls from rain and snow. A reflective (white or cool) roof reduces heat gains, as discussed earlier.

The options discussed in this section, as well as many other sections, may influence the aesthetics of the building and neighborhood. Nevertheless, by today most, if not all, sustainable energy solutions can be implemented in buildings that do not need to compromise on aesthetics.

10.4.2.4 Role of Building Size

Building size is an important factor in energy use. Increased size tends to reduce surface to volume ratio, thereby reducing thermal losses and gains relative to floor area. However, total surface area and hence total energy use will increase unless the envelope is sufficiently improved. In the United States, the living area in dwellings per family member increased by a factor of three between 1950 and 2000 (Wilson and Boehland, 2005). This is due in part to declining average family size (from an average of 3.67 to 2.62 members) and in part due to larger houses (from an average of 100 m^2 to 217 m^2). A moderately insulated 3000ft^2 (~300 m^2) house in Boston requires more heating and cooling energy than a poorly insulated 1500 ft^2 house in the same location. The larger house also requires substantially more materials. According to a designer-builder quoted by Wilson and Boehland (2005), the growth in house size is due to: (1) the loss of a sense of community and public life, so that the house becomes more of a fortress that needs to provide multiple forms of entertainment instead of basic shelter; (2) the promotion of the idea that "bigger is better" by the building industry; and (3) the diminishing craftsmanship in house construction and design, leading to a substitution of greater size to counteract the sterility of modern homes. Wilson and Boehland (2005) list various strategies to make more efficient use of space, so that smaller houses provide the same services.

10.4.2.5 Multi-unit Housing, Office and Retail Space

Multi-floor, multifamily housing is significantly more energy efficient than single-family housing, especially one-floor, single-family housing.

15 This section is a highly condensed discussion drawn from Harvey (2006, 2009, 2010).

This is due to the sharing of walls and reduction in roof area, with concomitant reduction in heat loss. Stacking housing units vertically, or designing single-family houses as two- or three-story houses rather than as one-story houses will increase the opportunities for passive ventilation in the summer by exploiting the buoyancy of warm internal air, and protects the lower floors from solar heat gain.

Analyses carried out by Smeds and Wall (2007) indicate that over twice the thickness of insulation is needed in a single-family house as in a multi-unit apartment, along with substantially better windows, in order to achieve the same reduction in heat loss. Conversely, adoption of about the same insulation levels and window performance in an apartment building as in high performance houses in Sweden reduces the annual energy use to one-third of that of the high performance house and to about one-tenth of that of conventional single-family Swedish houses.

Multifamily housing has a smaller surface to volume ratio than single-family housing, which reduces the building cost per unit of floor area by reducing the relative importance of the external envelope to the total cost. Construction material requirements are also reduced, while public transit, walking, and cycling are enhanced and land is spared because a more compact urban form can be created. Thus, multifamily and multi-unit office and retail buildings simultaneously reduce energy use and investment costs and enhance possibilities for alternatives to automobile use.

Another benefit of multi-unit housing and mixed (housing and commercial) development is that the connection to district heating and cooling grids is more likely to be economically justifiable, as explained later. However, large-scale office and retail buildings exceeding 30 meters in depth need more energy for lighting, ventilation, and cooling than small-scale office buildings. This is because natural lighting cannot reach the center of the building, so artificial lighting has to be relied upon; natural ventilation cannot provide enough outdoor air, causing a reliance on mechanical ventilation; and heat generated inside cannot be released through the envelope, so more cooling is needed. Different shapes – e.g., U-shaped or E-shaped rather than rectangular – provide better natural lighting and ventilation, but with an increase in exterior walls.

10.4.2.6 District Heating and Cooling

A district heating system consists of a network of underground pipes carrying steam or hot water from a centralized heating facility or heat source to individual buildings, while a district cooling system is a network of pipes to carry chilled water. District heating systems provide an energy savings if they make use of heat that would otherwise be wasted. The most common source of waste heat is heat produced from the generation of electricity in fossil fuel or biomass power plants. Conversely, district heating supplied entirely from centralized boilers does not save any energy, and may in fact increase energy use, compared to the use of on-site condensing boilers. System efficiency is maximized if heat from the cogeneration of electricity is supplied at the lowest possible temperature, as this minimizes the reduction in electricity generation caused by withdrawing useful heat from a steam turbine, maximizes the fraction of waste heat used, and minimizes heat losses during distribution. This, in turn, requires buildings with a high performance thermal envelope and ideally with radiant floor or ceiling heating systems, which permit low heat delivery temperatures, as discussed later. However, the heat load in this case might be so low that a district heating network cannot be economically justified unless the building density is very high.

District cooling can be supplied from large, dedicated centralized electric chillers or from absorption chillers that are driven with steam from steam turbines for electricity generation. The latter is referred to as "trigeneration," as it involves the concurrent production of electricity, hot water, and chilled water. In principle, district cooling from large, centralized chillers can provide significant (up to 45%) savings compared to the use of separate chillers in individual buildings (Dharmadhikari et al., 2000). This rate of savings is due to the larger full-load efficiency of large chillers compared to small chillers, and the ability to operate each chiller in a centralized system at, or close to, its maximum efficiency. Further savings are possible if the centralized system can make use of heat sinks, such as sewage or lake, river, or sea water that would not be available to chillers in individual buildings. However, in practice there may be no savings or even an increase in energy use if unfavorable behavioral changes – such as switching from cooling only individual rooms as needed, to cooling the entire building all of the time – accompany the switch to district cooling, as already highlighted in earlier sections of the chapter.

The total cost of district cooling systems can be less than the total cost of equipping individual buildings with their own chillers. This is due to low unit costs for large chillers, the need for less total capacity in centralized systems – because the peak cooling loads in individual buildings do not all occur at the same time – and the need for less backup capacity (IEA, 1999; Harvey, 2006). District cooling systems also eliminate the need for rooftop cooling towers, thereby freeing up roof space for other purposes, such as rooftop gardens or solar panels.

District heating networks can be coupled with the large-scale underground storage of heat that is collected from solar thermal collectors during the summer and used for space heating and hot water requirements during the winter (Schmidt et al., 2004; Harvey, 2006). Heat can also be supplied with biomass, as part of a biomass cogeneration system or from geothermal heat sources. If both heat and coldness are stored, then heat pumps can be used to recharge the thermal storage reservoirs or to directly supply heat or coldness to the district heating and cooling networks during times of excess wind energy. This, in turn, permits the sizing of wind systems to meet a larger fraction of total electricity demand without having to discard as much, or any, electricity generation potential during times of high wind and/or low demand.

10.4.3 Options Related to Building-Scale Energy Systems and to Energy Using Devices[16]

10.4.3.1 Key Messages

The energy use of buildings depends to a significant extent on how the various energy using devices (pumps, motors, fans, heaters, chillers, and so on) are put together as systems, as well as the efficiencies of individual devices. Savings opportunities at the system level are generally many times what can be achieved at the device level, and these system-level savings can often be achieved at net investment-cost savings. Significant savings are also possible for business and household plug loads.

The following subsections briefly explain how extraordinary savings can be achieved. Examples are presented of exemplary buildings from around the world, spanning a wide range of climates, followed by information on the initial investment cost of low energy buildings compared to conventional buildings. Much more detailed information can be found in Harvey (2006).

10.4.3.2 Integrated Design Processes

The key to achieving deep reductions in building energy use is to analyze the building as an entire integrated system, rather than focusing on incremental improvements to individual energy using devices. This requires a new approach to building design, referred to as the Integrated Design Process (IDP) (Lewis, 2004). IDP requires setting ambitious energy efficiency goals at the very beginning of a project, and requires an early brainstorming session involving all the members of the design team to develop a number of alternative concepts for achieving the energy target. The integrated design process also entails two-way interaction between the design team and the contractors. Simulation is an important tool in an IDP process. As a building will be operated over a large range of outdoor climates and indoor states, simulation can tell what happens in a part-load situation and help the design to achieve high efficiency during part-load conditions. It often happens that the building and its system perform very well during the hot and cold season (the design states), but very poorly during transitional seasons.

As Harvey (2006) discusses, the steps in the most basic IDP are to: (i) consider building orientation, form, thermal mass; (ii) specify a high performance building envelope and other measures to reduce heating and cooling loads; (iii) maximize passive heating, cooling, ventilation, and daylighting; (iv) install efficient systems to meet remaining loads; (v) ensure that individual energy using devices are as efficient as possible and properly sized; and (iv) ensure the systems and devices are properly commissioned.

16 Subsections 10.4.3 to 10.4.9 are a condensed discussion drawn from Harvey (2006, 2009, 2010).

By focusing on building form and a high performance envelope, heating and cooling loads are minimized, daylighting opportunities are maximized, and mechanical systems can be greatly downsized. This generates cost savings that can offset the additional cost of a high performance envelope and the additional cost of installing premium (high efficiency) equipment throughout the building. These steps alone can usually achieve energy savings on the order of 35–50% in new commercial buildings, while utilization of more advanced or less conventional approaches has often achieved savings on the order of 50–80%.

10.4.3.3 Reducing Heating and Cooling Loads

The term "heat load" refers to the rate of heat loss from a building during the heating season. This heat has to be replaced by the heating system in order to maintain a steady indoor temperature, and so represents a load on the heating system. The term "cooling load" refers to the rate of unwanted heat gain during the cooling season, heat that must be removed in order to maintain a steady indoor temperature.

Heating loads can be dramatically reduced through the use of a high performance thermal envelope, consisting of: (i) high levels of insulation in the walls, ceiling, and basement; (ii) avoidance of thermal bridges; (iii) windows and doors with a very high resistance to heat loss; and (iv) a high degree of airtightness, combined with mechanical ventilation with heat exchangers to recover heat or coldness from exhaust air and possibly waste water, depending on the season.

The heating energy requirement is the difference between heat losses and useable internal and passive solar heat gains. High levels of insulation, combined with high performance windows and airtightness and coupled with mechanical ventilation and heat recovery, can readily reduce heating energy requirements by a factor of 4–10 compared to current practices in cold climate regions. In areas with mild winters where previous practice was for no insulation, rather moderate levels of insulation can substantially reduce heating energy requirements, as well as reduce summer cooling energy use by a factor of two or more (Florides et al., 2002).

Heat loss through high performance windows is so small that perimeter heating units, usually placed below windows to prevent drafts, can be eliminated, even when winter temperatures dip to -40°C (Harvey and Siddall, 2008). When perimeter heating is eliminated, ductwork or hot water piping can be made shorter, as all the radiators can be located closer to the central core of the building, with associated cost savings but also savings in fan and pump size and energy use. If the default design involves floor-mounted fan-coil units, their elimination will increase the amount of useable floor space.

Options to reduce the cooling load include:

- orienting a building to minimize the wall area facing east or west;

- clustering buildings to provide some degree of self-shading, as in many traditional communities in hot climates;
- using high reflectivity building materials; for example, Parker et al. (2002) found that houses in Florida with white reflective roofs have a cooling-energy demand about 20–25% lower and peak power demand about 30–35% lower than houses with dark shingles;
- increasing insulation; for example, Florides et al. (2002) found that for a one-story house in Cyprus, adding 5cm of polystyrene insulation to the roof reduces the cooling load by 45% and the heating load by 67%, while addition of 5cm of polystyrene insulation to the walls reduces the remaining cooling load by about 10% and the remaining heating load by 30%;
- providing fixed or adjustable shading, as external shading devices block 90% of incident solar heat, compared to 50% for internal devices (Baker and Steemers, 1999);
- using windows with a low solar heat gain – as low as 25%, compared to 70% for a clear double glazed window – and avoiding excessive window area, particularly on east- and west-facing walls;
- using highly efficient lighting and household appliances, electronics, and office equipment to reduce internal cooling loads;
- utilizing thermal mass to minimize daytime interior temperature peaks, combined with nighttime cooling; and
- using vegetation to directly shade buildings and to indirectly reduce cooling loads by reducing ambient air temperature through evapotranspiration. Vegetation integrated into building surfaces, such as walls and roofs, also contributes to cooling by reducing heat gains and through evapotranspiration.

Thermal mass does not reduce the heat gain by a building and so does not represent a reduction in cooling load (as defined here). However, a high thermal mass reduces the temperature increase for a given heat gain and, for short temperature spikes, can eliminate the need for air conditioning. Porta-Gándara et al. (2002) simulated the cooling load for housing built with traditional adobe bricks and modern hollow concrete blocks (having minimal thermal mass) in Baja California, and found the air conditioner load of the former to be one-fourth that of the latter during the hottest summer months. However, unless temperatures drop sufficiently at night to remove the heat that enters the thermal mass by day, the temperature of the thermal mass will build up over a period of days, so it will become less and less effective in limiting daytime temperatures. The nighttime removal of daytime heat can be enhanced through deliberate nighttime ventilation of the building with outside air when the outside air is sufficiently cool, as discussed in the next subsection. External insulation will inhibit daytime penetration of outside heat into the thermal mass while leaving it exposed to cool air during nighttime ventilation.

Thermal mass can also be provided through phase change materials (PCM), the most common being a paraffin wax that melts at around 25ºC. The PCM can be embedded in drywall or plaster inside 50-µm capsules. The waxes will not rise in temperature above their melting point as they melt, just as ice will not rise above 0ºC as it melts. Air in contact with the plaster or spheres will rise only a few degrees above the melting point of the wax. At night the waxes refreeze if they can be cooled to below their melting point with cool night air, releasing the heat that they absorbed during the day as they melted.

The combination of switching to a high albedo surface and planting shade trees can yield dramatic energy savings. Rosenfeld et al. (1998) calculated the impact on cooling loads in Los Angeles of increasing the roof albedo of all five million houses in the Los Angeles basin by 0.35 (a roof area of 1000 km^2), increasing the albedo of 250 km^2 of commercial roofs by 0.35, increasing the albedo of 1250 km^2 of paved surfaces to 0.25 (by using whiter, limestone-based aggregates in pavement whenever roads are resurfaced), and planting 11 million additional trees. In the residential sector, they computed a total savings of 50–60%, with a 24–33% reduction in peak air conditioning loads. Akbari et al. (2008) estimate that a net albedo increase for urban areas of about 0.1, which they consider achievable by increasing both roof and pavement albedos by about 0.25 and 0.15 respectively, can achieve the equivalent of offsetting about 44 Gt of CO_2 emissions on a global scale. At the same time, these measures would induce significant savings in cooling costs, with an estimated savings potential in excess of US$1 billion/yr in the United States. Growing vegetation on building walls can also provide important reductions in cooling energy use; simulations by Kikegawa et al. (2006) indicate a savings of 10–30% for residential buildings in Tokyo.

In hot-humid climates, the energy required to dehumidify air can represent a significant fraction of the total cooling load. This portion of the cooling load will not be reduced through measures such as shading, external insulation, or use of thermal mass and windows with low-solar heat gain, so these measures will provide a smaller percentage savings in overall cooling loads. However, materials that absorb moisture can be placed at the internal surface of rooms so as to maintain nearly constant relative humidity inside. On dry days, the moisture can be released back to the air through ventilation. This can greatly reduce the energy required for dehumidification.

Thermal mass will be less effective in reducing daytime temperature-related cooling loads in humid climates because of the smaller day-night temperature difference in hot-humid climates than in hot-dry climates. In hot-humid climates, it is more appropriate to employ urban and building forms that promote air movement between and through buildings, in order to employ low thermal mass to minimize the storage of heat so that buildings can cool quickly whenever temperatures decreases (Koch-Nielsen, 2002).

Table 10.6 | Major strategies for reducing different energy uses in buildings in different climate zones.

	Climate Zone			
	Cold Moderate	**Warm Moderate**	**Arid**	**Tropical**
Heating	• High levels of insulation and air tightness with heat-recovery ventilation • Windows with high thermal resistance and high solar heat gain	• High levels of insulation and air tightness with heat-recovery ventilation • Windows with high thermal resistance and low solar heat gain	• Modest insulation • Windows with low solar heat gain	• Minimal or no insulation • Windows with low solar heat gain
Cooling	• Earth pipe • Shading • Thermal mass	• Earth pipe • Shading • Reflective surfaces • Thermal mass with external insulation and night ventilation	• Shading • Reflective surfaces • Thermal mass with external insulation and night ventilation • Compact form and self shading • Evaporative cooling	• Shading • Open structure with plenty of ventilation • Minimal thermal mass • Solar-driven desiccant dehumidification and evaporative cooling
Ventilation	• Hybrid passive-mechanical ventilation	• Hybrid passive-mechanical ventilation		

High performance thermal envelopes can readily reduce heating energy requirements by 75–90% in cold climates, while modest levels of insulation may eliminate the need for winter heating altogether in regions with mild winters. Modest levels of insulation are also effective in reducing cooling loads by about half in hot climates. Thermal mass, combined with external insulation and nighttime ventilation, can largely eliminate cooling requirements in hot-dry climates. In hot-humid climates, the potential to reduce cooling loads is smaller, due to the greater importance of dehumidification loads and the smaller diurnal temperature range. In both hot-dry and hot-humid climates, however, the remaining cooling loads can be handled through a variety of low-energy systems.

Table 10.6 summarizes the features of low-energy buildings that depend on the climate where the building is situated. These features largely pertain to building form and envelope, and the applicability of earth pipe, evaporative, or desiccant cooling systems. These and other building features and internal energy loads are discussed in the following subsections.

10.4.3.4 Passive and Passive-low-energy Heating and Cooling

Having reduced the cooling load through the techniques described above – often by a factor of two or more – the next strategy in priority is to use passive and/or passive-low-energy cooling strategies. A purely passive cooling technique requires no mechanical energy input at all. Other techniques involve small inputs of mechanical energy to enhance what are largely passive cooling processes. Some examples of passive and passive-low-energy cooling techniques are described below.

Natural Ventilation

Natural ventilation has a cooling effect whenever the outdoor air temperature is below the indoor air temperature. It reduces the perceived temperature due to the greater ability of moving air to remove heat from a warmer body, and increases the acceptable air temperature due to enhanced psychological adaptation to warmer conditions in naturally-ventilated buildings compared to buildings with mechanical ventilation.

Natural ventilation can be achieved through:

- cross ventilation and wind, a technique that has been widely employed in traditional architecture around the world and in passive ventilation stacks that are commonly used in north European residential buildings;
- solar chimneys, which consist of a tower in which air is heated and rises, drawing cooler outside air through the building. A striking example is the Building Research Establishment offices in Garston, United Kingdom, which is illustrated in Figure 10.A.3.in the GEA Chapter 10 online appendix;
- atria, which can induce natural ventilation through proper placement of air inlets and outlets, along with shading controls or passive measures, such as the geometry of laser-cut glazing, to avoid overheating in summer;
- cool towers, in which water is pumped into a honeycomb medium at the top of a tower and allowed to evaporate, thereby cooling the air at the top of the tower, which then falls through the tower and into an adjoining building under its own weight. These have been used in the Visitor Center at Zion National Park, United States (Torcellini et al., 2002), and at the Torrent Pharmaceutical Research Centre in Ahmedabad, India (Ford et al., 1998); and
- airflow windows, which are designed to facilitate the passage of outgoing exhaust air or incoming fresh air between the glazing in a double glazed window. In the Tokyo Electric Power Company

(TEPCO) research and development (R&D) center, constructed in Tokyo in 1994, this technique reduced the inward heat transfer by one-third to two-thirds compared to double glazed windows with interior or built-in blinds, and eliminated the need for perimeter air conditioning (Yonehara, 1998).

Nighttime Passive and Mechanical Ventilation

Where the day-night temperature variation is at least 5–7 degrees, cool night air can be mechanically forced through hollow core ceilings or through the occupied space to cool the building prior to its use the next day. Where artificial air conditioning is still needed by day, external air can be pre-cooled by passing it through the ceiling that has been ventilated at night. Effective night ventilation requires a high exposed thermal mass, an airtight envelope, minimal internal heat gains, and a building configuration that induces natural airflows so that minimal fan energy is required. In such buildings in the southern United Kingdom, as well as in Kenya, cooling energy savings of 30–40% can be achieved this way, as simulations for both places have shown (Kolokotroni, 2001). External insulation should be used in order to inhibit the inward penetration of daytime outside heat while leaving the thermal mass exposed to the cooling effect of nighttime ventilation and free to absorb internal heat during the day.

For Beijing, da Graça et al. (2002) found that thermally- and wind-driven nighttime ventilation eliminates the need for air conditioning of a six-unit apartment building during most of the summer, when an extreme outdoor peak of 38°C produces a 31°C indoor peak. Simulations by Springer et al. (2000) indicate that nighttime ventilation is sufficient to prevent peak indoor temperatures from exceeding 26°C over 43% of California's geography in houses that include improved wall and ceiling insulation, high performance windows, extended window overhangs, tight construction, and modestly greater thermal mass compared to standard practice in California.

Where mechanical air conditioning is used in combination with night ventilation, the energy savings from night ventilation depend strongly on the daytime temperature setpoint. For a three-story office building in La Rochelle, France, Blondeau et al. (1997) found through computer simulation that night ventilation with a 26°C setpoint requires only 9% of the cooling energy as the case with a 22°C setpoint and no night ventilation for this particular building and climate.

The combination of external insulation, thermal mass, and night ventilation is particularly effective in hot-dry climates, as there is a large diurnal temperature variation in such climates, and placing the insulation on the outside exposes the thermal mass to cool night air while minimizing the inward penetration of heat into the thermal mass. As previously noted, low thermal mass and an open design with plenty of cross ventilation are normally recommended in hot humid climates, although Tenorio (2007) finds that in humid tropical areas of Brazil, thermal mass combined with night ventilation and selective use of air conditioning can reduce cooling energy use in a two-story house by up to 80% compared to a fully air conditioned house.

Evaporative Cooling

Evaporation can cool water down to the wet bulb temperature (T_{wb}).[17] The difference between T_{wb} and the ambient temperature is greater the lower the absolute humidity, so the potential cooling effect of evaporative cooling is greater in arid regions, although the availability of water could be limiting. Evaporative cooling can provide comfortable conditions most of the time in most parts of the world (see Harvey, 2006). A number of residential evaporative coolers are on the market in the United States. Energy is required to operate the fans, which draw outside air through the evaporative cooler and directly into the space to be cooled, or into ductwork that distributes the cooled air. Simulations for a house in a variety of California climate zones indicate savings in annual cooling energy use of 92–95%, while savings are somewhat less (89–91%) for a modular school classroom (DEG, 2004). Evaporative cooling has been widely used in western China (such as XinJiang and Gansu Provinces) and some regions in India. It can provide very good cooling for office buildings, hotels, and shopping malls with outdoor temperatures as high as 38°C. As the energy savings would be much less in humid climates, a better approach is to enhance the evaporative cooling capacity using desiccants, as described later.

Underground Earth Pipe Cooling

Outside air can be drawn through a buried coil, cooled by the ground, and used for ventilation purposes. Simulations by Lee and Strand (2008) indicate that earth pipes can meet 70% of the June-August cooling load in Illinois and 65% in Spokane, Washington. The performance of such a system can be characterized by the ratio of the rate of heat removal by the air exchange to the power used by the fans – analogous to the coefficient of performance (COP) of a heat pump or air conditioner. The measured COP of a ground loop for a building in Germany is 35–50 (Eicker et al., 2006). Argiriou et al. (2004) built and tested an earth pipe that was coupled to a photovoltaic array on a building in Greece that directly powers a 370W DC motor, thereby avoiding the need for DC to AC conversion normally associated with PV power. The fan speed increases as the incident solar radiation increases, matching the need for increased cooling. The measured average COP (based on DC power output) was about 12. In climates with warmer mean annual temperatures, the ground temperature will be warmer, so the benefits of earth pipe cooling will be smaller.

Water can also be circulated through underground pipes and pre-cooled or pre-heated. This is ideal in conjunction with radiant floor heating or radiant ceiling cooling, and has been used in Europe, usually with a heat pump to enhance the heat extraction from or transfer to the ground.

17 Wet bulb temperature is a type of temperature that reflects the physical properties of a system with a mixture of a gas and a vapor, usually air and water vapor. It is the lowest temperature that can be reached by the evaporation of water only (Hart & Cooley Inc. 2009)

Desiccant Cooling and Dehumidification

Solid or liquid desiccants[18] can be used to remove moisture from air, with the desiccant subsequently regenerated using solar thermal heat such as can be provided by flat-plate solar thermal collectors. Desiccants combined with conventional heating for regeneration are sometimes used in supermarkets today, where their substantial drying capacity is an advantage over traditional dehumidification techniques. If the air is over-dried, evaporative cooling can be used to bring the air temperature close to the desired final temperature, with only supplemental cooling with mechanical air conditioners. Heat is required to regenerate the desiccant. A great advantage of desiccant cooling systems is that they avoid overcooling the air and then reheating it for dehumidification purposes. However, the COP of a desiccant system is typically only about 1.0, compared to typical values of four to six for electric chillers, so primary energy use may increase or decrease, depending on the efficiency of the electric power plant that supplies the displaced electricity and the extent of overcooling. However, in the hot and humid climate of Hong Kong, solid desiccant systems can reduce overall energy use for cooling and dehumidification by 50% if solar thermal energy is used for regeneration of the desiccant (Niu et al., 2002).

Passive heating techniques

Passive heating refers to the simple absorption of solar radiation inside a building, preferably by elements with a high thermal mass such as stone walls or concrete walls and floors, thereby minimizing overheating during the day and providing the opportunity to slowly release heat at night. Passive heating can occur directly, through absorption of solar radiation within the space to be heated, or indirectly, through thermal mass located between the sun and living space.

10.4.3.5 Heating equipment

Commercial buildings, multi-unit residences, and many single-family residences, especially in Europe, use boilers that produce hot water or, in some exceptional cases, steam, that is circulated, generally through radiators. Efficiencies (ratio of heat supplied to fuel use) range from 75% to 95%, not including distribution losses. Modern residential furnaces, which are used primarily in North America and produce warm air that is circulated through ducts, have efficiencies ranging from 78% to 96%, again not including distribution system losses. Old equipment tends to have an efficiency in the range of 60–70%, so new equipment can provide substantial savings. Space heating and hot water for consumptive use, e.g., showers, can be supplied with heat from small wall-hung boilers with an efficiency in excess of 90%.

Heat pumps are another option for heating. They transfer heat from something that is relatively cold, such as the outdoor air, ground, or outgoing exhaust air, to the warmer ventilation air or hot water heating system. They make very effective use of electricity, as the ratio of heat supplied to electricity used (the COP) is at least three for ground source heat pumps and at least six to seven for exhaust air heat pumps (Halozan and Rieberer, 1997). Heat pumps provide one means of decarbonizing building heating, once the electric grid itself is decarbonized. If a building has a high performance thermal envelope, so that it loses heat very slowly when the heating system is turned off, heat pumps – like air conditioners – can serve as a dispatchable electricity loads that can, to some extent, be turned on and off to match variations in wind or solar generated electricity supply.

State-of-the-art biomass pellet boilers, with efficiencies of 86–94%, are another option for heating with renewable, carbon-neutral energy.

10.4.3.6 Heating, Ventilation, and Air Conditioning (HVAC) Systems

In the crudest HVAC systems, heating or cooling is provided by circulating enough air at a sufficiently warm or cold temperature to maintain the desired room temperature. The volume of air circulated in this case is normally much greater than what is needed for ventilation purposes, in order to remove contaminants and provide fresh air. The energy required to transport a given quantity of heat or coldness by circulating water is 25–100 times less than the energy required by circulating air. Thus, by using chilled or hot water for temperature control and circulating only the volume of air needed for ventilation purposes – that is, separating the ventilation and heating or cooling functions – considerable energy savings are possible. This is a system level change.

With regard to residential buildings in cold climates, distributing heat by circulating warm water rather than warm air can reduce the energy used to distribute heat by a factor of 10 to 15 and eliminates the infiltration of outside air through pressure differences induced by unbalanced airflow in ductwork (Harvey, 2006; see also Chapter 4). In radiant floor systems, the entire floor serves as a radiator by circulating warm water through pipes embedded in the floor. In this way, heat can be delivered at the coolest possible temperature – at 30°C rather than at 70–90°C – which improves the efficiency of furnaces or boilers and especially improves the efficiency of heat pumps. It would also improve the efficiency of district heating and cogeneration systems by allowing a lower temperature of the hot water provided to such systems. Ventilation requirements can then be met with a much smaller airflow that, during heating or cooling seasons when windows are closed, is circulated with fans. Heat exchangers allow 80–95% of the heat in the outgoing exhaust air to be transferred to the incoming fresh air.

In commercial buildings, three features of advanced HVAC systems with significant energy savings potential are (1) chilled ceiling cooling, (2) displacement ventilation, and (3) demand-controlled ventilation. Chilled ceiling (CC) cooling, which was pioneered in Europe in the 1980s, involves circulating water at a temperature of 16–20°C through radiant

18 A desiccant is a substance that induces or sustains a state of dryness (desiccation) in its local vicinity in a moderately well-sealed environment. In this context desiccants are used to dehumidify air in a physical or chemical way rather than through air conditioning.

panels that cover a large fraction of the ceiling area, or through hollow concrete ceiling slabs. Stetiu and Feustel (1999) carried out simulations of buildings with all-air and combined air/CC cooling systems for a variety of climates in the United States, assuming the same rate of intake of outside air for the two cases. They found that radiant cooling reduces energy use by an amount ranging from 6% in Seattle to 42% in Phoenix. The savings are smaller in hot-humid or cool-humid climates than in hot-dry climates because relatively more of the total air conditioning energy is used for dehumidification, which is not affected by the choice of all-air versus air/CC chilling.

In displacement ventilation (DV), fresh air is introduced from many holes in the floor at a temperature of 16–18°C, is heated by heat sources within the room, and continuously rises and displaces the pre-existing air. Compared with conventional ventilation systems, which rely on the turbulent mixing of air from ceiling outlets, the required airflow is reduced because of the greater ventilation effectiveness of a given air flow. DV, like CC cooling, was first applied in northern Europe. By 1989, it had captured 50% of the Scandinavian market for new industrial buildings and 25% for new office buildings (Zhivov and Rymkevich, 1998). In a system where most of the cooling is done with chilled water, the airflow is reduced to that needed only for fresh air purposes, meaning that it will be completely vented to the outside and replaced with 100% fresh air after one circuit. This is referred to as dedicated outdoor air supply, or DOAS. Because the air in a DV rises from the occupants to the ceiling, and from there directly to the outside, heat picked up at ceiling level does not need to be removed by the chillers. Calculations by Loudermilk (1999) indicate that for an office in Chicago about one-third of the total heat gain – including 50% of the heat gain from electric lighting – can be directly rejected to the outside in this way. An overall savings in combined cooling and ventilation energy use of 30–60% can be achieved through a combination of DV and CC cooling (Bourassa et al., 2002; Howe et al., 2003).

Having decoupled the ventilation and heating or cooling functions of an HVAC system using some hydronic cooling method, preferably CC, one is free to vary the ventilation rate based on actual and changing ventilation requirements, rather than using a fixed ventilation rate or varying it according to some inflexible schedule. This is referred to as demand-controlled ventilation (DCV). Depending on the kind of building and occupancy schedule, DCV can save 20–30% of the combined ventilation, heating, and cooling energy use in commercial buildings (Brandemuehl and Braun, 1999).

Introducing high performance air conditioners is another way to save energy. Cooling and heating individual rooms by using air conditioners is as common in small- and medium-size non-residential buildings as in homes. The coefficient of performance (COP) – the ratio of heat removed to energy used – of package air conditioners for residential use is 4.9 for cooling, and 5.4 for heating. This COP value has significantly improved in Japan by recent technology development (Figure 10.17). In contrast,

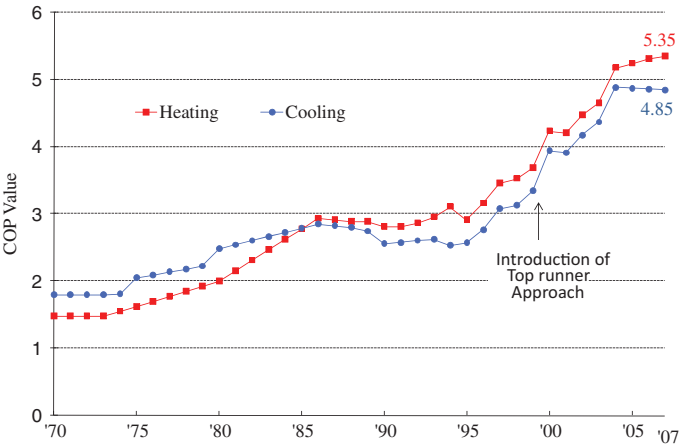

Figure 10.17 | COP values of air conditioners in Japan over time. Source: Jyukankyo Research Institute, 2007.

typical COPs of air conditioners available today in North America and Europe are 2–3.

In very humid climates, the task of air conditioning is to reduce both humidity and temperature. To remove humidity by condensing water vapor, 5–7°C chilled water is needed. However, for temperature control alone, water at 16–18°C is adequate, and this can often be obtained naturally or produced with a chiller at very high COP (up to 10). Liquid desiccants eliminate the need for producing water at 5–7°C because they can cool and dehumidify the air directly to the desired final conditions without overcooling and reheating. As noted earlier, savings of up to 50% are possible if the desiccant is regenerated with solar thermal energy.

10.4.3.7 Domestic Hot Water

The use of non-renewable energy to make hot water can be reduced by: (1) reducing the amount of hot water needed and used; (2) heating water as much as possible with solar energy using hot water panels; and (3) heating water more efficiently. Options for reducing the amount of hot water demand include using low flow showerheads (up to 50% savings), using more efficient washing machines and dishwashers, which require less water as well as less electricity, and washing using cold(er) water.

Where there are simultaneous inflows and outflows of water, as during showers, more than 50% of the heat in hot wastewater can be captured and used to preheat cold incoming water or air (Vasile, 1997).

If hot water is stored in a tank between periods when it is being used – the normal situation in North America – standby heat losses, which can account for one-third of total hot water energy use, will occur. Large losses can also occur from pipes that deliver hot water to where it is needed. These losses can be largely eliminated through

tankless point-of-use water heaters, which are common in Europe and Asia. However, electrical tankless water heaters can amplify peak electrical loads. Solar water heaters can supply 50% or more of hot water requirements in most parts of the world and require a storage tank.

Heat pumps using CO_2 as a working fluid are ideal for hot water applications, as they can more readily reach the required 55–60°C water temperature. Compared to conventional combustion type water heaters, they enable about 30% energy conservation and about 50% reduction in CO_2 emissions given the electricity mix of Japan.[19]

Finally, substantial energy savings are often possible by upgrading existing hot water boilers. Older hot water boilers have efficiencies as low as 60%, compared to 80–85% for a modern non-condensing boiler and 92–95% for a condensing boiler.

10.4.3.8 Lighting

Lighting energy use constitutes 25–50% of the total electricity use in commercial buildings in OECD countries, and about 10% in residential buildings (see Figure 10.9 and Figure 10.A.2). Lighting energy use can be reduced by 75% or more through: (1) better design of lighting systems, including provision for task lighting; (2) maximizing the use of daylight, with light and occupancy sensors to add electric lighting only as needed; and (3) use of the most efficient lighting equipment (IEA, 2006).

Advances in window technology make it possible to increase window area to up to 40–60% of wall area without increasing heat loss in winter, after accounting for solar heat gain, and with minimal impact on cooling loads in summer. Detailed measurements and/or simulations demonstrate annual savings of 30–80% from daylighting of perimeter offices in commercial buildings (Rubinstein et al., 1998; Jennings et al., 2000; Reinhart, 2002; Bodart and De Herde, 2002; Li and Lam, 2003; Atif and Galasiu, 2003). The economic benefit of daylighting is enhanced by the fact that it reduces electricity demand most strongly when the sun is strongest, which is when the daily peak in electricity demand tends to occur during summer. Daylighting can also reduce cooling loads. This is because the luminous efficacy (the ratio of light to heat) of natural light is 25–100% greater than that of electric light systems.

In retrofits of fluorescent lighting systems, 30–50% lighting electricity savings can be routinely achieved. With considerable effort, 70–75% savings in retrofits are possible. In new construction, 75% and larger savings compared to current standards can be readily achieved. These remarkable energy savings could be increased yet further through advances in the efficiency and performance of the individual components of the lighting system (described in Rubinstein and Johnson, 1998).

Light output is measured in lumens (lm), which takes into account differences in the sensitivity of our eyes to different wavelengths of light.[20] The ratio of lumens of light output to watts of energy used by a lamp is called the efficacy. At present,

- compact fluorescent lamps (CFLs) are about four times as efficacious as incandescent lamps, two to three times as efficacious as halogen infrared reflecting (HIR) lamps, and three times as efficacious as halogen lamps – all of which can be replaced in almost all applications;
- the 80-series T8 and T5 fluorescent tubes are about 60% more efficacious than T12 tubes used in old lighting and 25% more efficacious than standard (70-series) T8 tubes; and
- the ceramic metal halide lamp is about twice as efficacious as the HIR lamp, which it can replace.

Light-emitting diodes (LEDs) have the potential to be substantially more efficacious than any of the above. Commercially available LEDs currently have an efficacy of about 30 lm/W, compared to 10–17lm/W for incandescent lamps, 50 lm/W for CFLs, 105lm/W for the T5 fluorescent tubes, and up to 140lm/W for high-pressure sodium lamps. However, laboratory research LEDs have achieved an efficacy of up to 152lm/W at low current (Den Baars, 2008), and it is thought that efficacies of 150–200lm/W will be eventually achieved in commercial products. This would reduce electricity requirements by up to a factor of two compared to the best fluorescent tubes, a factor of four compared to CFLs, and a factor of 20 compared to the least efficacious incandescent lamps, which are still widely used. The effectiveness of LEDs is further improved by the fact that LEDs produce light that can be directed into only the directions where it is needed. By selective lighting, LEDs will be able to achieve energy savings compared to other lamps even before they achieve parity on a lamp-efficacy basis.

10.4.3.9 Commissioning, Control Systems, and Monitoring

Commissioning is the process of systematically checking that all of a building's systems – security, fire, life and safety, HVAC, lighting, electric, etc. – are present and function properly. It also involves adjusting the system and its controls to achieve the best possible performance. Commissioning costs about 1–3% of the HVAC construction cost, but in

19 Calculation based on 43°C quantity of hot water conversion (by Institute for Building Environment and Energy Conservation in Japan); primary energy and CO_2 emission intensity for electricity are based on Japanese Law.

20 Light is a form of energy. However, the efficiency of a lamp in producing light cannot be specified as the ratio of watts of light output to watts of electrical energy input. This is because not all watts of light are equal; our eyes are more sensitive to some wavelengths of radiation than to others.

the United States, only 5% of new buildings are commissioned (Roth et al., 2002). Consequently, the control systems never operate as intended in many buildings. Even if a building is commissioned after construction, it is important to continue adequate monitoring of the HVAC system. In a program involving over 80 buildings mentioned by Piette et al. (2001), improved controls reduced total-building energy cost by over 20% and combined heating and cooling energy costs by over 30%.

10.4.3.10 Appliances, Consumer Electronics, and Office Equipment

Residential appliances and office equipment are important uses of energy in their own right and, for office equipment and electronics in particular, can be an important source of internal heat gain that needs to be removed by the cooling system during summer from perimeter offices and year round from internal offices.

Appliances, consumer electronics, and office equipment in buildings are responsible for a large share of a building's electricity consumption and a share of natural gas use. In the United States they account for 40% of the electricity consumption and 12% of the natural gas use of buildings (US DOE, 2008; see also Chapter 1).

The energy use of most appliances used in buildings can be significantly reduced through increased equipment efficiency. Energy efficiency has increased gradually over time, as manufacturers develop new efficiency design options and incorporate them into their products as an enhancement of quality and performance.

New systems designs will reduce the energy requirements of energy services. For example, daylighting and controls or passive building shell design measures reduce the energy required for thermal comfort. Further significant reductions in energy requirements for energy services can be identified by examining specific technologies (IEA, 2008a; National Research Council, 2009). Some cross-cutting technologies offer significant promise for reducing energy use for devices providing a range of energy services. Examples include: electronics, computing and office equipment, display technologies (e.g., organic LEDs), motors (e.g., brushless DC permanent magnet rotors or variable reluctance motors), domestic refrigeration, and ceiling fans (Garbesi and Descroches, 2010). Sensors and controls for energy using devices deserve special attention, since they have many applications that can eliminate waste by limiting energy use to times and places when occupants are present and in need of the specific energy service.

Electronics and Computing and Office Equipment

Since the product life cycles of electronic products are typically months to years, much shorter than appliances or HVAC equipment, rapid improvements in energy efficiency of these products is possible. Currently, large amounts of energy are consumed while only a small capacity of devices is being utilized. Power management can reduce energy use by turning off unneeded capacity. For example, implementing sleep modes in computers can reduce power consumption by as much as 5W to 65W. Ultimately, energy use can be minimized by proxying, in which a variety of internet connected devices maintain an internet presence while in sleep mode, unlike the current situation where those devices are kept in a higher power mode only in order to remain connected to the internet (Nordman and Christensen, 2010). Servers are designed for maximum demand, and thus are usually underutilized. Virtualization involves software that allows one server to take on the functions of several, while the others reduce power. Virtualization seems applicable to 80% of servers, with potential energy savings of 70%. Computer components are also expected to become more efficient. Laptops are efficient in order to maximize battery life. Replacing desktop computers with laptop technology provides large energy savings. Replacing disk drives with solid state drives could reduce that component's energy use by 70% or more.

Display Technologies (e.g., televisions and monitors)

Energy savings of 50–70% are possible from active power management, such as controlling the brightness of display technologies based on ambient lighting, only operating in the presence of a viewer, and lower brightness for dark colors (color content). In plasma TVs, energy use can be reduced with new phosphors, improved cell design, improved gas mixtures, and optimized electronic circuits. In current TV designs, significant light loss occurs from the backlight to the viewer. Future designs may eliminate backlighting completely, using organic light emitting diodes (OLEDs) that produce light themselves, currently in use in some mobile phones. Prototypes larger than 50 inches (diagonal screen size) have been demonstrated. Alternative technologies under development include efficient electronic circuits, quantum dots, and laser display phosphors.

Motors

Motors come in many sizes and have many residential and commercial applications, making them one of the most ubiquitous components in energy-using equipment. Most motors are single-speed induction. The most efficient on the market are brushless DC permanent magnet motors (BDCPM), which avoid rotor magnetization losses and have lower heat losses, providing a secondary benefit of reduced cooling energy. BDCPM motors require less material and operate at higher efficiency when under low loads than single-speed motors. Major reductions in energy use by motors could be achieved with a BDCPM having interior magnets in the motor, advanced core design, low resistance conductors, and low friction bearings. Further savings would result by including variable speed in the design.

Domestic Refrigeration

From 1974 to 2006, electricity consumption per new top-mount refrigerator-freezers in the United States declined by 70% due to technological improvements and mandatory energy efficiency standards. Changes included using polyurethane foam instead of fiberglass for insulation, improved compressors, improved heat exchangers, and better controls. Notably, after each major efficiency improvement, new approaches

identified even further opportunities to reduce energy use. Today, the most efficient models available use 30% less energy than the maximum allowed. Research is underway on alternatives to vapor compression, including magnetic and thermo-acoustic refrigeration. The potential energy savings are not yet known.

Ceiling Fans

Fans suspended from the ceiling can provide thermal comfort in summer in some climates without compressor-driven air conditioning. Most fans have a light attached. A typical fan with a shaded pole motor has a power draw of 35W, with incandescent lighting requiring an additional 120W. An Energy Star[21] fan requires 30W, and its fluorescent lights require 30W. The most efficient model has a motor that requires 10W. A conceivable design with a DC motor, airfoil shaped blades and LED lights could draw as little as 5W for the fan, and 10W for the lights.

In large spaces, mostly commercial applications, substituting one large fan for several smaller ones results in higher efficiency. The same volume of air can be moved with larger blades at lower speed, and a more-than-linear decrease in energy use.

10.4.3.11 Energy and Greenhouse Gas Mitigation From Advanced Biomass-Based Cooking Technologies

Improved cookstoves have been disseminated since the 1980s to reduce demand for solid biomass fuels and to reduce health hazards related to cooking with open fire. Much experience was gained from early programs, which were generally not very successful. An exception is China, which put in place 250 million improved cookstoves as part of one of the largest social programs in the world. As a result of this learning process, a whole new generation of advanced biomass-based cookstoves, and dissemination approaches have been developed in the past ten years and the field is now bursting with innovations. An estimated 820 million people in the world are currently using some sort of improved cookstove (WHO, 2009). This new generation of cookstoves shows clear reductions in fuel use, indoor air pollution, and GHG emissions compared to open fires.

Innovations in the biomass cooking field relate to the: (1) technology (cooking devices); (2) dissemination approaches; and (3) monitoring and evaluation of the impacts.

Technology

Advanced biomass stoves (ABSs) for household cooking include: (1) direct combustion stoves; (2) gasifier stoves, (3) biogas, ethanol or other type of processed biomass fuels; and (4) hybrid models, which provide heat for cooking and water heating or other needs.

Direct combustion ABSs are cookstoves that directly burn biomass fuels. They include cookstoves designed to burn fuelwood, agricultural residues, and charcoal. The stoves fall typically into either portable, low-mass stoves (like the Rocket, which Envirofit disseminated in Africa and Asia, and the Darfur stove aimed at refugee camps in Africa) and high-mass chimney stoves (like the Patsari and Onil stoves disseminated in Latin America, and most of the Chinese models). These include improvements in the combustion chamber (such as the Rocket "elbow"), insulation materials, heat transfer ratios, stove geometry, and air flow (Still, 2009). Some models include a fan. As a result, combustion efficiency is greatly improved compared to open fires. The cost ranges between US$10 or less for the simpler models, to more than US$100 for the more sophisticated models. Fuel savings reach from 30% to 60%, measured in field conditions (Berrueta et al., 2008). Indoor air pollution levels are reduced up to 80–90% compared to the open fires in models with chimneys (Masera et al., 2007; Smith et al., 2007). Carbon mitigation has been estimated to range from 1–2 tCO_2-eq/yr for the simpler models, and have been measured in the field to range between 3–9 tCO_2eeq/yr for more sophisticated models such as the Patsari model in Mexico (Johnson et al., 2008).

Gasifier stoves have gone through a major development in the last five years. Stoves using wood-chips as fuel, with or without an electric blower, are commercially available in China and India (Bhattacharya and Leon, 2004). These stoves deliver 1–3kW of power with an efficiency of 35–40%. Major corporate enterprises have been involved in research and testing gasifier stoves – such as Shell and British Petroleum – and Philips is disseminating a model in India (Hegarty, 2006). Available data from lab testing indicates the potential for significant decreases in emissions of GHGs and health damaging pollutants. Programs are initially targeting urban areas, as the capital cost is still high and the stoves need pre-prepared fuel such as chips or pellets. A major challenge for their widespread dissemination so far is the need for standardizing currently used biomass into chips or pellets.

Biogas cookstoves, and stoves using other forms of processed biomass, provide clean combustion, and using animal dung as a feedstock have been disseminated worldwide, particularly in China, India, and Nepal on a large scale (Dutta et al., 1997). These cookstoves have the distinct co-benefits of enhancing the fertilizer value of the dung and serving to reduce the pathogen risks of human waste. Economic barriers include a high initial cost, which can run up to US$300 for some systems, including the digestion chamber unit. However, new designs of biogas digesters reduce the digestion time, increase the specific methane yield, and make use of alternate or multiple feedstocks, such as leafy material and food wastes. This substantially reduces the size and cost of the digestion unit (Lehtomäki et al., 2007).

Ethanol stoves have also been developed and tested in India, Nigeria, and other African countries (Rajvanshi et al., 2007). The Indian stove uses low-concentration ethanol (50%) and the Nigerian stove uses an ethanol-gel to minimize risks of explosion.

21 Energy Star means that products meet strict energy efficiency guidelines set by US Environmental Agency. Energy Star qualified ceiling fan/light combination units are over 50% more efficient than conventional units and use improved motor and blade designs (US EPA 2011).

Figure 10.18 | A stove with a thermoelectric unit includes a 2–4W power unit, which helps generate 100 lumens with a LED-based lantern. Source: BioLite, 2011.

Hybrid, or multiple-service, stoves serve multiple energy end-uses. There is currently a rapid development of these cookstoves. Commercially, stoves that provide both cooking and water heating are well established in Brazil (e.g., Ecofogao) and China (many models). A new exciting innovation is the development of thermo-electric modules, which will allow the stove's blower to generate electricity for lighting, either through CFLs or LED lanterns. Pilot units have been tested in Nepal. A modified Rocket model (Figure 10.18) shows significant improvements in stove performance as a result of the blower and is expected to sell for US$30 (BioLite, 2009).

Table 10.7 shows cooking costs for different types of stoves used in India. It can be seen that all the stoves are cheaper than LPG on an annualized cost basis. Some have high capital costs and thus need financial mechanisms or subsidies to foster dissemination.

Impact of Current Dissemination Programs

A second major innovation in the field of ABSs has to do with the production and marketing of the stoves. State-of-the-art manufacturing facilities are now in place that aim for disseminating stoves on a mass scale while at the same time assuring a quality product. Improved stoves, designed to appeal to consumers in various market segments and to be suitable for microfinance mechanisms, have been developed. As a result, several companies now produce over 100,000 stoves/yr. More than 70 stove programs are currently in place worldwide, with recently launched large-scale national programs in India and Mexico, as well as large donor-based programs in Africa.

The market for ABSs has also benefited from the recognition that using multiple fuels, rather than complete fuel switching to LPG or electricity, is the norm in many developing countries (Masera et al., 2000). Therefore, even households that already have access to LPG and kerosene continue using woodfuels, and many times an early-adopter market for ABS devices provide substantial benefits for the adopting families (Masera et al., 2000).

Overall, ABSs can provide substantial benefits in terms of energy, health, and climate change mitigation. Approximately 2.4 billion people, representing 600 million households, cook with solid biofuels worldwide. Assuming fuel savings from 30–60%, and energy use of 40 GJ/household/yr for cooking with open fires, the technical energy mitigation potential ranges from 7 to 14 EJ/yr. Also, using a unit GHG mitigation of one to four tCO_2-eq/stove/yr compared to traditional open fires, the global mitigation potential of ABSs reaches between 0.6–2.4 $GtCO_2$-eq/yr, without including the effect of the potential reduction in black carbon emissions. Actual figures will depend on renewability of the biomass used for fuel, the characteristics of the fuel and stove, and the actual adoption and sustained used of the ABS.

Future Needs

Critical needs for ABSs include increased R&D, particularly for new insulating materials, as well as robust designs that endure several years of rough use. More field testing and stove customizing for user needs is required. There is also the need for strict product specifications and testing and certification programs. Finally, it is important to better understand the patterns of stove adoption given multiple devices and fuels, as well as mechanisms to foster long-term use.

10.4.4 Incorporation of Active Solar Energy into Buildings

10.4.4.1 Key messages

Potential active solar energy systems include PV panels for generation of electricity, solar thermal collectors for production of domestic hot water, the production of hot water or heating of air for space heating, the production of hot water to operate desiccant or other thermally-driven cooling systems, and the active collection and concentration of sunlight for daylighting. PV panels on all suitable rooftops and façades of existing buildings in a range of developed countries could supply 15–60% of current total electricity demand in these countries.

10.4.4.2 Active solar technologies

The design of low energy buildings incorporates passive solar energy in many forms – passive solar heating, passive ventilation and cooling, and daylighting – and is part of the package that can achieve 75% or greater savings in overall space conditioning energy use compared to conventional local practice. This level of energy use is so low that much or all of the remaining energy demand, or even more, can be met through active solar energy features such as photovoltaic panels on roofs and façades and solar thermal collectors. Thermal energy from solar collectors can be used for space heating, domestic hot water, or solar air conditioning, the

Table 10.7 | A comparison of annualized cost of cooking energy per household.

	Capital cost (US$)	Fuel Price (US$/kg)	Annualized cost for cooking (US$/household)
Traditional stoves	1.25	0.025	30
Improved combustion stoves	25	0.025	23
Gasifier stoves	40–75	0.075	40–64
Biogas (Family unit)	300	0.0	47
LPG (subsidised)	64	0.49	65
LPG (non-subsidised)	64	0.8	100

latter either driving absorption chillers or desiccant-based dehumidification and cooling systems.

Active solar energy systems, while sometimes driving the use of off-site energy by the building to zero and even making the building a net exporter of energy, tend to be expensive at present. This is in contrast to the system level measures discussed above, which can deliver the first 75% or even more of the transition to zero-energy buildings at very low cost or even with a net savings in investment cost (as discussed below).

The potential energy generation from building integrated photovoltaics (BiPV) is large. Gutschner et al. (2001) estimated the potential power production from BiPV in member countries of the International Energy Agency, taking into account architectural suitability (based on limitations due to construction, historical considerations, shading effects, and the use of the available surfaces for other purposes) and solar suitability (restricting the useable roof and façade area to those elements where the solar irradiance is at least 80% of that on the best elements in a given location, defined separately for roof and façade elements). They estimate that 15% to almost 60% of current total national electricity demand could be provided using all available roof and façade surfaces, depending on the country. Thus, systematic incorporation of BiPV into new buildings, and into old buildings when they are renovated and whenever this is feasible, can make an important contribution to electricity supply.

PV modules typically cost between below US$2 and 5 per peak watt of output (US$2–5/$W_p$, see Chapter 11.7), with total system costs including installation typically running from US$4/$W_p$ to US$9/$W_p$ (IEA, 2008c). However, a number of studies have identified ways in which the cost of modules might eventually reach US$1/$W_p$ (Hegedus, 2006; Swanson, 2006) or even US$0.2–0.3/$W_p$ (Zweibel, 2005; Green, 2006). Keshner and Arya (2004) have presented perhaps the most aggressive scenario for future cost reductions, with an installed cost of US$1/$W_p$ or less for various thin film modules. At 5% financing over 20 years, a US$1/$W_p$ installed cost translates into an electricity cost of about US¢4/kWh for 12% efficient modules in sunny locations (2000 kWh/m^2/yr irradiance) and US¢6.7/kWh for 7% efficient modules.

BiPV provides a number of benefits beyond the mere provision of electricity. This should be taken into account in deciding whether or not to incorporate PV into a building (Eiffert,2003). These benefits include the role of BiPV as a façade element, replacing conventional materials and providing protection from UV radiation; providing thermal benefits such as shading or heating; augmenting power quality by serving a dedicated load; serving as backup to an isolated load that would automatically separate from the utility grid in the event of a line outage or disturbance; and reducing power transmission bottlenecks and the need for peaking power plants. The grid and load saving benefits to the power utility are worth about US$100–200/yr/kW of peak power produced. Inasmuch as BiPV is used as part of an aesthetic design element in a building, it can replace rather expensive building materials. The cost of PV modules ranges from US$400–1300/m^2. By comparison, the costs of envelope materials in the United States that PV modules can replace range from US$250–350/m^2 for stainless steel, US$500–750/m^2 for glass wall systems, to at least US$750/m^2 for rough stone and US$2000–2500/m^2 for polished stone (AEC, 2002).

10.4.4.2 Net-zero-energy buildings

The 'net-zero-energy building' is taken here to mean a building that generates onsite and exports to the grid an amount of electricity sufficient to offset the amount of electricity drawn from the grid at other times plus other energy (such as fuels for heating) that is supplied to the building. Requiring buildings to be zero-net-energy is not likely to be the lowest cost or most sustainable approach in eliminating fossil fuel use, and is sometimes impossible. Net-zero-energy buildings are feasible only in certain locations and for certain building types and uses.

Highly energy-efficient residential and commercial buildings have a total energy intensity of 50–100 kWh per m^2 of floor area/yr (compared to a typical value of 200–400 kWh/m^2/yr today), which corresponds to an annual average energy flow of 5.7–11.4 W/m^2. Annual average solar irradiance ranges from 160 W/m^2 (middle latitudes) to 250 W/m^2 (in the sunniest regions). If 80% of the roof area is covered with PV modules and converted to electricity with a net sunlight-to-AC electricity conversion efficiency of 10%, and 20% of the roof area collects solar energy that is converted to useful heat (which can be used for space heating, production of domestic hot water, and desiccant cooling and dehumidification) with an efficiency of 50%, the overall capture of solar energy

per unit of roof area is in the order of 30–45 W/m^2. Although additional electricity could be generated from some PV panels on the equator-, east-, or west-facing façades if shading is not an issue, total building energy demand will greatly exceed the solar energy supply in buildings that are more than a few stories high, even if the buildings are highly energy efficient. It is typically single-family or low-rise, lower-density multifamily residential neighborhoods that can become zero net energy users for their energy needs, excluding transportation. Therefore, care needs to be exercised that ill-conceived, uniform, zero-energy housing mandates do not incentivize further urban sprawl that leads to further automobile dependence and growth in transport energy use.

As discussed in Chapter 11, many forms of off-site renewable energy are less expensive than on-site PV generation of electricity, and are thus able to achieve more mitigation and sustainable energy supply from the same limited resources. Although PV electricity is currently expensive, as noted above, there are good prospects for a factor of two reduction in the installed cost of PV systems in buildings. Furthermore, PV must compete against the retail rather than the wholesale cost of electricity produced off-site. On-site production of electricity also improves overall system reliability by relieving transmission bottlenecks within urban demand centers.

In aiming for zero fossil fuel energy use as quickly as possible, an economical energy strategy would implement some combination of: (1) reduced demand for energy; (2) use of available waste heat from industrial, commercial, or decentralized electricity production; (3) on-site production of energy; and 4) off-site supply of C-free energy, taking into account all the costs and benefits and the reliability of various options.

10.4.5 Worldwide Examples of Exemplary High-Efficiency and Zero-energy Buildings[22]

10.4.5.1 Key Messages

Numerous examples exist worldwide of residential and commercial buildings that have annual energy use that is up to two to four times less than that of recently-built conventional buildings in the same jurisdictions. The most dramatic energy savings are seen in heating energy use, where many buildings have been built with heating requirements that are four times less than that for recent conventional new buildings and up to ten times less than that of the existing stock average.

10.4.5.2 Advanced Residential Buildings

Hamada et al. (2003) summarize the characteristics and energy savings for 66 advanced houses in 17 countries. For the 28 houses where the savings in heating energy use are reported, the savings compared to the same house built according to conventional standards range from 23% to 98%, with eight houses achieving a savings of 75% or better.

Several thousand houses that meet the Passive House Standard – a house with an annual heating requirement of no more than 15kWh/m^2/yr, irrespective of the climate – have been built in Europe (Passivehaus Institut, 2009). By comparison, the average heating load of new residential buildings is about 60–100kWh/m^2/yr in Switzerland and Germany, but about 220kWh/m^2/yr for the average of existing buildings in Germany and 250–400kWh/m^2/yr in central and eastern Europe (Enerdata, 2009). Thus, Passive Houses represent a reduction in heating energy use by a factor of four to five compared to new buildings, and by a factor of 10–25 compared to the average of existing buildings. Technical details, measured performance, design issues, and occupant response to Passive Houses in various countries can be found in Krapmeier and Drössler (2001), Feist et al. (2005), Schnieders and Hermelink (2006), and Hastings and Wall (2007a, 2007b), with full technical reports at www.cepheus.de.

Holton and Rittelmann (2002), Gamble et al. (2004), and Rudd et al. (2004) have shown how a series of modest insulation and window improvements can lead to energy savings of 30–75% in a wide variety of climates in the United States. In all three studies, alterations in building form to facilitate passive solar heating, use of thermal mass combined with night ventilation to meet cooling requirements, where applicable, or use of features such as earth pipe cooling, evaporative coolers, or exhaust air heat pumps are not considered. Thus, the full potential is considerably greater. Demirbilek et al. (2000) found, through computer simulation, that a variety of simple and modest measures can reduce heating energy requirements by 60% compared to conventional designs for two-story single-family houses in Ankara, Turkey.

For single-family houses in the hot and relatively humid climate of Florida, Parker et al. (1998) show how a handful of very simple measures – attic radiant barriers, wider and shorter return air ducts, use of the most efficient air conditioners with variable speed drives, use of solar hot water heaters, efficient refrigerators, lighting, and pool pumps – can reduce total energy use by 40–45% compared to conventional practices. These savings are achieved while still retaining black asphalt shingle roofs that produce roof surface temperatures of up to 82°C. Further significant reductions in cooling energy requirements can be achieved through increasing the albedo surface of roofs (Akbari et al., 2008).

10.4.5.3 Commercial Buildings

Many commercial buildings in North America, Europe, and Asia have achieved a reduction of 50% or greater in overall energy use compared to current local conventional practice. A recent survey of such buildings can be found in Harvey (2009). The National Renewable Energy Laboratory (NREL) in the United States extracted key energy-related parameters from a sample of 5375 buildings in a 1999 commercial

22 Sections 10.4.5–10.4.7 is a highly condensed discussion drawn from Harvey (2006, 2009, 2010).

buildings energy use survey. They then used energy models to simulate the buildings' energy performance (Torcellini and Crawley, 2006). The results of this exercise were as follows:

- Average total energy use as built (including thermal and electric loads) is 266 kWh/m^2/yr;
- Average energy use if complying with the ASHRAE 90.1–2004 standard is 157kWh/m^2/yr, a savings of 41%; and
- The potential average energy use in new buildings is 92kWh/m^2/yr with improved electrical lighting, daylight, overhangs for shading, and elongation of the buildings along an east-west axis, a savings of 65%.

With the implementation of technological improvements expected to be available in the future, the gross energy use is so small that PV panels can generate more energy than the buildings use, so that many buildings could serve as a net source of energy.

In the United Kingdom, the energy use guidelines indicate that energy use for office buildings is about 300–330kWh/m^2/yr for standard mechanically-ventilated buildings, 173–186kWh/m^2/yr with good practice (a savings of about 40–45%), and 127–145kWh/m^2/yr for naturally-ventilated buildings with good practice (a savings of 55–60%) (Walker et al., 2007).

Voss et al. (2007) presented data on the measured energy use in 21 passively cooled commercial and educational buildings in Germany. The passive cooling techniques involve earth-to-air heat exchangers (nine cases), slab cooling directly connected to the ground via pipes in boreholes or connected to the groundwater (nine cases), and some form of night ventilation (16 cases), along with a limited window-to-wall ratio (0.27–0.43) and external sun shading. The buildings also have a high degree of insulation and many have triple glazed windows. Nine of the buildings have total onsite energy use of 25–55kWh/m^2/yr and 10 had 55–110kWh/m^2/yr energy use, compared to 175kWh/m^2/yr for conventional designs, so the rate of savings is up to a factor of seven. Three buildings have a heating energy use less than 20kWh/m^2/yr and eight have a heating energy use of 20–40kWh/m^2/yr, compared to a typical heating energy use of 125 kWh/m^2/yr.

In north China, represented by Beijing, typical energy demand of high standard office buildings is 60–80kWh/m^2/yr for heating and 30–100 kWh/m^2/yr electricity for air conditioning, lighting, and plug loads. In south China, represented by Shenzhen, energy demand is 60–120kWh/m^2/yr (all electricity) for all energy uses including office equipment. Design studies have also shown the feasibility of obtaining 50% savings through the use of relatively simple features in office buildings in Beijing (Zhen et al., 2005) and Malaysia (Roy et al., 2005). The measures in both cases involve insulation, shading, advanced windows, energy efficient lighting, and, in the Beijing case, natural ventilation. But measures such as displacement ventilation, chilled ceiling cooling, and desiccants were not considered, so the potential savings are even larger.

The Energy Base building in Vienna, illustrated in Figure 10.19, is another example of energy use in good practice. The glazing on the south façade is slightly overhanging to increase the proportion of diffuse to direct sunlight entering the room, while the incorporation of PV panels and reflective blinds enhances daylighting. In winter, the building combines solar preheating of ventilation air with heat recovery in a novel way, as illustrated in Figure 10.20. Ventilation air flows laterally from the north side to the south side of the building, then is overheated – to above the desired indoor temperature – by the space next to the glazing, which

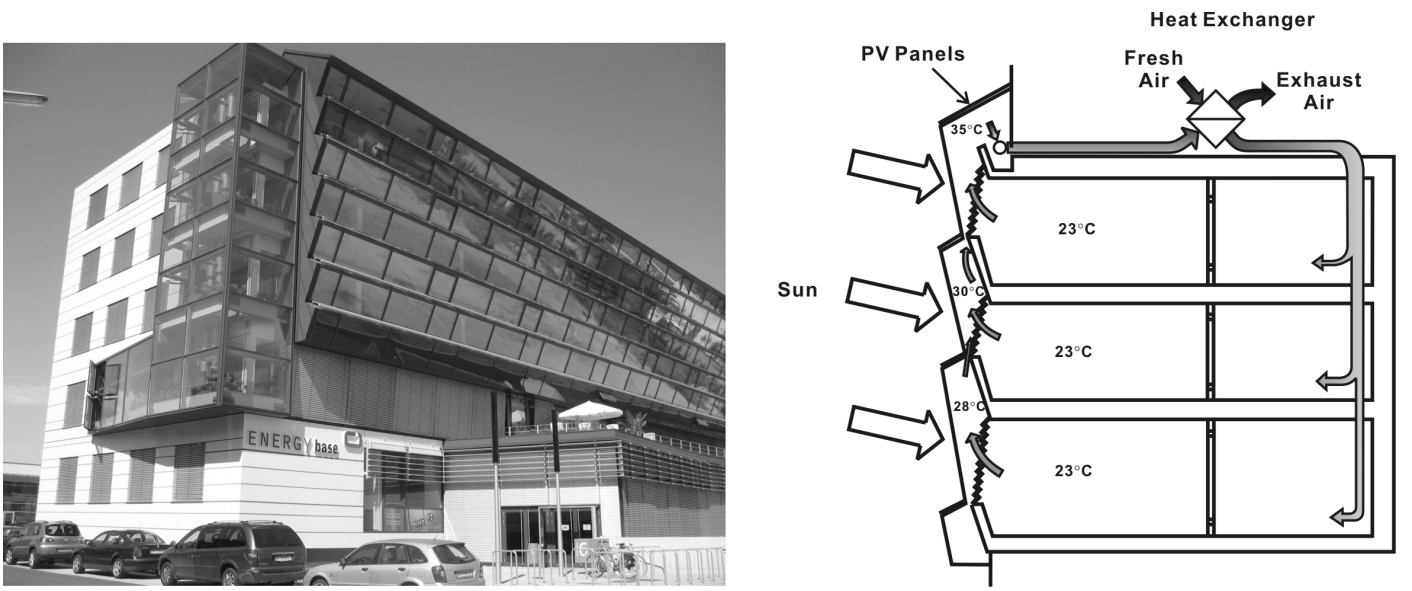

Figure 10.19 | Photograph of the energy base building in Vienna (left) and schematic diagram of the ventilation, solar-preheating, and heat recovery system (right). Source: Danny Harvey (photo); Ursula Schneider, Pos Architekton, Vienna.

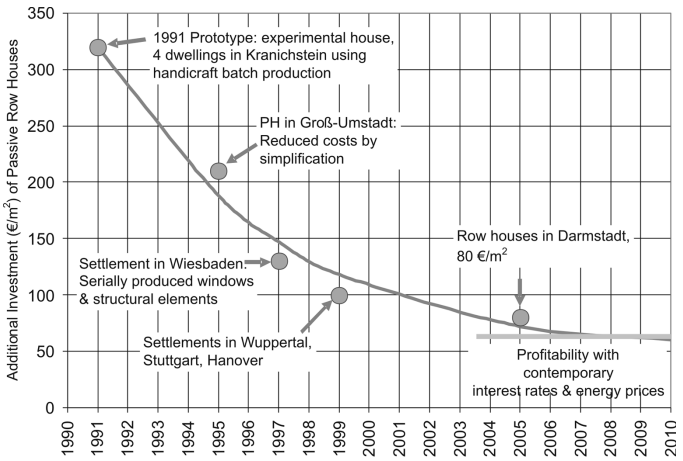

Figure 10.20 | Learning curve showing the progressive decrease in the incremental cost of meeting the passive house standard for the central unit of row houses. Source: Harvey, 2009.

functions as a solarium. This overheated air passes through a heat exchanger, where it is particularly effective in warming the incoming fresh air. At night, the system still has the benefit of heat recovery, unlike other systems for solar preheating of ventilation air. Additional heat is supplied by a ground source heat pump, which cools the ground sufficiently that the ground can be used for passive cooling (i.e., without operating a heat pump) of ventilation air during the summer. Solar regenerated desiccants are used for dehumidification during the summer.

10.4.6 Cost of New High Performance and Zero-energy Buildings

10.4.6.1 Key Messages

The additional cost of residential buildings in Central Europe that meet the Passive House standard has been steadily falling over the past two decades, and is now to the point where the additional costs are insignificant as compared to standard practice in Europe: in the range of 5–8% of the standard construction costs. In the case of high-performance commercial buildings in Europe, North America, and perhaps elsewhere, there is sometimes no additional cost or even cost savings compared to conventional buildings, because the extra cost of the high-performance envelope is offset by reduced costs for mechanical and electrical systems.

10.4.6.2 Residential Buildings

Figure 10.20 shows that in central Europe there is a progressive decline in the cost of the additional investment required to meet the Passive House standard, which uses four to eight times less heating energy than conventional new housing. Through learning, costs have fallen to the point where the incremental cost can be justified based on 2005 energy prices and interest rates. Schnieders and Hermelink (2006) report that the additional cost averaged over 13 Passive House projects in Germany, Sweden, Austria, and Switzerland is 8% of the cost of a standard house. When amortized over 25 years at 4% interest and divided by the saved energy, the cost of saved energy averages 6.2 €cent/kWh (app. 7.9 cent(US_{2005})/kWh; the range is 1.1–11 €cent/kWh – 1.4–14.1 cent(US_{2005})//kWh). This is somewhat more than the present cost of natural gas to residential consumers in most European countries, which ranges from 2–8 €cent/kWh (app. 2.7–11.1 cent(US_{2005})/kWh) (IEA, 2004). Audenaert et al. (2008) estimate extra costs of 4% for low-energy houses and 16% for Passive Houses in Belgium, having energy savings of 35% and 72%, respectively, relative to current standard houses in Belgium.

10.4.6.3 Commercial buildings

In the case of commercial buildings, the first (initial) cost of highly efficient buildings is sometimes less than the first cost of conventional buildings. This is due to the downsizing of mechanical systems that is possible in energy efficient buildings. As an example of the cost savings with advanced, energy efficient designs (Table 10.8) gives a breakdown of capital costs for commercial buildings in Vancouver, Canada, having conventional windows (double glazed, air filled, low-e with U=2.7 W/m²/K and SHGC=0.48) and a conventional heating/cooling system, and for buildings with moderately high-performance windows (triple glazed, low-e, argon filled with U=1.4 W/m²/K and SHGC=0.24) and radiant slab heating and cooling. The high performance building is 9% less expensive to build than a comparable conventional building, while using about half the energy.

Larger energy savings can cost less than smaller energy savings, as indicated by a survey of the incremental cost and energy savings for 32 buildings in the United States by Kats et al. (2003). These buildings meet various levels of the Leadership in Energy and Environmental Design (LEED) standard. Summary results are given in Table 10.9. The energy savings are broken into reductions in gross energy demand and reductions in net energy demand including on-site generation – by, for example, PV modules – which tends to be expensive. The cost premium is the total cost premium required to meet the various LEED standards and so includes the cost of non-energy features as well. Nevertheless, average incremental costs are less than 2% of the cost of the reference building and are smaller on average for buildings with 50% savings in net energy use than for buildings with 30% savings.

Measured performance information on ten buildings in the German SolarBau program where at least one year of data were available by 2003 is given in Wagner et al. (2004). Five of the ten buildings achieved the 100kWh/m²/yr primary energy target, compared to 300–600 kWh/m²/yr for conventional designs, but no building used more than 140 kWh/m²/yr of primary energy. Additional costs are reported to be comparable to the difference in cost between alternative standards for interior finishings.

The final example presented of the beneficial economics of energy efficient buildings is one of the first buildings to be built on the new Oregon

Table 10.8 | Comparison of component costs for a building with a conventional VAV mechanical system and conventional (double-glazed, low-e) windows with those for a building with radiant slab heating and cooling and high-performance (triple-glazed, low-e, argon-filled) windows, assuming a 50% glazing area/wall area ratio.Prices given in 2001 Canadian dollars.

Building Component	Conventional Building	High-performance Building
Glazing	$140/m^2	$190/m^2
Mechanical System	$220/m^2	$140/m^2
Electrical System	$160/m^2	$150/m^2
Tenant Finishings	$100/m^2	$70/m^2
Floor-to-floor Height	4.0 m	3.5 m
Total	**$620/m^2**	**$550/m^2**
Energy Use	180 kWh/m^2/yr	100 kWh/m^2/yr

Health and Science University, River Campus, and completed in 2006. This 16-story building is expected to achieve an energy savings of 60%, with a reduction in total construction costs of US$3.5 million out of an original budget of US$145.4 million and an operating cost savings of US$600,000/yr (Interface Engineering, 2005).

10.4.7 Renovations and Retrofits of Existing Buildings

10.4.7.1 Key messages

Comprehensive retrofits of existing residential buildings can usually reduce energy requirements, excluding plug loads, by a factor of at least two, with savings in heating energy requirements, which is the dominant energy use in cold climates, by up to a factor of ten. There are many examples of residential buildings, especially multi-unit residential buildings, which have been retrofitted to meet the Passive House standard. Fifty to 70% or more savings in non-plug energy use have been achieved through retrofits of commercial buildings throughout the world.

10.4.7.2 Residential Buildings

Energy use of residential buildings can be reduced through, among other things, upgrading windows, adding internal insulation to walls during renovations, adding external insulation to walls, adding insulation to roofs at the time that roofs need to be replaced, and through taking measures to reduce uncontrolled exchange of inside and outside air and introducing controlled ventilation with heat recovery. Some examples of modest retrofit measures and the corresponding energy savings are:

- the sealing of ductwork alone in houses in the United States saves an average of 15–20% of annual heating and air conditioning energy use (Francisco et al., 1998);
- retrofits of 4003 homes in Louisiana, including the switch from natural gas to a ground source heat pump for space and water heating, eliminated natural gas use and still decreased electricity use by one-third (Hughes and Shonder, 1998);
- an upgrade of multi-unit housing in Germany using, among other measures, External Insulation and Finishing Systems (EIFSs) achieved a factor of eight reduction in heating energy use;
- an envelope upgrade of an apartment block in Switzerland reduced the heating requirement by almost a factor of three (Humm, 2000);
- retrofits of houses in the York region of the United Kingdom reduced heating energy use by 35% through air sealing and modest insulation upgrades, while a 70% savings was projected with more extensive measures (Bell and Lowe, 2000); and
- a comprehensive retrofit of an old apartment block in Zurich, including the replacement of the roof, achieved an 88% savings in heating energy use measured over a two-year period (Viridén et al., 2003).

There are many examples where old buildings that have been retrofitted to very high energy performance standards. Table 10.10 includes cases where 90% or more savings in heating energy use have been achieved. A striking example is the retrofit of a ten-story panel

Box 10.2 | The Solanova Project

The SOLANOVA (Solar-supported, integrated eco-efficient renovation of large residential buildings and heat-supply-systems) project of the European Commission began in January 2003 (see www.solanova.eu). The project goal was to provide best-practice examples of the renovation of large residential buildings in Eastern Europe which, at present, are being renovated with only minimal improvements in energy intensity. In 2005, one seven-story panel building in the Hungarian town of Dunaújváros was renovated as part of this project. Heating energy demand decreased from 220 kWh/m^2/yr before the retrofit to a measured demand of 30 kWh/m^2/yr over a two-year period (a reduction of 86%). Overheating in the summer was one of the worst characteristics of the original building, so triple-glazed windows with an internal Venetian blind were installed on the south- and west-facing walls, resulting in a dramatic reduction in solar heat gain through the windows. Mechanical ventilation was provided to each individual flat with a real heat recovery of 82%. The investment cost was 240 €/m^2 + VAT. The time to pay back the initial investment, based on energy-cost savings only and at current energy prices, is 17 years. However, an unattractive and uncomfortable building was turned into an attractive and comfortable building at the same time. In Eastern Europe, about 100 million people live in large panel buildings, but results demonstrated in Dunaújváros can be transferred to the large stock of Western European panel buildings as well.

Table 10.10 | Documented examples of deep savings in heating energy use through renovations of buildings.

Building and Location	Year Built	Year Renovated	Energy intensity (kWh/m^2/yr)		
			Before	*After*	*Metric*
Apartment buildings in Ludwigshafen, Germany	1950s	2001	250	30 (m)	System
Villa in Purkersdorf, Vienna, Austria	Late 19th century	2008	---	20 (m)	System

[a] Adjusted to an indoor temperature of 20°

building in the Hungarian town of Dunaújváros, of which hundreds of thousands of this similar type building exist in Eastern Europe and the former Soviet Union (see Box 10.2). Various studies indicate that the energy demand in old buildings in western Europe (EU-15) can be reduced by more than 50% with no additional cost over a thirty-year lifetime, and by up to 85% in new countries of the EU-27 (Petersdorff et al., 2005a, 2005b). Today's advanced solutions do not even need to compromise aesthetics: for instance, several historic and heritage buildings have also been already retrofitted to passive house standards.

In apartment buildings with balconies, the balcony slabs are a conduit for heat loss. Glazing the balconies so that they serve to preheat ventilation air, and integrating the balcony with the ventilation system of the apartments, can turn a thermal liability into an asset. Other solar options are transpired solar air collectors over vertically extensive equator facing walls, transparent solar insulation, construction of a second (glass) façade over the original façade, and installation of conventional solar air thermal collectors. Savings of 60–70% in old (per-1950) buildings and 30–40% in new (1970 or later) buildings in Europe have been obtained these ways (Boonstra et al., 1997; Haller et al., 1997; Voss, 2000).

A number of single-family and multi-unit residential buildings have been upgraded to the Passive Standard in Europe. In the case of an old detached house (Haus der Zukunft, 2006) the renovation reduced the heating energy use from 280kWh/m^2/yr to 14.6 kWh/m^2/yr at 16% greater cost than a conventional renovation, but the impact of the extra cost on mortgage payments is less than the energy cost savings. In the case of a 50-unit residential building (Haus der Zukunft, 2007), heating energy use was reduced from 179kWh/m^2/yr to 13.3kWh/m^2/yr at 27% greater renovation cost.

10.4.7.3 Commercial Buildings

Measures that can be taken to reduce energy use in existing commercial buildings include upgrades to the thermal envelope such as the reduction in air leakage, or the complete replacement of curtain walls, the replacement of heating and cooling equipment, the reconfiguration of HVAC systems, the implementation of better control systems, lighting improvements, and the implementation of measures to reduce the use of hot water. The quantitative savings from specific measures depend on the pre-existing characteristics, climate, internal heat loads, and occupancy pattern for the particular building in question. However, large (50–70% or more) savings in energy use have been achieved through retrofits of commercial buildings throughout the world.

Examples of savings achieved through relatively simple measures are:

- projected savings of 30% of total energy use in 80 office buildings in Toronto through lighting upgrades alone (Larsson, 2001);
- realized savings of 40% in heating, cooling, and ventilation energy use in a Texas office building through the conversion of the ventilation system from constant airflow to variable air flow (Liu and Claridge, 1999);
- realized savings of 40% of heating energy use through the retrofit of an 1865 two-story office building in Athens, where low energy was achieved through some passive technologies that required the cooperation of the occupants (Balaras, 2001);
- projected savings of more than 50% of heating and cooling energy for restaurants in cities throughout the United States by optimizing the ventilation system (Fisher et al., 1999);
- projected 51% savings in cooling and ventilation energy use in an institutional building complex in Singapore through upgrades to the existing system (Sekhar and Phua, 2003);
- realized savings of 74% in cooling energy use in a one-story commercial building in Florida through duct sealing, chiller upgrade, and fan controls (Withers and Cummings, 1998);
- realized fan, cooling, and heating energy savings of 59%, 63%, and 90%, respectively, at a university in Texas, roughly half due to a standard retrofit and half due to adjustment of the control system settings to optimal settings (Claridge et al., 2001);
- average realized savings of 68% in natural gas use after conversion of ten schools in the United States from non-condensing boilers producing low pressure steam to condensing boilers producing low temperature hot water, and an average savings of 49% after conversion of ten other schools from high to low temperature hot water and from non-condensing to condensing boilers (Durkin, 2006);
- projected savings of 30–60% in cooling loads in an existing Los Angeles office building by operating the existing HVAC system to make maximum use of night cooling opportunities (Armstrong et al., 2006);
- projected savings of 48% from a typical 1980s office building in Turkey through simple upgrades to mechanical systems and replacing existing windows with low-e windows having shading devices, with an overall economic payback of about six years (Çakmanus, 2007); and
- projected savings of 36–77% through retrofits of a variety of office types in a variety of European climates, with payback periods generally in the one to 30 year range (Hestnes and Kofoed, 1997, 2002; Dascalaki and Santamouris, 2002).

It should be emphasized that comprehensive retrofits of buildings are generally done for many reasons in addition to reducing energy costs. Thus, measures that are extensive enough to significantly reduce energy use may not pay for themselves in terms of energy cost savings alone, but may be feasible when complementing the regular renovation cycle of the building. In addition, accelerated retrofits may make economic sense if done to capture other non-energy benefits such as improved comfort or productivity, energy security, reduced greenhouse gas emissions, and increased employment (Ürge-Vorsatz et al., 2010).

A significant potential area for reduced energy use in existing buildings is through the replacement of existing curtain walls or upgrades of existing insulation and windows. Given the current trend of constructing nearly all-glass buildings, yet not using high-performance glazing, replacing existing glazing systems and curtain walls will be an essential future activity if deep reductions in heating and cooling energy use are to be achieved. Recently, the curtain walls were replaced on the 24-story 1952 Unilever building in Manhattan (SOM, 2010), which indicates that it is technically possible to completely replace curtain walls on high-rise office buildings.

In the case of brick or cement façades, one option is to construct a second, glazed façade over the first to create a double-skin façade, which opens up opportunities for passive ventilation and reduced cooling loads through the provision of adjustable external shading devices. This has often been done in Europe. A North American example of the construction of a second façade over the original façade is provided by the TELUS headquarters

building in Vancouver. In this case, the second façade was constructed as part of seismic retrofitting. Construction of a second façade can also be undertaken as a measure to preserve original façades that are deteriorating due to moisture problems related to defects in original construction.

10.4.8 Professional and Behavioral Opportunities and Challenges

As shown in previous sections, energy use is profoundly affected by building design, social norms, and occupant behavior. This section draws on socio-technical studies to focus on two dimensions of the relationship between people, energy, and buildings. It describes how organizations and individuals are central to:

- providing energy efficient buildings and technologies;
- using buildings and energy using technologies in appropriate ways.

For technical solutions to affect energy use, they must be preceded by human decisions about design, purchase, installation, and use. Reducing the amount of energy used in buildings therefore depends on these factors to varying degrees.

The broader relationship between energy service demands and socio-economic factors, particularly in developing countries, is discussed in Chapter 21. This section focuses more closely on the opportunities and challenges of reducing energy used to create comfort, visibility, cleanliness, and convenience in buildings.

Delivering a global transformation to a low energy building stock raises a number of social challenges, including in the professions responsible for the built environment, wider society, and individual building owners and users. A major effort to train the construction sector workforce will be needed in all countries. Lifestyle and management practices consistent with low energy buildings will need to be encouraged. Programs will be required to deliver appropriate education, information, and advice to building designers, constructors, and users. Better feedback to users via smart meters has an important role to play, but alone it is insufficient.

10.4.8.1 Providing Energy Efficient Buildings: a Professional Challenge

Professionals and practitioners in the building industry are essential agents of the transformation towards energy efficient new builds and refurbishments. Section 10.6 sets out scenarios for the global transformation of new and existing buildings to very high efficiency standards that are currently demonstrated but not widely used. The number of buildings requiring transformation implies a huge challenge for the construction sector. This challenge is particularly difficult in the area of housing refurbishment, which is generally fragmented in small- and medium-sized enterprises. The WBCSD (2009) suggests that a new "system integrator" profession is needed to develop the workforce capacity to save energy. The United Kingdom is training domestic energy assessors to draw up Energy Performance Certificates (Banks, 2008), while the Australian government is vigorously supporting the development of a new profession of in-home energy advisors (Berry, 2009). These efforts are essential in achieving the technical potential described above.

10.4.8.2 Using Buildings and Technologies Differently: A Personal Challenge

This section addresses how people can reduce energy by using buildings and technologies differently. It considers changing lifestyles, habits, norms, and practices, and increasing awareness.

Lifestyles

Substantial reduction, and in some cases even elimination, of energy use is possible by changing lifestyle through changing energy service demands – for example, through higher building occupancies, the use of internal temperatures closer to ambient temperatures, lower lighting levels, and the natural drying of clothes. In some cases, the change can be considered a loss of energy service (or utility), rather than providing the same service more efficiently. But levels of energy service that are considered normal, or even desirable, are a function of culture and lifestyle. Varying lifestyles require varying levels of energy service, both in different societies (Wilhite et al., 1996) and within the same society (Lutzenhiser, 1993). The variation is not only dependent on cost and income, but also on cultural practices.

The threat of climate change adds a new motivation for lifestyle change and has already generated a large number of new information sources, especially carbon footprinting web tools (Bottrill, 2007). Available evidence finds this has yet to have a major effect on most consumers (Lorenzioni et al., 2007), although there is some evidence of it providing a catalyst for community-based activity (Burgess, 2003; Darby, 2006a). However, as the thermal performance of buildings improves due to technical measures, the scope increases for occupant behavior to lead to 'in use' performance deviating (in percentage terms) from 'as designed'.

There are few quantitative studies on the impact of lifestyle change on energy demand in buildings. However, those that exist show potential for modest rates of lifestyle change to produce substantial energy use reductions in the long term, through changes in the use of energy coupled with higher propensities to adopt low energy technologies. Scenarios involving this type of lifestyle change can reduce energy use in buildings by 50% from existing levels in both Japan (Fujino et al., 2008) and the United Kingdom (UKERC, 2009). Dietz et al. (2009) examined the reasonably achievable potential for near-term reductions by altered adoption and use of available technologies in homes and non-business travel in the United States. They found that the implementation of these interventions could save an estimated

20% of household direct emissions or 7.4% of US national emissions, with little or no reduction in household well-being. Similar absolute reductions are not possible in developing countries where energy service demand will grow. However, the rate of growth of energy demand in buildings can be reduced by lower demand lifestyles (Wei et al., 2007). Although lifestyles vary across any society, lifestyle change is strongly affected by social interactions (Jackson, 2009) and therefore may be affected by policy. Chapter 21 contains a further discussion of this topic.

Changing Habits, Practices, and Norms

Even without major lifestyle changes, it is possible in high consumption societies for energy demand to be reduced through minor changes in behavior and conscious control of energy use. The reduction or elimination of wasteful behaviors generally requires increased awareness.

Behavioral changes that might take place include allowing higher/lower internal temperatures within acceptable comfort levels; the better use of shutters, blinds, or other artificial or natural shading (e.g., trees) to prevent unnecessary heat gains; reducing unnecessary air change (e.g., open windows) when heating or cooling; using showers rather than baths; using low water temperatures for clothes washing; naturally drying clothes; not overfilling pans and kettles; switching off lights in unoccupied space; using off, or other low power down states, for unused electronics. Box 10.3 gives two examples in residential and commercial buildings that further highlight social and cultural dimensions of energy use.

As shown in Section 10.1.3, conditioning living space to an acceptable temperature and humidity is generally the largest use of energy. Adaptation to higher/lower internal temperatures is therefore the most important single behavioral issue. Thermal comfort is subjective, variable, and to some extent influenced by previous experience. Recent studies have shown that people in different countries consider themselves comfortable at very different temperatures; that they will accept higher temperatures in naturally ventilated buildings than in mechanically-cooled buildings; and that indoor seasonal and diurnal temperature fluctuations may not be a bad thing. Box 10.4 discusses the concept of adaptive comfort in further detail.

Box 10.3 | Encouraging Adaptive Thermal Comfort in Japan

The importance of culture in determining buildings energy use is well demonstrated by the case of Japan. Japan is one of the most affluent countries in the world, but per capita space heating thermal energy demand per degree-day (heating degree day, or HDD) is significantly lower than in most other developed countries – about 8 GJ/capita compared to an OECD average of ~20 GJ/capita at 2700 HDD (IEA, 2007b). Japanese demand for space-heating is approximately one-third of that of other developed countries.

Beyond the typically much lower per capita floor area (29 m^2 per person compared to the OECD average of 46 m^2 per person (IEA, 2007b)), the reason is that most Japanese homes do not heat the entire living space, but use a modification of a traditional method to provide thermal comfort. In traditional Japanese homes, fire pits or charcoal braziers were generally used to warm the body. The "kotatsu," a direct body-warming apparatus unique to Japan, was common in Japanese houses. A kotatsu is a low table covered with a futon (a heavy quilted cover) placed on a tatami (floor mat). The inside of the futon is warmed by an electric heater attached to the bottom surface of the table. People sitting on the tatami put their feet under the table for direct body warmth. People can live comfortably in a room using a kotatsu even if the room air temperature is low; in many cases, rooms equipped with a kotatsu are heated only to a low temperature, or no heating is used at all. According to a detailed survey of residential energy use, the annual energy use of a house that uses a kotatsu as the main heating apparatus is approximately 40% less than the average use of all the houses studied (Sugihara et al., 2003). Over recent years, Japanese residences have been changing from a low-energy direct body-warming system such as kotatsu to a space heating system. This is one reason why energy use in the Japanese residential sector has been increasing.

Another example of a non-technological measure to reduce energy use is the Japanese "Cool Biz" program. Recognizing the fact that thermal comfort is highly dependent on clothing, which in turn is often determined by culture and dress codes, Japan attempted to change its existing dress code culture to a more sustainable one. In 2005, the Japanese Ministry of the Environment (MOE) promoted office building air conditioning settings of 28ºC during summer. As a part of this campaign, MOE has been promoting a new standard for summer dress codes, "Cool Biz," to encourage business people to wear cool and comfortable clothes to work in summer rather than the traditional multi-layered, heavy and dark standard attire that often results in air conditioners having to be set to low temperatures. MOE estimated that CO_2 emissions had been reduced by approximately 460 thousand tonnes as a result of the campaign. MOE will continue to promote Cool Biz and higher summer temperatures in offices (MOE, 2006).

Box 10.4 | Focus on Adaptive Comfort

Warmer interior temperatures are acceptable on hot days and colder interior temperatures are acceptable on cold days, if an individual knows what to expect and is accustomed to it. In fact, surveys have shown that individuals typically find acceptable indoor temperatures to be several degrees lower in the heating season than in the cooling season (de Dear and Brager, 1998). The psychological adaptation to warmer/cooler temperatures is enhanced if an individual can *control* his or her environment by being able, for example, to open or close windows, or to activate or deactivate a fan. Research in Denmark indicates that a temperature of 28°C with personal control over air speed is overwhelmingly preferred to a temperature of 26°C with a fixed air speed of 0.2 m/s (de Dear and Brager, 2002). In Thailand, Busch (1992) found that the maximum temperature accepted by 80% of survey respondents is about 28°C in air conditioned offices and 31°C in naturally ventilated offices. Despite this evidence, most air conditioned buildings are operated to maintain a temperature in the lower part of the 23–26°C range, irrespective of outdoor conditions.

Although the percentage savings from increasing the thermostat setting for air conditioning diminish the warmer the outdoor temperature, the implications are substantial. Increasing the thermostat from 24°C to 28°C in summer will reduce annual cooling energy use by more than a factor of three for a typical office building in Zurich and by more than a factor of two in Rome (Jaboyedoff, Roulet et al., 2004), and by a factor of 2–3 if the thermostat setting is increased from 23°C to 27°C for night-time air conditioning of bedrooms in apartments in Hong Kong (Lin and Deng, 2004).

Increasing Awareness

Many countries and regions now have energy efficiency agencies that promote "easy" behavioral actions (e.g., ADEME, 2009; Efficiency Vermont, 2009; EST, 2009). There are a number of approaches that are designed to assist energy users voluntarily to change their own energy using behavior by increasing their awareness of energy issues. The types of measures that fall within this category are: feedback, education, information, and advice.

a. Feedback – Billing and Metering

Feedback is the provision of information about personal energy use. This may be retrospectively with fuel bills, or in real time through metering and display technology. Reviews by Darby (2006a, 2006b) found that bills and other forms of indirect feedback can produce savings of 0–10%; savings from metering and direct feedback are typically in the range of 5–15%.The persistence of the effect is not well established. The use of smart metering for building energy management is growing. There is no agreed definition of smart metering. In some cases, programs of automated meter reading (AMR), i.e., remote meter reading, have been described in this way (Morch et al., 2007). These are already used extensively in some places, e.g., Italy, Sweden, and the Canadian province of Ontario (IBM, 2007; Haney et al, 2008) and provide clear benefits for energy suppliers through more timely and accurate information (Morch et al., 2007). Energy efficiency benefits within buildings are likely to be limited to those resulting from users making better decisions based on more accurate and frequent bills and incentives like dynamic pricing structure.

Greater involvement of building occupants demands two-way information flows. This is described as automatic meter management (AMM) or advanced metering infrastructure (AMI) (NETL, 2008). Information may be transferred through a range of communication channels, e.g., power lines, mobile phone text message, or radio, with results provided in real time within the building, e.g., via TV screens or internet (Wood and Newborough, 2003; Darby, 2008).

The costs of smart metering are expected to fall and the functionality to improve. Future technology will potentially use electrical harmonics, load profile data, and learn to identify, and feedback individual appliance consumption from aggregate meter data. A driver for smart metering is the need for smart grids to deal with the greater use of intermittent generation in low carbon electricity systems (see Chapter 11). These require electricity retailers and their customers to consider rescheduling of loads when possible, i.e., load switching or demand response measures(Hartway et al., 1999; Vojdani, 2008).This could be via building users responding to time-dependent price signals or by electricity supplier control over loads that are not time critical, e.g., cold appliances. In either case, smart meters potentially facilitate greater involvement of buildings in balancing electricity systems.

To effectively influence user behavior – whether to reduce demand or encourage load switching – information will need to be relevant and easy to assess. While the principle is clear, the exact format of the information that will be most effective is less obvious. Metrics could include energy, cost, or carbon and representations could be numeric or graphical, and could be based on comparisons with past use or other users. Different forms and levels of information will be required for professional users and householders, and may need to reflect other user differences, including culture and building type. More detailed research on the interaction between technology and behavior is required to maximize potential benefits.

b. Education

Education is mainly targeted at young people. The objective is to provide the knowledge and skills about energy use that will allow them to make informed choices as energy users. Energy and environment form part of

the curriculum in many countries, but not in all countries and not yet at adequate levels. A recent review of environmental programs around the world found that, although environmental education is growing, energy and energy efficiency are under-represented in national and international environmental educational programs (Harrigan and Curley, 2010). There is some evidence that education can be effective in the short term in influencing child and parent behavior (Heijne, 2003), but the lack of longitudinal studies makes firm conclusions about long-term impacts difficult.

c. Information

Information is the provision of material on energy saving opportunities via government campaigns, the media, and other means, including energy company billing. Information may be combined with motivational content design to change behavior, generally focusing on either cost savings or environmental benefits. There is some evidence that information from public and not-for-profit sources is more trusted and effective than from energy companies (DEFRA, 2005).

d. Advice

Advice differs from generally available information, as it targets the needs of the individual based on personal circumstances. There are a number of variants including face-to-face, telephone, and, more recently, internet-based advice systems. There is experience of this for energy use in businesses and households (Darby, 2003). Cost effectiveness of advice-oriented programs is generally very good. In one case, cost savings for consumers were 40 times the cost of the program (DEFRA, 2006b). Face-to-face advice is the most effective but least cost effective (Sadler, 2002). Much of the benefit resulting from advice leading to technical change persists longer than simple behavioral change.

10.5 Barriers Toward Improved Energy Efficiency and Distributed Generation in Buildings

10.5.1 Key Messages

Technologies and practices that are cost effective from an engineering-economic perspective are often not widely adopted in practice. The barriers include: lack of or imperfect information, transaction costs, limited access to capital, externalities, energy subsidies, risk aversion, principal agent situations, fragmented market and institutional structures, lack of feedback, administrative and regulatory barriers, and lack of enforcement. This section categorizes the barriers as financial costs and benefits, hidden costs and benefits, market failures, and behavioral, cognitive, and organizational barriers.

Solutions for the observed barriers must address many principal actors and their intermediaries and include increased education and training of professionals and consumers, improved information, pricing policies, and regulations (e.g., building codes and energy efficiency standards).

10.5.2 Introduction

The previous sections demonstrated that there is a broad spectrum of opportunities in buildings to significantly reduce energy demand without compromising the energy service delivered. This chapter attests that many opportunities offer net private or societal benefits. Subsidized energy prices (Kosmo, 1989; Lin and Jiang, 2010) and specific characteristics of the buildings sector – their occupants; agents who relate to construction, operation, maintenance, and use of buildings; and market characteristics – limit the "perfect" and "rational" energy efficiency function of buildings (de T'Serclaes, 2007). The IPCC (2007) concluded that the barriers that prevent many cost-effective energy efficiency and building-integrated distributed generation investments from being captured by market forces in present economic and political environments are especially strong in the built environment. Recent research identifies possible approaches to increase uptake of many of these opportunities (Brown et al., 2008; Brown et al., 2009; US DOE, 2010).

This section reviews barriers and solutions based on literature published since previous assessments, such as the IPCC (2007) and the World Energy Assessment (WEA) (2000; 2004). While the literature has been extensive in accounting for and explaining these imperfections, recent demands have become stronger for the quantification of these barriers to better inform private and public decision making. For instance, expenditure-based, climate change target setting, quantification of GHG reduction potentials at various cost levels, as well as several other policy goals require an understanding of the quantified importance of these barriers, the monetized impact of some of them, and an assessment of how much of these indirect costs can be prevented by policies. This section also aims to summarize quantitative estimates of these barriers so that their impacts can be incorporated into estimates of energy saving potential, in addition to incorporating co-benefits of energy efficiency (see Section 10.7). Different barriers are grouped according to typology as presented by the IPCC (2007) and summarized in Table 10.11.

10.5.3 Financial Costs and Benefits

Energy issues remain a low priority to most building owners and occupiers because energy is a relatively small part of the total costs in commercial and residential sectors (WBCSD, 2009). While other investments are subject to risk assessment, energy budgets for buildings are rarely analyzed (Jackson, 2008). Financial barriers to the penetration of energy efficiency and building-integrated distributed generation technologies include factors that increase the investment costs and/or decrease savings resulting from the improvement. These factors result in prolonging the payback time and downsizing the internal rate of return on investments. These factors include high initial costs of advanced technologies, costs associated with risks of implementation and financial operations (transaction costs), high discount rates for households and commerce,

Table 10.11 | Taxonomy of barriers that hinder the penetration of energy efficient technologies/practices in the buildings sector.

Barrier categories	Definition	Examples
Financial costs/benefits	Ratio of investment cost to value of energy savings	Higher up-front costs for more efficient equipment Lack of access to financing Energy subsidies Lack of internalization of environmental, health, and other external costs
Hidden costs/benefits	Cost or risks (real or perceived) that are not captured directly in financial flows	Costs and risks due to potential incompatibilities, performance risks, transaction costs etc.
Market failures	Market structures and constraints that prevent the consistent trade-off between specific energy-efficient investment and the energy saving benefits	Limitations of the typical building design process Fragmented market structure Landlord/tenant split and misplaced incentives Administrative and regulatory barriers (e.g. in the incorporation of distributed generation technologies) Imperfect information
Behavioral and organizational non-optimalities	Behavioral characteristics of individuals and organizational characteristics of companies that hinder energy efficiency technologies and practices	Tendency to ignore small opportunities for energy conservation Organizational failures (e.g. internal split incentives) Non-payment and electricity theft Tradition, behavior, lack of awareness, and lifestyle Corruption Lack of enforcement/implementation/monitoring

Source: Carbon Trust, 2005.

lack of or limited access to financing, cost of capital, and energy subsidies that do not allow for estimating the real energy cost savings (IPCC, 2007; de T'Serclaes, 2007).

Table 10.12 illustrates that transaction costs, high discount rates, and lack of real-time pricing are studied to the largest extent in the financial group of barriers. Based on the information available, the financial barriers are concluded to be very strong. For example, the transaction costs of energy efficiency and renewable energy projects in the buildings sector reach as high as 20% of investment costs.

Higher investment costs of efficiency technologies require significant investment in research as well as government programs to push market development further and faster. Since energy codes are relatively new in several developing nations, green products and services including insulation, CFLs and T5 lamps, efficient glass, and efficient HVAC systems – required by buildings to comply with some code requirements – are not readily and abundantly available or competitively priced.

Consolidation of the majority of global production in a handful of multinational manufacturers for each product type creates an opportunity for a well-designed set of policies, including voluntary labels, mandatory performance regulations, and financial incentives, to rapidly increase the production of energy efficient products. The energy efficiency standards and the Energy Star program for some products provide examples where most production has shifted toward higher efficiency, having several sequential updates for some products. Updating those policies and continued R&D are necessary to maintain the long-term trend in decreasing energy use and costs per product to support sustainable development in the building sector. For building retrofits, accessible mechanisms for providing information and capital are needed.

10.5.4 Market Failures

In traditional economic analysis, market failures refer to flaws in the ways that markets operate in practice compared to theoretically perfect markets. They are violations of one or more of the neoclassical economic assumptions that define an ideal market, such as rational behavior, costless transactions, and perfect information (Brown, 2001; Jaffe and Stavins, 1994). These failures are caused by misplaced incentives; administrative and regulatory barriers; imperfect information; unpriced environmental, health, social, and other external costs and benefits; fragmented market structure; and limitations of the typical building design and construction process. Decisions that result in the energy performance of buildings are fragmented, being made by building owners, architects, craftsmen, and occupants. Their motivations and opportunities for efficiency differ. Recently, social science gained new insights concerning positive drivers for efficiency and renewables – e.g., social prestige using the image of being socially responsible or "green," education, and social networking.

As Table 10.12 shows, the impacts of market failures are rarely measured, with the exception of misplaced incentives which have been covered recently by a few publications. Meier and Eide (2007) estimated that up to 100% of energy services and up to 80% of primary energy use of buildings are affected by misplaced incentives. If the barrier is removed, the energy savings, for instance for space and water heating, may reach 50–75%. The impact of administrative and regulatory barriers is difficult to measure, but researchers attest that there are a number of distorting policies against installing distributed generation (see, e.g., Brown, 2001). Methodologies exist for monetizing externalities, but final consumers have little information or incentive to undertake the level of effort required to include external costs and benefits in their decisions.

Table 10.12 | Selected barriers to GHG mitigation in the buildings sector and methodologies for their quantification in the literature.

Barriers	Case study	Methodologies used for quantification	Quantified impact of the barriers	References
Financial (including hidden) costs and benefits				
Transaction costs	World, India (IN), Sweden (SE), United Kingdom (UK), United States (US)	Empirical survey Literature review Interviews Review of official documentation Bottom-up estimates	SE: ≤ 20.5% and ≤ 14.4% of project costs for energy efficiency and renewable energy projects in buildings respectively IN: about 100 US$/t CO_2 in CDM projects targeting EE in housing sector World: ≤ 100 €/tCO_2 for CDM on EE in buildings World: €30,000 – €100,000 per JI/CDM project (almost for any project size) UK: 30% and 10% of investment costs for cavity wall insulation and CFL respectively US: information cost, vendor information cost, and consumer preferences add US$10, US$5, and US$5 respectively to the CFL price that was US$10/piece	Krey, 2005; UNFCCC, 2002;Michaelowa and Lotzo, 2005;Mundaca, 2007; Sathaye and Murtishaw, 2004; UNIDO, 2003
Limited access to capital	Australia (AU)	Case study	AU: In the case of energy efficient mortgage, stretching the credit ratio[a] by 2% allows a further 5% of loan application to succeed. However, as financial institutions frequently avoid softening the loan conditions, it may be concluded that these 5% loan application fail postponing or cancelling the intended energy efficiency projects	de T'Serclaes, 2007
Lack of real-time pricing	US, Japan (JP),Canada (CA), Netherlands (NL)	Case study on residential energy demand feedback devices Questionnaires Statistical analysis (Chi-square test)	USA: energy savings from providing real-time energy feedback is about 10–15% JP: feedback devices caused a 18% electricity saving and 9% gas saving CA: feedback displays produced electricity savings of 13% NL: daily feedback led to a 10% reduction in household gas consumption USA, CA: electricity savings totaled to 5% in Quebec and to 7% in California	Parker et al., 2006; Ueno et al., 2006; Dobson and Griffin, 1992; Van Houwelingen and Van Raaij, 1989; Hutton et al., 1986.
Behavioral: high discount rates (DR)	US, NL	Present value analyses Option value method Capital asset pricing model (CAPM) Discrete choice models Econometric models	US: DR is 5.1% – 89%/yr. in an inverse order of household income; average 20%/yr. US: DR < 15% a choice is a CFL; > 15% – an incandescent; = 15%/yr – indifferent US: DR = 21%/yr. at electricity price of 4.8 ¢/kWh; 27–28%/yr. – 6 ¢/kWh, and 30%/yr. – 7.5 ¢/kWh NL: high-efficiency durables to be bought at DR 0% – 1.4%/yr. or, in a more myopic case, 8% – 101.3%/yr.; low-efficiency durables – at DR 1.4% – 8%/yr. or, in a more myopic case,> 101.3%/yr.[b]	Hausman, 1979; Thompson, 1997; Sanstad et al., 1995; Kooreman and Steerneman, 1998

Market failures				
Market fragmentation	US	Empirical study	US: Uncaptured social returns from R&D are ≥ 50% than estimated private returns because of the fragmentation within the sector	CEA, 1995
Uncertainty in future prices	US	Economic model of irreversible investment	USA: Investment in energy efficiency under uncertainty falls from 25%/yr. to ~ 1%/yr. and is less than 5% after 20 years	Hassett and Metcalf, 1993
Misplaced incentives (principal agent problem)	US, Norway (NO), NL, AU, JP	Survey Authors' estimation Top-down analysis Case study	NO: the problem in the commercial offices affects around 80% of the energy use; energy use is ca 50 kWh/m2 higher in leased office space; the potential energy savings are 3.24 to 5.4 PJ/yr., or 15% of the total energy use in the Norwegian commercial sector US: savings from 2003 sales of water heaters would amount to 9.6 PJ/yr. of final energy and 12.6 PJ/yr. (about 7%) of primary energyuseif PA problems were solved NL: after removing the barrier, ca 20% of houses can be additionally insulated with an energy saving of 50%-75%/house for space heating (2–4 PJ/yr.) NL: The energy use affected by problems is more than 24.5 PJ per year, which accounts for over 40% of total energy use in commercial offices JP: energy use in commercial offices affected by the problem is 0–1.5% of total national electricity consumption	Meier and Eide, 2007;Ecofys, 2001;OECD/IEA, 2007
Behavioral and organizational non-optimality				
Lack of understanding	US	Case study, regression analysis, survey	US: energy savings amounted to 10% due to campaign (ca $130,000/yr.)	McMakin et al., 2002

[a] The ratio, expressed as a percentage, which results when a borrower's monthly payment obligation on long-term debts is divided by his or her net income or gross monthly income (Business Dictionary Online, 2008)

[b] Difference: more myopic consumers are more reluctant to buy EE goods (this is true for both high- and low-efficient durables). On the other hand, consumers are more myopic in case of low-efficiency durables.

Box 10.5 | Design Challenges of Efficient Buildings

In developing countries located in tropical regions, most of the residential buildings and several commercial building types are still designed as unconditioned spaces. Thus, the construction methods do not address issues of proper weather stripping, infiltration control or use of appropriate building materials, such as insulation or doubling glazing. However, changing climate and lifestyles have triggered retrofit of such buildings with window/packaged air conditioners. This leads to inefficient energy use.

Designing efficient buildings typically leads to a reduction in cooling loads and lighting loads and thus reduced sizes for installed system, with an imminent reduction of capital expenditure on systems. Typically a consultant's remuneration is a percentage of the capital cost, and thus a consultant may not be positively inclined to reduce the capital cost of a project, if there is no provision for added incentive for doing so. Designers and contractors are often slow to adopt energy efficient designs due to inertia or lack of training.

10.5.5 Behavioral and Organizational Non-optimalities

There are different behavioral and cognitive characteristics of individuals and organizational characteristics of companies that hinder energy efficiency technologies and practices in buildings. Perhaps the strongest barrier in this category is a major lack of technical, economic, and general knowledge related to low-energy buildings (see Box 10.5). This knowledge gap exists not only among building designers and architects, but also among politicians, investors, tenants, and consumers.

Beginning with the design side, there is a lack of knowledge among designers of how to best incorporate efficiency practices into building design to meet or exceed building code requirements. This is due to the novelty of energy efficiency concepts in buildings, especially in developing countries until recently. Furthermore, the capability of designers and architects to perform energy simulations to quantify the potential savings from energy efficiency is also very limited in developing countries.

Even once some efficient buildings have been designed effectively, the building construction industry is not generally prepared to apply these measures practically on site and remains largely unaware of the environmental impacts of its operations. Actual energy performance is generally not reported back to designers, builders, or contractors and they are not held accountable for inefficient designs or poor construction practices.

There are very few university programs in architecture and engineering in which curricula include energy efficiency issues in buildings. A report in the United States on workforce education and training identified 43 (of 492) higher education and/or training programs that meet minimum criteria of a specific emphasis on energy efficiency (Goldman et al., 2009). Due to the fact that courses on energy efficiency topics are not always compulsory, the number of graduates who have studied these subjects is even lower.

Insufficient education for building professionals causes the problem of ineffective communication with specialists in related fields and lower production in the construction process. Gallaher et al. (2004) estimated that the costs caused by ineffective communication between different stakeholders in the US building industry, including architects, engineers, general constructors, suppliers, owners, etc., is about US$15.8 billion. Improvement of building professionals' communication skills and ability to use modern software and electronic systems for the exchange of information can reduce such costs. In addition to the education of architects and effective communication of opportunities to consumers, an adequate trained workforce is needed to install and maintain efficient buildings and equipment. The training of a modest workforce (about 24,000 jobs) to commission non-residential buildings is expected to yield significant benefits, including US$30 billion in energy savings by year 2030 and annual greenhouse gas emissions reductions of about 340 megatonnes of carbon dioxide (Mills, 2009). Studies of energy service companies in the United States estimate the 2008 workforce to be about 120,000 person/yr equivalents (PYE), or equivalent to about 400,000 employees, and it is expected to grow by a factor of two to four by 2020, if they can overcome a number of key challenges (Goldman et al., 2010).

For designers and architects to shift their design and building practices, there needs to be a demand for efficient buildings from investors, developers, owners, and building occupants. This demand is currently low in developing countries due to several factors. There is a lack of knowledge about green investments and returns on efficient buildings. The value of energy efficient designs are underestimated by appraisers and reduced energy bills are not generally considered by mortgage lenders. Most consumers are also unaware of the comparative costs of the future operation and maintenance of buildings, and therefore they do not take building efficiency into consideration when making purchasing decisions. Because of this, most builders do not consider the future costs of operating the building during design and construction. Finally, there is a lack of awareness of the financial, environmental, and health benefits of operating buildings efficiently.

Also, many consumers are still unaware of the availability of green products and energy efficiency labeled products. With attention primarily on

purchase costs and without adequate consideration of the lifecycle costs and benefits of efficient products, the perception of higher upfront cost limits purchases of efficient products. An owner who wants to improve his or her house may find it difficult or impossible to get a proper offer from a construction firm on how to refurbish a building with a focus on the whole house and its energy efficiency.

Decisions about installing original or replacement appliances, lighting, and equipment (e.g., heating and cooling, water heating) in buildings face similar barriers. The situation is improved by the existence of energy labels, and more so by minimum energy performance standards and building codes that mandate cost-effective efficiency levels.

10.5.6 Barriers Related to Energy Efficiency Options in Buildings in Developing Countries

Table 10.12 presents an assessment of impacts of different groups of barriers on the scope or the costs of energy conservation potential. Analysis of Table 10.12 finds that the research has extensively covered only a few barriers, namely transaction costs, lack of real-time pricing, and the principal-agent problem, and only in developed countries. Table 10.12 also illustrates that studies use different indicators to measure the impacts of different barriers, making it difficult to compare these impacts or to estimate the overall aggregated effect of the barriers on energy conservation potential in the built environment and its costs and benefits. Therefore, unification of the methods is important to have a comprehensive analysis. This section attempts to look at the barriers through a regional lens.

Major barriers to energy efficiency improvements in the building sector in developing countries include lack of awareness of the importance of, and the potential for, energy efficiency improvements, lack of financing, lack of qualified personnel, and insufficient energy service levels (Ürge-Vorsatz and Koeppel, 2007). Also, negative experiences with energy efficient equipment such as in the case of some low cost CFLs that fail prematurely, can pose barriers. The biggest building market – single-family homes – is often unorganized and outside the control of local authorities. When homes are part of the informal sector, building codes or standards are not applied. In Brazil, for example, 75% of the residential sector falls under the informal category.

Subsidized energy prices are another strong barrier in many developing countries. However, these subsidies enable access to minimal energy service levels for certain population groups, which means that removing subsidies may be socially difficult and undesirable. In these cases energy efficiency programs may be especially important because improved efficiency can either reduce the need for public subsidies or enable elevated service levels and the more effective use of subsidies. In countries or regions with a lack of access to reliable energy supply, such as parts of Africa, the priority of governments may be to improve access to energy for inhabitants rather than to improve energy efficiency. In such cases, renewable energy projects and rural electrification often play a more important role for governments than energy efficiency. A scenario for implementing cost-effective efficiency for electricity in India, primarily through end-use technologies in buildings, is expected to reduce government payments of energy subsidies, to involve lower capital costs than the costs of new supply, to eliminate the chronic electricity supply shortage in a few years' time, and to improve the national economy by increasing the availability of electricity for commercial and industrial enterprises (Sathaye and Gupta, 2010).

The increased influence of western architecture, such as glass-dominant structures for commercial use, is very common in India. Being in primarily a cooling-dominant climate, this often leads to large cooling loads and hence increased energy demand. Also in developing countries, the regulatory frameworks for the implementation of energy efficiency in buildings are often inadequate. In India, for example, while there are regulations – such as environmental clearance of large construction projects by the state or central environment departments or ministries – implementation and monitoring mechanisms are inadequate.

Lack of knowledge among architects and system providers to incorporate energy efficiency is another major barrier. Energy efficiency in buildings is not taught as a part of the curriculum in most schools of architecture. Another key barrier is inadequate availability of products and services related to energy efficient buildings, which often leads to a monopoly of a few providers and thus higher costs. The absence of suitable financial products, such as low interest loans for energy efficient buildings and robust energy performance contract mechanisms to offset and/or build confidence in incremental costs, is a major barrier that hinders the penetration of energy efficiency in buildings.

10.6 Pathways for the Transition: Scenario Analyses on the Role Of Buildings in a Sustainable Energy Transition

10.6.1 Key Messages

This section presents scenarios for future regional and global energy use in the buildings sector that meet the multiple objectives outlined in the GEA. The energy demand scenarios developed here served as input to and have been harmonized with the main assumptions in the GEA transition pathways presented in Chapter 17. The scenarios demonstrate that reducing approximately 46% of final thermal energy use in buildings is possible by 2050, as compared to 2005. This is achievable through the proliferation of existing best practices in building design, construction, and operation, as well as accelerated state-of-the-art retrofits. This is attainable in concert with increases in thermal comfort, the elimination of energy poverty, economic development, and living space increases in some regions. Realization of this potential requires undiscounted

cumulative investments of approximately US$14.2 trillion (or US$18.6 trillion without technology learning) by 2050. At the same time, these costs will be substantially recovered by the approximately US$58 trillion in undiscounted energy cost savings during the same period. However, scenarios also show a great risk of lock-in effect – about 80% of thermal energy savings can be locked in the global building sector if suboptimal solutions continue to be pursued.

New appliances, IT, and other electricity using equipment also have significant potential for energy use reduction – up to 65% by 2020 in relation to the baseline – due to the worldwide utilization of present and foreseen cutting-edge technologies.

10.6.2 Description of the GEA Building Thermal Energy Use Model

Providing thermal comfort in buildings contributes significantly to global energy use, yet this energy end-use sector is also the most poorly understood one. Little data and detailed information exist related to the heating and cooling of our buildings. Consequently, few global models exist. The model in this report is a newly constructed one prepared for the GEA pathway analysis, but is built on earlier results as well as present state-of-the-art work in progress, using a novel approach.

The energy demand scenarios developed here served as input to and have been harmonized with the main assumptions in the GEA transition pathways presented in Chapter 17.

The building thermal energy use model constructed for the GEA is novel in its method, as compared to earlier global world energy analyses. It reflects a new emerging paradigm that builds on an emerging approach to building energy transformation: one that takes advantage of the fact that buildings are complex systems rather than sums of components. This holistic approach is based on a performance-oriented concept of building energy use, as opposed to a component-oriented approach. It also focuses on providing energy services rather than energy per se. Applying this approach to building energy saving potential assessment typically results in much higher energy saving potentials than earlier approaches, which do not integrate systemic opportunities or opportunities emerging through focusing on the provision of energy services. However, this approach is consistent with the empirically observed opportunities presented earlier in this report for various technologies and know-how, based on the savings that are possible by treating buildings as systems rather than as sums of separate components. Electricity use by appliances (except cooling appliances) and other plug loads is treated separately and does not require the consideration of system level savings opportunities. These energy uses (in contrast to cooling), are more complex from modeling purposes and do require the consideration of system level opportunities; thus, they have been modeled using conventional approaches in a separate module.

The following subsections describe the models of thermal energy use and electric plug loads and their results. The driving questions were:

- How large of a role can buildings play in an energy transition for sustainability?
- How far can buildings take us in mitigating climate change and addressing other energy-related challenges outlined in this report?

The scenarios presented here analyze pathways in which energy efficiency in buildings is pushed toward the state-of-the-art, but do not extend to assessing building-integrated sustainable energy generation options such as renewables, or to assessing the role of lifestyle/behavioral changes, due to time and other constraints.

They represent feasible deployment potentials (i.e., techno-economic potentials that also consider deployment constraints), assuming a very strong supporting policy framework globally. It is important to note, however, that the building scenarios share the fundamental philosophy of the GEA in that they presume the increase in the thermal energy service to satisfactory levels to all populations worldwide, i.e., they assume that fuel poverty is eliminated and sufficient thermally conditioned minimal living space is provided for all by the end of the modeling period. Originating from the nature of these end-uses, the timeframe for these projections is different. In contrast to other GEA pathways, the building scenarios only extend until 2050 since, due to the shorter lifetime and high changeability of the equipment covered, any projections beyond the midterm become extremely speculative and thus lack robustness.

10.6.2.1 Model Design and Novelty

Prior models of building energy use or mitigation opportunities have focused on individual building components or the equipment used for heating and cooling, or other end-uses and alternatives to these that can save energy. One example of a model mastering this approach is the Bottom Up Energy Analysis System (BUENAS) of the Lawrence Berkeley National Laboratory, focusing on appliance efficiency. The model projects increases in appliance – space heating and cooling systems included efficiency on total final energy use. This model was used for the plug load part of the GEA pathways. (The BUENAS model is described in more detail in Section 10.6.3.)

A new thinking has been emerging recently in building energy science and analysis that represents a shift of paradigm – a system-based, performance-based, holistic approach. This replaces the component-based, piecemeal approaches of earlier efforts. The new approach recognizes that buildings are more complex systems than just the sum of their components, and that there are many synergistic opportunities and trade-offs, too. It also recognizes that the same levels of energy performance can be obtained through different pathways – i.e., different packages of energy-efficiency measures, which gives optimal freedom

for the constructors and designer to reduce energy use in a particular set of circumstances (Laustsen, 2008).[23] This new thinking is reflected in performance-based building energy regulations – i.e., that specify building codes based on energy use per square meter useful space, or other similar complex systemic performance indicators, rather than those regulating individual building components.

Following this paradigm change, a number of countries and jurisdictions have been revising their building energy codes based on new performance-based approaches (Hui, 2002). These include building regulations in the United States, Canada, the European Union and its member states (i.e., the Energy Performance of Buildings Directive (EPBD)), and Singapore (Hui, 2002).

At the same time, building energy and climate scenario modeling related to buildings has not yet reflected this paradigm change. The GEA building pathway assessment is among the first models using the performance-based approach, and has been developed in close cooperation with the few other ongoing efforts using a similar logic for global building energy modeling (Harvey, 2010; Laustsen, forthcoming).

Another novel aspect of the present model is in that it focuses on providing energy services rather than energy per se. This is reflected in the fact that the model's end goal is to provide adequate thermal comfort for living and commercial floor spaces needed by the population, and first examines options how this can be provided with the least energy input. As a result, architectural and engineering solutions that maximize the thermal performance of buildings are emphasized, often significantly reducing, and sometimes eliminating, the heating and/or cooling load that needs to be met by energy input, even before a technological solution needs to be applied. Therefore, a focus on energy services rather than energy allows for many non-energy solutions or a larger portfolio of innovative options to reducing energy use, and thus unlocks much larger mitigation options and energy saving potential.

10.6.2.2 Modeling Logic, Structure, and Main Assumptions

As described earlier, the GEA model is grounded in a performance-based logic that considers buildings as entire complex systems and not the sum of their components. Specifically, buildings energy use is not modeled based on individual energy efficiency measures, but are computed based on marker exemplary buildings with measured, documented energy performance levels and associated investment costs. A fundamental thesis of the model is that building energy performance depends less on precise degree days (cooling and heating) and technical efficiencies of individual devices than on state-of-the-art design, construction, and operation know-how and technology packages, as well as main climate types. The total energy requirement for thermal loads is derived as the product of energy intensity and floor area, summed over all building types, vintages, regions, and climate zones. Thus, key model inputs include floor space developments and specific energy demand values for existing and replicable, economically feasible, exemplary buildings in each region and each climate zone.

The logic of the model leaves it to the creativity of the architect and energy engineers to decide how – through which technologies or design and operational measures – the state-of-the-art performance level is exactly achieved. It assumes that once the selected type of exemplary buildings have demonstrated the feasibility of a certain ambitious level of energy performance and the promise of economic viability in the respective climate and building type, such levels are broadly attainable in that particular climate zone, building type, and vintage. The model then presumes that such state-of-the-art construction and renovation becomes the standard, e.g., through strictly enforced building codes.

Each time a new building is constructed or reaches its retrofit cycle, it is assumed to reach state-of-the-art specific energy demand levels for its category and climate type, after a certain transition period. The transition period is allowed so that markets and industries have ramp-up time for large-scale deployment of exemplary building construction technologies, materials, and know-how, as well as allowing time for the needed ambitious enabling policies to be enacted and the necessary supporting institutional framework to be introduced. The model assumes ten years for this transition period, which is shown by recent literature likely to be a very conservative assumption (Ürge-Vorsatz et al., 2010; in preparation).

Separate final energy intensity levels are specified for different building types (single family (detached or attached), multifamily (four or more levels, terraced, etc.), and commercial and public buildings) in four different climate zones (warm moderate, cold moderate, tropical, and arid) in each of 11 GEA regions (North America (NAM), Western Europe (WEU), Pacific OECD (PAO), Eastern Europe (EEU), Former Soviet Union (FSU), Centrally Planned Asia (CPA), South Asia (SAS), Other Pacific Asia (PAS), Middle East and North Africa (MEA),Latin America and the Caribbean (LAC), and sub-Saharan Africa (AFR)).

The specified energy intensity levels for advanced new buildings and retrofits are based on demonstrated energy and financial performance results in each region, but energy values are adjusted upward to allow for difficulties in achieving the best-observed performance in all cases.

The model distinguishes three different categories of buildings: all three categories of buildings exist in all eleven GEA regions of the world and are then split by four climate types (for regions, climates, and the floor area model see the sections below). The model uses business-as-usual construction and demolition rates. However, as became clear in the first

23 Note that with greater flexibility for designers, the performance-based standards require using computer-based models and a deeper understanding of the building principles (Laustsen, 2008). However, there are developments in this area as well, and European Committee for Standardization (CEN) and the International Organization for Standardization (ISO) are developing international standards founded on performance-based approaches (Laustsen, 2008).

modeling runs, retrofit dynamics fundamentally determine the attainability of ambitious sustainability goals in the mid-century, so the model assumes an approximately doubled retrofit rate (i.e., 3% as opposed to the average 1.5%). This requires policy intervention. Most of the model's non-building input data, such as on GDP and population growth, urbanization, and other key macroeconomic parameters are derived from the main GEA pathway work, and as such is consistent with its assumptions on GDP and population growth, urbanization, and other key macroeconomic parameters. These are explained in Chapter 17.

The model estimates the additional investment costs needed for energy efficient construction and retrofits assumed and an estimation of the resulting energy cost savings. The cost values are calculated based on marginal expenditures as compared to standard construction and retrofit investments, while overall energy cost savings are based on comparison with a business-as-usual scenario, taking into account policies in place or in the pipeline. The overall model logic diagram is shown in Figure 10.A.4 in the GEA Chapter 10 Online Appendix.

10.6.2.3 Description of the Analyzed Scenarios

Two scenarios have been elaborated in the presented global building energy use model: state-of-the-art and sub-optimal efficiency scenarios, which are described below.

State-of-the-art Efficiency Scenario
This scenario demonstrates how far today's state-of-the-art construction and retrofit know-how and technologies can take us in meeting the GEA objectives as far as the provision of thermal comfort in buildings is considered, were they to become standard practice after a transition period. These standards are applied to all buildings in their respective categories as they are retrofitted or constructed during the modeling period, except for the small share of heritage buildings where lower efficiency levels can be achieved in renovation.

Sub-optimal Efficiency Scenario
The rationale for this scenario is to illustrate the potential lock-in effect in building infrastructure that can be caused by accelerated major policy efforts (such as the ones currently implemented by many governments and international organizations for climate change mitigation)which do not mandate sufficiently ambitious performance levels. Specifically, the scenario assumes the same accelerated renovation rates as the state-of-the-art scenario, to reflect that many countries recognize the importance of energy-efficient retrofits and energy-efficient building codes, but these accelerated retrofits and advanced new buildings are still built and renovated to far less efficient levels than are achievable according to the state-of-art scenario; thus they are referred to as "suboptimal" levels.

New buildings in this scenario are assumed to be built to the building codes for the region. Only in Western Europe (WEU) is it assumed that highly efficient buildings are being built in relatively large numbers, but the maximum fraction of these advanced building is only 5% in this scenario. Renovations are carried out to achieve approximately 35% energy savings from the stock average, as opposed to the state-of-the-art savings, which can be as high as 95% in some climate and building types, as demonstrated by best practices.

10.6.2.4 Main Assumptions and Input Data

The model's main assumptions and data sources are briefly described in the GEA Chapter 10 Online Appendix. For a more detailed description, see Ürge-Vorsatz and Petrichenko et al. (in preparation).

The world's building stock is broken into the same eleven regions as are used elsewhere in the GEA (such as Chapter 17), which are presented in the technical appendix. These are: North America (NAM), Western Europe (WEU), Pacific OECD (PAO), Eastern Europe (EEU), Former Soviet Union (FSU), Centrally Planned Asia (CPA), South Asia (SAS), Other Pacific Asia (PAS), Middle East and North Africa (MEA),Latin America and the Caribbean (LAC), and sub-Saharan Africa (AFR).

Specific Energy Demand Assumptions
Table 10.13 shows the specific energy demand figures that are used as an input to the model. It is important to note that it has been extremely challenging to arrive at these figures. Necessary statistics are rarely available, and even if they are, they contain different groupings, and thus during the regrouping new assumptions needed to be introduced. For the majority of the regions, however, experience transfer and extrapolations, combined with interviews and expert judgments, had to be applied to derive these figures. New and retrofit data represent advanced standard practice today – i.e., reflecting new building codes and relatively ambitious energy retrofits taking place as a result of support programs. Advanced new and advanced retrofit data are based on exemplary buildings for the respective climate zones, assuming that these can become standard practice from a technological and economic perspective, after sufficient learning and deployment phases, and under mature market conditions, but with some allowance for lesser performance when scaled up to the entire building stock. Figure 10.5, shown earlier, maps these values weighted by respective floor areas.

10.6.2.5 Results of the World Building Thermal Energy use Scenario Analysis

As Figure 10.1 demonstrates, if today's existing regional best practices in building construction and retrofit proliferate and become the standard, approximately 46% of global building heating and cooling final energy use can be saved by 2050 as compared to 2005 levels. This is in spite of the approximately 126% increase in floor area during the period and a significant increase in comfort and energy service levels arising

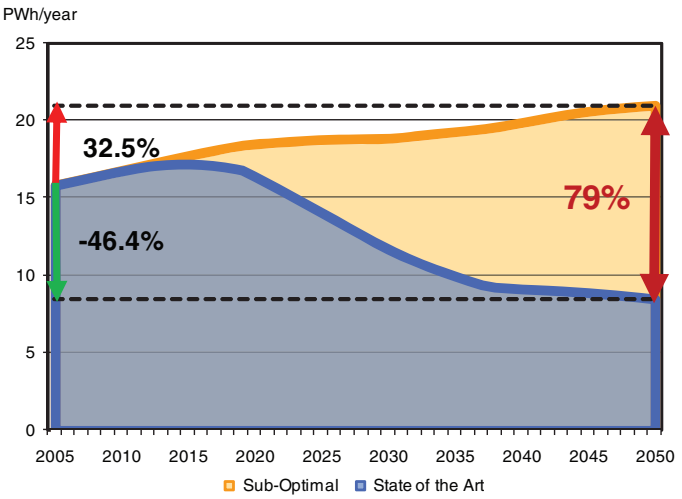

Figure 10.21 | World space heating and cooling final energy use, 2005–2050, sub-optimal and state of the art efficiency scenarios.

from a general improvement in affluence. The savings correspond to a drop from 15.8 Petawatt-hour (PWh)/yr to 8.5 PWh/yr in final heating and cooling energy use during the period. At the same time, fuel poverty is eliminated as a basic assumption, in accordance with the GEA multiple objectives.

At the same time, if similarly broad and strong efforts are invested in proliferating building codes and accelerating energy-efficient retrofits worldwide, but only suboptimal performance levels are mandated instead of the state-of-the-art ones that have been demonstrated to be feasible and economic in the particular region, global building heating and cooling final energy use will *increase* by 33% by 2050 as compared to 2005 instead of decreasing (Figure 10.21). Since buildings are constructed or renovated for very long periods, this represents a significant lock-in – 79% of 2005 total global heating and cooling final energy demand in this case – as it is not feasible or is extremely uneconomic to capture the remaining energy savings opportunities outside of renovation and construction cycles. The lock-in problem is described in more detail below.

In the state-of-the-art scenario, most regions are able to decrease final thermal energy use in buildings, with the largest drop in OECD countries (73%), followed by emerging economies (66%) (see Figure 10.22 for the five aggregate GEA regions). Even in Asia, the final energy use decreases, after an initial increase, ending 16.5% lower than in 2005. Regions in which the increase in conditioned floorspace and thermal comfort levels exceed efficiency gains are Latin America and the Caribbean, as well as the Middle East and Africa, with 15% and 71.5% increases, respectively.

The Significance of the Lock-in Effect

The model demonstrates the major risk of the lock-in effect in the building infrastructure. If present standards prevail for new construction, combined with suboptimal efficiency levels[25] for renovation, 79% of 2005 final heating and cooling energy use will be locked in by 2050, even with accelerated renovation rates. This will result in 21 PWh/yr consumption in the sub-optimal scenario – a 32.5% increase as opposed to a consumption rate of 8.5 PWh/yr in the state-of-the-art scenario.

There has not been an extensive discussion in the literature of the lock-in risk in the buildings sector. The GEA scenarios show, for the first time, the significance of strong policies that are insufficiently ambitious in efficiency targets – ones that prevail today in many developed countries. While from merely an energy savings perspective, the lock-in effect is less problematic since energy saving targets may be reached at a later stage, i.e., in the next renovation or construction cycles although some potentials will never be possible to unlock, which is more due to building structures related to urban design, plot sizing, and orientation, etc. From the climate change perspective, it is essential that buildings deliver greater energy savings in the midterm, such as 2050. Since this chapter shows that buildings are one of the lowest cost options to reach GEA objectives, including climate change, locked-in potential in buildings means that other options will need to replace building-related measures for reaching very ambitious midterm climate change goals. This may be problematic, because building-related measures come with a wide range of multiple benefits, as later sections here and Chapter 17 show, which may not be present in the case of the replacement mitigation measures at comparable costs. Also, there may not be alternative measures of such magnitude at similar cost levels.

The architecture of the suboptimal scenario is based on present efforts taking place in countries, jurisdictions, and institutions strongly committed to solving the climate problem. Many countries and multilateral international foundations and institutions recognize the importance of the building sector, and have passed improved building codes or encouraged high-efficiency or even zero-energy buildings and facilitated an acceleration of energy efficiency retrofit activities. However, in few of these cases are energy efficiency levels close to what is achievable by the state-of-the-art scenario, especially for retrofits. Therefore, the suboptimal scenario already depicts a world in which strong efforts are devoted to solving the building energy problem, and thus shows the danger with which even a well-intended path may be associated.

The lock-in problem originates from the fact that if suboptimal performance levels become the standard in new buildings or retrofits, it can either be impossible or extremely uneconomic to go back for the potentially remaining measures for many decades to come, or in some cases, for the entire remaining lifetime of the building. For instance, lower performance levels originating from suboptimal land use planning and constraints related to plot and building orientation can never be corrected in the building's life or longer. If, during a refurbishment or

25 Suboptimal renovation levels are determined for each region, climate, and building type, as shown in Table 10.2, but are typically in the 35% energy savings range where no other data were found.

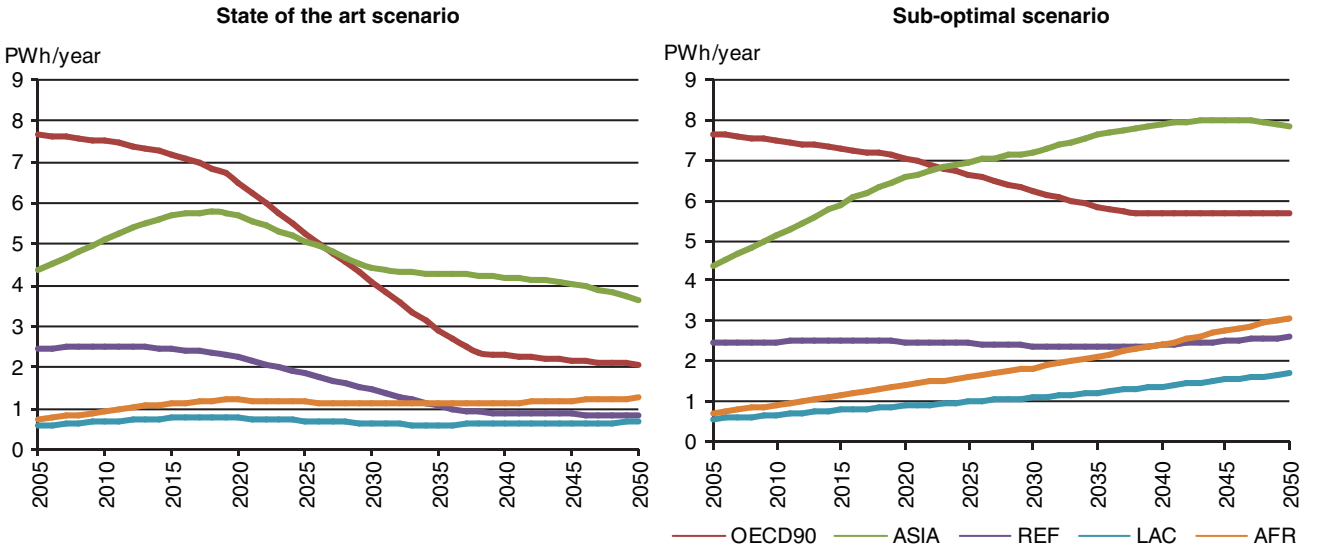

Figure 10.22 | Space heating and cooling final energy use in the five aggregate GEA regions, 2005–2050, in state-of-the-art and sub-optimal scenarios for the five regions: heating and cooling final energy use development for scenarios (i.e., assuming sub-optimal renovation and construction energy performance levels).

new construction, a holistic optimization is not followed, later installation of even the highest efficiency equipment or building materials will not be able to capture the savings otherwise attainable in a comprehensive refurbishment. For instance, heat losses and gains will still occur through other, non-optimized building parts. Finally, each retrofit is associated with significant transaction costs and inconveniences, including finding contractors, planning, preparing contracts, perhaps obtaining the financing, putting up scaffolding or other construction support structures, painting and finishing surfaces after it is done, etc. Thus, in subsequent "top-up" retrofits, energy savings are smaller and costs higher, with fixed costs comparable to those for a comprehensive, deep retrofit. As a result, going back for non-captured savings after suboptimal retrofits or new construction is typically so expensive on a specific cost, such as cost/tCO_2 saved, basis that other mitigation or sustainability measures will likely become much more attractive, whereas this is not the case if they are originally part of an integrated, deep design retrofit or construction.

Figure 10.22 shows large increases in energy demand in the suboptimal scenario for the regions of the developing world, where the ASIA region (Asia, excluding the OECD90 countries[26]) has the most pronounced increase. The results for the OECD90 countries show that there is still a decrease in total building energy demand in the sub-optimal scenario due to already gradually strengthening new building codes, less dynamically growing floor space, and actions taken toward efficient retrofits. Conversely, in ASIA there is a major increase in energy demand due to presently unsaturated thermal energy service levels and partially less ambitious building codes.

26 OECD90 comprises countries that were members of OECD in 1990.

The lock-in risk is high in all regions, in the range of 40–200% of 2050 state-of-the-art energy use, but its composition is different. The relative importance of renovation and new construction is different in each region. Figures 10.23–10.26 show state-of-the-art and sub-optimal renovation scenarios in the eleven GEA regions broken down by vintage (age) and efficiency level. In OECD, the difference in energy use is primarily due to differences in renovation efficiency levels (see Figure 10.23), while in Asia it is almost entirely due to sub-optimal performance standards in the new building stock (Figure 10.24). In regions of the world that are highly developed or had built the majority of their building stock up to 100 years ago, there is great potential to incur a future energy penalty due to the renovation lock-in effect. This occurs when there is a large part of the building stock that has been built to lower energy standards in the past and is not scheduled for demolition or a deep energy retrofit in the near term. This problem is exacerbated by the fact that buildings have a very long service life, over 150 years in some parts of Europe, and will continue to have the same energy demand until they are appropriately renovated. This points to the importance of different priorities in building-related policymaking in the different regions. In historic regions, ambitious renovation policy – consisting of accelerated renovation dynamics emphasizing state-of-the-art energy performance levels – is important, while in dynamically developing regions new building codes are paramount for achieving a low building energy future. Figure 10.23 demonstrates that retrofits are also important in the more dynamically developing regions.

The Rebound Effect and the Elimination of Fuel Poverty

The logic of the model is that when a new building is constructed it applies the average specific energy use of the new stock – either low or high efficiency – that is either based on state-of-the-art case studies or building codes, i.e., assuming full thermal comfort in the entire building. As a result,

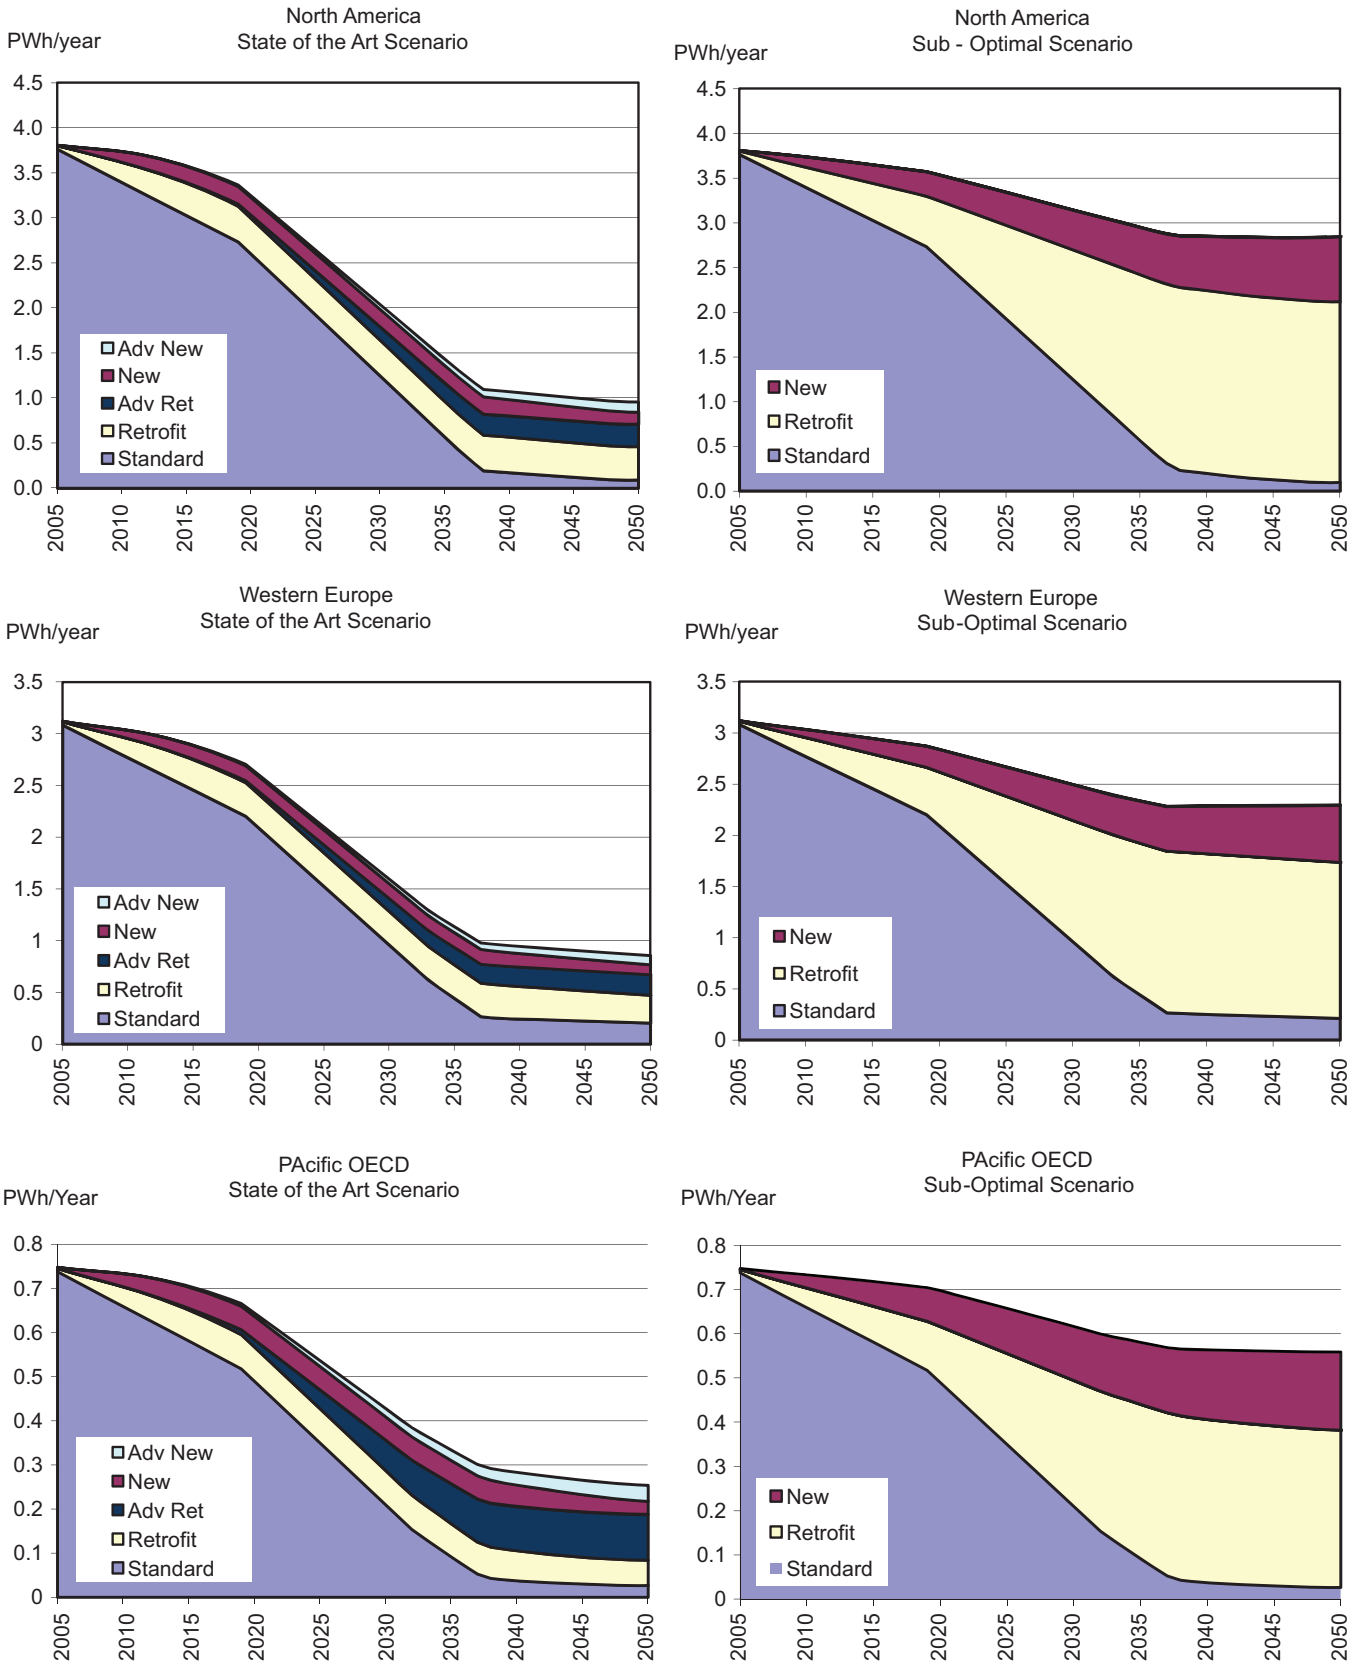

Figure 10.23 | Comparison of the two GEA building scenarios for OECD90 regions, final thermal energy use by construction type.

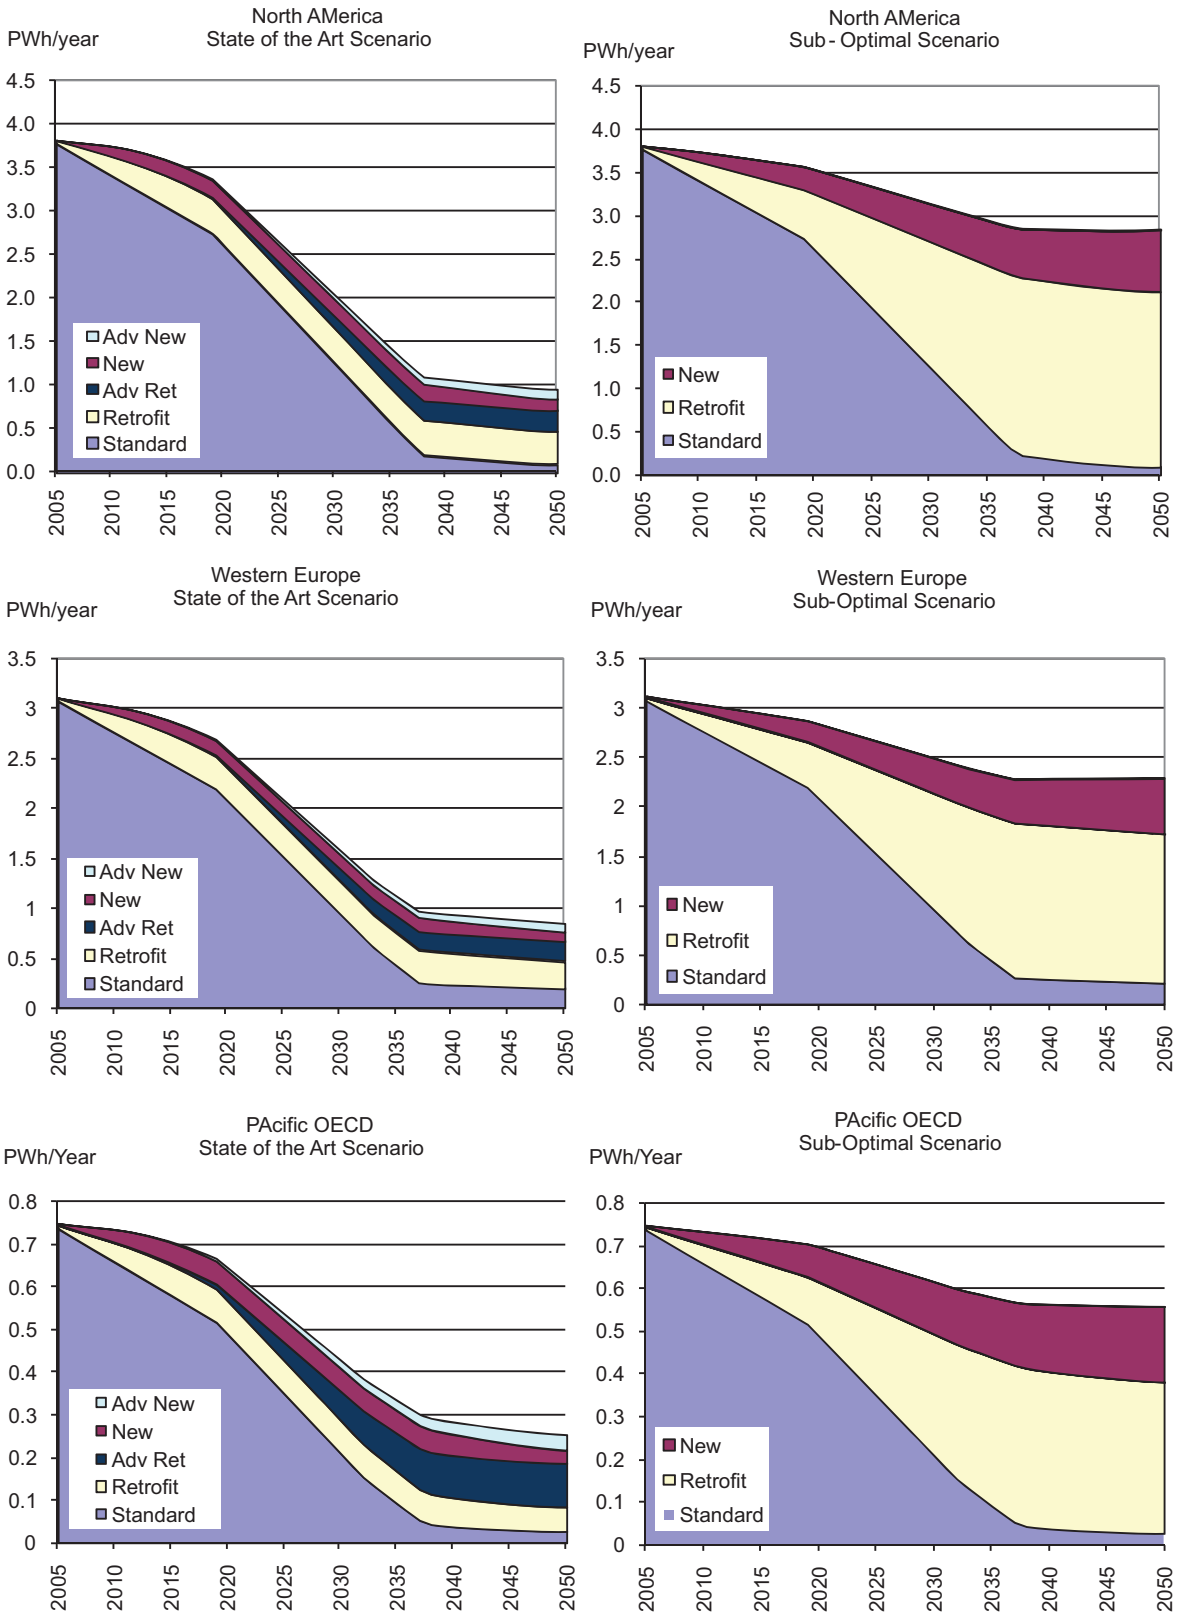

Figure 10.24 | Comparison of the two GEA building scenarios for ASIA Regions, final thermal energy use by construction type.

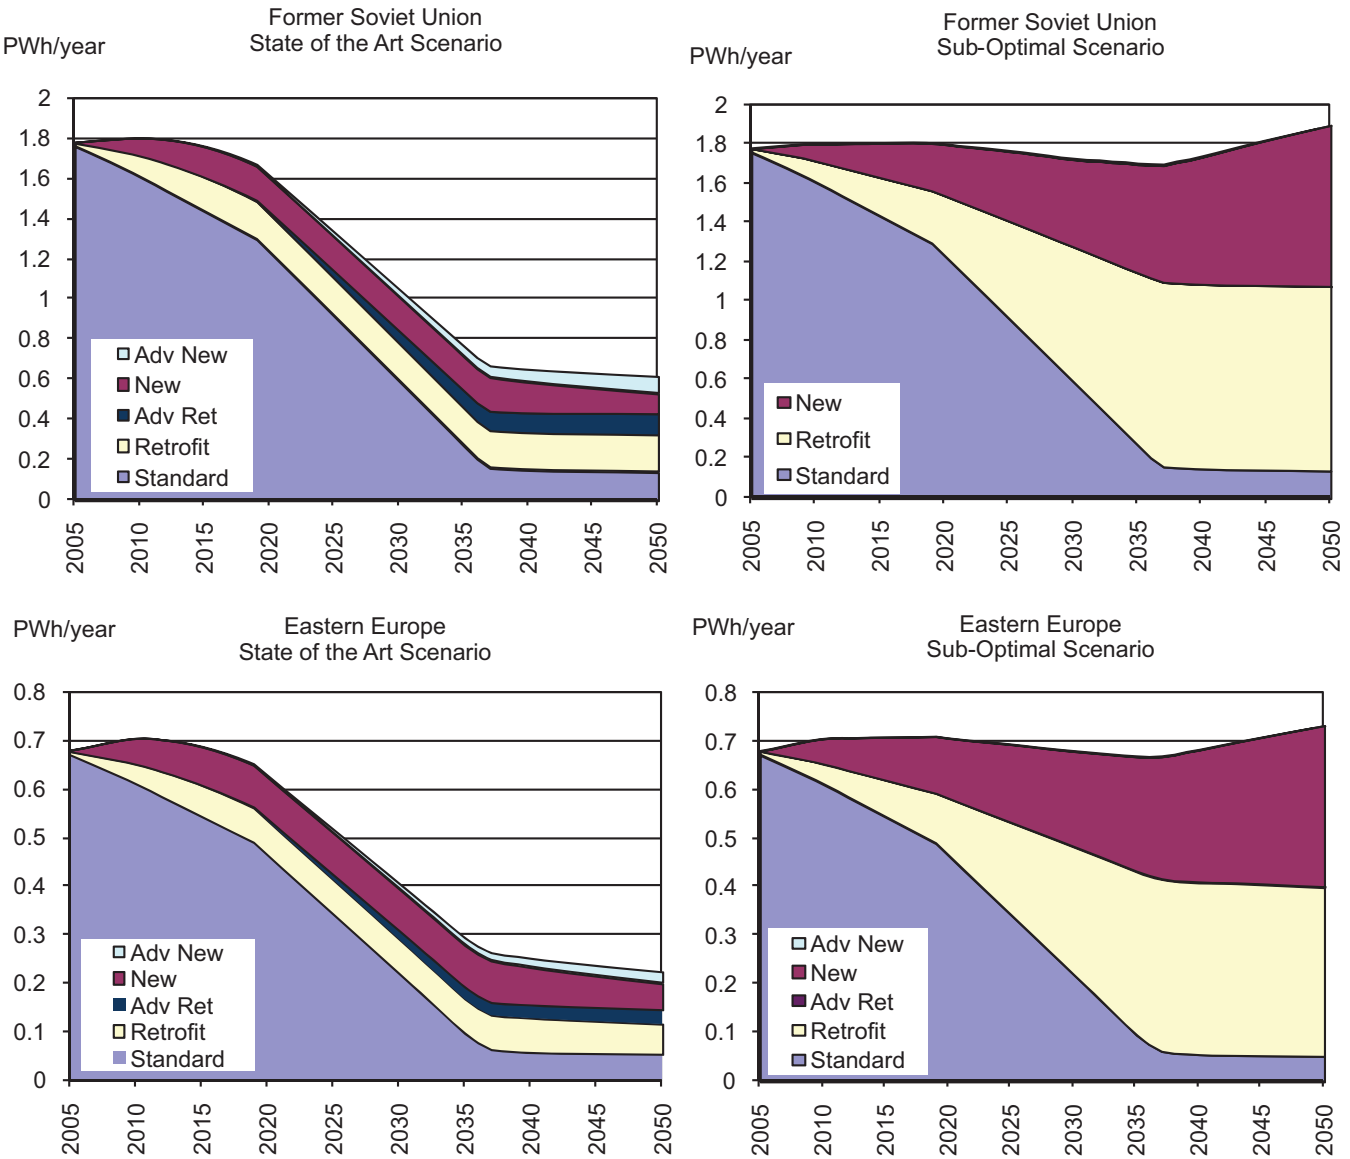

Figure 10.25 | Comparison of the two GEA building scenarios for REF regions, final thermal energy use by construction type.

fuel/energy poverty is fully eliminated by the time the entire building stock has been either replaced or renovated, i.e., before 2050 through assuming full thermal comfort to everyone. This results in significant thermal comfort increases, especially in regions having unsaturated thermal comfort levels – i.e., spaces not heated or cooled to medically acceptable levels – in all of our scenarios. As a result, it is possible that the state-of-the-art new building is actually more energy intensive than the inefficient existing ones. Traditionally, this is referred to as the rebound effect; it is important to note that the direct rebound effect has been fully considered in the scenarios. It is not possible to have more thermal comfort, since heating or cooling beyond the comfortable levels will not result in increases in well-being but rather compromises it. However, this is not considered an undesirable effect, but rather, one of the primary goals of the scenarios and an integral part of the GEA approach: to provide adequate energy service levels to those presently suffering from energy poverty or other limitations due to inadequate thermal energy services.

Investment Costs and Energy Cost Savings

Implementation of the state-of-the-art-scenario worldwide requires approximately US_{2005}14.2 trillion of cumulative undiscounted investments until 2050, if a 60% cost learning[27] is assumed for new technologies and know-how. This value is US_{2005}18.6 trillion without any cost learning. In contrast, these investments result in a US_{2005}57.9 trillion cumulative undiscounted energy cost saving for the same period. Figure 10.27 shows these results on cumulative investments and energy cost savings by 2050 for the different GEA regions of the world.

The cost values are calculated based on marginal expenditures as compared to standard construction and retrofit investments, and energy

27 Approximately 60% reduction in costs of low-energy buildings construction and renovation by 2030 as a result of large market size, technology learning, and optimization.

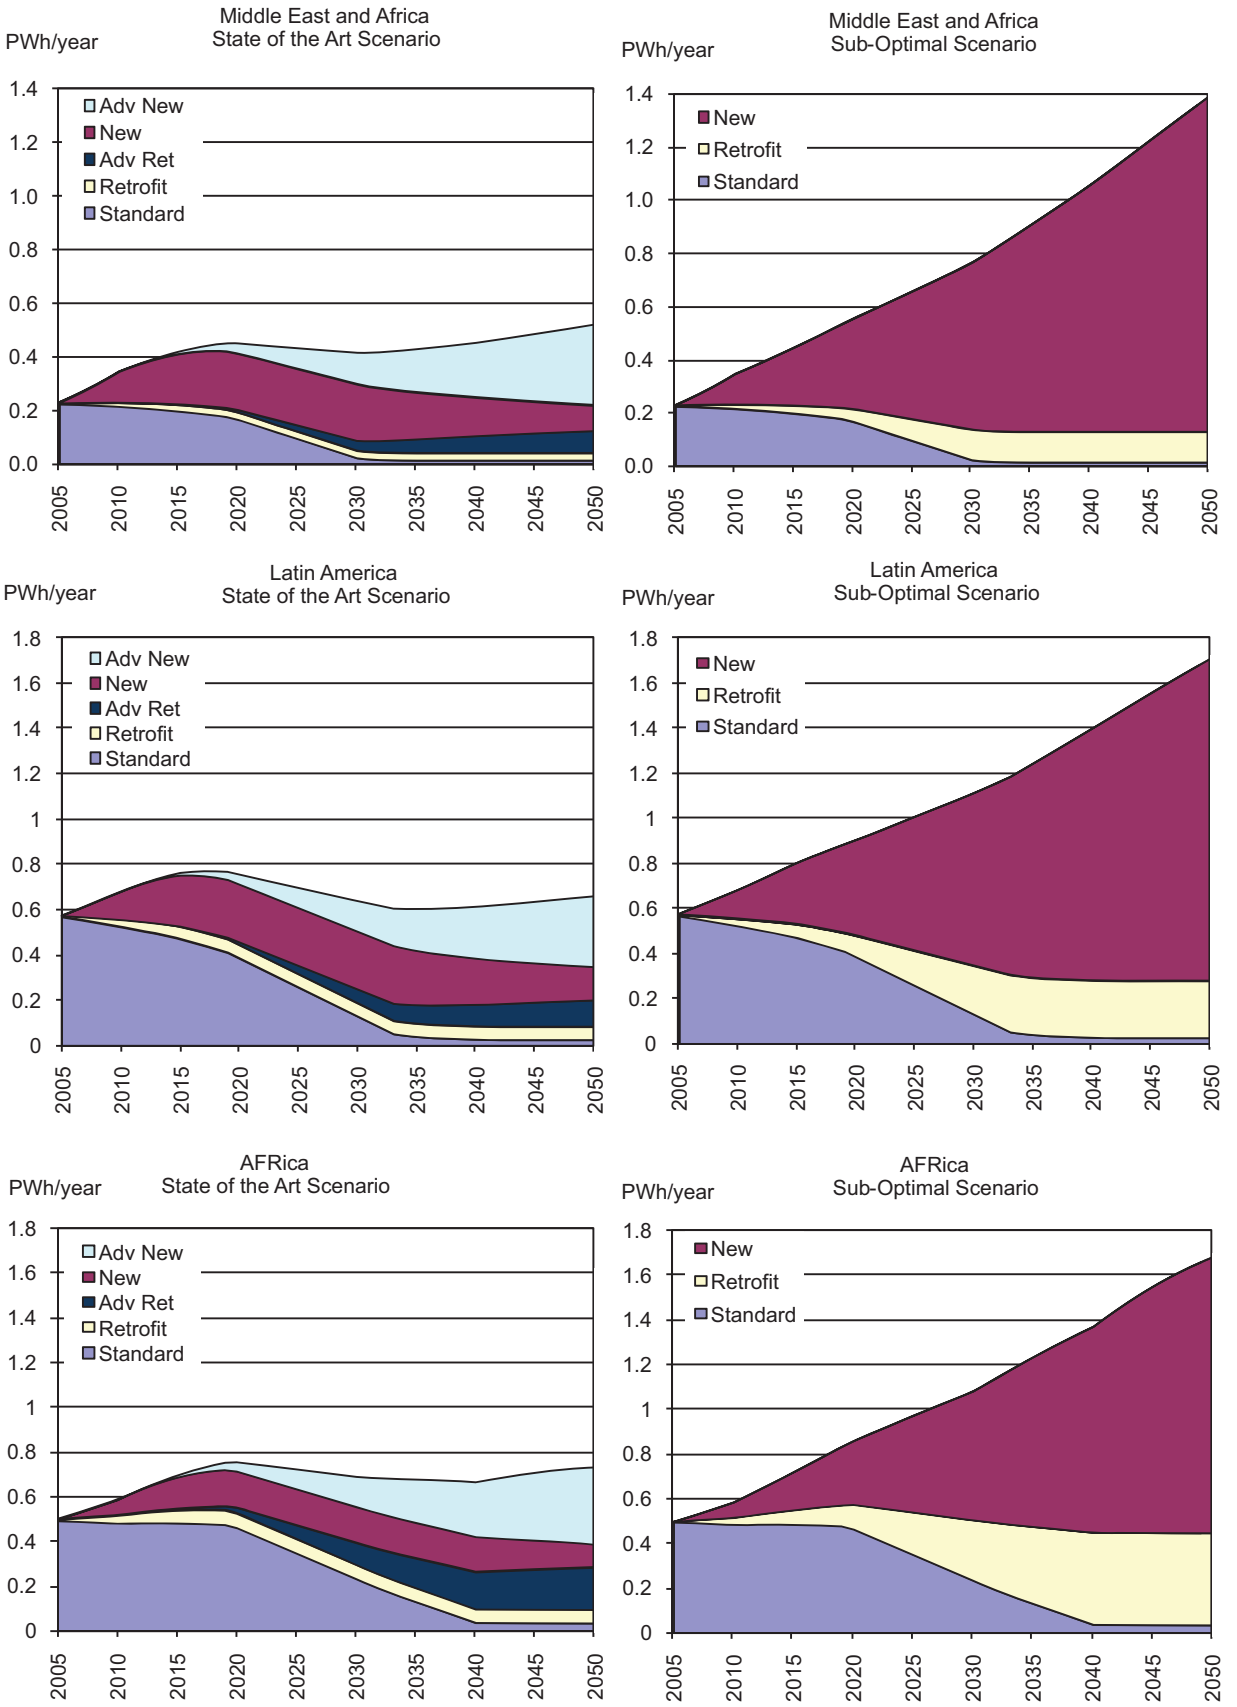

Figure 10.26 | Comparison of the two GEA building scenarios for MEA, LAC, and AFR regions, final thermal energy use by construction type.

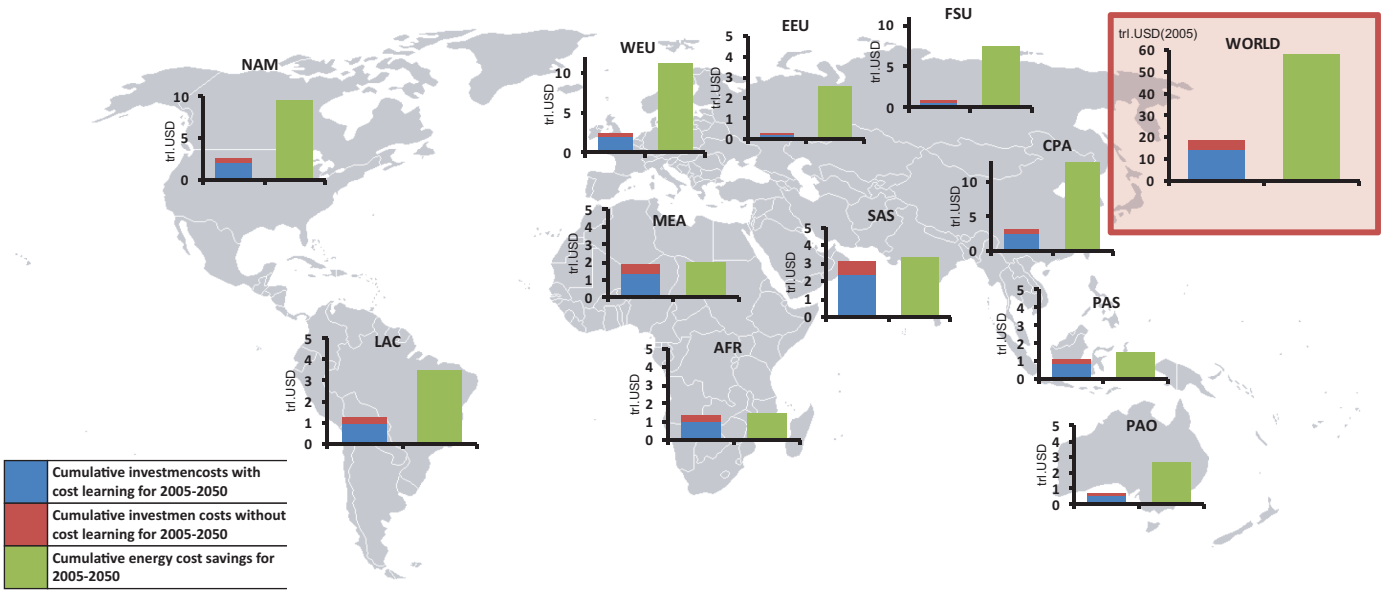

Figure 10.27 | Cumulative undiscounted investment costs and energy cost savings in different regions and worldwide, US_{2005} trillion.

cost savings as compared to a business-as-usual scenario, taking into account policies in place or in the pipeline. Energy prices and projections are based on IEA statistics and US EIA data (2010). An update of the calculations and further details of the methodology and assumptions is documented in (Ürge-Vorsatz and Petrichenko et al., in preparation).

The results presented in Figure 10.27 are comparable to other existing estimations. For example, in Laustsen (forthcoming) cumulative additional incremental investments for the period 2010–2030 in a case with considerable reduction in final energy use for heating, cooling and hot water are about US_{2005}16 trillion. Cumulative investment costs for the realization of the Blue Scenario in IEA (2010a) – which assumes maximizing the deployment of energy-efficient technologies, achieving substantial renovation of three-quarters of the OECD building stock by 2050, and ensuring the widespread deployment of new technologies – are around US$12 trillion for the period 2007–2050.

Comparison of the Results with Other Existing Models

In order to verify the findings of the model, the authors have calibrated global estimations of energy use in the building sector of a few landmark and reliable recent studies. The results of the comparison are presented in detail in Ürge-Vorsatz and Petrichenko et al. (in preparation), and summarized in Figure 10.28, as well as in Table 10.14. However, it is important to note a few major points that limit how far the messages of such comparison can be interpreted. First, the GEA buildings model specifically covers the final energy use for space heating and cooling, while most other models include other end-uses – e.g., Laustsen (forthcoming) also considers domestic hot water (IEA, 2006; IIASA, 2007; IEA, 2008a; IEA, 2010a; IEA, 2010b). Moreover, methodologies, assumptions, and metrics differ among the analyzed studies. Thus, precise comparison among the models is not possible. However, the general trends can be captured. Figure 10.28 illustrates all the scenarios analyzed and Table 10.14 presents the percentage of change in thermal energy use from 2005 to 2050.

Therefore, while numbers should not be precisely compared, the figures illustrate well that most major building energy use scenarios reinforce the achievability of this sector's significant energy use reduction potential with ambitious policies, and its substantial growth without strong efforts (except WEO10 New Policy and WEO06 ALT).

The GEA Chapter 10 Online Appendix discusses, in detail, how these scenarios relate to the main GEA scenarios described in Chapter 17, and further discuss the limitations of the model.

10.6.2.6 Conclusions from the GEA Building Thermal Energy Scenarios

GEA building scenario analysis has demonstrated that building thermal energy use can significantly decrease by the mid-century despite expected growth in living space, well-being, and energy service levels, and despite the GEA assumption that fuel poverty is fully eliminated in two decades. Assuming that today's state-of-the-art becomes standard practice in new construction and retrofit, world space heating and cooling energy use can decline by 46% in 2050 from 2005 levels, in spite of the approximately 126% growth in global floor space, elimination of fuel poverty, and significant increases in thermal comfort levels. The implementation of such a scenario requires an approximately US$14.2 trillion undiscounted investment (US$18.6 trillion without technology learning), but results in US$58 trillion savings in undiscounted energy expenditures. However, while this scenario is achievable at net profit, it does require significant policy effort.

At the same time, the analysis has also demonstrated the significant risk of the lock-in effect. If policies are implemented to reduce building energy use, such as building codes and support to accelerate energy-efficient renovation, but these do not mandate the state-of-the-art,

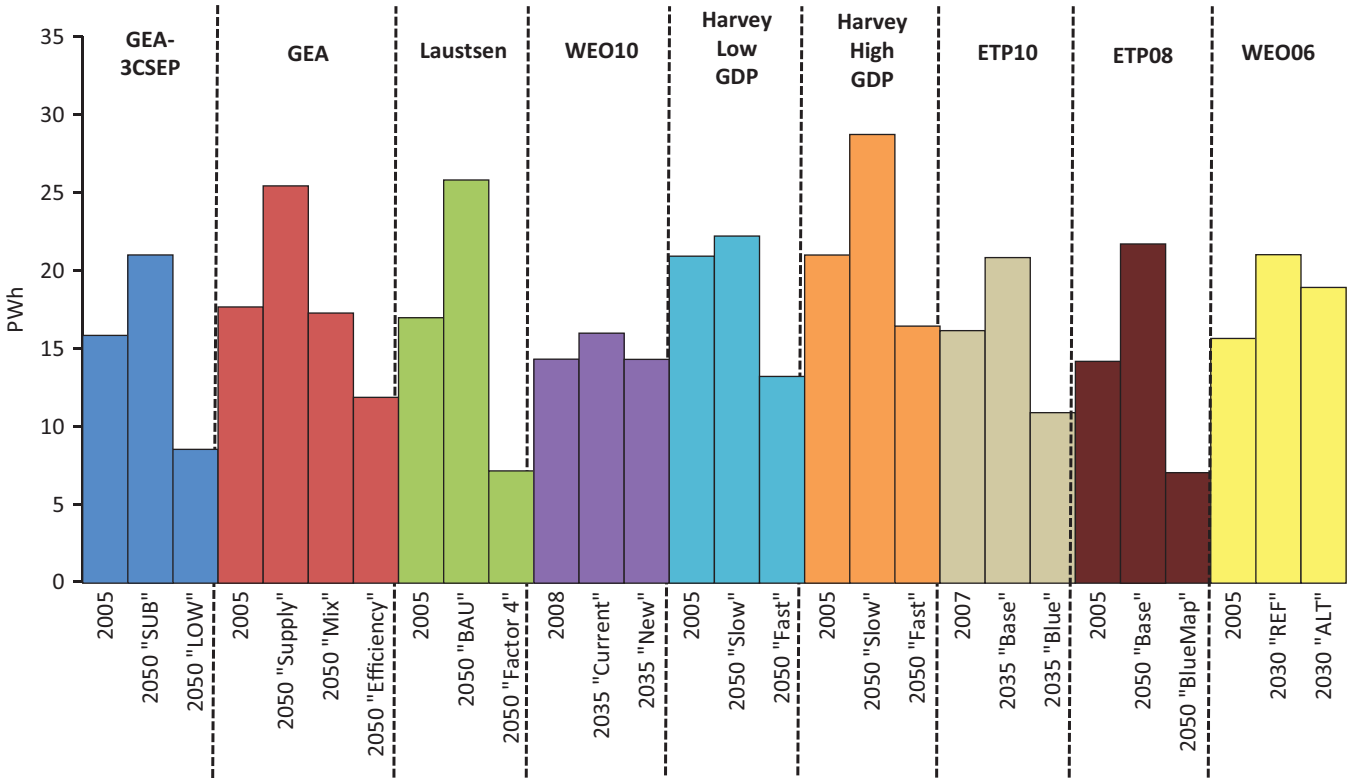

Figure 10.28 | Thermal energy use in the global building sector for different scenarios projected by different models. Note: Bars should not be compared precisely due to the reasons described in the text.

but rather only suboptimal efficiency levels, there will be substantial energy penalties; thus, energy use is locked-in for many decades due to the very long lifetime and renovation cycle of buildings. As a result, energy use increases by 32.5% by 2050 instead of a 46% decline as compared to 2005, resulting in a 79% lock-in by 2050 as expressed in terms of 2005 world building thermal energy use. Therefore, it is essential that building-related energy policies do not compromise target performance levels, and are most ambitious from as early as possible.

The state-of-the-art scenario, while extremely ambitious, can be achieved through a combination of policy instruments, of which building codes and equipment energy performance standards are the pillars. While state-of-the-art new construction is often a little more expensive than conventional new-built, it can sometimes be less expensive, and deep retrofits do incur substantial capital investments. Although these are investments that pay back well within the remaining life of the building, financing is key for renovation. Section 10.8 is devoted to exploring the policy space and the menu and effectiveness of different policy options that can take us to this more sustainable building energy future, and which are necessary for the implementation of the state-of-the-art scenario.

10.6.3 Description of Appliance Energy Scenarios

If the world embarks upon an ambitious strategy to improve the energy performance of its buildings, currently already pursued in several regions, the building energy demand toward the middle of the century may start to be dominated by electric appliances and other plug-in loads. Therefore it is paramount to also investigate the possibilities of energy savings through improved efficiency in energy-using equipment. The present section describes the potential of energy savings if very aggressive energy efficiency programs would be applied to the equipment in buildings in different world regions.

The description of the Bottom-Up Energy Analysis System (BUENAS) model, developed by LBNL, and its adoption to the GEA scenario exercise is included in the GEA Chapter 10 Online Appendix.

10.6.3.1 BUENAS Model Results

In the long term, that is, beyond 2030 and up to 2050, the efficiency improvements to the stock initiated in 2010 and enhanced in 2020

will have permeated the stock almost completely due to the replacement of old appliances with more efficient ones. Therefore, relative energy use of the stock after 2030 will largely scale according to the efficiency level in 2020 relative to the baseline. In order to avoid dependence on assumptions of market-driven efficiency improvements, BUENAS calculates energy savings demand versus a frozen efficiency case rather than a business-as-usual scenario. Frozen efficiency electricity demand, absolute savings, and percent savings are shown in Table 10.15.

The results show that electricity consumption for appliances studied, which is estimated at 1582 terawatt hours (TWh) in 2005, will double by 2025, and will nearly double again to 5696 TWh in 2030 in the absence of significant efficiency improvement. Much of the growth in appliance use during this period will occur in developing countries, especially in ASIA. By 2050, the OECD90 countries will still have the highest consumption for most appliances, but will be surpassed by ASIA for refrigerators, fans, and televisions, appliances that will be present in nearly all Asian households by that time.

Electricity savings will vary between appliances and regions. In absolute terms, savings in 2050 will be largest for refrigerators, with 1171 TWh, followed by standby power with 961 TWh and televisions with 842 TWh. In relative terms, standby power offers the largest opportunity for savings, with the assumption of the technical capability to reduce standby nearly to zero (0.1 W) per appliance. The total savings for all appliances is 3718 TWh, or 65% of the demand. The savings for all other appliances is 50% or greater, with the exception of washing machines in Latin America and the Caribbean. In that case, efficiency gains are expected to be largely offset by increases in capacity and market shifts from semi- to fully-automatic washing machines.

Figure 10.29 shows a graphical representation of the efficiency scenario. In this picture, appliance efficiency is currently rising rapidly, but growth will be slowed somewhat by standards in 2010, then more dramatically curtailed in 2020. From 2020 to about 2030, growth will actually be negative, and by 2030 total consumption will be roughly equivalent to 2005 levels. After that, however, the demand begins to grow again, although at a much lower rate than base case demand.

In conclusion, the scenario shows that a very significant reduction in appliance electricity demand is possible, given the current state of technologies. It is unlikely, however, that technologies common on today's market will result in energy demand that is only a small fraction of today's consumption. For that to happen, new, very high efficiency technologies must be developed, marketed, and adopted on a wider scale. Such a high tech scenario, which at this point would be somewhat speculative, is an interesting topic for further study.

Table 10.15 | Appliance electricity demand and savings in 2025 and 2050.

10.7 Co-benefits Related to Energy Use Reduction in Buildings

10.7.1 Key Messages

A future involving highly energy-efficient buildings also results in significant associated benefits – typically with monetizable benefits at least twice the operating cost savings, in addition to non-quantifiable or non-monetizable benefits now and avoided impacts of climatic change in the future. Multiple benefits beyond climate change mitigation include: improvements in energy security and sovereignty; net job creation; elimination or reduction in indoor air pollution-related mortality and morbidity; other health benefits; alleviation of energy poverty and improvement of social welfare; new business opportunities, mostly at the local level; stimulation of higher skill levels in building professions and trades; improved values for real estate and enhanced ability to rent; and increased comfort, well-being and productivity.

A survey of quantitative evaluations of such multiple benefits shows that even single energy efficiency initiatives in buildings in individual

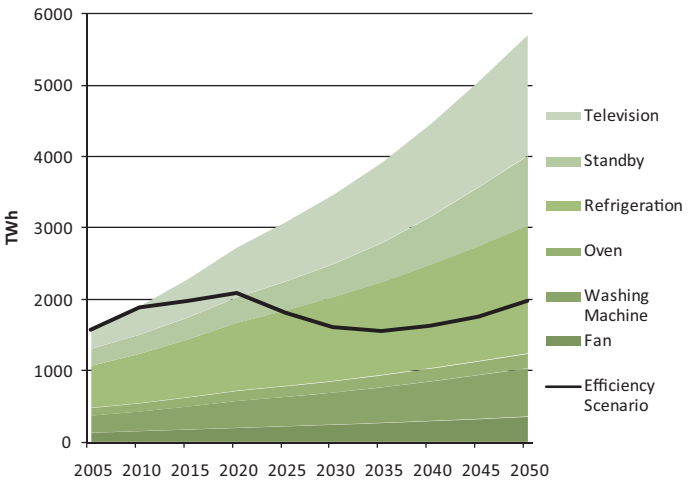

Figure 10.29 | Appliance electricity demand in base case and high efficiency scenario.

countries and regions alone have resulted in benefits with value in the range of billions of dollars annually for single benefits, such as health improvement-related productivity gains and cost aversions. Due to their significance, co-benefits can often present attractive entry points to policymaking, and point to the crucial importance of policy integration.

10.7.2 The Importance of Non-energy Benefits as Entry Points to Policymaking and Decision Making

Traditionally, energy cost savings have been regarded as a key rationale for implementing energy efficiency measures and environmental benefits for introducing policies to promote them. However, only a limited portion of such opportunities has been taken up by individuals as a result of the cost saving motivation and few policies implemented. Energy efficiency being the key strategy in climate change mitigation has provided a new rationale, giving rise to further policies that foster efficiency in developed countries. However, strong policy commitment to climate change mitigation only exists in a few countries and even there energy efficiency policies still fall very short of capturing the potential for cost-effective efficiency.

This section demonstrates that co-benefits are very significant in the building sector and offer new entry points into policy- and decision making. In jurisdictions where environmental benefits do not play a strong role in public policy, other benefits, such as poverty alleviation, employment creation, or improved energy security may be important enough to motivate such policies. For private decision makers, for whom energy cost savings are not sufficient to take steps, other benefits, such as improved comfort and health or corporate productivity gains, can unlock action.

While a single benefit, such as climate change mitigation, energy cost saving, or energy security gains, may not be sufficient to motivate action to capture saving potentials or to fare positive in a cost-benefit calculation, considering multiple benefits together may help the total benefits significantly outweigh the costs, or be sufficient motivation to enable action. However, this is only possible if public policymaking frameworks are adequately integrated to allow benefits in such otherwise disjointed areas to be combined. Private decision makers can take advantage of multiple benefits in decision making if tools are available that facilitate complex, integrated assessments of costs and benefits.

This section focuses on demonstrating the significance of co-benefits to sustainable energy action in buildings in several areas to illustrate that they are sufficient enough for offering alternative avenues for decision- and policymaking.

10.7.3 Typology of Benefits Of Energy Efficiency And Building-Integrated Renewable Energy

The co-benefits – often also called non-energy benefits – of energy efficiency and distributed energy generation in buildings are numerous. Many of the existing studies do not give an explicit classification of these benefits in the building sector. One classification is proposed by Skumatz and Dickerson (1997). They group non-energy benefits depending on the recipient: as (1) energy efficiency program participants, e.g., increased comfort, improved health; (2) society, e.g., cleaner outdoor air, employment creation, lower energy prices; or (3) a utility, e.g., lower bad debt write-off, decreased transmission costs. In addition, there are a few classifications of benefits of energy efficiency and GHG emission mitigation in general that might be applied to the benefits of energy-using sectors. For instance, Davis et al. (2000) suggest three categories of co-benefits: health, ecological, and economic and the IPCC (2007) lists co-benefits in the buildings sector in a similar way adding improved social welfare and poverty alleviation. Table 10.16 classifies co-benefits of energy efficiency in the buildings sector synthesizing these approaches. Table 10.16 also contains indicators showing how specific benefits can be measured. Once quantified, and with certain caution, many of these figures could be monetized and integrated into cost-benefit assessments of energy efficiency and saving actions. The following sections elaborate on a selection of co-benefits, avoiding repetitions of previous assessments.

10.7.4 Health Effects

The existing links between public health and the use of energy at home have been explored and quantified following two main directions: the health impacts of indoor and outdoor (regional) pollution, and the health impacts of inadequate access to energy, mostly heating in regions with a cold season. That way, it is likely that the most important health non-energy benefit of providing more energy-efficient solutions in buildings is the large number of lives that could be potentially saved through the provision of safe, clean, and energy-efficient cooking plus heating and lighting equipment in developing countries for population segments not

Table 10.16 | Typology of benefits of energy efficiency and distributed energy use in the buildings sector and selected indicators for their potential quantification.

Category	Non-energy benefits	Examples of indicators and concepts for its quantification
Health effects	Reduced mortality	Mortality risk (acute and chronic), Years of Life Lost (YLL), Loss of Life Expectancy (LLE), Value of a Life Year (VOLY), Value of a Statistical Life (VSL), hedonic wages.
	Reduced morbidity and other negative physiological effects	Avoided hospital admissions, Restricted Activity Days (RAD), Years Lived with Disability (YLD), Disability Adjusted Life Years (DALY), Quality Adjusted Life Years (QALY), Cost of Illness (COI: direct medical costs plus cost to the society from lost earnings), productivity loss and lower learning performance.
Ecological effects	Reduced impacts on ecosystems and crops	Acidification, eutrophication, exposure to tropospheric ozone, atmospheric deposition of pollutants, critical loads, number of protected hectares, Potentially Disappeared Fraction (PDF)
	Construction and demolition waste reduction	Percentage of reduction in construction and demolition wastes.
	Lower water consumption and sewage production	Percentage of reduction in water consumption and sewage production,
Economic effects	Lower energy prices[1]	Inverse price elasticity of supply.
	Employment creation[2]	Employments per unit of investment, multiplier effect, working age population relying on unemployement benefits,
	New business opportunities	New market niches
	Rate subsidies avoided[3]	Decrease in the number of subsidized units of energy sold, percentage of the energy price subsidized,
	Enhanced value of the buildings capital stock.	Higher resale and rental prices.
	Energy security	Reduced dependence on imported energy,.
	Improved productivity	Drop in absenteeism rates, reductions in voluntary terminations, GDP/income/profit generated.
Service provision benefits	Transmission and distribution loss reduction	Value of eliminated energy losses.
	Fewer emergency service calls	Saving staff time and resources necessary for attending the calls.
	Utilities' insurance savings[4]	Decrease in the insurance costs of utility companies.
	Lower bad debt write-off[5]	Decrease in the average size of bad debt written off, decline in the number of such accounts.
Social effects	Fuel poverty alleviation	Reduced expenditures on fuel and electricity; reduced fuel / electricity households debt; reduced excess winter deaths.
	Increased comfort	Mean household temperature,reduction of outdoor noise infiltration (dB).
	Safety increase (fewer fires)	Reduced number of fires and fire calls.
	Increased awareness	(Conscious) reductions in energy use, higher demand for energy efficiency measures.

Notes:
1. However, it is unlikely that initiatives at local, regional or even national scales bring sufficient reductions in the overall energy demandto affect prices set internationally.
2. To be incorporated as a benefit into cost-benefit analysis, only net employment creation can be accounted for.
3. Rate subsidies can be defined as lower, subsidized rates provided by utilities for their low-income customers (Schweitzer and Tonn 2002).
4. Reducing gas leaks and repair of faulty appliances (as a part of weatherization programs) decreases the insurance costs of utility companies.
5. Writing off the portion of a bad debt which is not paid by customers to the utilities (Schweitzer and Tonn 2002).

having access to clean energy sources. The health benefits of avoiding the inefficient indoor burning of traditional biomass and other solid fuels is thoroughly discussed in Chapter 4; it could translate into avoiding up to 1.5 million deaths/yr by 2030 (IEA, 2010d).

Providing access to cleaner fuels like LPG and more efficient stoves with enhanced ventilation systems would substantially improve in-house air quality and reduce household fuel collection and cooking time (Hutton et al., 2007). Furthermore, indoor air pollution is also a health concern in developed countries because of problems related to inadequate ventilation (Kats, 2005) and the so-called Sick Building Syndrome (SBS), discussed earlier in the chapter, which result in low work and learning performance and loss of productivity (WHO, 2000). Improving building ventilation and insulation allows the control of air exchange rates and reduces indoor air pollution and outdoor noise infiltration (Jakob, 2006). This provides opportunities for enhancing public health protection through retrofitting and weatherization programs.. In particular, state-of-the-art buildings eliminate, or significantly reduce, the health effects of indoor radon, dampness and mold, house dust mites, Volatile Organic Compounds (VOCs), NO_2, and secondhand tobacco smoke (see Chapter 4).

The buildings sector will also play a role in reducing mortality and morbidity if energy-efficiency and -saving programs are able to reduce outdoor air pollution, thus lowering end-use energy demand, especially

when emissions arise from the direct combustion of fossil fuels like coal and oil for heating and cooking (see Chapter 4). Many studies (Aunan et al., 2000; Samet et al., 2000; DEFRA, 2004; Rypdal et al., 2007; van Vuuren et al., 2008) have translated the reduction of human mortality and morbidity stemming from outdoor air quality improvements and climate policies into monetary terms. In the European Union, large research initiatives such as ExternE (Bickel and Friedrich, 2005), NEEDS (Ricci, 2009), and CASES (FEEM, 2008) have identified and put an economic value on the negative health-related externalities of the life cycle of energy provision that can also be avoided through energy demand reductions.

Additionally, connections have been established between cold and damp houses and excess winter deaths, respiratory illness, asthma, and impaired mental health (Morrison and Shortt, 2008). Therefore, improving building capital stocks for fuel poverty alleviation is also expected to generate physical health (Clinch and Healy, 2001) and psychosocial and mental health benefits related to warmer indoor environments, as discussed in Chapter 4. Such weatherization programs are especially beneficial in countries with poor housing conditions, where the problem of fuel poverty is especially acute (Clinch and Healy, 1999).

10.7.5 Ecological Effects

Reducing energy use in buildings results in a lower concentration of outdoor air pollutants (NO_x, NH_3, SO_2, VOC, or PM) that damage ecosystems and crops, which will then be better protected against acidification and eutrophication and less exposed to elevated ground level tropospheric ozone concentrations (EEA, 2006; van Vuuren et al., 2008). This includes the reductions in of various negative externalities like the impacts of acid rain and ozone in forests and the effects of acidification on recreational fisheries, as well as a reduction in noise pollution, visual amenity disruption, and major accident risks (European Commission, 1995). A growing body of literature on the economic value of ecosystem services (Costanza et al., 1997; Torras, 2000; CBD, 2001; Hein et al., 2005; Nahuelhual et al., 2007) provides a basis to establish a connection between energy efficiency and saving actions and enhanced ecosystem services provision.

Retrofitting and weatherization programs also extend the lifetime of buildings and increase resource use efficiency. For instance, Kats (2005) and SBTF (2001) estimated that building green and efficient houses could reduce construction and demolition wastes over 50%, and up to a maximum of 99%, as compared to an average practice. In the United States, Schweitzer and Tonn (2002) found significant reductions in water consumption and sewage production over the lifetime of energy-efficiency measures, i.e., low-flow showerhead and faucet aerators. Since building construction, operation, and decommissioning are energy-using activities, as is water provision and treatment (see Section 10.1.4), longer building lifetimes and lower resource consumption will bring about reduced amounts of embodied energy and GHG emissions.

10.7.6 Economic Effects

Creating employment and enhancing the overall productivity of the economy are broad macroeconomic goals that energy efficiency and saving programs can help to achieve. In underdeveloped, often rural regions the lack of modern energy is a primary cause of poverty. Improving energy efficiency would result in better energy security and less dependence on imported energy sources (IEA, 2004; Behrens and Egenhofer, 2007). Also other co-benefits, such as the increased value of real estate and lower energy prices, have welfare implications for households.

Characteristics of buildings and indoor environments significantly influence rates of communicable respiratory illness, allergy and asthma symptoms, sick building symptoms, and worker performance (Fisk, 2000). Related to that, productivity increase at the micro level has been documented and may reach about 6–16% in efficient buildings (Lovins, 2005), which translates into direct financial benefits: a 1% increase in productivity, ~5 minutes/employee/day, is calculated at US$600–700/employee/yr or US$3/ft2/yr in the United States (Kats, 2003).

Research also indicated that investing in energy efficiency renovation in the buildings sector has positive net employment effects once job losses in energy supply sectors are accounted for. Given the distributed nature of direct, indirect, and induced employment effects, additional jobs are expected to be geographically widespread (for Hungary, see Ürge-Vorsatz et al., 2010). The experience has pointed at spatial overlaps of fuel poverty and high unemployment. Promoting energy-efficient renovations in fuel poverty affected areas will benefit fuel-poor households by also providing additional income-earning opportunities (ACE 2000).

10.7.7 Service Provision Benefits

Improvement of energy efficiency and emission reduction in the buildings sector may result in higher quality provision of a number of energy-related services. This category of co-benefits include, inter alia, transmission and distribution (T&D) loss reduction, fewer emergency service calls, utilities' insurance savings, and lower bad debt write-off (Schweitzer and Tonn, 2002; Stoecklein and Skumatz, 2007). Even though these are mostly related to the functioning of utility companies, they can well translate into economic benefits, i.e., positive welfare changes, as long as similar comfort and service provision levels are achieved with fewer resources.

10.7.8 Social Effects

Energy efficiency in the buildings sector can also contribute to tackling social issues, such as poverty and fuel poverty. High-efficiency retrofitting of the existing building stock or the construction of near-zero-energy new buildings, can alleviate, and in some cases fully eliminate, fuel poverty. This, in turn, saves large amounts of public funds that are being spent on relief for those in fuel or energy poverty.

In general, improved domestic, corporate, and public energy efficiency lowers energy expenditures, therefore leaving higher disposable incomes for bill payers, and thereby improving social welfare.

In addition to immediate social co-benefits – including higher thermal comfort levels, noise protection, and improved indoor air quality – there is an increase in safety – namely fire prevention, as well as a number of long-term social benefits. The conveniences of education and health have far-reaching societal consequences on the development of equity, citizens' rights, and gender and child protection.

10.7.9 Worldwide Review of Studies Quantifying the Impact of Benefits Related to Energy Savings in the Built Environment

When societal interests are considered, many of the identified co-benefits related to improved building energy efficiency should be included in economic cost-benefit assessments that support decision-making processes and to determine whether certain measures or actions are justified on a societal basis or not. Similarly, non-energy benefits, especially those obtained at micro (household or firm) level, are important determinants of private decision making. At the same time, there are a limited number of potential studies or other cost-benefit assessments related to energy efficiency and GHG emission mitigation strategies that incorporate such benefits into the analysis.

Table 10.17 reviews the literature that is available in the public domain that has quantified non-energy benefits in the building sector. Typically these studies quantify physical impacts of energy conservation or GHG mitigation and monetize them. The survey revealed that different types of co-benefits have been examined to different extents. For instance, the effects of reducing outdoor air pollution – e.g., avoided morbidity and mortality – and productivity gains have been intensively studied. The authors were unable to locate research on the quantification of co-benefits such as new business opportunities and costs avoided due to increased awareness.

Most studies focus only on a few regions. The United States is subject of many studies, followed by only a few countries of the European Union. No studies were found that aggregated the quantified co-benefits, especially at regional or national levels. A global aggregation would be especially challenging, because ideally such an effort applies a uniform methodology and approach which has not yet been possible for potential assessments either.

10.8 Sector-Specific Policies to Foster Sustainable Energy Solutions in Buildings

10.8.1 Key Messages

- A wide range of policies has been demonstrated that are successful and cost-effective in reducing energy use in buildings. These include stringent and well enforced building and appliance standards, codes, and labeling, applying also to retrofits.

- Urgent introduction of strong building codes mandating near-zero-energy performance levels, progressively improving appliance standards, as well as strong promotion of state-of-the-art efficiency levels in accelerated retrofits of the existing building stock are crucial. Particular attention should also be paid to addressing non-compliance related to building codes. However, net-zero-energy building mandates may be not feasible for every type of building and in all regions, and in many cases their economics are unfavorable compared to high-efficiency buildings. Policy instruments to encourage deep retrofits should be implemented, including performance standards, performance contracting, energy audits and incentive mechanisms.

- Appropriate energy pricing is fundamental for promoting energy efficiency in buildings. Taxation provides an impetus for a more rational use of energy sources, but especially in poor regions or population segments, subsidies of highly efficient capital stock can be more effective and acceptable.

- Awareness campaigns, education, and the provision of more detailed and direct information, including smart metering, enhance social and behavioral changes. Combining regulation, incentives and information measures has the highest potential to increase energy efficiency in buildings.

10.8.2 Overall Presentation and Comparison of the Policy Instruments

The previous sections, in addition to earlier work, have demonstrated that there is a very broad spectrum of technologies and know-how that can save significant amounts of energy in buildings without compromising the level of energy services provided, often at net societal benefits rather than costs (Levine et al. 2007; Ürge-Vorsatz et al., 2007). Much of this potential though has not been captured due to the especially strong and diverse barriers that prevail in this sector. However, many of these barriers can be removed or lowered by appropriate policies, programs, and measures.

Table 10.17 | Benefits of GHG mitigation in the buildings sector and methodologies for their assessment in the worldwide literature.

Co-benefits	Country/ region	Impact of GHG emissions or energy demand reduction		References
		Physical indicator	Monetary indicator	
Health effects				
Morbidity and other negative physiological effects reduction	USA, New Zealand, Denmark	• USA: Improved indoor air quality reduced asthma occasions by 38.5%; a 25% reduction in asthma incidence in an average 900-student school translates into 20 fewer children/yr. with asthma. • Denmark: The improvement of thermal air quality led to better concentration of 15% of respondents and a 34% decrease in the number of respondents with sick building syndrome.	• USA: Ventilation increased may result in net savings of US_{2005}527/employee-yr. that represent the productivity lost on a national scale of US_{2005}30 billion/yr. • USA: Better ventilation and indoor air quality could reduce influenza and cold by 9–20% in population (ca. 16–37 million fewer cases) that translates into annual savings of US_{2005}7.5–17.4 billion.	National Medical Expenditure Survey, 1999; Kats, 2005 Milton et al., 2000; Schweitzer andTonn, 2002; Stoecklein andSkumatz, 2007; Fisk,1999
Mortality reduction	Hungary; USA, Ireland, Norway, worldwide	• USA: Every 10 g/m^3 increase in ambient particulate matter (the day before deaths occur) brings a 0.5% increase in the overall mortality. • Ireland, Norway: The share of excess winter mortality attributable to poor thermal housing standards is 50% for cardiovascular disease and 57% for respiratory disease. • Worldwide: more than 3 billion people cook with solid fuels on open fires or traditional stoves, resulting in more than 1.5 million deaths annually and a multitude of negative economic and environmental impacts.	• Hungary: The energy saving program resulted in the total health benefit of US_{2005}854 million/yr. due to a decrease of chronic respiratory diseases and premature mortality. • reland: the expected health-benefits (mortality and morbidity reduction) of a proposed domestic energy efficiency program amount to US_{2005}1.88 billion (at the 5% Irish government's discount rate) over 20 years. • Worldwide: the global annual economic benefits (incl. less expenditure on health care, health-related productivity gains, fuel collection and cooking time savings, and environmental impacts) of halving the population currently lacking access to cleaner fuels (LPG) would amount to US_{2005}91 billion at a net intervention cost (incl. fuel, stove, and program costs, from which monetary fuel cost savings are subtracted) of US_{2005}13 billion. Improving stoves would generate US_{2005}105 billion in economic benefits at a negative net cost of US_{2005}34 billion.	Aunan et al., 2000; Samet et al., 2000; Clinch and Healy, 1999; Clinch and Healy, 2001; Hutton et al., 2007
Ecological co-benefits				
Reduced impacts on ecosystems and crops	Europe	• The application of the Kyoto protocol in Europe is expected to reduce from 16.1% (93.4 million ha in 1990) to 1.5% (8.7 million ha in 2010) the share of ecosystems unprotected to acidification. The figures for areas with excess deposition of nutrient nitrogen are, respectively, 30.5% (166 million ha in 1990) and 18.8% (103 million ha in 2010).		Van Vuuren et al., 2008
Construction and demolition waste benefits reduction	USA	• The Construction and demolition diversion rates are 50–75% lower in green buildings (with the maximum of 99% in some projects) as compared to an average practice		SBTF, 2001; Kats, 2005

Continued next page →

Table 10.17 | (*cont.*)

Co-benefits	Country/ region	Impact of GHG emissions or energy demand reduction		References
		Physical indicator	Monetary indicator	
Lower water consumption and sewage production	USA	• The NPV of reduction in waste water and sewage over the measure lifetime isUS$3.4–657/ household.		Schweitzer andTonn, 2002
Economic co-benefits and ancillary financial impacts				
Lower energy prices	USA	• A 1% decrease of the national natural gas demand through energy efficiency and renewable energy measures leads to a long-term wellhead price reduction of 0.8% – 2% or 0.75% – 2.5%;		Wiser et al., 2005; Platts Res. &Consult, 2004
Employment creation	USA, EU	• USA: The US Department of Energy's Office of Energy Efficiency and Renewable Energy (EERE) macroeconomic (input-output) analysis of its energy efficiency residential and commercial buildings program found a potential to increase employment by up to 446,000 jobs by 2030. • EU: the SAVE program, based on data for 9 EU countries in the 1990s, estimated that investing in energy efficiency in residential and commercial/public buildings generated between 4.0 and 12.3 jobs per million $US_{2005}$$.		Scott et al., 2008; Wade et al., 2000
Rate subsidies avoided	USA	• The NPV of avoided rate-subsidies over the lifetime of the measures is US$6 – 70/household.		Schweitzer andTonn, 2002
Enhanced value of the buildings capital stock.	Switzerland, the Netherlands	• An economic analysis using the hedonic pricing approach shows a valuation of energy efficient windows of 2–3.5% of the selling price of existing single-family houses and reveals that new single-family houses certified with the 'Minergie' Label yield higher selling prices by almost 9% (with a standard error of about 5%) • A hedonic value analysis of the Dutch housing sector, where an early, voluntary adoption of the EU EPBD energy labeling system is in place, found out a premium in the sale value of energy-efficient properties, with a 2.8% higher transaction price in houses with an A, B, or C certificate.		Borsani and Salvi, 2003; Brounen and Kok, 2010.
Energy security	USA	• The Oak Ridge National Laboratory estimated the energy security benefits of reduced US oil use at $13.58: $8.90 coming from monopsony component plus $4.68 related to macroeconomic disruption / adjustment costs. This approach estimates the incremental benefits to society not reflected in the market price of oil, in US_{2004}per barrel, of reducing US imports.Omitted from this "oil premium" calculation are environmental costs and possible non-economic or unquantifiable effects, such as effects on foreign policy flexibility or military policy		Leiby, 2007
Improved productivity	USA	• In efficient buildings labor productivity rises by about 6–16%; students' test scores shows ~20–26% faster learning in schools well day lighted; retail sales can rise 40% in well day lighted stores	• Estimated potential annual savings and productivity gains of better indoor environments related with building energy efficiency in the $US_{2005}$$7.5–17.4 billion (reduced respiratory diseases); $US_{2005}$$1.2–5 billion (reduced allergies and asthma); $US_{2005}$$12.5–37.3 billion (reduced sick building syndrome symptoms); and $US_{2005}$$25–200 billion (direct improvements in worker performance unrelated to health)	Lovins, 2005; Fisk, 2000; Kats, 2003;

Service provision benefits				
T&D loss reduction	USA	• The NPV over the lifetime of the measures installed ranges US$33–80/household.		Schweitzer andTonn, 2002
Fewer emergency gas service calls	USA	• The NPV of fewer emergency gas service calls over the measure lifetime is US$39–201/household.		Schweitzer andTonn, 2002
Utilities' insurance savings	USA	• The NPV of utilities insurance cost reduction over the lifetime of the measures is US$0–2/household		Schweitzer andTonn, 2002
Decreased number of bill-related calls	New Zealand	• Bill-related calls became less frequent after the implementation of weatherization program, which amounted savings of $US_{2005}$$24.6 /household-yr, that is 7% of the total saved energy costs		StoeckleinandSkumatz, 2007
Lower bad debt write-off	USA	• The NPV of lower bad debt write-off over the lifetime of the measures is US$15–3462 / household.		Schweitzer andTonn, 2002
Social co-benefits				
Fuel poverty alleviation	UK	• UK: Energy efficiency schemes applied to 6 million households in January-December 2003 resulted in an average benefit of $US_{2005}$$19.9/household-yr.		DEFRA, 2005
Increased comfort,	Ireland, New Zealand, Switzerland	• Ireland: the mean household temperature once completed the proposed domestic energy efficiency program increases from 14 to 17.7 ˚C. • Switzerland: old windows reduce the level of external noise in the interior of the building by about 20–25 dB, whereas new ones achieve 33–35 dB. 38–40 dB reductions are also possible if asymmetric triple glazing is applied	• Ireland: The total comfort benefits of a proposed domestic energy efficiency program amount to $US_{2005}$$748 million discounted at 5% (Irish government's discount rate) over 20 years; • New Zealand: Comfort (including noise reduction) benefits gained after the implementation of weatherization program amount to $US_{2005}$$130.3/household-yr, equivalent to 43% of the saved energy costs.	StoeckleinandSkumatz, 2007; Jakob, 2006; Clinch and Healy, 2001
Safety increase (fewer fires)	USA	• The NPV over the lifetime of the measures installed is US$0–555/household.		Schweitzer andTonn, 2002

Note: (i) conversion of monetary units to $US_{2005}$$ was done whenever possible by applying Consumer Price Index (CPI) and exchange rates of the corresponding years or periods and nations.

A great variety of policy instruments have been implemented worldwide to promote energy efficiency in the buildings sector. There is no single policy instrument that can capture the entire energy saving potential. Due to the especially diverse and strong barriers in this sector, it requires an equally diverse portfolio of policy instruments for effective and far-reaching energy conservation. Policy instruments for promoting energy efficiency in the buildings sector can be classified in five major categories, namely:

- *Control and regulatory mechanisms*, which are institutional rules aimed at directly influencing the energy performance of buildings and/or energy equipment used in buildings. Policy instruments classified in this group include appliance standards, building codes, procurement regulations, energy efficiency obligations, quotas, etc.

- *Regulatory informative instruments*, which are also institutional schemes that aim to inform energy users about energy efficiency. These comprise mandatory labeling and certification programs, mandatory audit programs, utility demand-side management programs, etc.

- *Economic and market based instruments*, such as energy performance contracting[28], cooperative technology procurement, energy efficiency certificate schemes, the Kyoto flexible mechanisms, regional carbon trading platforms and carbon offset programs, etc. These are directly or indirectly aimed at steering economic actors toward improved energy efficiency.

- *Fiscal instruments*, which usually correct energy prices through either the implementation of taxes, tax exemptions or reductions, public benefit charges, the removal of fossil fuel subsidies, etc., or by providing financial support, e.g., capital subsidies, grants, subsidized loans, rebates, property-assessed clean energy (PACE)[29] financing, etc., if first cost-related barriers are to be addressed.

- *Support and information programs and voluntary action*. Instruments classified under this group are very diverse and comprise voluntary certification and labeling programs, voluntary agreements, public leadership programs, awareness-raising, education and information campaigns, detailed billing and disclosure programs, the establishment (and sufficient funding) of energy agencies, awards and competitions, personalized advice, training of building professionals, etc.

Table 10.18 | Indicators of Cost-effectiveness of policy instruments based on best practice cases.

	High	Medium	Low
cost of energy conserved US_{2005}/kWh	<0	0 – 0.01	>0.01
benefit-cost ratio (B/C)	>1	0.8 – 1	<0.8

In this section, the final effects of key categories of policy instruments used in the building sector to improve energy efficiency are reviewed and evaluated. In total, over 80 studies, review articles, and other relevant publications were identified from over 50 countries, covering each inhabited continent. Experts agree that even a brilliantly designed policy tool may lose its value if inadequately enforced. However, the greatest attention is usually given to policy design, whereas implementation and enforcement processes are often neglected (Khan et al., 2007). Due to this reason, special attention was given to limitations and success factors.

Recent reviews (Khan et al., 2007; Novikova, 2010) examined the outcomes of policies. These are: (a) the degree to which a policy tool achieves the target, often referred to as policy effectiveness; (b) the extent to which a tool has made a difference compared to the situation without it, referred to as net impact of the policy tool; and (c) the relationships between the net impact and spending required, referred to as cost-effectiveness. What follows is summarized from perspectives of effectiveness for energy saving and cost-effectiveness of policy tools. Also, the best attempt has been made to identify limitation and success factors.

Since studies reviewed used different methodologies for evaluation of policy effectiveness, these estimates were converted to a uniform format. For each implemented policy case study, the amount of energy saved as a result of the policy instrument in question was determined, both in absolute and relative terms – i.e., compared to a logical baseline, such as total national energy or electricity consumption in the particular sector and/or end-use. However, this was often not possible due to lack of data. Furthermore, the comparability of these estimates with other cases or policy instruments is in many cases very limited. Thus, the effectiveness of the various policy instruments examined was evaluated in a qualitative way, by assigning grades of "low," "medium," and "high" based on energy saving figures, but taking into account the overall applicability and potential of the instrument. The effectiveness of policies working in limited end-use categories was balanced with those affecting most end-uses; if the instrument works in a narrow energy end-use but can achieve an important reduction in that category, such as appliance standards, it could qualify as "high." (See Table 10.18.)

The cost-effectiveness of the policy instruments examined was also evaluated with qualitative grades, which are based on best practice cases and on the approximate ranges presented in Table 10.18.

28 Energy performance contracting is not a policy tool *per se*, but a business model that delivers a similar impact on transformation of the market toward higher energy efficiency as policy tools. Due to this reason, energy performance contracting is often added to policy tools.

29 The PACE model is a relatively new financing structure that enables local governments to raise money through the issuance of bonds or other sources of capital to fund energy efficiency and renewable energy projects, thus lowering the up-front cash payment for property owners. The financing is repaid over a set number of years through a special tax or assessment only on those property owners who voluntarily choose to attach the cost of their energy improvements to their property tax bill. The PACE approach attaches the obligation to repay the cost of improvements to the property, not the individual borrower, creating a way to pay for the improvements if the property is sold.

The comparative assessment of policy instruments presented in Table 10.19 reveals significant differences between them, especially concerning cost-effectiveness. The governmental costs of policy tools in the sample varied widely: figures ranged between -0.13 $US_{2005}$$/kWh (i.e., a significant net benefit) and 0.11 $US_{2005}$$/kWh. Despite the fact that economic performance of the policy instruments examined is presented in a variety of forms – i.e., economic cost or benefit per unit energy saved, benefit-cost ratio, total amount of estimated savings, etc. – making comparative evaluation extremely difficult, it can be generally stated that appliance standards, energy efficiency obligations and quotas, utility demand-side management (DSM) programs, and tax exemptions were found to be the most cost-effective policy tools in the sample, all achieving significant energy savings at negative costs in several applications. Regarding effectiveness for energy saving overall, appliance standards, building codes, labeling, utility DSM programs, and tax exemptions achieved the highest savings in the sample. More specifically, the implementation of building codes and tax exemptions (investment tax credits) policies in the United States are the two single policy instruments in the sample that have resulted in the maximum absolute energy savings, amounting to 174 TWh/yr each.

When comparing the five different categories of measures, the collected case studies indicate that regulatory and control measures are probably the most effective in terms of energy savings as well as the most cost-effective category, at least in developed countries. They all achieved ratings of high or medium according to both criteria, i.e., effectiveness and cost-effectiveness. Measures that can be designed both as voluntary and as mandatory, such as labeling or energy efficient public procurement policies, have been revealed as more effective when they are mandatory. The Mesures d'Utilisation Rationnelle de l'Energie (MURE) database (MURE, 2007; 2008), which collects and evaluates ex-post estimates of energy savings delivered by policies in the European Union member states and their neighbors, confirms the findings above.

The effectiveness of economic instruments varies, but some of them, such as energy performance contracting (EPC) and cooperative procurement, are promising. Project-based instruments that require credits for savings, e.g., white certificates, may have limited effectiveness due to the complex nature of buildings and resulting high transaction costs, the many efficiency upgrades, and the small project size, if complex monitoring and evaluation are required, but can otherwise be highly cost effective (Eyre et al., 2009).

Fiscal instruments also vary considerably in effectiveness and have numerous success conditions. For instance, in the short run, instruments that increase the energy price such as taxation are often less effective than fiscal incentives for capital investment in energy efficiency, such as tax exemptions, loans, and subsidies, due to the limited energy price elasticity in buildings – i.e., the percentage change in energy demand associated with each 1% change in price. Financing grants and rebates are especially needed in both developed and developing countries, particularly for low-income households, because the first cost barrier often prevents energy efficiency improvements. In general, tax exemptions were found to be the most effective tool in the category of fiscal instruments, while subsidies, grants, and rebates can also achieve high savings, but are usually costly to society.

Voluntary instruments vary in effectiveness that depends, for example, on the demand for energy-efficient products in the case of voluntary labeling and on whether the companies take voluntary commitments seriously. Though they have often failed to reach their goals, they can be a good starting point for countries that are just introducing building energy efficiency policies or when mandatory measures are not possible. Private sector commitments may be more effective where there is the clear prospect of regulation as an alternative, i.e., where they are in the context of negotiated agreements rather than purely voluntary. Finally, information instruments can be effective, but have to be specifically tailored to the target group.

Identification of the most cost-effective instruments was much more difficult because for some instruments, no quantitative information could be found. In the assessed sample, appliance standards, mandatory audits, utility demand-side management programs, mandatory labeling, energy efficiency obligations, energy performance contracting, cooperative procurement, and tax exemptions seem to be the most cost-effective policy measures. Thus, the category of regulatory and control instruments is apparently also the most cost-effective one, in contrast to a generally prevailing expectation that economic instruments are the most cost-effective (IPCC, 1995). These findings are partly confirmed by the MURE database. Such results are specific to the building sector, and might be explained by considering which barriers specific policy instruments address and the low sensitivity to prices of most non-intensive energy users.

Table 10.20 summarizes the major barriers and corresponding potential policy instruments to overcome them.

10.8.3 Combinations or Packages of Policy Instruments

Every policy measure is tailored to overcome one or a few market barriers, but none can address all the barriers and all targets and target groups. In addition, most instruments achieve higher savings if they operate in combination with other tools, and often these impacts are synergistic, i.e., the impact of the two is larger than the sum of the individual expected impacts (IEA, 2005b). Figure 10.A.8 in the GEA Chapter 10 Online Appendix diagrams the combined effect of the three policy instruments: appliance standards, labeling, and financial incentives.

A number of combinations of policy instruments are possible, as illustrated in Table 10.21. Usually, combining sticks (regulations), and carrots (incentives), with tambourines (measures to attract attention such as information or public leadership programs) has the highest potential to increase energy efficiency (Warren, 2007) by addressing a number of barriers.

Table 10.19 | Comparative assessment of all policy instruments from a governmental standpoint.

Policyinstrument	Country/ regions examples	Effective-ness	Energy reductions for selected best practices	Cost-effectiveness	Cost of energy reduction for selected best practices in US_{2005}	Special conditions for success, major strengths and limitations, co-benefits	References
Control and regulatory mechanisms – normative instruments							
Appliance standards	EU, USA, JPN, AUS, BRA, CHN, MAR, DEU, NLD	High	DEU: app. 214 GWh/yr USA: 129 TWh in 2000 = 2.5% of electricity use, 6% = 252 TWh in 2020 NLD (coupled with rebate): 0.06 TWh/yr. in 1995–2004	High / Medium	AUS: -0.13$/kWh EU: -0.08$/kWh USA: -0.05$/kWh MAR: 0.009$/kWh NLD: 0.07–0.11 $/kWh	Factors for success: periodic update of standards, independent control, information, communication and education	IEA 2005b, Schlo-mann et al. 2001, Gillingham et al. 2004, ECS 2002, WEC 2004, Australian GHG office 2005, IEA 2003, Fridley and Lin 2004, Khan et al.2007
Building codes	SGP, PHL, HKG, EGY, USA, UK, NLD, CHN, EU	High	HKG: 1% of total el. saved USA: 174 TWh in 2000 EU: up to 60% energy savings for new dwellings CHN: 15–20% of bdg. energy saved in urban regions NLD: 0.2 TWh/yr. or 0.1% of the sectoral reference energy use in 1996–2004	Medium	NLD: 0.02–0.05$/kWh for society, -0.09 – -0.002 $/kWh for end-user	No incentive to improve beyond target. Only effective if enforced.	WEC 2001, Lee and Yik 2004, Schaefer et al. 2000, Joosen et al. 2004, Geller et al. 2006, ECCP 2001, IEA 2005a, DEFRA 2006c, Khan et al 2007
Procurement regulations	USA, EU, CHN, MEX, KOR, JPN	High	MEX: 4 cities saved > 5,000 MWh in 1 year CHN: 4.6 TWh expected EU: 52–115 TWh potential EU: Energy+ programme for cold appliances 0.3 TWh/yr. in 1999–2004 USA: 18–61.6 TWh by 2010	Medium	MEX: $1million in equipment purchases saves $ 726,000/yr. in electricity costs EU: 0.007$/kWh EU: Energy + programme for cold appliances 0.001$/kWh	Factors for success: Enabling legislation, energy efficiency labelling and testing. Energy efficiency specifications need to be ambitious.	Borg et al. 2003, Harris et al. 2005, Van Wie McGrory et al. 2006, Gillingham et al. 2006, Khan et al 2007
Energy efficiency obligations and quotas	UK, BEL, FRA, ITA, DNK, IRL	High	UK: In 2002–2005: 2.5 TWh/yr. or 0.5% of sectoral reference energy use; 2010 savings: 6.1 TWh of electricity, 7.4 TWh of natural gas BEL: 0.36 TWh/yr. or 0.2% of sectoral reference energy in 2003–2004	High	Flanders: -0.04$/kWh for households, -0.014$/kWh for other sectors UK: -0.02$/kWh UK: 0.00004 $/kWh BEL: 0.0001 $/KWh	Continuous improvements necessary: new energy efficiency measures, savings target change, short term incentives to transform markets etc.	UK government 2006, Sorell 2003, Lees 2008, Collys 2005, Bertoldi and Rezessy 2006, DEFRA 2006c, Khan et al 2007

Regulatoryinformative instruments							
Mandatory labelling and certification programs	USA, CAN, AUS, JPN, MEX, CHN, CRI, EU, ZAF	High	AUS: 6.3 TWh savings 1992–2000, 102 TWh 2000–2015 ZAF: 623 GWh/yr DNK: 8 TWh	High	AUS:-0.02$/kWh	Effectiveness can be boosted by combination with other instrument, and regular updates.	WEC 2001, OPET network 2004, HoltandHarrington 2003, IEA 2003
Mandatory audit programs	USA, FRA, NZL, EGY, AUS, CZE	High but variable	USA: Weatherisation pro-gram: 22% saved in weatherized households after audits (30% according to IEA)	Medium/ High	USAWeatherisation program: BC-ratio: 2.4	Most effective if combined with other measures such as financial incentives, regular updates, stakeholder involvement in supervisory systems.	WEC 2001, IEA 2005b
Utility demand-side management programs	USA, CHE, DNK, NLD, DEU, AUT, THA, JAM	High	USA: 54.7 TWh in 2004 JAM: 13 GWh/year, 4.9% less electricity use DNK: 179 GWh THA: 5.2 % of annual electricity sales 1996–2006	High / Medium	EU: -0.07$/kWh DNK: ca.-0.06$/kWh USA: average costs app. -0.05$/kWh THA: 0.01$/kWh	More cost-effectivein the commercial sector than in residences, success factors: combination with regulatory incentives, adaptation to local needs & market research, clear objectives.	IEA 2005b, Kushler et al. 2004, Evander et al. 2004, Mills 1991, Parfomak and Lave 1996, Gillingham et al. 2006
Economic and market-based instruments							
Energy performance contracting/ ESCO support	DEU, AUT, FRA, SWE, FIN, USA, JPN, HUN, CHN	High	FRA, SWE, USA, FIN: 20–40% of buildings energy saved EU: 104–144 TWh by 2010 USA: 6.3 TWh/yr CHN: 44 TWh	Medium/High	EU: mostly at no cost, rest at <0.008$/kWh USA: Public sector: B/C ratio 1.6, Private sector: 2.1	Strength: no need for public spending or market intervention, co-benefit of improved competitiveness.	ECCP 2003, OPET network 2004, Singer 2002, IEA 2003, WEC 2004, Goldman et al. 2005, Evander et al. 2004
Cooperative technology procurement	DEU, ITA, SVK, UK, SWE, AUT, IRL, USA, JPN	Medium/ High	USA: 15–56 TWh/yr estimated by 2010 USA: 192,750 MWh saved in refrigerator procurement DEU: German telecom company: up to 60% energy savings for specific units	High/ Medium	USA: -0.07$/kWh SWE: 0.12$/kWh (BELOK-program)	Combination with standards and labelling, choose products with technical and market potential.	Oak Ridge National Lab 2001, Le Fur B. 2002, Borg et al. 2003, Nilsson 2006, Gillingham et al. 2006
Energy efficiency certificate schemes	ITA, FRA	Medium	ITA: 3.25TWh in 2006, 9.1 TWh by 2009 expected	Medium	FRA: max. 0.01$/kWh estimated	No long-term experience yet. Transaction costs can be high. Adv. institutional structures needed. Profound interactions with existing policies. Benefits for employment.	OPET network 2004, Bertoldi/Rezessy 2006, Lees 2006, Defra 2006c, IEA 2006, Beccis 2006

Table 10.19 | (*cont.*)

Policyinstrument	Country/ regions examples	Effective-ness	Energy reductions for selected best practices	Cost-effectiveness	Cost of energy reduction for selected best practices in US_{2005}	Special conditions for success, major strengths and limitations, co-benefits	References
Fiscal instruments and incentives							
Taxation (on household fuels)	NOR, DEU UK, NLD, DNK, CHE, SWE	Low/ Me-dium	DEU: household energy usereduced by 0.9 % in 2003: app. 10 TWh NOR: 0.1–0.5% 1987–1991 NLD: 1.1–1.6 TWh in 2000 SWE: 5% 1991–2005, 48 TWh	Low		Effect depends on price elasticity. Revenues can be earmarked for further energy efficiency improvements. More effective when combined with other tools.	WEC 2001,Kohlhaas 2005, Larsen and Nesbakken 1997, MURE 2007, Brink and Erlandsson 2004
Tax exemptions/ reductions	USA, FRA, NLD, KOR	High	USA: 174 TWh in 2006 FRA: 25 TWh NLD[1]: 0.4 TWh/yr. or 0.3% of sectoral reference energy in 1997–2004	High / Medium	USA: B/C ratio Com-mercial buildings: 5.4 New homes: 1.6 NLD: 0.02$/kWh	If properly structured, stimulate introduction of highly efficient equipment and new buildings.	Quinlan et al. 2001, Geller and Attali 2005, MURE 2007, Khan et al 2007
Public benefit charges	BEL, DNK, FRA, NLD, USA, BRA	Medium	USA: 0.1–0.8% of total el. sales saved each year, 2.8 TWh/yr savings in 12 states NLD: 7.4TWh in 1996 BRA: 1.95 TWh	Medium	USA:0.03–0.05$/kWh	Success factors: Independent administration of funds, involve-ment of all stakeholders, regular evaluation/ monitoring& feed-back, simple and clear program design, multi-year programs	Western Regional Air Partnership 2000, Kushler et al. 2004, Lopes et al. 2000
Capital subsidies, grants, sub-sidised loans	JPN, SVN, NLD, DEU, CHE, USA, CHN, UK, ROU, DNK, BRA	High/ Medium	SVN: up to 24% energy savings for buildings BRA: 5.2 TWh UK: 13 GWh/yr ROU: 414 GWh DEU: 0.7–1.0 TWh/yr. or 0.1% of sectoral reference energy in 1996–2004	Estimates vary from Low to High	DNK: -0.004$/kWh UK: 0.01$/kWh for government, -0.05$/kWh net NLD: 0.02–0.05$/kWh DEU: 0.02–0.04$/kWh	Positive for low-income households, risk of free-riders, may induce pioneering investments.	ECS 2002, Martin Y. 1998, Schaefer et al. 2000, Geller et al. 2006, Joosen et.al. 2004, Shorrock 2001, Berry and Schweitzer 2003, Khan et al 2007
Support, information and voluntary action							
Voluntary certification and labelling	DEU, CHE, USA, THA, BRA, FRA	Medium/ High	BRA: 5.3 TWh in 1998 USA: 53 TWh in 2004, 3558 TWh in total by 2012 THA: 311 MWh	High	USA: -0.03$/kWh BRA: $20 million saved	Effective with fiscal incentives, voluntary agreements and regulations, adaptation to local market is important.	OPET 2004, Geller et al. 2006,WEC 2001, Webber et al. 2003, US EPA 2003

Voluntary and negotiated agreements	Mainly Western Europe, JPN, USA, DEN	Medium/ High	USA: app. 275 TWh in 2000 EU: 100 GWh/yr (300 buildings) UK: app. 41 TWh in 2006 DEN (coupled with subsidies): 0.3 TWh/yr. or 0.5% of sectoral reference energy in 1996–2003	Medium	SWE: 0.02$/kWh DEN: 0.01$/kWh	Can be effective when regulations are difficult to enforce. Effective if combined with fiscal incentives, and threat of regulation. Inclusion of most important manufacturers, and all stakeholders, clear targets, effective monitoring important.	Geller et al. 2006, Cottrell 2004, Gillingham et al. 2006, Bertoldi et al. 2005, Bertoldi and Rezessy 2007, DEFRA 2007a, Khan et al 2007
Public leadership programs	NZL, MEX, USA, PHL, ARG, BRA, ECU, ZAF, DEU, GHA	Medium/High	DEU: 25% public sector energy savings in 15 years USA: 4.8 GWh/yr USA: 0.4% of sectoral reference energy in 1985–2004 BRA: 140 GWh/yr GHA: 27 MWh (14% of baseline) MEX: 200 GWh/yr(13% of baseline)	Medium	USA: DOE/FEMP estimates $4 savings for every $1 invested USA: 0.04 $/kWh EU: $13.5 billion savings by 2020 ZAF: 0.07$/kWh BRA: -0.08$/kWh	Can be used to demonstrate new technologies and practices.Man-datory programs have higher potential than voluntary ones. Clearly state, communicate and monitor, adequate funding and staff, involve building managers and experts.	Borg et al. 2003 &2006, Harris et al. 2005, Van Wie McGrory et al. 2006, OPET 2004, Van Wie McGrory et al. 2002, Khan et al 2007
Awareness raising, education, information campaigns	DNK, USA, UK, FRA, CAN, BRA, JPN, SWE, ARG	Low/ Medium	UK: app. 50 GWh annually ARG: 25% in 2004/05, 4.1 TWh FRA: 1 GWh/yr BRA: 69 GWh/yr, 203–381 TWh/yr with voluntary labeling 1986–2005 SWE: 48 GWh/yr	Medium/ High	BRA: -0.002$/kWh UK: -0.02$/kWh (households), -0.02$/kWh(business) SWE: 0.02$/kWh	More applicable in residential sector than commercial. Deliver understandable message and adapt to local audience.	Bender et al. 2004, Dias et al. 2004, IEA 2005b, Darby 2006b, Ueno et al. 2006, Defra 2006c, Lutzenhiser 1993, Savola, 2007
Detailed billing and disclosure programs	Ontario, ITA, SWE, FIN, JPN, NOR, AUS, USA, CAN, UK	Medium	Max.20% energy savings in households concerned, usually app. 5–10% savings UK: 3% NOR: 8–10 % USA: 2.1%	High	NOR: -0.04$/kWh USA: -0.07$/kWh	Success conditions: combination with other measures and periodic evaluation. Comparability with other households is positive.	Crossleyet al., 2000, Darby 2000, RobertsandBaker 2003, Energywatch 2005, Wilhite and Ling 1995, Allcot 2010.

Country name abbreviations: DZA – Algeria, ARG – Argentina, AUS – Australia, AUT – Austria, BEL – Belgium, BRA – Brazil, USA/Cal – California, CAN – Canada, BC/CAN – British Columbia, CEE – Central and Eastern Europe, CHN – China, CRI – Costa Rica, CZE – Czech Republic, DEU – Germany, DNK – Denmark, ECU – Ecuador, EGY – Egypt, EU – European Union, FIN – Finland, FRA – France, GHA – Ghana, HKG – Hong Kong, HUN – Hungary, IRL – Ireland, ITA – Italy, JAM – Jamaica, JPN – Japan, KOR – Korea (South), MAR – Morocco, MEX – Mexico, NLD – Netherlands, NOR – Norway, NZL – New Zealand, PHL – Philippines, POL – Poland, ROU – Romania, ZAF – South Africa, SGP – Singapore, SVK – Slovakia, SVN – Slovenia, CHE – Switzerland, SWE – Sweden, THA – Thailand, UK – United Kingdom (Great Britain and Northern Ireland), USA – United States.

[1] The tool covers the commerce and the industry and the results are for both sectors.

Table 10.20 | Barriers to energy efficiency and policy instruments as remedies.

Barrier category	Examples of barriers	Instrument category	Policy instruments as Remedies
Economic barriers	Higher up-front costs for more efficient equipment / buildings; lack of access to financing; energy subsidies; lack of internalization of environmental, health, and other external costs	Regulatory-normative/ regulatory-informative Economic instruments Fiscal instruments	Appliance standards, building codes, energy efficiency obligations, requiring the use of a technology or a building with specific standards. Procurement regulations ensuring the purchase of energy efficient equipment. DSM programs. Under EPC, ESCOs finance energy efficiency improvements (addressing the issues of high front-up costs as well the lack of access to financing) and are paid from the energy cost reductions achieved. Cooperative procurement, which is used by big buyers to specify the energy efficient standards for the equipment they use. Energy efficiency certificates. Other risk-sharing/financing instruments like co-operation with banks/public-private partnerships, guarantee schemes. Tax exemptions, subsidies/rebates/grants to reduce up-front costs. Taxation and/or public benefit charges to increase energy prices and to internalize externalities.
Hidden costs/benefits	Costs and risks due to potential incompatibilities, transaction costs, etc.	Regulatory-normative Economic instruments Support action	Appliance standards and building codes, requiring the use of particularly technologies or solutions. Labelling for informing the public about product standards, etc., resulting in reducing transaction costs for seeking information. ESCOs can undertake a significant part of these hidden costs and risks. Public leadership programs to demonstrate new technologies and to gain experience from their implementation. Information and advice programs.
Market imperfections	Limitations of the typical building design process; fragmented market structure; landlord/tenant split and misplaced incentives; administrative and regulatory barriers (e.g., in the incorporation of distributed generation technologies)	Regulatory-normative/ regulatory/informative Economic instruments Fiscal instruments Support, information, voluntary action	Appliance standards, building codes, energy efficiency obligations, imposing specific standards to buildings/equipment. A holistic approach engaging engineers, architects, etc., from the early stages of the design process. Mandatory labelling for informing the public about product standards. Procurement regulations and DSM programs. Regular monitoring and evaluation of programs and implemented policies. ESCOs can handle more effectively the administrative barriers for implementing energy conservation in buildings. Energy efficiency certificates and Kyoto Flexibility mechanisms can create incentives for implementing energy conservations measures. Taxation and public benefit charges giving the right price signals. Tax exemptions, subsidies/rebates/grants to accelerate first-movers. Public leadership programs, awareness raising campaigns.Education programmes for builders, architects, engineers, etc.
Cultural/ behavioral barriers	Tendency to ignore small opportunities for energy conservation, organizational failures (e.g., internal split incentives); tradition, behavior, lack of awareness and lifestyle; non-payment and electricity theft.	Support, information, voluntary action Fiscal instruments Regulatory-normative	Awareness raising through information campaigns. Detailed billing programmes, providing information to the final consumers as regards the most energy-requiring uses and equipment. Public leadership programs to demonstrate new technologies and practices. Voluntary agreements between governmental bodies and a business or organization, which undertakes the responsibility to increase its energy efficiency. Voluntary labelling programmes. Taxation and/or public benefit charges to increase energy prices and to give the right signal in the market. Appliance and equipment standards as well as other normative measures are a good way to overcome the tendency to ignore small opportunities (cf. phasing out of incandescent bulbs).
Information barriers	Imperfect information.	Support, information, voluntary action Regulatory-informative	Awareness raising through information campaigns. Detailed billing programmes, providing information to the final consumers as regards the most energy-requiring uses/equipment. Public leadership programs to demonstrate new technologies and practices. Voluntary labelling programmes. Mandatory labelling for informing the public about product standards. Procurement regulations ensuring the purchase of energy efficient equipment. DSM programs. Mandatory audits.

Table 10.21 | Characteristic examples of possible policy instrument packages and examples of commonly applied combinations.

Measure	Regulatory Instruments	Information Instruments	Financial /Fiscal Incentives	Voluntary Agreements
Regulatory instruments	Building codes and standards for building equipment	Standards and information programs	Building codes and subsidies	Voluntary agreements with a threat of regulation
Information instruments	Appliance standards and labelling	Labelling, campaigns, and retailer training	Labelling and subsidies	Voluntary MEPS and labelling
Financial/Fiscal Incentives	Appliance standards and subsidies	Energy audits and subsidies Labelling and tax exemptions	Taxes and subsidies	Technology procurement and subsidies
Voluntary Agreements	Voluntary agreements with a threat of regulation	Industrial agreements and energy audits	Industrial agreements and tax exemptions	

10.8.3.1 Standards, Labeling, and Financial Incentives

There are several effective policy options available to accelerate the transformation of appliance markets toward higher efficiency, including MEPS (Minimal Energy Performance Standards), voluntary or mandatory consumer information labels, and publicity or rebate programs sponsored by utilities or government agencies. Appliance efficiency standard and labeling programs have by now become a core part of energy efficiency programs in many countries.

Among the oldest and most comprehensive programs are the US federal MEPS program, the comparative labeling program implemented by the European Union, and the Energy Star endorsement label program, which is a program of the United States but has become widely recognized internationally. Minimum performance standards are used in the European Union, as well as in developing countries such as China, Tunisia, and Thailand. Appliance standards have been perhaps the most successful policy for improving energy efficiency, in part because they capture 100% of the market in a few years' time (US DOE, 2008) and they remove key market barriers – such as lack of interest, incentives, etc. – and transaction costs.

For office equipment, voluntary information programs have induced manufacturers to improve efficiency (US EPA, 2007). The year 2007 brought new Energy Star specifications for office and imaging equipment. In addition to reducing power use of the products themselves, the new specifications also set additional requirements for accessories. If an imaging product is sold with an external power adapter, cordless handset, or digital front-end, these accessories must meet Energy Star External Power Supply, telephony, or computer specifications. These requirements ensure that the Energy Star represents only the market's most energy-efficient products. Energy Star-qualified office and imaging products use 30–75% less electricity than standard equipment.

Due largely to the example set by the success of programs in the United States, the European Union, and Japan, there has been a proliferation of similar programs throughout the world in the past two decades. The number of programs exceeds 60 (Wiel and McMahon, 2005), and they cover dozens of different residential, commercial, and industrial products.

Appliance standards are often combined with labeling and rebates in order to give incentives for investments beyond the level required by the minimum energy efficiency standard. McNeil et al. (2008) demonstrate the importance of implementing both energy efficiency labeling and standards, showing that enforcing such policies on a global scale would lead to worldwide savings of 1113 TWh/yr of electricity and 327 TWh/yr of fuels by 2020, and 3385 TWh/yr of electricity and 928 TWh/yr of fuels by 2030. In addition, rebates for the most energy-efficient products encourage consumers to buy these, which reinforces and sustains market transformation.

The Japanese Top Runner approach is another unique and successful method to improve the energy efficiency of appliances (Murakoshi et al., 2005). In the Top Runner approach, government sets target energy efficiency values and years for appliances, including scope, based on the highest energy efficiency products on the market, and encourages manufacturers to make products better than this target energy efficiency value. Energy efficiency values and indicator labels are voluntarily displayed in catalogs and other advertising and publicity material so that consumers can consider energy efficiency when making purchases. In addition, the Top Runner program sets fleet standards for appliances. This system of voluntary agreements between the Japanese government and manufacturers has been highly effective, leading Japan's appliance market to be among the most efficient in the world.

Building codes can also be combined successfully with voluntary or mandatory certification of buildings (IEA, 2010c) such as through rating systems like the British BREEAM,[30] the Japanese CASBEE,[31] and the

30 BREEAM (BRE Environmental Assessment Method) is a widely used environmental assessment method for buildings. It was developed by BRE (Building Research) Trust Companies and covers a wide range of building types (www.breeam.org/).

31 CASBEE (Comprehensive Assessment System for Built Environment Efficiency) is an assessment tool based on the environmental performance of buildings or urban area. CASBEE evaluates a building from the two viewpoints of environmental quality and performance (Q=quality) and environmental load on the external environment (L=load) and defines a new comprehensive assessment indicator, the Building Environmental Efficiency (BEE), by Q/L (www.ibec.or.jp/CASBEE/english/index.htm).

American LEED system.[32] The European Union's EPBD[33] is actually an example of combining codes with certification. A number of developing countries, such as China, intend to introduce building rating schemes to complement building codes (Ürge-Vorsatz and Koeppel, 2007). In the United States, mandatory energy efficiency regulations are sometimes coupled with voluntary labels, such as ENERGY STAR, and tax credits to manufacturers and to consumers. This combination eliminates the least efficient products, while compensating manufacturers for some of the increased production costs both through tax credits and through premiums charged for ENERGY STAR designs.

10.8.3.2 Regulatory and Information Programs

Regulatory policy instruments are usually effective, but lack of enforcement can be a barrier and the rebound effect may result in some benefits being taken as increased service rather than reduced consumption. Awareness might improve compliance and help overcome the rebound effect in more affluent population groups where energy service levels are not constrained.

10.8.3.3 Public Leadership Programs and Energy Performance Contracting (EPC)

By improving its own energy efficiency, the public sector can not only save costs, but also demonstrate to the private sector the potential and feasibility of energy efficiency improvements and trigger market transformation. EPC in the public sector is especially advantageous, as the budget of many public administrations is limited. Executive orders that oblige public authorities to reduce energy use by 30% and the federal energy management program in the United States, as well as the Energy Saving Partnership in Berlin, Germany, have boosted the energy service company (ESCO) industry (Ürge-Vorsatz and Koeppel, 2007). However, significant barriers still hamper EPC in the public sector in developing countries.

10.8.3.4 Financial Incentives and Labeling

In order for financial incentives such as loans, subsidies, and tax credits to be most effective, the labeling of energy efficient products is necessary, which ensures that only the most efficient categories of equipment are financially supported (Menanteau, 2007). On the other hand, labeling, particularly voluntary labeling alone, might not be effective (Menanteau, 2007), because if the premium labeled products are substantially more expensive, that discourages especially low-income households from purchasing them. This implies that governments might consider incentive schemes for companies that undertake labeling.

10.8.4 Policy Instruments Addressing Selected Barriers and Aspects Toward Improved Energy Efficiency in Buildings

10.8.4.1 Policies for Retrofit

While the majority of broad policy approaches – information, labeling, standards, incentives, etc. – are in principle as applicable to building retrofit as new buildings, there are clearly important differences in the policy measures required. In most countries, due to the long lifetime of buildings replacement rates of the building stock are low, and therefore retrofit will be essential to achieving rapid progress in energy efficiency.

Securing low-energy retrofit activity raises some different issues. This is partly because codes and standards are expected to deliver much more in new construction. Retrofitting existing buildings is a discretionary investment – no action is an option, and often an easier option. Building owners and occupiers therefore need to be persuaded not only of the merits of energy investment, but to finance it and bear whatever disruption it entails. Incentives may therefore need to be higher than for new buildings. This sub-section therefore focuses upon the differences in policy mix that may be required for building retrofit.

The incentive policies reviewed above are particularly relevant to retrofitting policies. In some cases, e.g., in the United Kingdom, there is support for energy efficiency measures in low-income households from government-funded programs. More commonly energy efficiency retrofits are supported through a variety of fiscal measures, including income tax credits – e.g., in the United States and France – and low rates of relevant sales taxes – e.g., reduced rate value added tax (VAT) in some European Union countries. In some cases, these formed part of green stimulus packages in 2009.

Programs of financial support for building energy efficiency through energy utility regulation are increasingly common and growing in size. First known as Demand Side Planning or Integrated Resource Planning and used in the United States in the 1980s in vertically integrated monopoly utilities, they have now been adapted to a range of regulatory environments. In principle, any category of energy efficiency may be addressed in this way, but in practice building retrofits predominate. In some states of the United States and some European Union countries, the United Kingdom, Italy and France, program savings approach or exceed 1% of regulated energy use (e.g., York, 2008; Eyre et al., 2009).

Performance contracting by energy service companies is widely used in many countries for the retrofitting of commercial buildings. Subsidized energy advice has been used widely to increase information on energy

32 LEED (The Leadership in Energy and Environmental Design) is a Green Building Rating System developed by the United States Green Building Council and providing a suite of standards for environmentally sustainable construction (www.usgbc.org/).

33 EPBD (EU Directive on the Energy Performance of Buildings) is a range of provisions aimed at improving energy performance of residential and non-residential buildings, both newly built and already existing (www.buildingsplatform.org/cms/).

efficiency opportunities in the existing building stock. These have been linked to incentive schemes, which may be in the form of grants, loans, tax incentives, or energy company incentive payments.

An audit is generally recognized as the precursor to effective retrofit investment. The logic of this is reflected in policies that increasingly require mandatory labeling and audit and certification of buildings, e.g., European Performance of Buildings Directive. The first aim of such labeling is to provide consumer information, but labeling schemes are also essential as a tool in incentive or regulatory policies that are linked to building performance.

Although codes and standards are best known for use in new buildings, they are increasingly used in retrofit. This can be to require performance standards at the time of major refurbishment, and this applies in the European Union to buildings through the Energy Performance of Buildings Directive. Standards are also applied to individual components in retrofit, e.g., heating, glazing, air conditioning, and this is very cost effective (e.g., DEFRA, 2007b). Germany has extended this principle to both fabric elements and whole building performance at the point of major refurbishment (Dilmetz, 2009). However, to date there has been very limited use of standards for whole building performance to require refurbishment, for example at the point of sale or rent. At present, actual regulation of this type has probably been confined to a few parts of the United States – San Francisco, Berkeley, Davis, Burlington, Ann Arbor, and the state of Wisconsin (CLG, 2010). The adoption of mandatory labeling and retrofit codes (e.g., in Europe) in principle provides a basis for wider use of this approach.

It is increasingly recognized that substantial retrofit will be required if older buildings are to reach the energy efficiency standards implied by the ambitious targets of many governments. Traditional incentive mechanisms that support individual components will not be sufficient to deliver the major changes in fabric, airtightness, and heating and cooling system efficiency that are required. Policies that support very substantial improvement are beginning to be explored. For example, in Germany there are 100% low interest loans up to Euro 50,000 (approximately $US_{2005}$$59,000) for CO_2 rehabilitation of buildings, supporting very low energy refurbishment (Schonborn, 2008). In Berkeley, California, to encourage energy-efficient renovations of residential and commercial buildings, the municipality provides funds that are to be repaid within 20 years through property taxes (Fuller et al., 2009). Since the 2009 financial crisis, with lending significantly reduced, schemes of this type are of increasing importance for supporting retrofits. However, policies of this type are on hold in the United States because of concerns that they infringe on contractual obligations to mortgage lenders.

Policies for retrofit to low energy standards also need to deal with practical complexities inherent in the diversity of current buildings, many already significantly altered since original construction and often poorly built, maintained, and documented. Retrofit has to deliver the range of outcomes defined by building owners or managers and provide the services expected by future occupants, when known. In general, these clients will have little energy knowledge and very little insight into the challenge of low energy retrofits. Moreover, in the case of minor changes and even major ones to small buildings, e.g., single-family dwellings, retrofit may frequently be done without the oversight of architects or energy services professionals. In this environment, delivering the very low levels of air infiltration and thermal bridging implied by passive building standards involves some practical challenges for the retrofit process. At the very least, the widespread adoption of low energy retrofit programs will also require a substantial program of training in the building sector (Killip, 2008).

10.8.4.2 Policies Addressing Non-compliance Related to Building Codes

Building codes have served as a major policy tool for reducing energy required, especially for building services such as heating, cooling, water heating, and lighting (Listokin et al., 2004). Existing practices in several countries show there are mainly two types of building codes: (1) overall performance-based codes requiring that a building's predicted energy demand or energy cost (usually determined through an energy modeling software), is equal to or lower than a baseline target that has been specified by the code; and (2) prescriptive codes, which set separate energy performance levels for major envelope and equipment components. A combination of an overall performance requirement with some component performance targets (e.g., wall insulation) is also possible.

Computer simulation tools have existed since the 1970s to calculate the energy performance of buildings based upon their design, and the results have been validated – or improved – by comparison with measured energy use. The full potential for energy savings from building codes has not been achieved, in part because compliance and enforcement are not complete. The range of experiences is broad, from jurisdictions where even the structural integrity of buildings may be compromised – sometimes revealed when earthquakes cause widespread damage in a region – to buildings failing to meet fire codes, to buildings meeting some but not all requirements, to those meeting all requirements.

Good statistics are lacking to quantify the problem globally. In many parts of the world, there are no legal requirements for building code enforcement. Even in some of the most prosperous regions, the level of resources available for enforcement, such as the number of local code enforcement officials or information and tools available to them, is often inadequate. In some developed areas, code compliance has been shown to be about 50% (Usibelli, 1997). A recent California study found rates of non-compliance by measure ranging from 28–73% for residential and 44–100% for non-residential. In both cases, the lowest non-compliance was for lighting, and the highest was for ducts (Sami Khawaja et al., 2008).

While performance measurement, by means of commissioning or research on occupied buildings, may be necessary to rigorously compare actual performance with the energy performance projected by computer models using design parameters, simpler inspections are sufficient to detect significant non-compliance. Failure to comply can occur because actual construction practice deviated from design, or inferior materials or equipment were substituted, or installation was flawed or incomplete. Studies have suggested ways to improve building regulations (for a recent European example, see Garcia Casals, 2006).

Aiming at enhancing the effectiveness of building codes, there has been much discussion recently about a new energy code compliance framework based on actual post-construction energy performance outcomes of buildings, called outcome-based building codes (Hewitt et al., 2010). In other words, owners would have the flexibility to pursue whichever retrofit strategies they deem appropriate to their individual buildings, but would be required to actually achieve a pre-negotiated performance target, demonstrated through mandatory annual reporting of energy use. Although no current codes regulate actual energy use, outcome-based codes may be a very critical tool toward deep energy savings in existing buildings. As existing buildings do have an energy performance history, benchmarking plays a vital role in establishing an outcome-based compliance path in energy codes (Denniston et al., 2010). An outcome-based performance path may be based on either requiring certain percent improvement in energy performance, assuming old energy performance needs are known, or absolute performance goals, given sufficient data about building performance needs in order to establish those goals are available.

Generally, successful building energy codes will likely require: (1) clear, consistent code documentation, that is as simple as possible; (2) providing sufficient information, training, and motivation to practitioners; (3) adequate local resources to check compliance, keeping in mind that the sheer size of the construction industry argues for simpler methods and sampling using statistical methods, rather than rigorous checking of every building; (4) feedback to architects, designers, builders, contractors, and consumers to identify good and bad practice; (5) penalties for consistent bad practice; and (6) performance-based rating systems to close the loop from actual performance back to design and construction.

10.8.4.3 Policies Addressing Professional, Social, and Behavioral Opportunities and Challenges

A substantial part of the huge energy conservation potential in buildings requires the effective engagement of human dimensions of providing, adopting, and using energy efficient technologies and buildings. These are set out in Section 10.4.8 above. In many cases, these factors constitute significant barriers for capturing even low cost, energy conservation potential. To overcome these barriers, appropriately designed policies or portfolios of policies can be implemented that are briefly described below.

The adoption of behavior to use less energy by building occupants can be enhanced through information, advice, and educational programs and the provision of more detailed and direct feedback on energy use by end-use and energy expenditures. It has been noted that, in many cases, people underestimate the amount of energy they use for specific energy uses. To this end, detailed billing and disclosure programs have been estimated to potentially save up to 20% of energy (Darby, 2000) and are mostly cost-effective (Ürge-Vorsatz et al., 2007).

However, better feedback to final consumers on energy use may increase costs and reduce revenues for the energy supplier. The policy implication is that regulation is likely to be needed to set a minimum standard for the quality and frequency of energy use information. This could include frequency of meter reading and billing and requirements for comparison with historical data and consumption of similar users. The advent of smart meters provides new opportunities to enhance information across the energy supply chain, including to final users. Again, this needs a clear regulatory framework to be successful, including timescales for deployment and standards for inter-operability, consumer information, and data transfer.

Carefully designed and targeted awareness-raising programs to secure specific outcomes can have a place in policy packages to reduce energy use. The Japanese "Cool Biz" campaign is a good example (see Box 10.3). However, there is limited evidence that general exhortation, e.g., advertising campaigns, has a significant lasting impact. Energy saving information needs to be clear and relevant and provided at the point of key decisions; product labeling is the best example of this. Advice on energy saving opportunities is generally most effective when it is specific to personal circumstances, especially when provided by trusted sources independently of energy companies and as part of policy packages including incentives and other support to act. Consumers are unlikely to seek this out, or pay for it at cost, and therefore it needs to be provided as a public or community service, for example by local government or specialist energy agencies.

Energy pricing may also be a useful tool for influencing energy use behavior in buildings. Furthermore, even if residential energy price elasticities are relatively low in high income countries, appropriate energy pricing systems, e.g., with the adoption of staggered rates, may provide impetus for a more rational use of energy sources in buildings (Reiss and White, 2008; National Action Plan for Energy Efficiency, 2009).

Finally, non-technological options to reduce energy use in new buildings related to architectural decisions at an early design stage, e.g., building shape, form, orientation, size, etc. (see Section 10.4.2), can be supported through appropriately designed building codes, regulations on urban density, building heights, and the mix of land uses, etc. (WBCSD, 2008). These mechanisms already exist in many countries. However, their effective implementation and particularly their revision to incorporate energy efficiency aspects remain a challenge in most developing and in several developed countries.

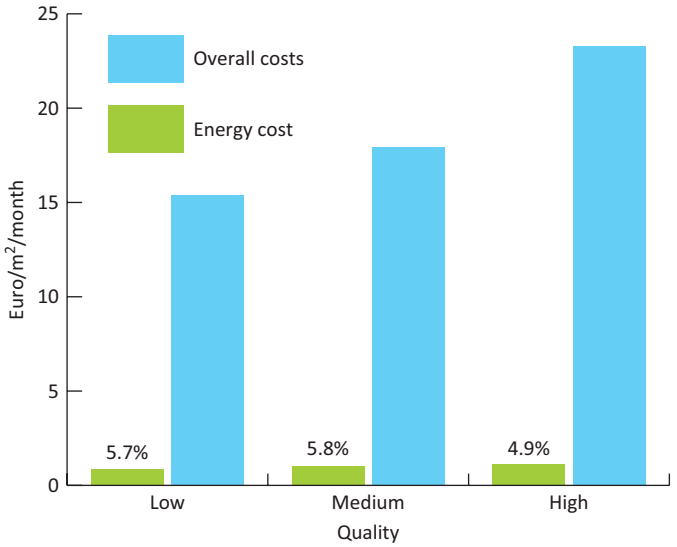

Figure 10.30 | Average values of total costs by quality of fittings. Source: Jones Lang LaSalle, 2006; based on 397 buildings with six million m^2 in 2006.

Most policies to address human dimensions of energy use in buildings are designed to improve energy efficiency, rather than to bring about more fundamental lifestyle changes. However, broader policy frameworks do have implications for culture and lifestyle, although these raise complex and controversial issues. Greater attention to these may be required in the future and should be the subject of further research. These broader lifestyle issues are addressed in Chapter 21.

10.8.4.4 Energy Cost Information and Analysis

Energy is typically a small proportion of total operating costs for buildings. For example, in a high quality office building in Germany, heating and electricity made up less than 5% of the total running cost of the building – about 1.1 out of every €23.3 (1.4 out of $US_{2005}$$29.8) spent (see Figure 10.30).

Energy costs are more significant for direct investors. Energy efficiency is part of the due diligence for the procurement of new properties by those who will own and operate them. For other investors, energy costs are not important. There is emerging evidence that an energy-efficient building can command a premium. One US study (McGraw-Hill Construction, 2006) found that professionals expect greener buildings to achieve an average increase in value of 7.5% over comparable standard buildings, together with a 6.6% improved return on investment. Average rents were expected to be 3% higher.

The insurance industry faces substantial risks from climate change. Based on the consideration of those risks, many insurance companies are providing incentives toward more energy efficient, and climate neutral, buildings. Green insurance is not very common yet, and only exists in developed countries, but is gaining increasing significance.

While energy costs are a relatively small part of total occupancy costs, they can still be a significant factor in motivating energy efficiency action. But profitable opportunities for energy savings are often overlooked because of inadequate cost information. Despite real estate managers' stated interest in energy efficiency, a study in 2006 found that only two-thirds of companies tracked energy data and only 60% tracked energy costs (WBCSD, 2007).

In the United States, only 30% of real estate managers or facilities managers claimed to have included energy efficiency requirements into requests for proposals. Despite these findings, the study surprisingly suggested that energy costs are the most important driver for energy efficiency, both currently and in the future. Energy managers and investment decision makers need to develop a common methodology and language for valuing energy efficiency projects in a similar manner to other investments (Jackson, 2008). With such a risk analysis framework in place, energy efficiency experts and investment decision makers could exchange the information they need to expand investment into energy efficient buildings projects. Accurate and robust analysis demands a high level of understanding of the physical aspects of energy efficiency, which enables physical performance data to be translated into the language of investment. However, while there is a general recognition that energy efficiency practices and products are becoming more widespread in the market place, there are limited data on how these factors impact the value of buildings. The financial effectiveness of capital improvements that target energy demand reduction is usually assessed in terms of simple payback times and does not typically reflect a property investor's valuation methods.

10.8.4.5 New Business Models – ESCOs

Appropriate commercial relationships can increase the focus on energy costs by altering commercial relationships, removing the split incentives problem and introducing more effective incentives for reducing energy use and costs.

An energy performance contract is an arrangement between a property owner and an ESCO that covers both the financing and management of energy-related costs. It involves a variety of mechanisms to help property owners use the knowledge of energy professionals to reduce energy costs. While the effectiveness of ESCOs is well documented, miscalculation of financial and technical risks has caused many failures of these firms.

ESCOs generally act as project developers, installers, and operators over a seven–ten year time period. They assume the technical and performance risk associated with the project. The services offered are bundled into the project's cost and are repaid through operational savings generated, with the ESCO's profit coming from a proportion of cost savings or a fixed fee based on projected energy savings.

As an additional service in most contracts, the ESCO provides any specialized training needed so that the customer's maintenance staff can take over at the end of the contract period. ESCOs have placed great emphasis on measurement and verification and have led the way to verify, rather than estimate, energy savings. One of the most accurate means of measurement is the relatively new practice of metering, which is the direct tracking of energy savings according to sanctioned engineering protocols.

10.8.4.6 New Financial Instruments

Ways to shift the financial equation in favor of energy-efficient investment include reducing the first cost or increasing the savings in the early years.[34] One widely recognized way of increasing potential savings is to increase the cost of energy. These are useful mechanisms across the broader economy. However, WBCSD modeling shows they are likely to have a limited impact on building energy investment decisions if set at a level that is acceptable politically and economically. Even a relatively high carbon price, for example US$60/tCO$_2$, does not add enough to the energy cost to make energy savings sufficiently attractive.

Potential savings can be increased through commercial means. In some countries, utility-charging practices may encourage waste because of discounts for higher use – the unit rate typically declines above specified consumption levels. Reversing this practice would increase the cost of energy at higher consumption levels. This is already the case in Japan, where the first 120kWh of monthly electricity consumption are charged at JPY17.87/kWh (US¢18), increasing to JPY22.86 (US¢23) up to 300kWh and JPY24.13 (US¢24) above that level. A high feed-in tariff for renewable energy supplied to the grid may encourage investment in on-site renewable generation, as is already the case in countries like Germany and France.

WBCSD/EEB modeling has clearly shown that many potentially attractive energy investments do not meet the short-term financial return criteria of businesses, investors, and individuals. While significant savings are possible with relatively modest investment premiums, a first-cost-sensitive buyer will never adopt transformative solutions.

Solutions are to attract new sources of funding, learning from best practice and experience with business models such as ESCOs. Several opportunities are available to open up finance for energy investment:

- Pay as you save: the first cost is financed in full or in part by an energy utility, which recoups the outlay through regular surcharges on the monthly bill; these surcharges attach to the house, not the specific customer.
- ESCOs: utilities or other providers contract to achieve specified energy performance for a commercial building and share the savings with the owner.
- Energy performance contracting: schemes enabling energy services companies or other players to offer innovative contracts guaranteeing the level of services and the energy savings to the customer, as above.
- Locally available loans: local authorities provide loans to finance energy investment, and repayments are made through an addition to the property tax charge.
- Cross-subsidized mortgages for energy-efficient buildings: higher rates for low-efficiency buildings and lower rates for efficient ones.
- Energy efficiency investment funds: capitalizing on the lower risk of mortgage lending on low-energy housing, funds to provide such investment could be attractive to socially responsible investment funds.

10.8.4.7 Toward Low-energy and Zero-energy Buildings

Recently, several countries and organizations adopted ambitious goals with far-reaching implications regarding energy use in buildings. In the United Kingdom, the government is already committed to all new housing being carbon neutral from 2016. In the United States, a number of zero-energy initiatives have been adopted at the state level. For example, in California the zero-energy target has been specified for all new residential buildings by 2020 and for all new commercial buildings by 2030. Analogous targets have been adopted by several other countries, such as Denmark, France, the Netherlands, etc. Table 10.22 reviews these ambitious targets and the related policies that have been adopted by key countries to substantially reduce energy use in new buildings.

Also, the recast of the European Union's EPBD is stimulating Member States to develop frameworks – national plans, etc. – for higher market uptake of low- or zero-energy and carbon buildings. To this end, Member States shall set specific targets for 2020 with respect to the penetration of these buildings in relation to the total number of buildings and the total useful floor area.

The WBCSD in the context of the Energy Efficiency in Buildings project has adopted a vision in which all buildings in the world will consume zero net energy by 2050. In addition, the buildings must also be aesthetically pleasing and meet other sustainability criteria, especially for air quality, water use, and economic viability (WBCSD, 2008). Also, Architecture 2030, an independent nonprofit organization, proposed the 2030 Challenge in 2006, tasking the global architecture and building community to adopt a plan for making new buildings and major renovations carbon neutral by 2030. The plan sets an immediate energy

34 Increasing access to capital requires a very different set of tools, such as preferential rate loans, risk-guarantee mechanisms, or others.

Table 10.22 | Examples of countries and regions which already adopted ambitious targets toward low-energy and zero-energy buildings.

Country / Region	Nature of target	Explanation of the target	Year of target	Source	Legal status of target
UK	Zero carbon homes[1]	All new houses built in the UK must be carbon neutral by 2016. Intermediate targets: carbon performance of new houses to be improved by 25% by 2010 and 44% by 2013, as compared to 2006 Building Regulations.	2016 (with intermediate targets for 2010 and 2013)	Department for Communities and Local Government (2007)	Government plan to be cast into law over time according to the interim targets, until then not legally binding
California	Zero-net-energy buildings[2]	All new residential construction will be zero-net-energy by 2020, while all new commercial construction will be zero-net-energy by 2030.	2020 (for all new residential buildings) 2030 (for all new commercial buildings)	California Public Utilities Commission (CPUC), California Energy Efficiency Strategic Plan (2008)	Strategic goal, not legally binding
Denmark	Continuous reduction of energy use in new buildings	Maximum energy demand in new buildings must be, compared to the requirements[3] of 2006: – 25% lower by 2010 – 50% lower by 2015 – 75% lower by 2020	2010, 2015, 2020	Engelund Thomsen (2008), Danish Government (2009)	Agreement among all major parties of Danish parliament in 2008, confirmed by government strategy in 2009, but not yet cast into law
Austria	Passive house standard[4]	Social housing subsidies[5] shall only be granted for passive buildings from 2015.	2015	Engelund Thomsen et al. (2008), Federal Ministry of Agriculture, Forestry, Environment and Water Management (2007)	Goal of federal government, but not binding for federal states in charge of implementation
France	Energy positive buildings[6]	All new buildings must be energy positive from end of 2020. Intermediate target: maximum primary energy demand of 50 kWh/m^2 for new tertiary buildings from end of 2010 and all new buildings from end of 2012.	2020 (with intermediate target for 2010–2012)	Assemblée Nationale (2008)	Legislative process for binding law ongoing as of May 2009
Germany	Climate-neutral buildings	All new buildings should use zero amount of primary energy by 2020. Existing buildings should undergo efficiency renovation in 2020–2050 to achieve a 80% reduction in their primary energy demand.	2020 for new buildings; 2050 for existing buildings	Ministry of Economics and Technology and Ministry of Environment, Nature Conservation, and Nuclear Safety (2010)	The targets set in the national Energy Concept. The supporting Laws, regulations, and other implementation documents are under discussion and development.
Hungary	Zero carbon residential and public buildings	Granting building permits for residential and public buildings only if they are carbon neutral.	2025	Ministry of Environment and Water (2008)	Strategic goal, not legally binding
The Netherlands	Energy-neutral buildings[7]	All new buildings shall be energy neutral from 2020. The following intermediate targets apply: – 2011: 25% improved energy performance[8] compared to regulations of 2007 – 2015: 50% improved energy performance compared to regulations of 2007	2020 (with intermediate targets for 2011 and 2015)	Engelund Thomsen et al. (2008), Ministry of Economic Affairs (2007), Ministry of Housing, Spatial Planning and the Environment (2007)	Government target, not yet cast into law

[1] Zero carbon means that a home should be zero carbon (net over the year) for all energy use in the home. This would include energy use from cooking, washing and electronic entertainment appliances as well as space heating, cooling, ventilation, lighting and hot water.

[2] CPUC defines zero-net-energy building as a building with a net energy use of zero over a typical year, i.e. the amount of energy provided by on-site renewable energy sources is equal to the amount of energy used by the building.

[3] The minimum requirements for energy efficiency in buildings in Denmark as of April 1, 2006, are defined as follows: the total demand of supplied energy to a building to deal with heat losses, ventilation, cooling and domestic hot water must not exceed 70 + 2200/A kWh/m^2/a for residential and 95 + 2200/A kWh/m^2/a for offices, schools, institutions and other buildings (A is the heated gross floor area).

[4] Passive house standard is defined in Austria as annual heating energy use ≤15 kWh/m^2, where the area refers to net area in Austria in general, but to the useful area in the federal state of Styria and to heated area in the federal state of Tirol.

[5] The share of social housing is high in Austria, this measure is therefore expected to have a great impact on market development for low-energy buildings.

[6] Energy positive buildings are defined as buildings with a lower consumption of primary energy than the amount of energy they produce themselves from renewable sources.

[8] Energy-neutral buildings are defined as not requiring any fossil fuel.

[9] The Netherlands use an Energy Performance Coefficient to measure energy performance. In 2007, its maximum value for new residential buildings was 0.8. This will be lowered to 0.6 from 2011 and to 0.4 from 2015, which roughly corresponds to passive house standard for heating.

reduction target of 50% for all new buildings and major renovations compared to the regional or national average of each building type, with a goal of increasing this target by 10% every five years, reaching 100% by 2030. These goals have been adopted by several organizations, including the American Institute of Architects, the United States Green Building Council, the Environmental Protection Agency, and ASHRAE (Arens, 2008).

However, as mentioned earlier, zero-energy buildings may not be feasible for every type of building and in all regions, and in many cases their economics are unfavorable compared to high-efficiency buildings. They also may not be the most environmentally sustainable solution, as compared to very high-efficiency buildings supplied with partially on-site renewable and zero-carbon grid energy. In fact, universal net zero-energy mandates may even have negative environmental consequences. First, they may encourage urban sprawl, since net zero-energy buildings are easier – or even technologically only feasible – to implement in low-density, low-rise developments, but these increase transportation energy use. Second, if limited budgets of investors and building owners are forced to be spent on relatively more expensive PV panels, larger opportunities are foregone that would have been unlocked if the same investments had been made into efficiency measures that might have eliminated the need to produce more energy.

Nevertheless, in cases where zero-energy and very low-energy buildings are economically and environmentally justified, their promotion requires the implementation of a portfolio of policies that will motivate the several stakeholders and the billions of building owners and occupants.

The adoption of stricter energy performance requirements is of particular importance. As an example, in the United Kingdom the tightening of local planning regulations and building codes will be the basic policy instruments to achieve the carbon neutral target for all new buildings by 2016. Also, the adoption of stricter appliance and equipment standards that are periodically updated will decrease the total electricity loads that should be compensated by on-site generation.

The implementation of economic incentives in the form of subsidies, tax exemptions, etc., either for entire buildings, or for specific equipment components, will improve the economic performance of low-energy and zero-energy buildings and will accelerate the integration of renewable or other efficient technologies in their design. As an example, in France, new buildings respecting certain environmental criteria can be exempted from property taxes for 15–30 years (European Commission, 2009). There is some evidence that economic incentive programs are critical for preparing the market to adopt zero-energy goals in the present (premature) phase (Arens, 2008).

The adoption of preferably mandatory energy performance certification schemes and labeling programs will ensure compliance with energy code requirements and achievement of the targets set, thus enhancing market value. In fact, development of the Passivhaus scheme in Germany and the MINERGIE standards in Switzerland was instrumental in the strong development of low-energy buildings over the past decade.

Lack of awareness and technical capabilities for constructing low-energy and zero-energy buildings among practicing architects, engineers, interior designers, and professionals in the building industry may be a major impediment to their development and the fulfillment of the ambitious goals set. Consequently, the development of capacity building programs to expand know-how is of particular importance. More specifically, there is a significant need in most countries to create comprehensive, integrated programs at universities and other educational establishments to train current and future building professionals in the design and construction of low-energy buildings. Finally, the development of pilot projects is helpful to demonstrate the effectiveness and the everyday functionality of the new buildings. In this context, the role of the public sector as an early adopter is crucial.

10.8.5 Energy conservation versus the rebound effect

Energy efficiency measures often have other, unintended effects on society. These ripple effects include rebound effects, co-benefits, and trade-offs with other resource use and pollution, and spillovers (Hertwich, 2005a). The rebound effect is defined first in Chapter 2, and discussed in detail in Chapter 22. Here it is reviewed with regard to building energy efficiency programs.

There have been a large number of empirical and modeling studies addressing the rebound effect (Greening et al., 2000; Schipper and Grubb, 2000; Hertwich, 2005a; Sorrell, 2007). Empirical studies of the micro-rebound effect consistently find that simple engineering-economic estimates of energy savings from an energy efficiency measure overestimate the savings by 0–30% (Table 10.23), with some outliers in the case of energy poverty (Roy, 2000). When people cannot afford to heat or cool their homes, but efficiency measures make these energy services affordable, these efficiency measures can in fact increase energy use. In all cases, the "rebound" implies that consumers enjoy a higher level of energy service as a result of increased efficiency.

With regard to macro effects, the main concern is that increased efficiency leads to the substitution of energy services for other inputs to production such as labor, capital, and land, alleviating resource constraints and thus enabling economic growth. Empirical studies show that the substitution effect does not lead to an increase in energy use for the same basket of goods (Schipper and Grubb, 2000). As energy is usually a small portion of the overall costs of a product or service, changes in the energy content of the product or service are unlikely to have a substantial effect on demand. It can be observed, however, that energy productivity has increased more slowly than labor productivity. Overall, the input of physical work has increased in lock-step with economic output (Ayres and Warr, 2005), suggesting that increased efficiency of converting primary energy to physical work may have contributed

Table 10.23 | Rebound effect for energy efficiency measures for different energy services.

Energy service	Rebound	Region/study
Residential space heating	10–30% 10–30% (1.4–60%) 20–30%	Review USA (Greening et al., 2000) Review OECD (Sorrell, 2007) Austria (Haas and Biermayr, 2000)
Residential space cooling	0–50% 1–36% 57–70%	Review USA (Greening et al., 2000). OECD (Sorrell, 2007) S.Korea (Jin, 2007)
Appliances	0 0	Austria (Haas, Biermayr et al., 1998) USA (Greening et al., 2000).

substantially to economic growth. Increased input of energy services in agriculture was essential both for raising yields and for freeing labor for work in industry (Erb et al., 2008). Empirical evidence for the importance of energy efficiency for economic growth, however, remains contested (Schipper and Grubb, 2000). The debate about how much energy efficiency increases economic growth and thus demand for energy services has yet to be resolved.

Taxes on energy or energy-related pollution or a cap and trade approach have been identified as an effective way to counteract both micro-rebound and macro-rebound effects because these effects are envisaged to operate through a price mechanism. The rebound effect, while limiting the effectiveness of efficiency measures in reducing overall demand, provides additional economic welfare arguments for energy efficiency as necessary for overcoming energy poverty and as being potentially beneficial for economic growth.

10.8.6 Focus on Developing Countries

10.8.6.1 Existing Policy Instruments in Developing Countries

A recent review of building energy codes (Janda, 2009) found that at least 61 countries had energy codes for buildings in 2008 of which the majority (40) were mandatory. The majority of these are developed countries, but several developing countries are included in this list: Mexico, Singapore, Vietnam, the United Arab Emirates, Jamaica, Jordan, Kazakhstan, Kuwait, Cote d'Ivoire, Thailand, India, China, Chile, South Africa, Indonesia, Malaysia, the Philippines, Lebanon, Tunisia, and Pakistan. Several more plan to introduce building energy codes, including Morocco, Brazil, and Colombia (Janda, 2009), as well as Kenya and Uganda, often supported by international organizations. The most commonly applied measures are voluntary and mandatory labeling, appliance standards, building codes, public leadership programs, DSM programs, subsidies, grants and rebates, awareness-raising campaigns, and mandatory audits. However, only very few evaluations of instruments in these countries are available.

10.8.6.2 Enabling Factors: High Energy Price Levels and Energy Shortages

Increasing energy prices are often considered the most important precondition for improved energy efficiency in developing countries (Levine et al., 2007). Low, subsidized energy prices in many developing countries imply very long payback periods for energy efficiency investments, which renders such projects unprofitable. The differences in energy prices explain why certain governments in the Mediterranean region, such as Tunisia and Morocco, are interested in energy efficiency while others, especially oil-producing countries such as Algeria, are not or are less interested. Revenues from lower energy price subsidies can be rechanneled into rebates for energy efficient programs, loans, and special assistance for low-income households to increase their energy efficiency and thereby reduce energy costs. Since policymakers often consider energy efficiency a lower priority than more vital economic goals, such as poverty alleviation or increased employment, it is essential that non-energy benefits are well mapped, quantified, and well understood by policymakers.

10.8.6.3 Need For Technical Assistance and Training

Sustainable construction know-how needs to be introduced into the base curriculum of architects and other construction-related professions all over the world. This is even more important in developing countries because of the often much more dynamic new construction rates. As the training of a countries' own nationals will take some time, technical assistance through international organizations can bridge this gap for a period. Even in Tunisia – which is often considered a best practice developing country due to its successful energy efficiency policy in the buildings sector (Ürge-Vorsatz and Koeppel, 2007) – representatives of the energy efficiency agency request technical assistance for the development of thermal building standards due to a lack of national expertise in this area (Ürge-Vorsatz and Koeppel, 2007).

10.8.6.4 Need For Demonstration Projects and Information

In addition to the lack of information and awareness, there are also human barriers – for instance, a lack of trust. Trust and awareness can be raised through pilot projects or demonstration projects in the public

sector. Demonstration programs at all levels, from the capital city to villages, such as the Green Buildings for Africa program in South Africa, prove the advantages of energy efficiency to every citizen irrespective of education level.

10.8.6.5 Need For Financial Assistance or Funding Mechanisms

The higher first cost of energy efficient technologies may still hamper penetration in developing countries, especially if the technologies must be imported. For example, high-performance glass is an expensive proposition in many countries, including India. Though it is proven to save energy, the higher first cost of about six-seven times that of the conventional single glazing systems deters many users from investing in it. However, as the market grows, the industry is expected to achieve economies of scale and thus the cost of such technologies should be reduced. Tax breaks can provide an initial push toward energy efficient technologies. Other financial mechanisms such as low interest loans from banks for energy efficient and renewable energy technologies are important, too. For example, in India, interest subsidy is available to buy solar water heating systems.

Especially poorer consumers need investment support or affordable loans, governmental funding, or ESCO financing (Deringer et al., 2004). For example, in July 2008, the World Bank approved a US$15 million grant to Argentina in order to support energy efficient projects and develop incentives for reducing demand on fossil fuels (WB, 2008). Developing countries can raise money on their own through public benefit charges or taxes. For instance, Brazil has obliged utilities to spend 1% of annual revenues on end-use energy efficiency improvements and on R&D. In 2007, India introduced prepayment electricity metering in public buildings and for private consumers to ensure bill payment (IEA Online Database). In Thailand, the government has raised funds through a petrol tax since 1992 (Brulez and Rauch, 1998). The tax revenues are collected in a fund and are now used to support energy efficiency projects. It is important that such funds are managed by independent agencies or institutions to avoid political influence.

10.8.6.6 The Role of Regulatory Measures

Many developing countries, such as Malaysia, Brazil, Morocco, and partly Thailand, first introduced voluntary standards or voluntary labeling for appliances or buildings which are, however, often less effective than mandatory ones. Mandatory audits for public buildings and commercial sector buildings above a certain annual demand are a frequently used instrument, applied, for example, in Tunisia and Thailand. However, compliance is often difficult to achieve. In order to ensure enforcement, special efforts are necessary, such as combining regulatory measures with incentives like subsidies or awards.

10.8.6.7 Importance of Monitoring and Evaluation

While many strategies to encourage or mandate energy efficient buildings or energy efficiency get introduced by government, many fail due to the lack of proper implementation and monitoring mechanisms. There is a major gap between political statements and actual action or changes in building design and construction. For instance, in India, while the government has initiatives to encourage integration of the Energy Conservation Building Code with the National Building Code for the uniform and larger adoption of the energy code, there is currently no concrete plan for the implementation of the code, or for monitoring and verification. Incentives, both financial and symbolic, are crucial for the wider adoption of these programs.

In many countries, baseline data on energy demand are missing. This is problematic, since measuring the success of implemented policy instruments requires knowledge of the baseline consumption. Regular monitoring and evaluation of programs are necessary in order to adapt the program, if possible, to changing circumstances and maximize its outcome. Evaluation studies quantifying energy savings are needed to determine cost-effectiveness and make necessary program adjustments (Jannuzzi, 2005).

10.8.6.8 Role of Institutionalization

Developing countries with successful energy efficiency policies have usually started with the adoption of an Energy Efficiency law or an Energy Efficiency Strategy, as is the case in Thailand, South Africa, and Tunisia. For example, the Tunisian National Agency for Energy Management is one of the main drivers behind the country's currently successful energy efficiency programs. Numerous Arab states are currently introducing such agencies, often with external assistance. The agency can be established as a nonprofit foundation, which provides flexibility in hiring and contracting (Szklo and Geller, 2006). The aim of this institutionalization is to get energy efficiency recognized as a priority among government officials, as well as among utilities and other stakeholders. Furthermore, in universities, the establishment of energy management curricula can contribute to knowledge dissemination and the training of professionals. These professionals can then become competent staff members of the mentioned institutions.

10.8.6.9 Importance of Adaptation to Local Circumstances

Finally, although best practices and experiences can be shared and regional cooperation is useful, the success of programs depends, among other factors, on adaptation to the local economic, political, social, and cultural context. Many programs have already failed because they copied programs from other countries without taking into account differences in culture, political systems, or other areas (Ürge-Vorsatz and Koeppel, 2007). Therefore, a thorough assessment of the local social,

economic, political, and cultural fabric as it affects the operation of the policy instrument is important before decisions are taken. In large countries, the design of energy efficiency programs is most effective if adjusted to different regional contexts and institutional realities, such as the frailty of the regulatory certainty or the tendency of high contract failures. Moreover, the specificities of emerging economies – the social, legal, or economic context – can result in an increasing difficulty for customers in accessing capital. As it is, the higher rates of contractual failures in India or China, for instance, have resulted in investors finding it even more difficult to invest in energy efficiency projects (Taylor et al., 2008).

10.8.7 Implications of Broader Policies on Energy Efficiency in Buildings

10.8.7.1 Liberalization and Restructuring of Electricity Markets

Substantial literature exists on the impacts, both actual and estimated, of the liberalization and resulting restructuring of electricity markets on energy use in final demand sectors and particularly in residential and commercial buildings.

A number of authors (Burtraw et al., 2000; Sondreal et al., 2001; Sevi, 2004; Pollitt, 2008) suggest that electricity restructuring results in lower average prices for electricity, particularly in cases in which the regulated utilities were relatively inefficient. They point out that lower prices are likely to generate higher demand from consumers. However, as household sector long run price elasticity is relatively low, energy market liberalization may have only a small effect on demand even if price reductions are quite substantial. Following liberalization, prices will not necessarily fall in all areas, as price changes may start from different initial levels. If the local regulated utility is a low cost supplier of electricity compared to its neighbors, then prices in the local area could actually rise under competition (Palmer, 1999; Sevi, 2004). Furthermore, the experience with retail competition in Massachusetts and Pennsylvania shows that large industrial and some medium-size customers are the likely beneficiaries of lower prices, while the average price to residential and small commercial customers is likely to rise over time (Sverrisson et al., 2003).

The restructuring of electricity markets is also expected to produce more widespread use of time-differentiated pricing of electricity. This form of pricing will lead to a shifting of demand from peak to off-peak periods and will encourage building occupants to improve their energy-using behavior.

Several studies also indicate that the trend in new utility-funded DSM programs has been downward in the United States due to the deregulation of electricity markets (Eikeland, 1998; Palmer, 1999; Dubash, 2003; Sverrisson et al., 2003; Sevi, 2004; Blumstein et al., 2005) unless there is a regulatory environment that decouples sales of electricity from profits (WBCSD, 2008). For instance, in the United States, many state restructuring laws and federal restructuring bills also include a mechanism for funding DSM initiatives, e.g., through an electricity surcharge, which does not discriminate among electricity suppliers and could result in some energy savings. The Consortium for Energy Efficiency reports a doubling of total DSM expenditures by 88% of the utilities in the United States from 2006 through 2009 (Nevius et al., 2010). In many European countries, energy market reform has been accompanied by the introduction of a formal regulatory system for the first time. In some cases the opportunity has been taken to introduce energy saving obligations on energy companies, using "white certificates" or related mechanisms. In these countries, the introduction of energy efficiency obligations in conjunction with market restructuring has resulted in significantly increased activity on energy efficiency by energy companies (Pavan, 2008; Lees, 2008; Eyre et al., 2009).

The impact of energy market restructuring on energy efficiency is therefore dependent on the prior conditions and details of policy. The restructuring of electricity markets may also lead to increased penetration of distributed generation, both in industrialized and developing countries. More specifically, in a region with relatively high electricity prices stemming, for example, from expensive past investments, a customer can avoid these expenses by operating a distributed generator (e.g., PV units, small wind mills, etc.).

In developing countries, different patterns of current energy use and the relative unavailability of electricity distribution infrastructure will likely lead to very different effects of electricity restructuring than are likely in the developed world. The removal of subsidies that many developing nations provide to energy use, as well as the diversification in the level of service and pricing to reflect local actual costs, could lead to higher electricity prices in many cases, enhancing the attractiveness of investments in rural electrification (Burtraw et al., 2000; Nagayama, 2008). However, without an explicit effort, energy markets restructuring will result in decreased electricity accessibility to the poorer segments of the population (Dubash, 2003).

10.8.7.2 Energy Taxation and High Energy Prices

Inevitably, higher end-use energy prices, while not addressing all the market failures in the buildings sector, increase the energy conservation potential. However, the effect of price increases on energy demand depends on how sensitive demand is to energy price fluctuations. As already pointed out, household sector long-term price elasticity is relatively low, at least in developed economies, indicating that variability in energy prices may have only a small effect on demand even if price increases are quite substantial. For example, in the Netherlands, short run price elasticity for electricity in households was estimated to be between 0 and -0.25, whereas the long run elasticity was estimated to be -0.3 to -0.45 (Berkhout et al., 2000). This is mainly attributable to the

fact that in richer countries, energy prices are often a relatively insignificant cost component and therefore receive inadequate attention from building occupiers and owners (WBCSD, 2008).

There is some evidence that energy use behavior may be seriously affected when a significant part of available income is spent on energy. Energy tends to be used carefully in developing countries, and this is also true in richer countries during the last five years due to very high increases in international fuel prices. In the United States, high energy prices over the last five years have stimulated energy saving initiatives. In 2007, two-thirds of United States homebuilders were planning to build green in 15% of their projects, citing customer concern about energy costs as the main reason (Kelleher, 2006).

The increase of end-use energy prices through the imposition of energy taxes at some point in the energy supply chain may provide a second means to energy efficiency through the investment of the tax revenues – or at least part of them – in energy conservation related activities, such as mandatory DSM measures, subsidy schemes, green funds, or other mechanisms.

10.9 Gaps in Knowledge

While buildings are ubiquitous and some aspects are well researched and documented, such as the engineering aspects, there is surprisingly little understanding about their energy use and thus how problems related to their energy demand can be mitigated – both at the micro and macro levels. This section identifies a selection of important gaps in this knowledge, as considered important by the authors of this chapter.

Perhaps the most glaring problem with the knowledge is the shortage of related data and information. Little data exist on how energy in buildings is concretely used and how it is broken down by end-uses, building types, technologies, or other variables. Knowledge gaps exist about detailed energy use by energy service. Another major knowledge gap pertains to region-specific costs of new buildings in relation to their energy performance and region-specific costs of retrofits of existing buildings in relation to the savings in energy use achieved. Sufficient knowledge is also lacking about best practices, that is, the most sustainable means for providing energy services in each developmental, cultural, and individual situation. The interaction between life cycle energy use, environmental impacts, and cost aspects are also not well studied. Most of the published literature on life cycle assessments of different building types is very recent and the field is not yet very mature. Most engineering, environmental, and economic assessments related to sustainability options for buildings rely on their direct energy use, costs, and emissions. However, considering the entire life cycle would probably affect the validity of many decisions and policies, as there are often trade-offs.

The situation regarding energy policies in developing countries clearly requires further research. Only very few ex-post policy impact evaluation studies are currently available and even fewer include quantitative data on effectiveness, cost-effectiveness. The cumulative effect of policy packages, incremental and double counting effects of policy tools, as well as synergy effects, are poorly understood. While the area of co-benefits or ancillary benefits of energy efficiency in the buildings sector also needs to be further explored, even less is known about ancillary costs, which are seldom mentioned in literature. This relates to the better researched field of the obstacles or barriers to the deployment of energy efficiency in the sector.

10.10 Novelties in GEA's Global Building Energy Assessment

There have been several assessments completed recently on building-related opportunities for climate change mitigation or sustainable energy by various organizations. There are several new elements in this chapter as compared to these earlier assessments. These include:

- An energy service-centered approach: the discussion and consideration of opportunities recognizes that energy services are needed rather than energy per se, allowing for a broader spectrum of more innovative alternatives and solutions.
- Life cycle energy and emissions versus only operational ones: considering life cycle energy use and emissions when possible rather than just the operational energy and emissions in buildings, and recognizing the trade-offs. Novel policy recommendations originate from applying such a perspective.
- Applying a holistic, performance-based approach that recognizes that buildings are complex, integrated systems rather than sums of individual components.
- A novel global building energy use model using a performance-centered logic; presenting building thermal en pathways until 2050.
- The importance of the lock-in effect in the building sector has been shown for the first time, as well as detailed quantification of it.
- Large database on quantified or monetized co-benefits, illustrating the large orders of magnitude of such benefits.
- A detailed assessment of non-technological opportunities and challenges, emphasizing human dimensions.

Executive Summary

Renewable energy sources – including biomass, geothermal, ocean, solar, and wind energy, as well as hydropower – have a huge potential to provide energy services for the world. The renewable energy resource base is sufficient to meet several times the present world energy demand and potentially even 10 to 100 times this demand. This chapter includes an in-depth examination of technologies to convert these renewable energy sources to energy carriers that can be used to fulfill our energy needs, including their installed capacity, the amount of energy carriers they produced in 2009, the current state of market and technology development, their economic and financial feasibility in 2009 and in the near future, as well as major issues they may face relative to their sustainability or implementation.

Present uses of renewable energy

Since 1990 the energy provided from renewable sources worldwide has risen at an average rate of nearly 2% a year, but in recent years this rate has increased to about 5% annually (see Figure 11.1.) As a result, the global contribution of renewables has increased from about 74 EJ in 2005 to about 89 EJ in 2009 and represents now 17% of global primary energy supply (528 EJ, see Figure 11.2). Most of this renewable energy comes from the traditional use of biomass (about 39 EJ) and larger-scale hydropower (about 30 EJ), while other renewable technologies provided about 20 EJ.

As summarized in Table 11.1 many renewable technologies have experienced high annual growth rates – some (biofuels, wind, solar electricity, solar thermal, and geothermal heat) even experiencing double-digit growth rates globally over the past five years – and now represent an economy with more than $US_{2005}$$230 billion of investment annually. With cumulative installed contributions to the power, fuel, and thermal heat markets growing rapidly, turnkey costs reflect not only the capital intensity and most often zero or low fuel costs of these solutions, but also the technology and scale advancements of the past decades. The levelized costs of energy, particularly for the more mature renewable technologies, offer competitively priced solutions in some markets but are still comparatively expensive in others under current economic pricing schemes.

In 2009, the contribution of renewable energy technologies to the world's electricity generation was roughly 3800 TWh, equivalent to about 19% of global electricity consumption. Renewable power capacity additions now represent more than one-third of all global power capacity additions.

Note that in the figures presented in Table 11.1, the contribution of renewables to the primary energy supply based on the substitution calculation method is presented. Using this method, non-traditional renewables contributed 50 EJ in 2009. Following other calculation methods – see Chapter 1 and Table 11.2 – the total result for 2009 would be different: 28.5 EJ when using the physical content calculation method and 26 EJ when using the direct equivalent calculation method.

Potential and obstacles for renewable energy technologies

The potential of renewables to provide all the energy services needed is huge, as described in Chapter 7 and in the Special Report on Renewable Energy Sources and Climate Change Mitigation of the Intergovernmental Panel on Climate Change, published in 2011 (IPCC, 2011). Further developing and exploiting renewable energy sources using modern conversion technologies would enhance the world's energy security, reduce the long-term price of fuels from conventional sources, and conserve reserves of fossil fuels, saving them for other applications and for future generations. It would also reduce pollution and avoid safety risks from conventional sources, while offering an opportunity to reduce greenhouse gas emissions to levels that will stabilize greenhouse gases in the atmosphere, as agreed upon globally. It could also reduce dependence on imported fuels, minimize conflicts related to the mining

and use of limited available natural resources, and spur economic development, creating new jobs and regional employment.

But using energy from renewable sources also faces a number of challenges because of their often low spatial energy intensity (J/m^2) or energy density (J/m^3) compared with most fossil fuel and nuclear energy sources, their generally capital-intensive installation costs, their sometimes higher-than-desirable operational costs, and a variety of environmental and

social concerns related to their development. An additional important issue is the intermittent character of wind, solar, and several ocean energy, requiring backup system investments or other innovations to secure a reliable energy supply.

System integration of renewable energy technologies

System integration studies show no intrinsic ceiling to the share of renewables in local, regional, or global energy supplies, depending on the resource base and energy demand. Intelligent control systems, supported by appropriate

Table 11.2 | Contribution of modern renewables to primary energy supply in 2009 using three calculation methods: the substitution method (with GEA conversion efficiencies), the physical content method, and the direct equivalent method.

Technology	Primary energy supply in 2009 (EJ/yr) using the substitution method	Primary energy supply in 2009 (EJ/yr) using the physical content method	Primary energy supply in 2009 (EJ/yr) using the direct equivalent method
Biomass energy	12.1	12.1	12.1
Hydroelectricity

Low-temperature solar thermal energy	0.5	0.43	0.43
Ocean energy	0.005	0.002	0.002
Total supply	*49.9*	*28.5*	*25.9*

energy storage systems and energy transport infrastructure, will help renewable energy meet the energy demands of different sectors. However, the variability of wind, solar, and several ocean energy resources can create technical or cost barriers to their integration with the power grid at high levels of penetration (20% or above).

To reduce or overcome these barriers, the main approaches in the electricity sector involve: drawing power from geographically larger areas to better balance electricity demands and supplies; improving network infrastructures; increasing the transmission capacity, including the creation of so-called supergrids for long-distance power transmission; developing the Smart Grid further; applying enhanced techniques to forecast intermittent energy supplies hours and days ahead with high accuracy; increasing the flexibility of conventional generation units (including dispatchable renewables) to respond to load changes; using demand-side measures to shift loads; curtailing instantaneous renewable supplies when necessary to guarantee the reliability of power supplies; and further developing and implementing energy storage techniques.

Financial and investment issues

Annual investments in new renewables have increased tremendously, from less than US_{2005}2 billion in 1990 to about US_{2005}191 billion in 2010, excluding investments in larger-scale hydropower. Including large hydropower, investments were about US_{2005}230 billion in 2010. The quickest growth in sustainable energy financing has come from three sectors of the financial community that had previously shown little interest: venture capital and private equity investors, who provide the risk capital needed for technological innovation and commercialization; public capital markets, which mobilize the resources needed to take companies and projects to scale; and investment banks, which help raise capital and arrange mergers and acquisitions. The engagement of these new financial actors has signaled a broader scale-up in asset financing of the investment in actual generating plant capacity.

In the period 2004–2009, the annual growth rates in renewable energy investments were 32% for financing technology commercialization, 45% for financing the construction of projects, and 85% for financing equipment manufacturing and scale-up. This fast-tracking of alternative energy technologies into the commercial mainstream is beginning to change

the energy paradigm, although much more growth will be needed before renewables can become the world's primary source of energy.

Policy instruments and measures

A key issue is how to accelerate the deployment of renewables so that deep penetration of these technologies into the energy system can be achieved quickly. Renewable energy technologies face a number of factors that make it harder for them to compete based solely on costs: their capital intensity, scale, and resource risk; their discounted value to traditional utility operators; their real or perceived technology risk; the absence of full-cost accounting for environmental impacts on a level playing field; generous subsidies to the use of conventional energy sources; and a lack of recognition of their long-term value for reducing utilities' exposure to variable fuel costs. These issues have a negative impact for investors by extending the time frame for returns or by increasing risk and the expected rate of return. The risks can be reduced by using public-sector financial or market instruments such as guarantees in terms of market access, market size, and price security.

A wide range of regulatory, fiscal, and voluntary policies have been introduced globally to promote renewable energy – whether renewable electricity, renewable heat, or renewable fuels. These serve a range of technology-specific objectives, including innovation, early-stage development and commercialization, manufacturing, and market deployment, as well as wider political goals such as creating new manufacturing bases for a technology, local and global environmental stewardship, and economic prosperity. These policies all help to reduce risk and encourage renewable energy development, and they are generally used in combination. Integrating renewable energy into the conventional energy system will require a portfolio approach that addresses key issues such as comprehensive and comparable cost-benefit analysis of all energy options, provision of stable and predictable policy environments, and removal of market barriers and competing subsidies for fossil fuels, thus increasing the probability for successful innovation and commercialization, provided that the policies complement one another.

Of the market pull policies, two are most common. Feed-in tariffs (FITs) ensure that renewable energy systems can connect and supply their power to the grid and offer a set price for renewable energy supplies. Policies known as quota or obligation mechanisms (also referred to as Renewable Portfolio Standards, Renewable Electricity Standards, or Renewable Fuel Standards) set an obligation to buy but not necessarily an obligation on price. So far, FITs have been used for electricity only, although some countries are now considering how to provide them for heat. Quotas have so far been used for electricity, heat, and transport. Biofuel mandates are now common globally.

The rapid expansion in renewables, which has largely taken place in only a few countries, has usually been supported by incentives or driven by quota requirements. The FITs used in the majority of European Union countries, China, and elsewhere have been exceptionally successful. The number of states, provinces, and countries that have introduced policies to promote renewable energy doubled in the period 2004–2009.

Future contribution of renewable energy

Many studies have been done on the potential of renewable energy in the remainder of the twenty-first century. Most of them indicate that the contribution of these sources, excluding traditional and non-commercial uses, could increase from today's 10% of world energy supply to 15–30% in 2030, to 20–75% in 2050, and to 30–95% in 2100, depending on assumptions made about economic growth, the volume of investments in energy efficiency and energy technology development, policies and measures to stimulate the deployment of different technologies, and public acceptance of these technologies. Some studies suggest that by 2050, renewable sources could provide 75–95% of the world's

energy, or even all of it, if there is enough societal and political will to choose a path of clean energy development that focuses mainly on renewable sources; on new energy transmission, distribution, and storage systems; and on strong improvements in energy efficiency. There is, however, no consensus on whether such a deep penetration of renewables can be achieved in practice within the indicated time frames because of physical limits on the rate at which new technologies can be deployed, the need to design targeted policies to accelerate the deployment of specific technologies, and the difficulty of curtailing energy use through actions on the demand side.

11.1 Introduction

This chapter presents an in-depth examination of major renewable energy technologies, including their installed capacity and energy supply in 2009, the current state of market and technology development, their economic and financial feasibility in 2009 and in the near future, as well as major issues they may face relative to their sustainability or implementation. Renewable energy sources have been important for humankind since the beginning of civilization. For centuries, biomass has been used for heating, cooking, steam generation, and power production; solar energy has been used for heating and drying; geothermal energy has been used for hot water supplies; hydropower, for movement; and wind energy, for pumping and irrigation. For many decades renewable energy sources have also been used to produce electricity or other modern energy carriers.

Renewable energy can be defined as "any form of energy from solar, geophysical, or biological sources that is replenished by natural processes at a rate that equals or exceeds its rate of use" (Verbruggen et al., 2011). In a broad sense, the term renewable energy refers to biomass energy, hydro energy, solar energy, wind energy, geothermal energy, and ocean energy (tidal, wave, current, ocean thermal, and osmotic energy). In the literature (see, e.g., UNDP et al., 2000) the term "new renewable" is also used, referring to modern technologies and approaches to convert energy from renewable sources to energy carriers people can use, taking into account sustainability requirements. In general, "new renewable" includes modern biomass energy conversion technologies, geothermal heat and electricity production, smaller-scale use of hydropower, low- and high-temperature heat production from solar energy, wind conversion machines (wind turbines), solar photovoltaic and solar thermal electricity production, and the use of ocean energy (UNDP et al., 2000; REN21, 2005; Johansson et al., 2006).

11.1.1 Renewable Energy Sources and Potential Energy Supplies

The energy of renewable sources originates from solar radiation (solar energy and its derivatives), geothermal heat (from the interior of the earth), and gravitational energy (mainly from the moon). The energy flow from these sources on Earth is abundant. Tapping just a small fraction of it would in theory be enough to deliver all energy services humanity needs.

A major energy source on Earth is solar energy. As indicated in Figure 11.3, the amount of solar energy directly available for energy conversion in principle is at least more than 1000 times the primary energy use of humankind at present (about 528 exajoules (EJ) in 2009). And in theory, the potential of geothermal energy and ocean energy is also impressive. In practice, however, only a fraction of these potentials can be exploited. Nevertheless, this chapter describes how this fraction can be equivalent to perhaps several times present global energy use.

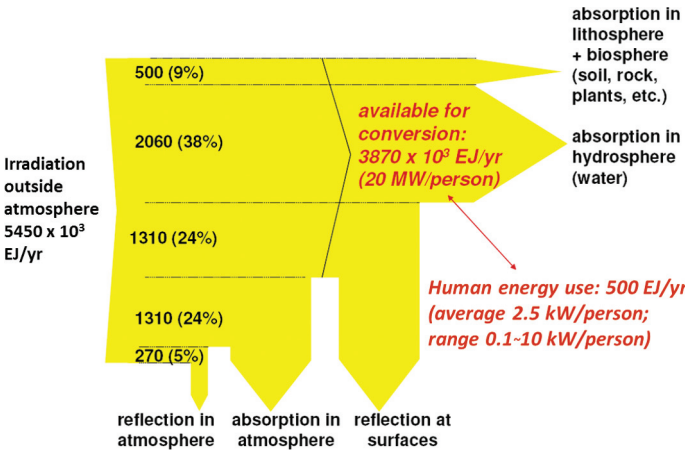

Figure 11.3 | The solar resource and its flows on Earth. The amount of solar energy available on Earth (estimated at 3.9 million EJ/yr) is many times the present human energy use (~528 EJ in 2009).

Table 11.3 presents a summary of the theoretical and technical potential of renewable sources to contribute to the production of energy carriers, based on the *World Energy Assessment* (WEA) published in 2000 (UNDP et al., 2000), on the Special Report on Renewable Energy Sources and Climate Change Mitigation of the Intergovernmental Panel on Climate Change (IPCC, 2011) and on Chapter 7. This chapter focuses on the techno-economic potential of renewables in the longer term, which is a portion of the technical potential, taking into account socioeconomic and environmental constraints. In the literature, "market potential" and "implementation potential" of renewables are also sometimes distinguished, showing a further reduction of the potential of renewables as socioeconomic barriers are taken into account and, in the case of "implementation potential," as policies to promote the deployment of renewables as well as public attitudes are considered.

11.1.2 Renewable Energy Conversion Technologies

A wide variety of technologies are available or under development to provide affordable, reliable, and sustainable energy services from renewables (see Table 11.4), but the stage of development and the competitiveness of various technologies differ greatly. In addition, performance and competitiveness are determined by local aspects such as resource availability, technological infrastructure, socioeconomic conditions, policy measures, and the cost of other energy options.

All renewable energy sources can be converted to electricity. Only a few of them can be used to produce solid, liquid, or gaseous fuel directly, as well as heat. Some of the major sources are intermittent, e.g., solar and wind energy, which can create challenges in adopting these sources while maintaining the reliability of the overall energy supply, depending on how widely they are used.

Table 11.3 | Overview of the technical potential of renewable energy sources in EJ/yr.

Renewable Energy Source	Technical Potential (EJ/yr)		
	WEA (2000)	Chum et al. (2011)	GEA (2012)
Geothermal energy[a,b]	5000	130–1420	810–1545
Direct solar energy[c,a]	> 1575	1575–50,000	62,000–280,000
Wind energy[d,a]	640	85–580	1250–2250
Biomass energy – land-based[e,a]	> 276	50–500	160–270
Hydropower[a]	50	50–52	50–60
Ocean energy[f,a]	not estimated	7–331	3240–10,500
TOTAL	> 7600	1900–52,800	76,500–294,500

[a] Figures from WEA and GEA are based mainly on their own assessment, whereas those from Chum et al. are the result of a review of available literature.

[b] The WEA estimates relate to the amount of energy stored underground; the GEA estimates, to the annual terrestrial heat flow.

[c] Differences in outcome between WEA and GEA are due to different approaches to calculating the potentials.

[d] One reason for the increase of the technical potential between WEA and GEA is the inclusion of offshore wind energy.

[e] Excluding marine biomass energy; the difference in theoretical potential between WEA and GEA can be explained by different calculation methods; restrictions related to sustainability criteria are the main reason for the decrease in estimated technical potential between WEA and GEA.

[f] The indicated technical potential comes mainly from ocean thermal energy conversion; the GEA numbers refer to the potential before conversion, the IPCC SRREN numbers to the potential after conversion.

11.1.3 Advantages and Disadvantages of Renewables

Developing and exploiting renewable energy sources using modern conversion technologies can be highly responsive to national and international policy goals formulated because of environmental, social, and economic opportunities, objectives, and concerns:

- Diversifying energy carriers for the production fuels, electricity, and heat; enhancing energy security; and reducing the long-run price of fuels from conventional sources;
- Reducing pollution, environmental emissions, and safety risks from conventional energy sources that damage human health, natural systems, crops, and materials;
- Mitigating greenhouse gas emissions down to levels that can be sustained;
- Improving access to clean energy sources and conversion technologies, thereby helping to meet the Millennium Development Goals (MDGs) while taking advantage of the local availability of renewables;
- Reducing dependence on and minimizing spending on imported fuels;
- Reducing conflicts related to the mining and use of limited available natural resources, as most renewable energy sources are well distributed;
- Spurring economic development, creating new jobs and local employment, especially in rural areas, as most renewable energy technologies can be applied in small-, medium-, and large-scale systems in distributed and centralized application;
- Balancing the use of fossil fuels, saving them for other applications and for future generations.

Making use of renewable energy sources also has some disadvantages and drawbacks, part of which are intrinsic and part of which are due to the status of technology development:

- The spatial energy intensity (J/m^2) or density (J/m^3) of renewable energy sources is often low compared with most fossil fuel and nuclear energy sources. Consequently, space is needed where these renewable sources are converted to allow them to deliver most – and finally, perhaps all – of the energy needed. But this may create competition with other claims and requirements for the use of land, including food production, the protection of ecosystems, and biodiversity conservation. Strategies to mitigate these concerns include multifunctional land use, technologies with high conversion efficiencies, and the combination of renewables with measures to improve energy efficiency.
- Although the energy from renewable sources is most often available for free (which reduces vulnerabilities associated with the price volatility of fossil fuels), renewable energy conversion technologies are often quite capital-intensive: operating costs (fuel costs) are replaced by initial costs (installed capital costs). This can make renewables less attractive, especially when high discount rates are

Table 11.4 | Modern renewable energy conversion technologies.

Technology	Energy Product	Status
Biomass energy		
Combustion (domestic scale)	Heat (cooking, space heating)	Widely applied; improvement of technologies
Combustion (industrial scale)	Heat, steam, electricity, CHP (combined heat and power)	Widely applied; potential for improvement
Gasification/power production	Electricity, heat, CHP	Demonstration phase; large-scale deployment of small units in certain countries
Gasification/fuel production	Hydrocarbons, Methanol, H2	Development and demonstration phase
Hydrolysis and fermentation	Ethanol	Commercially applied for sugar/starch crops; production of fuels from lignocellulose under development
Pyrolysis/production liquid fuels	Bio-oils	Pilot and demonstration phase
Pyrolysis/production solid fuels	Charcoal	Widely applied commercially
Extraction	Bio-diesel	Commercially applied
Digestion	Biogas	Commercially applied
Marine biomass production	Fuels	R&D phase
Artificial photosynthesis	H2 or other fuels	Fundamental and applied research phase
Hydropower		
Mini-hydro	Movement	Remotely applied; well-known technology
Small and larger-scale hydropower	Electricity	Commercially applied
Geothermal energy		
Power production	Electricity	Commercially applied locally
Direct heating	Heat, steam	Commercially applied locally
Heat pumps	Heat	Increasingly applied
Wind energy		
Small wind machines	Movement, electricity	Water pumping / battery charging
Onshore wind turbines	Electricity	Widely applied commercially
Offshore wind turbines	Electricity	Demonstrated; initial deployment phase
Solar energy		
Passive solar energy use	Heat, cold, light, ventilation	Demonstrations and application, combined with energy-efficient buildings
Low-temperature solar energy use	Heat (water and space heating, cooking, drying) and cold	Solar collectors commercially applied; solar drying and cooking locally applied
Photovoltaic solar energy conversion	Electricity	Widely applied, remote and grid-connected; high learning rate
Concentrated solar power	Heat, steam, electricity	Demonstrated; initial deployment phase
Ocean energy		
Tidal head energy	Electricity	Applied locally; well-known technology
Wave energy	Electricity	Some experience; research, development, and demonstration (RD&D) phase
Tidal and ocean current energy	Electricity	Some experience; RD&D phase
Ocean thermal energy conversion	Heat, cold, electricity	Some experience; some application of cold use; other technologies mainly in RD&D phase
Salinity gradient / osmotic energy	Electricity	RD&D phase

applied, depending on the level of investments needed as well as governmental interventions.

- The levelized cost of energy (LCOE) from renewables is often not yet competitive in the (distorted) marketplace, especially in grid-connected applications. This may change, however, as renewable energy costs are brought down through technological learning while penetrating markets. Also, using conventional energy sources will become more expensive due to resource depletion and policies to internalize external costs.

- The exploitation of renewable energy sources may entail environmental and social concerns, as experienced with, for instance, electricity production from hydropower and wind energy and the use of biomass resources.

- The intermittent character of the production of energy carriers from wind, solar, and wave energy may set specific requirements for the total energy system to achieve a reliable energy supply. It may require methods to predict renewable energy supplies many hours ahead, management of energy demands, availability of backup power, development of storage options, and enhanced flexibility of energy systems.

As most of these issues have to be solved in an acceptable manner within a few decades (see Cluster I, Chapters 2–6 of this assessment), this chapter also discusses policies and measures to create an environment that will enable deep penetration of renewable energy technologies into existing and new energy systems in the period 2020–2050.

11.1.4 Contribution of Renewables to Global Energy and Electricity Supply

In 2009, renewable energy, including traditional use of biomass, contributed about 89 EJ (17%) to the world's primary energy use, mostly

Table 11.5 | Contribution of renewables to global primary energy supply in 1998, 2005, and 2009, calculated using the substitution method (see Chapter 1).

Category	Renewable Energy Supply		
	1998 (WEA)	2005 (IPCC 2007)	2009 (this chapter)
Traditional biomass[a]	38 EJ	37 EJ	39 EJ
Larger-scale hydropower	26 EJ	24 EJ[b]	30 EJ
New renewables			
- Modern biomass	7.0 EJ	9.0 EJ	12.1 EJ
- Geothermal energy	0.6 EJ	1.9 EJ	1.2 EJ
- Wind energy	0.2 EJ	0.9 EJ	3.7 EJ
- Smaller-scale hydropower	0.9 EJ	0.8 EJ	2.2 EJ
- Low temp. solar energy	0.05 EJ	0.2 EJ	0.55 EJ

[a] After correction for differences between calculation methods applied.

[b] It is unclear why in 2005 the energy produced is below the WEA figure for 1998, whereas installed capacity increased substantially (see also Table 11.6).

through traditional biomass (about 39 EJ or 7%)[1] and larger-scale hydropower (about 30 EJ or nearly 6%), whereas the share of new renewables was 20 EJ (about 4%).[2] The contribution of renewables to electricity production in 2009 was around 3800 terawatt-hours (TWh), equivalent to about 19% of global electricity consumption, with new renewables accounting for about 900 TWh (4.5%). Table 11.5 presents an overview of the share of renewables in global energy use in 1998, 2005, and 2009. Note that these figures originate from different sources and that they represent savings on fossil fuel consumption as explained in Chapter 1 and footnote 2.

Since 1990 the use of energy from renewable sources has increased about nearly 2%/yr. As total primary energy use has increased at about the same rate, the relative contribution remained almost constant (IEA, 2009), but it is increasing the last few years. Investments in new renewables have increased tremendously, from less than US_{2005}2 billion in 1990 to about US_{2005}191 billion in 2010, excluding investments in larger-scale hydropower. Including larger-scale hydropower, investments in 2010 were about US_{2005}230 billion (UNEP and BNEF, 2011; see Section 11.11).

To illustrate some impacts, Table 11.6 shows the increase in installed power generating capacity, heat and hot water production, and the production of liquid fuels between 1998 and the years 2008, 2009, and 2010 based on data published by UNDP et al. (2000) and by REN21 (2009; 2010; 2011). Throughout this chapter, an in-depth analysis of the status and contribution of each technology is made, sometimes providing slightly different numbers.

Many of the developments indicated in Table 11.6 are taking place in western industrial countries and in countries like China, Brazil, and India. However, impressive developments are also found in remote areas of developing countries (REN21, 2009). At present, nearly 600 million households depend on traditional biomass (fuelwood, dung, agricultural residues) for cooking and heating. Improving the efficiency of biomass stoves can save 10–50% of biomass consumption, strongly improve indoor air quality, and reduce time spent on collection of the biomass. More than 220 million improved stoves are now found around the world, mainly in China (180 million) and India (34 million), whereas in Africa this number is over 8 million (REN21, 2009).

In rural areas, small-scale thermal biomass gasification is also applied, especially in India and China, where the gas is used for cooking, milling, drying, and electricity generation, for example. About 25 million households worldwide, especially in China (20 million) and India (3 million), receive energy for lighting and cooking from biogas produced in household-scale plants (REN21, 2009). By 2007 more than 2.5 million households were receiving electricity, mainly for lighting and communication, from solar home systems. On the order of 1 million small-scale windmills are in use for mechanical water pumping, mainly in Argentina and South Africa. In remote areas and on islands worldwide, tens of thousands of mini-grids exist, often powered by hybrid electricity supply systems using renewables like solar PV, wind, biomass, and mini-hydro combined with batteries or backup power provided by a diesel generator (REN21, 2009). More than half of the global supply of low-temperature solar heat is found in China (see Section 11.8).

Many studies have been done on the potential contribution of renewable energy to the global energy supply in the twenty-first century. Figure 11.4 show the results for the BLUE Map scenario of the International Energy Agency (IEA), whereas Figure 11.5 also shows results for the baseline scenario of IEA and for other energy sources (IEA, 2010a). Most studies indicate that the contribution of renewables to future energy supply – excluding traditional and non-commercial uses – could increase from the present figure of about 10% up to 15–30% in 2030, 20–76% in 2050, and 30–95% in 2100, depending on assumptions made about economic growth, investments in energy efficiency and energy technology development, policies and measures to stimulate the deployment of different technologies, and public acceptance of these technologies. (See, e.g., UNDP et al., 2000; IPCC, 2000, 2007a, 2011; WGBU, 2003; Johansson et al., 2006; IEA, 2008a; 2008b; 2009a; 2010a; 2010b; Shell, 2008; 2011; Greenpeace and EREC, 2007; 2010; Krewitt et al. 2009; NEAA, 2009; ECF, 2010; WWF and Ecofys, 2011; See also Chapter 17.)

1 The contribution of traditional biomass in 2008 and 2009 can be estimated at 39 ±10 EJ; see Section 11.2.

2 Different studies present different numbers for the contribution of renewables to primary energy supply. This is partly due to uncertainty about the contribution of traditional biomass energy use. The main reason, however, is the calculation method applied when converting generated heat and electricity from renewables to primary energy; see Chapter 1 and table 11.2. GEA applies the substitution method for non-combustible fuels assuming a conversion efficiency of 35% in electricity production and 85% for heat production.

Table 11.6 | Installed capacity to generate electricity from renewable energy sources (gigawatts, GW) as well as amount of process heat (GW_{th}) and liquid fuels (billion liters per year) produced in 1998, 2008, 2009 and 2010

[b] As indicated in the WEA update in 2004 (UNDP et al., 2004), this figure is probably too low.

Source: UNDP et al., 2000; REN21, 2009; 2010; 2011.

Some studies suggest that 75–95% or even 100% contributions from renewables can be achieved by 2050 regionally (in the European Union (EU), for instance) as well as globally if there is enough societal and political will to choose an energy development focusing mainly on renewables and new energy transmission, distribution, and storage systems, along with strong improvements in energy efficiency (Greenpeace and EREC, 2007; 2010; Krewitt et al, 2009; ECF, 2010; WWF and Ecofys, 2011). Figures 11.6 and 11.7 show results of two of these studies.

It should be noted, however, that there is no consensus about whether deep penetration of renewables up to the level indicated in these studies can be achieved in practice within the time frames indicated in the Figures because of physical limits to the rate at which new technologies can be deployed, the need to design policies targeted at specific technologies to accelerate deployment, and actions required on demand side to (strongly) increase energy efficiencies and curtail energy use (Kramer and Haigh, 2009).

The remainder of this chapter investigates the status and potential development of renewable energy technologies as well as their market development, costs, environmental performance, deployment barriers, and incentives to overcome the barriers. The cross-cutting issues discussed in the final sections are the integration of renewables into reliable and secure energy systems, developments in renewable energy investments, and policies and measures to enhance the development and application of renewables.

11.2 Biomass Energy

11.2.1 Introduction

Globally, photosynthesis stores energy in biomass at a rate about seven times the current 500 EJ/yr rate of total global energy use. Less than 2% of this biomass is used for human energy consumption today. Biomass resources are diverse, and the global consumption volume of the largest category of these resources (fuelwood in developing countries) rivals that of industrial roundwood (see Figure 11.8). The geographic distribution of biomass resources is uniform relative to that of most fossil fuels (see Chapter 7).

When exploited sustainably, biomass can be converted to modern energy carriers that are clean, are convenient to use, and have little or no associated greenhouse gas (GHG) emissions on a life-cycle basis. Various conversion technologies are available or under development. Sustainable bioenergy has the potential to make large contributions to rural and economic development, to enhance energy security, and to reduce environmental impacts (Chum et al., 2011).

Projections from the IEA, among others, and many national targets count on increasing biomass production and use going forward. Chapters 7 and 20 discuss factors relating to sustainable feedstock production and estimate the quantities of supplies that might be available to 2050. This chapter focuses on summarizing the status and future prospects of modern biomass energy technologies.

11.2.2 Potential of Bioenergy

Biomass accounts today for about 10% (51 EJ) of global primary energy consumption (IEA, 2010a; see also Table 11.5). Its largest, mostly traditional use is found in developing countries. Dominating the traditional use is firewood for cooking and heating. On the other hand, an estimated 12.1 EJ of primary biomass energy was converted to modern energy carriers in 2009: an estimated 3.3 EJ were converted to 241 TWh of electricity (Electricité de France and Observ'ER, 2010) (more than 1% of all global power generation); about 3.6 EJ were converted to 2.3 EJ of biofuels (REN21, 2010) (about 2% of all global transportation energy) from primarily corn, rape, soy, and sugarcane; and the remainder (about 5.2 EJ) was converted to 4.2 EJ heat, including heat from combined heat and power (CHP) systems.[3]

The analysis in Chapter 7 indicates projected sustainable supplies by region of five categories of biomass supplies – energy crops, forestry residues, crop residues, municipal solid wastes (MSW), and animal wastes – in 2050. Combining these estimates with estimates of prospective efficiencies of biomass electricity generation or of so-called second-generation biofuels production described in this Chapter enables order of magnitude estimates to be made for the maximum potential supplies of low-GHG electricity or liquid transportation fuels in 2050.

Table 11.7 shows that if all sustainably producible biomass supplies were to be converted to electricity, the total electricity generation could approach today's global level of electricity generation from all sources.

3 The estimate of 12.1 EJ/yr biomass energy converted to modern energy carriers assumes an average biomass power generating efficiency of 26.3% (IEA, 2010a). Also, the 2.3 EJ of ethanol plus biodiesel produced in 2009 (REN21, 2010) is assumed to have been made from primary biomass with an average energy efficiency of about 60% (Chum et al., 2011). To estimate biomass use for heat, it was conservatively assumed that all biomass use reported for the Organisation for Economic Co-operation and Development by the IEA (2010a), other than biomass used for power generation and for biofuels production, was used for heat or combined heat/power. In addition, Brazil's use of biomass in the industrial sector (as reported by the IEA) is assumed to be for modern heating (e.g., bagasse CHP in the sugarcane industry, or black liquor CHP in the pulp and paper industry). All other non-power/non-biofuel biomass in the world, as reported by the IEA, is assumed to be used in traditional fashion. The IEA estimates are for 2008. It is assumed that there was no change in heat use of biomass between 2008 and 2009. The efficiency of converting primary biomass energy into heat is assumed to be 80% (Chum et al., 2011).

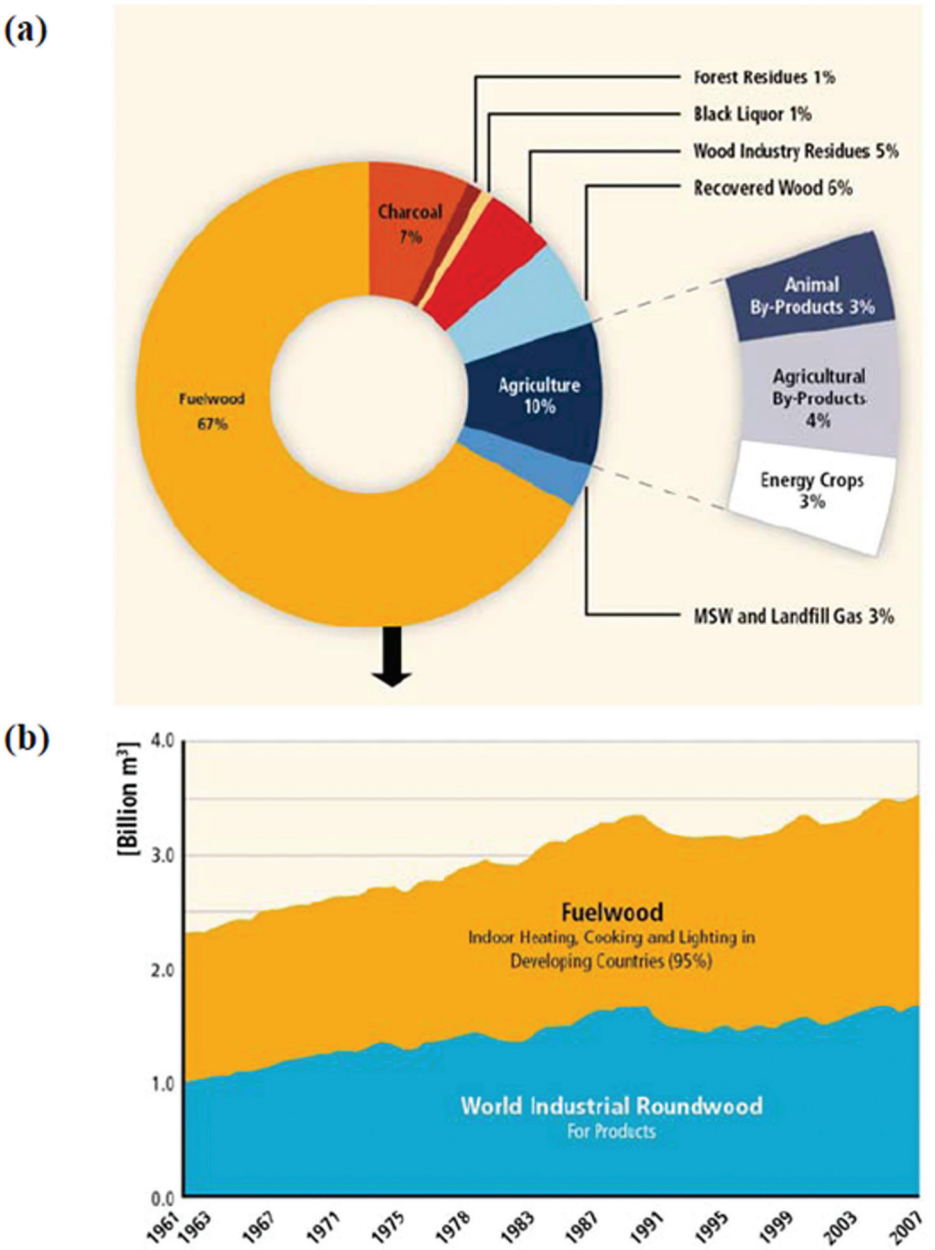

Figure 11.8 | (a) Shares of primary biomass sources in global primary energy use, (b) Fuelwood used in developing countries and world industrial roundwood production levels. Source: Chum et al., 2011.

Alternatively, if all of the biomass were to be converted to second-generation biofuels, the amount of fuel would be comparable to 70–85% of all petroleum-based transportation fuel use in the world at present. If the biomass were converted to transportation fuels in coal and biomass to liquids (CBTL) systems – that is, those that co-process some coal and capture and store by-product CO_2 (as described briefly in this chapter and more extensively in Chapter 12) – twice as much low GHG-emitting liquid transportation fuel could be produced as the level of petroleum transportation fuels consumed today.

It should be noted that in this assessment the potential to produce transportation fuels from algae was not taken into account because it is more speculative at this time. With the large number of diverse algal species in the world, upper range productivity potentials of up to several hundred EJ for microalgae and up to several thousand EJ for macroalgae have been reported (Sheehan et al., 1998; Florentinus, 2008; van Iersel et al., 2009; Chum et al., 2011). No reliable estimates are available yet on the techno-economic potential of energy from algae.

11.2.3 Market Developments

Nearly 80% of the total biomass use for energy today occurs in rural areas of developing countries (Chum et al., 2011), and biomass as a

[a] Average of high and low estimates for 2050 of potential sustainable biomass energy production (from Chapter 7).

[b] Assuming any available biomass is used only for electricity generation. All categories of biomass resource shown here except animal manures are assumed to be converted to electricity at the same efficiency. For small-scale electricity systems, the assumed conversion efficiency is 30% (gross heating value or HHV basis), a value that can be achieved today with biomass gasifier internal combustion engine systems. For large-scale systems, an efficiency of 40% (HHV) is assumed. This level is likely to be achievable with future gasifier gas turbine combined cycle systems. Animal wastes are assumed to be converted at 25% efficiency to biogas prior to conversion to electricity at the 30% and 40% efficiencies.

[c] Animal wastes are neglected for the transport fuel calculations. Forest residues (assumed HHV of 20 GJ/dry t) are assumed to yield 5.9 and 7.6 GJ_{LHV} per dry t biomass for the low and high estimates. Crop residues and municipal solid waste (assumed to have HHV of 18 GJ/dry t) are assumed to yield 7.3 and 9.3 GJ_{LHV} per dry t biomass for the low and high estimates. Liquid fuel yield from energy crops is assumed to be the average of yields from forest residues and crop residues. The "High with CBTL" case assumes 19.5 GJ_{LHV} liquid yield per dry tonne of biomass for each feedstock

[d] The global regions are defined in Annex II of this Assessment.

[e] CBTL means co-processing coal-and-biomass-to-liquid (CBTL) fuels.

whole accounts for 70% or more of total primary energy use in many of these countries (Karakezi et al., 2004).

Rural biomass use consists in general of charcoal, wood, agricultural residues, and manure used primarily by direct combustion for cooking, lighting, and space heating, with attendant negative health and socio-economic impacts that affect primarily the poor (see Chapters 2 and 4). In Asia, China's biomass consumption represented about 10% of total energy (2007), while in India and some other countries the average was about 25%. Latin American biomass use was about 20% of primary energy, while in Africa the average approached 50% (IEA, 2009a).

Biomass is used in industrial countries differently, typically first being converted into clean modern energy carriers (electricity, process heat, transport fuels). On average, biomass accounts for 3–4% of total energy use in these countries, although in countries with supportive policies (Sweden, Finland, Austria, and others), the contribution reaches 15–20% (REN21, 2011).

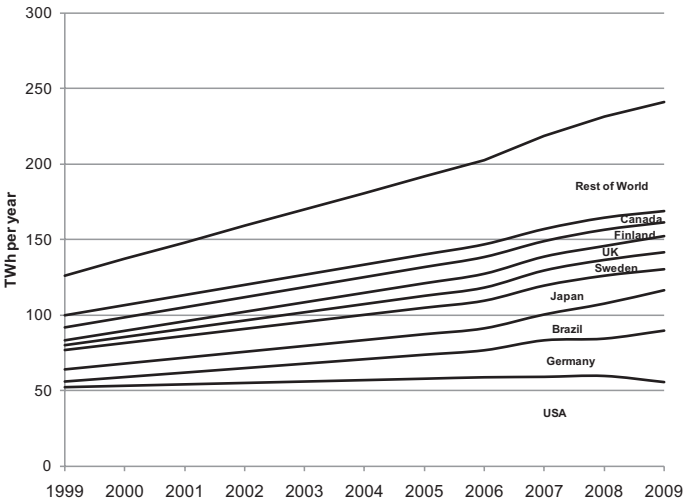

Figure 11.9 | Electricity generation from biomass in selected countries, 2007. Source: based on Electricité de France and Observ'ER, 2010.

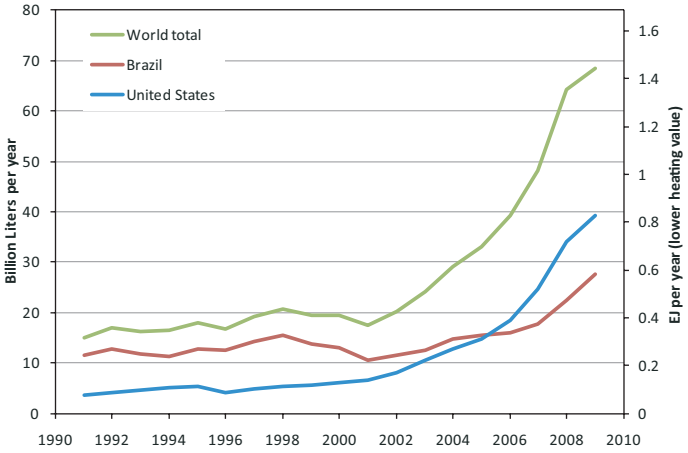

Figure 11.10 | Ethanol production from sugar and starch crops. Source: RFA, undated; UNICA, undated; BP, 2009.

Most electricity generation from biomass occurs in Organisation for Economic Co-operation and Development (OECD) countries, with Brazil being the leading producer outside the OECD (see Figure 11.9). Production of transportation fuels (biofuels) based on agricultural crops (principally corn, soy, rape, and sugarcane) has been growing faster than biopower generation. Figure 11.10 shows the recent rapid growth in ethanol production. Biodiesel production in the United States (from soybeans) and in Europe (from rapeseed) similarly has been growing rapidly in recent years. International trade of biofuels has also grown in recent years, with around 10% of all biofuels traded internationally. Similarly, a third of biomass pellets produced for energy are traded internationally (Junginger et al., 2011).

Combined heat and power systems in the pulp and paper industry accounted for most of the estimated 8500 MW of installed biomass-electric generating capacity in the United States by the end of 2009 (REN, 2010). Biomass CHP plants, with heat used for district heating, are found in Sweden, Finland, Austria, and elsewhere. In developing countries, biomass power generation is found most notably at sugarcane processing factories, where residue from juice extraction is the fuel. Globally, there is an estimated 4700 MW of sugarcane biomass power generating capacity.[4]

Co-combustion in existing coal-fired power plants is an important and growing conversion route for biomass in many EU countries (Spain, Germany, the Netherlands, and others).

Biogas production globally was an estimated 1 EJ in 2009, based on the following analysis. In China, 18 million small-scale anaerobic biomass waste digesters were installed in 2005, having increased an average of 16% per year starting in 2000 (Chen et al., 2010). Assuming an average per-digester production of about 400 m^3 of biogas per year (22 MJ/m^3 energy content) and continued 16% per year growth in installations from 2005–2009, the total biogas production (from 32.8 million digesters) in 2009 would have been 0.29 EJ. India is estimated to have several million digesters installed, and there are several hundred thousand in other developing countries (REN21, 2010). The number of digesters in industrial countries is much lower, but unit sizes are generally larger – located at large livestock processing facilities (stockyards), municipal sewage treatment plants, and landfills. Biogas production from all sources in the EU totaled 0.35 EJ in 2009, up 4.1% over 2008 (EurObserv'ER, 2010). Germany accounted for 50% of the production and the United Kingdom accounted for 21%. In the United States, biogas production in 2008 was an estimated 0.28 EJ, having increased at 4.3% per year from 2004 (US DOE, 2010a). Assuming continued growth at this rate, US production in 2009 was 0.29 EJ.

Large-scale partial-combustion biomass gasifier systems are not commercially operating today, but as a result of considerable research, development, and pilot-scale demonstration work during the past 25 years (Engstrom et al., 1981; Strom et al., 1984; Kosowski et al., 1984; Evans et al., 1987; Lau et al., 2003) these technologies are nearly commercially ready. The "downstream" components in systems for making liquid fuels from syngas derived via gasification are fully commercial in many cases. (See Chapter 12.)

The only operating commercial demonstration plant for second-generation ethanol (made from non-edible biomass) started in 2004 in Canada, using separate saccharification and fermentation to produce about 3 million liter/yr from wheat straw. Additional commercial-scale demonstration plants are under construction or in planning, largely in the United States (IEA Bioenergy Task 39, undated; US DOE, 2010c), where significant government incentives are available.

4 Based on the update of a survey carried out by The World Alliance for Decentralized Energy (WADE) in 2005, reported in Survey of Energy Resources (WEC, 2007).

11.2.4 Biomass Energy Conversion Technology Development

A wide variety of technologies are used today to convert raw biomass into modern energy carriers. Figure 11.11 is a simplified road map of the main options. Not shown in this figure but discussed in this section are biomass conversion systems that would include capture and storage of by-product CO_2 to achieve negative greenhouse gas emissions.

Figure 11.12 summarizes the development status of a range of technologies for producing heat and power from biomass, ranging from anaerobic digestion, co-firing, gasification, and combustion of biomass to the production of heat. The development status of different biomass densification techniques is also shown.

11.2.4.1 Electricity and Combined Heat/Power from Biomass

The predominant technology for generating megawatt levels of electricity from biomass today is the steam-Rankine cycle. Efficiencies are modest – often under 20%. To improve efficiency, most steam cycle power plants are located at industrial sites, where they are configured for combined heat/power production. Low efficiencies, together with relatively high capital costs, explain the reliance of most existing biomass power plants on captive, low-value biomass (primarily residues of agro- and forest-product-industry operations).

Biomass is co-fired in some existing coal-fired power plants. Benefits of this approach include typically high overall efficiency (~40%) because of the large scale of the plants and low investment costs. Aside from GHG emission reductions, co-firing also leads to lower sulfur and other emissions (Faaij, 2006). Generally, relatively low co-firing shares can be deployed with very limited consequences for boiler performance and maintenance.

Many EU coal plants are now equipped with some co-firing capacity. The interest in co-firing higher shares (for instance, up to 40%) is rising. At such high levels, good technical performance (of feeding lines and boiler, for example) is more challenging. Development efforts are focusing on such issues (van Loo and Koppjan, 2002). Power plants capable of co-firing various biomass types with natural gas or with coal exist in Denmark, where alkali-rich straw is a common fuel. Increased corrosion and slagging are common alkali-related problems

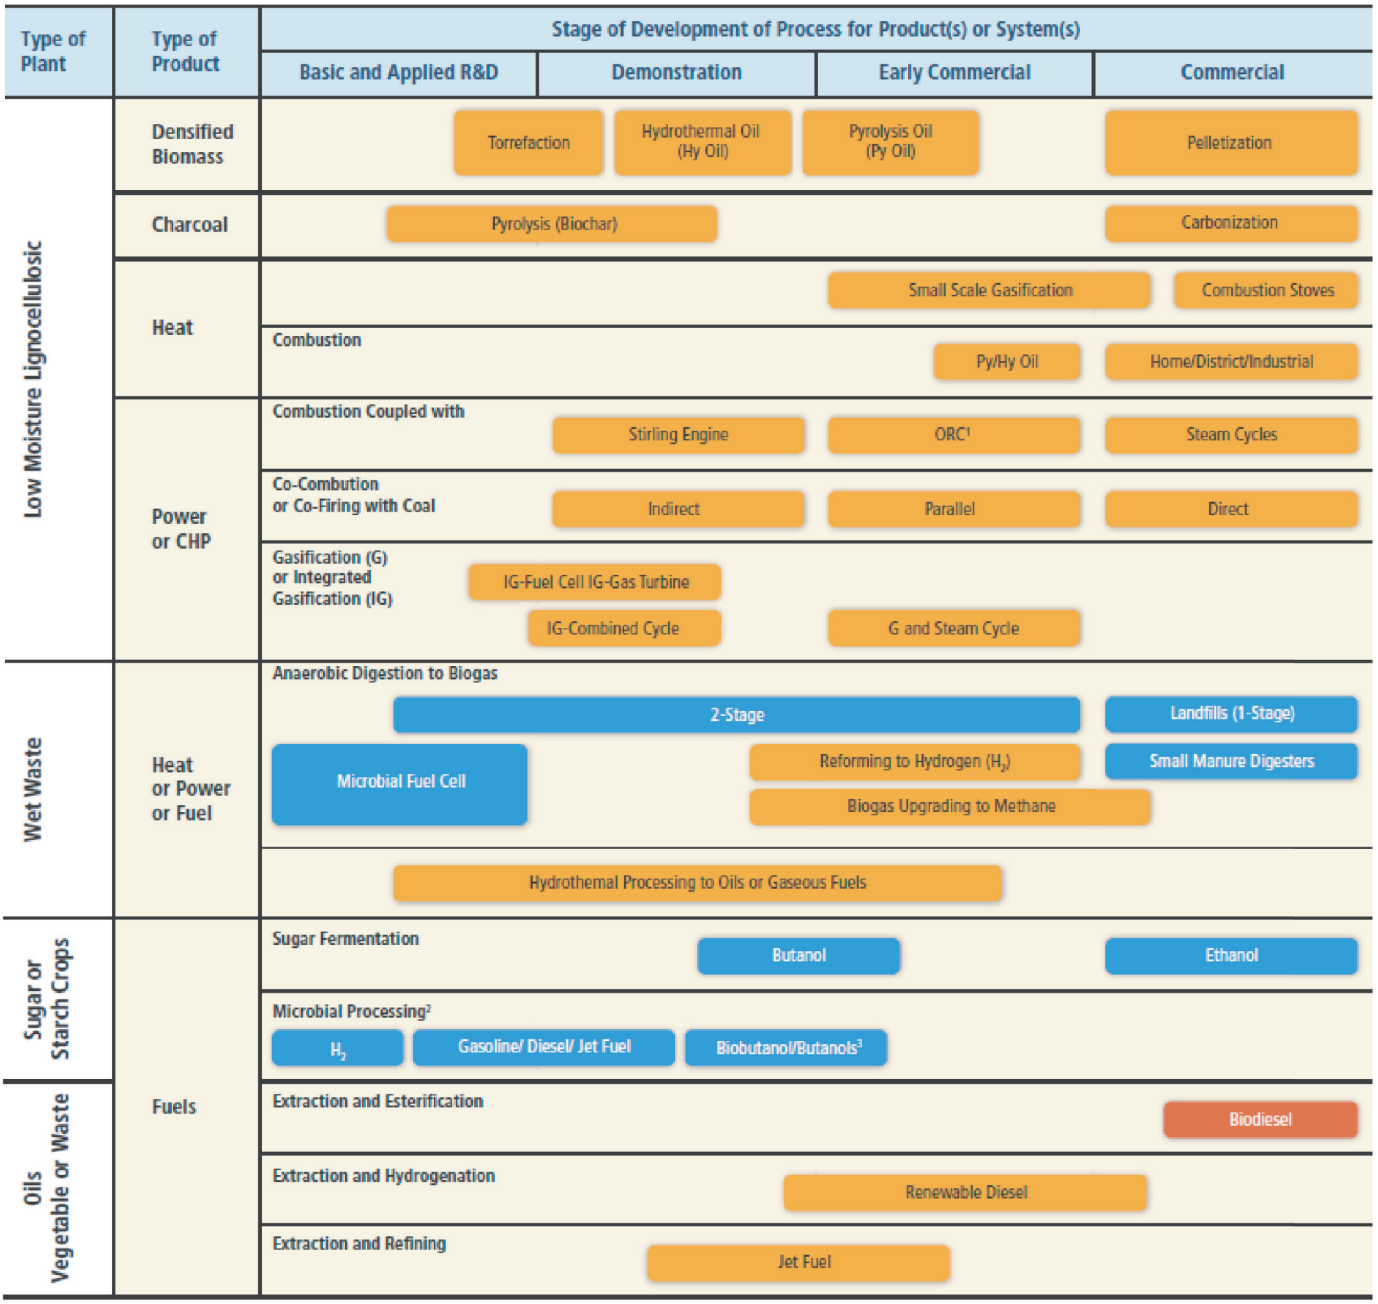

Figure 11.12 | Examples of stages of development of bioenergy: thermochemical (yellow), biochemical (blue), and chemical routes (red) for heat, power, and liquid and gaseous fuels from solid lignocellulosic and wet waste biomass streams, sugars from sugarcane or starch crops, and vegetable oils. Source: Chum et al., 2011.

Notes: 1. ORC: Organic Rankine Cycle. 2. Genetically engineered yeasts or bacteria to make, for instance, isobutanol (or hydrocarbons) developed either with tools of synthetic biology or through metabolic engineering. 3. Several four-carbon alcohols are possible and isobutanol is a key chemical building block for gasoline, diesel, kerosene and jet fuel and other products.

in conventional combustion systems. In multi-fuel systems, however, these problems can be largely circumvented by using straw to raise low temperature steam, which is then superheated using heat from fossil fuel combustion (Nikolaisen et al., 1998). Finally, there is also growing interest in co-feeding of biomass with fossil fuels in gasification-based systems, as briefly discussed later in this chapter and more extensively in Chapter 12.

Advanced biomass power technologies have been the focus of considerable research, development, and demonstration work over the past 25 years to improve conversion efficiency and reduce power generation costs. Gasification of biomass (producing a gas rich in hydrogen and carbon monoxide) coupled with gas engines (Bolhar-Nordenkampf et al., 2003; Salo, 2009) or with gas turbine combined cycles (Larson et al., 2001; Williams, 2004; Sipila and Rossi, 2002; Sydkraft et al.,

1998, 2001; DeLong, 1995; Lau, 2005) have gotten the most attention. Projected conversion efficiencies for Biomass Gasification Combined Cycle systems at a scale of tens to hundreds of MWs exceed 40% (higher heating value basis). At 5–10 MWs, Biomass Gasifier Engine (BGE) efficiencies of 28–30% (lower heating value, or LHV basis) are expected, with total efficiency reaching 87% (LHV basis) in combined heat/power mode (Salo, 2009). Key technical challenges for gasification-based systems are feeding of biomass, especially against pressure (Kurkela, 2008), and cracking of heavy hydrocarbons (tars and oils) that form at typical biomass gasification temperatures (Bergman et al., 2002; Kurkela, 2008; Swedish Energy Agency, 2008; Dayton, 2002; Pfeifer and Hofbauer, 2008). Progress is being made in both these areas.

11.2.4.2 Fuel Gas from Biomass

Biomass can be converted into several types of fuel gases. These gases can be used to generate heat or electricity but also to produce synthetic natural gas or liquid fuels. Anaerobic digestion is by far the most widely used option today for gas production from biomass. The term anaerobic digestion commonly refers to low-temperature biological conversion, with the resulting product (biogas) typically being 60% methane and 40% CO_2. Its use is limited to relatively small-scale applications. Animal and human wastes, sewage sludge, crop residues, carbon-laden industrial-processing by-products, and landfill material have all been widely used as feedstocks. High-moisture feedstocks are especially suitable. Anaerobic digestion has important direct non-energy benefits: it produces concentrated nitrogen fertilizer and neutralizes environmental waste.

11.2.4.3 Liquid Transportation Fuels from Biomass

A popular (non-technical) classification for liquid fuels made from biomass includes first-, second-, and third-generation biofuels. The different generations are distinguished primarily by the feedstocks from which they are derived and the extent to which they are commercially developed.

First-generation biofuels

First-generation biofuels are the only ones being used in significant commercial quantities today. These are made from sugars, grains, or seeds – that is, from only a specific (usually edible) portion of a crop. Relatively simple processing steps convert these feedstocks into fuels (see Figure 11.13), which provides for relatively low processing costs.

Representative fuel yields for the most common first-generation biofuels range from about 2 GJ ethanol per tonne of sugarbeet or sugarcane (LHV) up to about 15 GJ biodiesel per tonne of rapeseed. In terms of land utilization efficiency, the values range from an average of about 20 GJ/ha/yr for US soy biodiesel to about 160 GJ/ha/yr for Malaysian palm biodiesel (see Table 11.8).

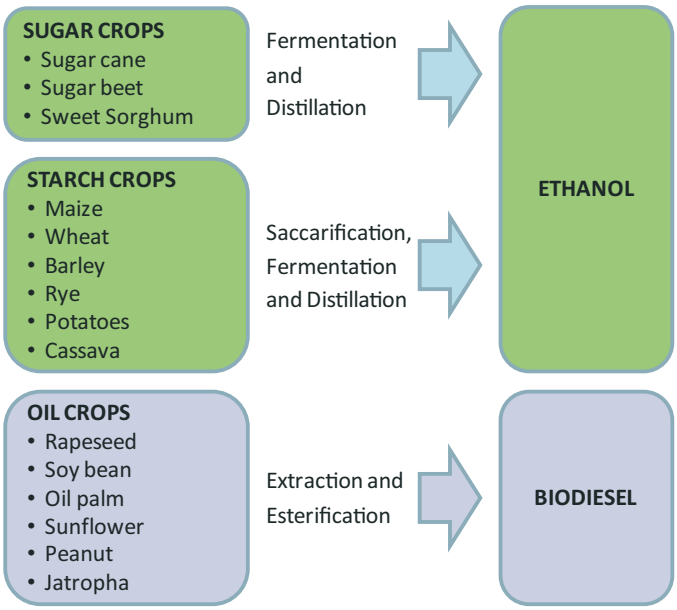

Figure 11.13 | Main feedstocks and conversion steps for first-generation biofuels.

Second-generation biofuels

Second-generation biofuels are those made from land-based non-edible lignocellulosic biomass, either residues of food crop production (such as corn stalks or rice husks) or whole-plant biomass (such as grasses or trees) (UNCTAD, 2008). There are a variety of technology routes for second-generation fuels production (Huber et al., 2006). Among these, second-generation ethanol or butanol can be made via biochemical processing, while most other second-generation fuels are made via thermochemical processing (see Figure 11.14), in some cases using processing steps that are nearly identical to those that would be used to produce synthetic fuels from fossil fuels (see Chapter 12).

Second-generation biochemically produced alcohol fuels are produced via pre-treatment, saccharification, fermentation, and distillation. Pre-treatment is designed to help separate cellulose, hemicelluloses, and lignin so that cellulose and hemicellulose can be broken down by enzyme-catalyzed or acid-catalyzed hydrolysis (water addition) into their constituent simple sugars. The use of acid hydrolysis was practiced commercially as long ago as the 1930s for ethanol production, but involves high capital and operating costs and low yields. Processes using enzymes for hydrolysis promise more competitive ethanol (UNCTAD, 2008).

A variety of process designs have been proposed for the production of second-generation ethanol, including separate enzyme-catalyzed hydrolysis (or saccharification) and fermentation steps, simultaneous saccharification and fermentation in a single reactor (Aden et al., 2002; Jeffries, 2006), and consolidated bioprocessing that incorporates enzyme production (from biomass) with saccharification and fermentation (Zhang and Lynd, 2005). Less work has been done on butanol, but similar processing ideas as for ethanol can be envisioned (UNCTAD, 2008).

Table 11.8 | Representative average yields of first-generation biofuels.

	Fuel yield from grain /seed[a]		Seed/Grain Yield[b]	Fuel per ha/yr	
	Liters/tonne	GJ/tonne	tonne/ha/yr	Liter/ha/yr	GJ/ha/yr
Bioethanol					
Corn (US)	413	8.7	10.2	4220	89
Sugarbeet (US)	100	2.1	60.6	6056	128
Sugarcane (Brazil)	95	1.8	70	5950	126
Biodiesel					
Soybean (US)	204	7.0	2.8	575	20
Rapeseed (EU)	441	15.2	3.6	1601	55
Oil palm (Malaysia)	230	7.9	20.6	4738	163

[a] Fuel yields from corn, sugarbeets, and soybean are estimated averages for 2012 in the United States (FAPRI, undated). Fuel yield from rapeseed is an estimate for the United Kingdom (ESRU, undated). Oil palm estimates are from FAO (2008). Fuel yield of ethanol from sugarcane is the current average in the Center-South region of Brazil in liters per tonne of sugarcane stalk (Hassuani, 2009). The lower heating values for ethanol and biodiesel are 21.1 MJ/liter and 34.5 MJ/liter, respectively.

[b] Corn grain, sugarbeet, and soybean yields are average 2008 yields in the United States (ERS, undated). Rapeseed yield is a representative 2008 average for the European Union (FAS, undated). Sugarcane yield is an estimate of the current Brazilian average in tonnes of cane/ha/yr (Matsuoka et al., 2009). Oil palm estimates are from FAO (2008).

Another biological approach to second-generation biofuels is "synthetic biology," which involves engineering microbes to produce specifically desired fuels, especially hydrocarbon fuels that are "drop-in" replacements for petroleum diesel and gasoline. The work that has been done thus far has been targeting the development of microbes that "eat" sugar molecules and excrete diesel-like fuel (Lee et al., 2008).

Thermochemical (gasification-based) processing of biomass can produce Fisher-Tropsch Liquid fuels, dimethyl ether, gasoline made via methanol, methanol, ethanol, and other fuels.

Gasification takes place in oxygen or via indirect heating (to avoid diluting the resulting gas with nitrogen). The resulting synthesis gas (syngas) is cleaned of contaminants, and in some cases the composition of the gas is adjusted to prepare it for further downstream processing (UNCTAD, 2008). Carbon dioxide is a diluent in the syngas and so is removed to facilitate downstream reactions and reduce equipment sizes. The major components of the clean, concentrated syngas are carbon monoxide (CO) and hydrogen (H_2), usually with a small amount of methane that is unavoidably formed at typical gasification temperatures (<1000°C).

Further gas processing can follow different routes. In one class of processes the syngas is passed over a catalyst that promotes reactions between the CO and H_2 to form liquid fuels molecules. The design of the catalyst determines what fuel is produced. Not all of the syngas passing over the catalyst will be converted to fuel. The unconverted syngas can be burned to make electricity for some or all of the power needed to run the facility and in some cases to export electricity to the grid (UNCTAD, 2008).

In a second class of processes, the CO_2-free syngas goes to a reactor containing specially designed micro-organisms that ferment the CO and H_2 into ethanol or butanol (Spath and Dayton, 2003). This combined thermochemical/biochemical route to a pure alcohol, if it can be made commercially viable, would enable the lignin in the biomass feedstock, as well as the hemicellulose and cellulose, to be converted to fuel (UNCTAD, 2008), unlike the case for purely biochemical "cellulosic ethanol," where the lignin is unfermentable.

Second-generation biofuel yields can be high. Table 11.9 gives estimated yields per tonne of dry biomass processed for several second-generation biofuels. Also shown are estimates of yields per unit land area in the United States on two qualities of land: one suitable for agriculture and one not well suited for it. On good-quality lands, yields for second-generation biofuels are likely to exceed by a considerable margin the yields of first generation-biofuels given in Table 11.8. Yields would be higher still on good-quality lands in tropical climates, due to the longer growing season.

Direct liquefaction is one additional class of second-generation conversion that deserves mention. Fast pyrolysis (Bridgwater and Peacocke, 2000) and hydrothermal upgrading (for moist biomass) (Goudriaan and Naber, 2008) represent different variants of liquefaction. Different reaction pressures and temperatures, catalysts, and rates of heating in the absence of oxygen produce different liquid, gas, and solid output compositions (Huber et al., 2006). The liquid product is typically a "biocrude oil" that is denser than water, highly acidic, odoriferous, and carcinogenic. It requires refining into finished transportation fuels. So-called green diesel can be produced from such oils using catalytic processing that resembles conventional petroleum refining (McCall et al., 2008).

A final comment is warranted regarding the concept of biorefining because of the potential it has for optimizing economics of biofuels production. Biorefining is analogous to current petroleum refining, which leads to an array of products, including liquid fuels, other energy products, and chemicals (Kamm et al., 2006). Although the biofuel and

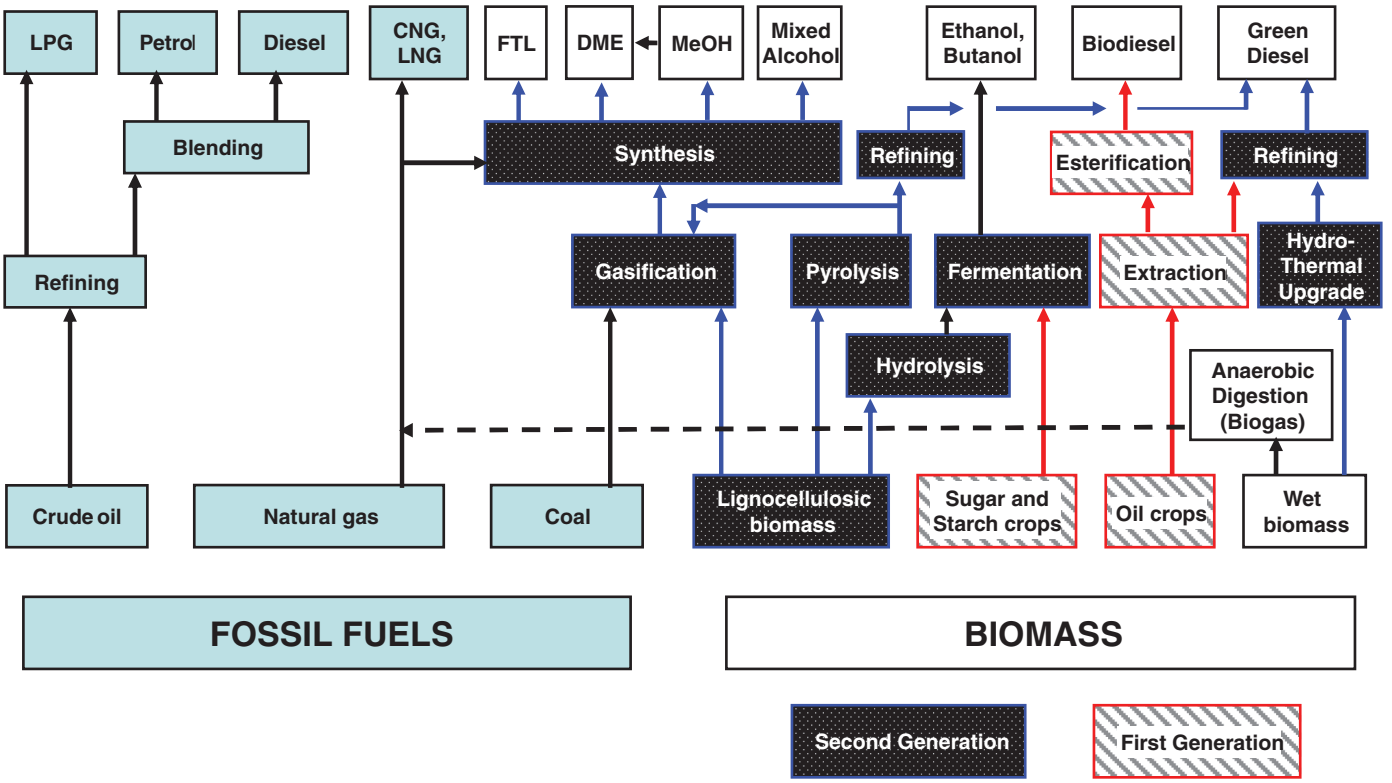

Figure 11.14 | Production paths to liquid fuels from biomass and, for comparison, from fossil fuels.

associated co-products market are not fully developed, first-generation operations that focus on single products (such as ethanol or biodiesel) are regarded as a starting point in the development of sustainable biorefineries. New sugarcane processing facilities are examples of commercial biorefineries, producing both ethanol and exported electricity (EPE, 2008). Advanced or second generation biorefineries would be based on more sustainably derived biomass feedstocks. These biorefineries aim to optimize the use of biomass and resources in general (including water and nutrients), while mitigating GHG emissions (Chum et al., 2011).

Third-generation biofuels

Third-generation biofuels are those that require considerable research and/or technology advances before they can begin to approach commercial viability. Fuels in this category include biological solar hydrogen production and photo-electrochemical fuel production (Aartsma et al., 2008), as well as algae-derived fuels (Sheehan et al., 1998a; Brennan and Owende, 2010). Such options have the potential to more easily meet sustainability constraints, especially land requirements, in part via substantially higher efficiencies of solar energy conversion than for second-generation biofuels. (See Figure 11.15.)

Among third-generation fuels, algae-derived fuels are attracting the most attention today. Algae production does not require the use of good-quality land (though water needs can be substantial). With the large number of diverse algal species in the world, upper range productivity potentials of up to several hundred EJ for microalgae and up to several thousand EJ for macroalgae have been reported (Sheehan et al., 1998a; Florentinus, 2008; van Iersel et al., 2009; Chum et al., 2011). No reliable estimates are available on the techno-economic potential of energy from algae.

Aquatic phototrophic organisms in the world's ocean (halophytes) produce annually 350–500 billion tonnes of biomass and include microalgae (such as Chlorella and Spirulina), macroalgae (seaweeds), and cyanobacteria (also called "blue-green algae") (Garrison, 2008). Microalgae such as Schizochytrium and Nannochloropsis can accumulate lipids, from which diesel-like oils can be extracted at reportedly greater than 50% of their dry cell weight (Chum et al., 2011). The US Department of Energy (US DOE) operated a significant algae energy research and development (R&D) program from the late 1970s until the mid-1990s, in which considerable progress was made in understanding the biochemistry of different microalgaes and their potential as a source of lipids. (Still, fewer than 100 microalgae species have been tested or used industrially out of about 100,000 known species.) A realistic yield of unrefined oil from algae with a 50% oil content located on the equator has been estimated to be 40,000–50,000 lit/ha/yr, and a mere 10% yield from this oil could match palm oil productivities of about 4700 lit/ha/yr (Weyer et al., 2009). Uncultivated macro-algae can reach yields that are higher than those of sugarcane (per unit area)

Table 11.9 | Estimated yields for second-generation biofuels with current and projected future technology levels (note: none of these systems are currently commercial).

Technology	Fuel yield per tonne dry biomass		Fuel yields from dedicated bioenergy US land, with projected 2020 biomass yields[f]	
	Liters/tonne	GJ_{LHV}/tonne	Low-quality land GJ_{LHV}/ha/yr	High-quality land GJ_{LHV}/ha/yr
Ethanol via enzymes[a]				
Current (woody biomass)	279	5.9	66	139
Best future (woody biomass)	362	7.6	86	180
Current (low lignin biomass)	346	7.3	82	172
Likely future (low lignin biomass)	396	8.3	94	197
Best future (low lignin biomass)	441	9.3	105	219
Ethanol via syngas fermentation[b]				
Future low	120	2.5	28	60
Future high	160	3.4	38	80
Fischer-Tropsch diesel/gasoline				
Current low[c]	75	2.6	29	61
Current high[c]	200	6.9	77	162
Future[d]	236	8.1	91	191
Future, biomass/coal co-processing w/CCS[e]	568	19.5	219	460

[b] Source: Sims et al., 2010, citing Putsche, 1999. Details of the feedstock and process designs considered are not given. The process likely begins with thermochemical gasification followed by fermentation of the syngas to ethanol.

[c] Source: Sims et al., 2010. Assumptions behind these estimates are not provided, but they appear to refer to only the diesel fuel that would be produced from a biomass-to-liquids (BTL) system (ignoring naphtha and other co-products).

[d] Source: Liu et al., 2011. Simulation results for a BTL system using herbaceous feedstock and producing both diesel and gasoline. Gasoline is produced by refining the naphtha fraction of the raw Fischer-Tropsch product. See Chapter 12 for addition discussion of BTL options.

[e] These estimates are for the CBTL-OTA-CCS (CO2 capture and storage) process configuration described in Chapter 12.

[f] Average yield of 11.2 dry t/ha/yr on lower quality lands, such as Conservation Reserve Program lands, and 23.6 t/ha/yr on lands with moist, fertile soils (NAS, 2009).

(Zemke-White and Ohno, 1999). Photosynthetic cyanobacteria can produce fuels like hydrogen directly.

Aside from questions about economic viability (Pienkos, 2009), fuels from algae grown by fertilizing with CO_2-rich flue gases from fossil fuel power plants, as is being proposed by many start-up companies today, would be far from "carbon-neutral" since the carbon in the algae originates from fossil sources and since considerable energy inputs are required for algae growing, harvesting, and oil extraction systems (Lardon et al., 2009; Cazzola, 2009).

11.2.5 Economic and Financial Aspects

Figure 11.16 presents projected ranges of commercial production costs for biomass-to-power and biomass-fired CHP plants (Bauen et al., 2009). Not all of the technologies included there are commercially mature, but the figure illustrates that there can be a wide range in costs for any technology, depending on feedstock cost, annual operating hours, and byproduct credit for heat in the case of CHP. A self-consistent set of electricity generating cost estimates for several commercially mature technologies is shown in Table 11.10. Analogous estimates for commercial biomass-fired heat production technologies are provided in Table 11.11.

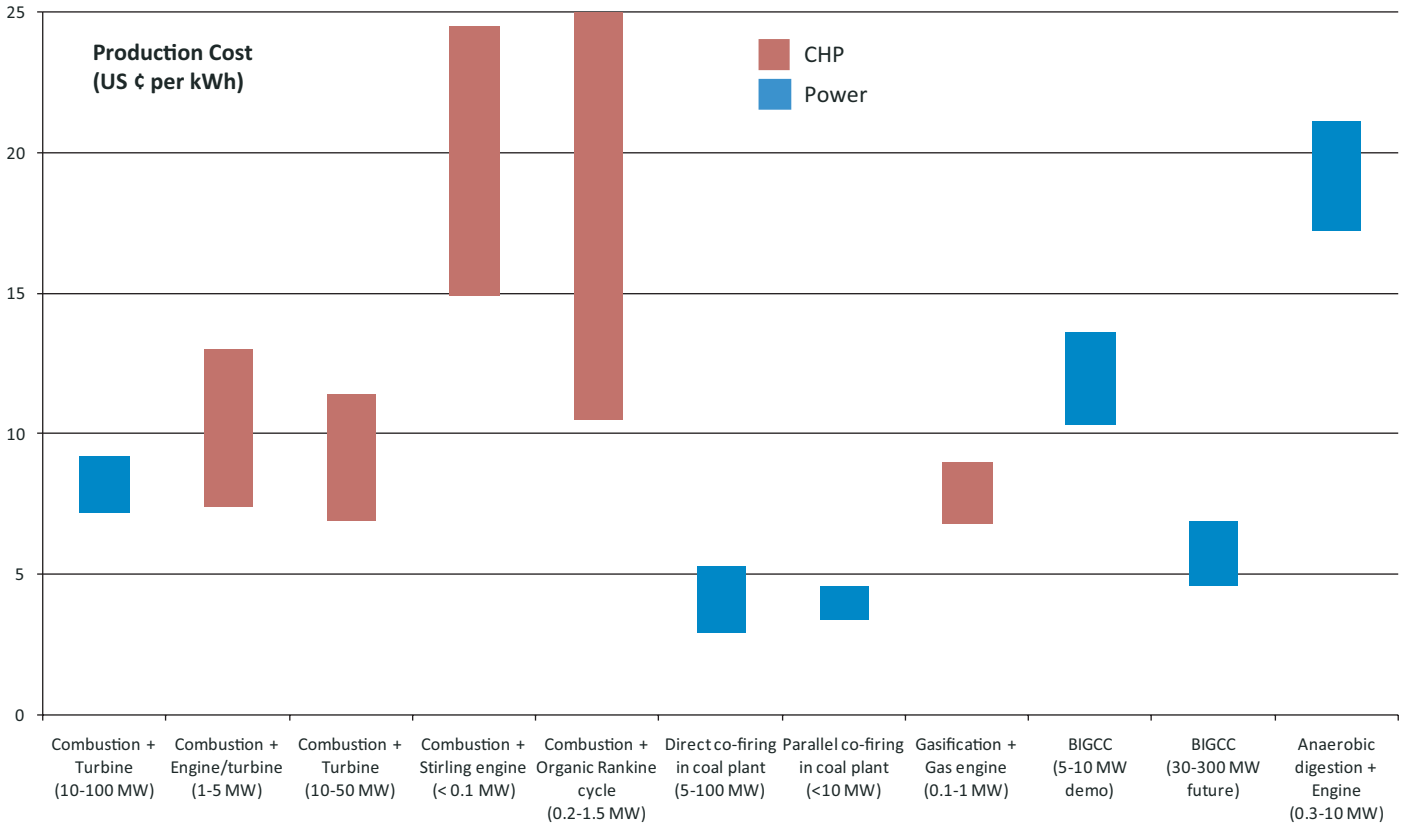

Figure 11.16 | Projected production costs for biomass to power and to CHP. Anaerobic digestion can also be operated in CHP mode; production cost will reduce by 60–80% (depending on technology and plant size) if "free" biomass feedstock is used, such as MSW, manure, or wastewater. Source: based on Bauen et al., 2009.

Table 11.10 | Estimated levelized cost of electricity for commercial biomass-fired electricity generating technologies. Capital investment, operating and maintenance costs, conversion efficiencies, and feedstock costs are from Annex III in IPCC (2011).

[a] Includes a byproduct heat credit of US¢5.4/kWhe.

For most first-generation biofuels, fluctuating crop prices during the past decade created large swings in production costs. Even in periods with low feedstock costs, however, essentially all first-generation biofuels (with one important exception) historically have been unable to compete on cost with prevailing petroleum-derived fuels. Table 11.12 provides a self-consistent comparison of first-generation biofuel production costs.

Ethanol made from sugarcane in Brazil is the lone first-generation fuel that has been able to compete with gasoline at prevailing oil prices

[a] Byproduct credits are included in each case. See Annex III of Chum et al., 2011 for details.

in the recent past. The Brazilian industry, launched in the 1970s, was subsidized (in decreasing amounts with time) for nearly 30 years. Long-term sugarcane breeding programs, together with research and development on agronomic and distillery practices, have led to significant reductions in sugarcane production costs over time in Brazil,[5] to the point where Brazilian ethanol competes today without subsidy with petroleum-derived gasoline (see Figure 11.17). Also, essentially all of the energy required for processing the cane into ethanol is derived from bagasse, the fibrous residue of juice extraction, so producers incur little or no purchased-energy costs, and net greenhouse gas emissions are modest.

The reliability of cost estimates for second-generation biofuels is difficult to assess due to the pre-commercial nature of technologies and the uncertainty of future feedstock costs, among other variables. With presently understood (but not yet commercially demonstrated) systems, ethanol is estimated to be competitive with oil-derived gasoline when

5 Increased sugarcane yields achieved by concerted research and development have been the main driving force behind cost reductions: sucrose content and thus ethanol yield have been increased; ratoon harvesting (multiple harvests from one planting) has been extended; efficiency of manual harvesting has improved; mechanical harvesting has increasingly displaced manual harvesting; and the use of larger transport trucks has further reduced feedstock costs. Residues used for electricity production, along with electricity production efficiency, have also been increasing.

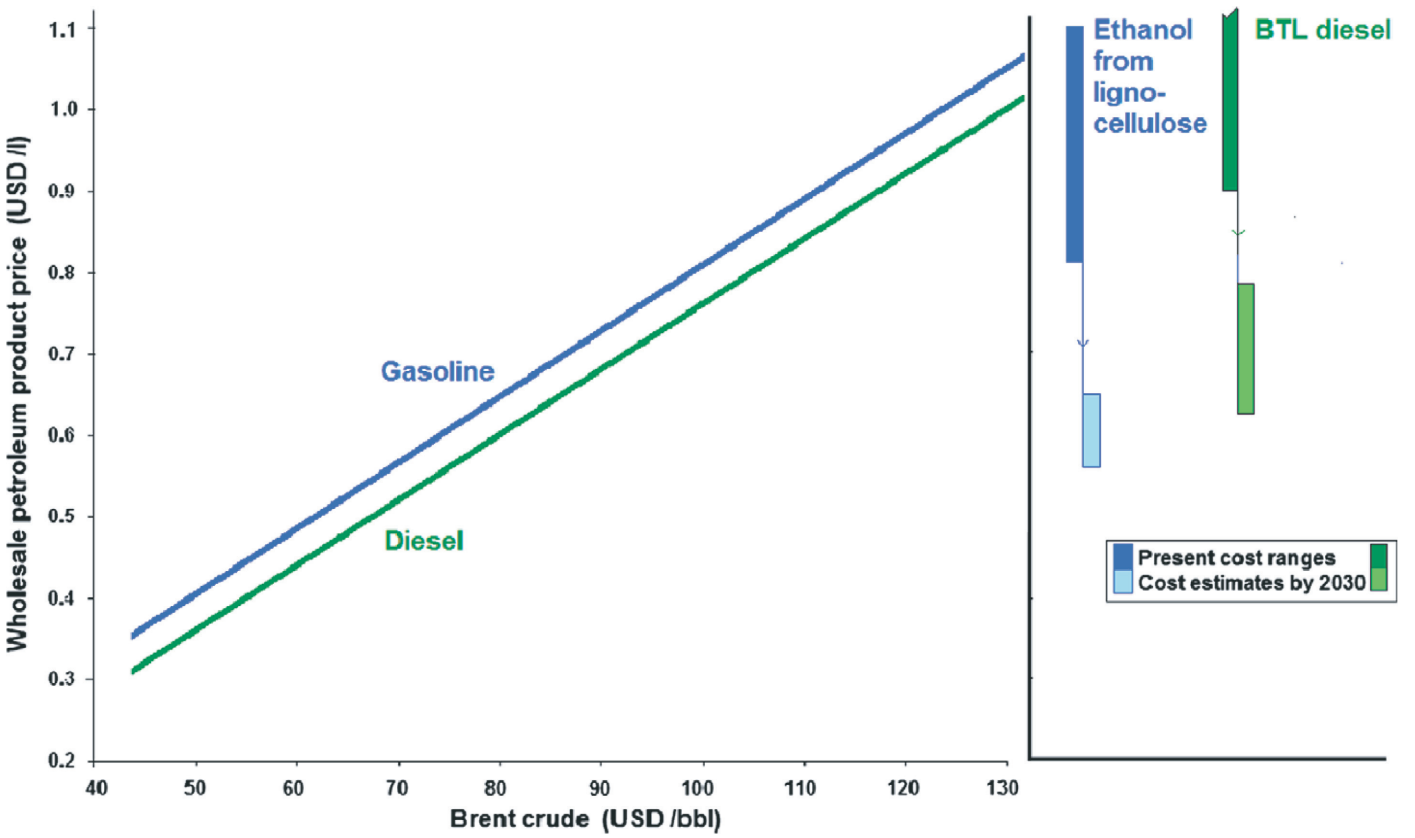

Figure 11.18 | Range of production cost estimates for second-generation biofuels (in $US_{2006}$$ per liter of gasoline equivalent). The 2030 estimates assume significant investment in RD&D. Source: Sims et al., 2010.

the crude oil price is in the range of US$100–140/bbl with the range for BTL (biomass-to-Fischer-Tropsch-liquid) being higher than this. (See Figure 11.18.) With significant investments in RD&D efforts over the next 20 years, the oil price at which ethanol competes with gasoline may fall to US$60–80/bbl (see, e.g., Hamelinck and Faaij, 2006) and to US$80–100/bbl in the case of BTL. Sims et al. (2010) suggest that greater cost reductions may be anticipated for ethanol than for BTL because many of the components of BTL systems are already commercially mature (in

other applications). Table 11.13 provides another perspective on projected costs for liquid biofuels in the 2020–2030 timeframe.

An important consideration is how the cost and performance of advanced biomass conversion technologies can be expected to change as commercial experience is gained. Bioenergy systems show technological learning and related cost reductions with progress ratios (a measure of the rate of reduction in cost with increasing cumulative production) comparable to those of other renewable energy technologies (Chum et al., 2011). This applies to cropping systems, supply systems, and logistics (as clearly observed in Scandinavia) and in conversion (ethanol production, power generation, biogas, and biodiesel). There has been clear technology learning for several important bioenergy systems (see Table 11.14), but with the exception of ethanol from sugarcane in Brazil or systems with unusually low biomass feedstock costs, most still require subsidies to be competitive.

In the 2030 timeframe, the performance of existing bioenergy technologies can be improved considerably, while new technologies offer the prospect of more-efficient and competitive deployment (Chum et al., 2011).

11.2.6 Sustainability Issues

Fossil fuel inputs are significant for producing most first-generation biofuels, as shown in Figure 11.18, with the notable exception of ethanol from sugarcane in Brazil. For the other biofuels in Figure 11.19, two parameters are especially important: the amount of fossil energy consumed that is assigned to non-biofuel co-products of the process and the energy source used to provide the process heat needed at the conversion facility.

The case of ethanol made from wheat grain illustrates the significance of these parameters. For each of the wheat ethanol cases shown in Figure 11.19, the low and high estimates correspond, respectively, to use of the co-product (distillers dried grains, or DDGs) as an energy source at the facility (reducing the need for external energy inputs) or

as an animal feed. For the latter case, the animal feed co-product was assigned fossil fuel emissions equivalent to the fossil energy that would have been consumed to produce animal feed from traditional sources (CONCAWE et al., 2007). The significance of external fuel used for processing energy is evident also in the wheat ethanol cases: fossil energy use is highest when lignite is used, somewhat lower when natural gas is used, and lowest when wheat straw (a non-fossil fuel) is used. In fact, when wheat straw and DDGs are used for fuel onsite, the facility is able to produce an excess of electricity that can be exported to replace electricity that would otherwise have been produced elsewhere from fossil fuels, resulting in net negative fossil fuel consumption.

Biofuels are often valued for the enhanced security of liquid fuel supplies that they provide. Thus petroleum use in the production of biofuels is an important subset of total fossil fuel use. For essentially all biofuels, petroleum use is relatively low. Estimates vary, depending on specific assumptions. In the case of corn ethanol in the United States, estimates of about 0.03–0.3 MJ of petroleum input per MJ of ethanol produced are indicated in a summary by Farrell et al. (2006).

Estimates of life-cycle GHG emissions associated with the production of first-generation biofuels span a wide range, depending on the assumptions used. As with the petroleum estimates, a particularly important assumption relates to how GHG emissions are allocated among co-products. Figure 11.20 shows ranges depending on co-product assumptions for several first-generation biofuels.

It is important to note that the results shown in Figure 11.20 exclude any considerations of GHG emissions arising from land use changes associated with production of the biofuels. Land use change emissions can result when land is converted from an existing use to production of biomass for energy (so-called direct land use change). Emissions may also result from land use changes in one region of the world as a result of establishing biomass energy production in another region (indirect land use changes). Chapter 20 discusses land use change impacts of biomass production.

The high yields for second-generation biofuels in term of GJ/ha/y (see Table 11.9) are achieved with relatively less need for fossil fuel inputs than for first-generation fuels. This is in part because well-designed second-generation conversion systems will use generally unconvertable portions of the incoming biomass as fuel to generate the energy needed to run the conversion facility. For example, lignin is envisioned to be used for this purpose in many biochemical ethanol production systems. The larger scale envisioned for second-generation biofuel production plants also enables more-energy-efficient processing.

The low fossil energy requirements result in relatively low life-cycle GHG emissions. Figure 11.21 shows estimates of emissions relative to petroleum-derived gasoline for a range of second-generation fuels (excluding any emissions associated with direct or indirect land use change). Especially notable are the highly negative emissions for systems that use CO_2 capture and storage (CCS, see Chapter 13) as part of the process.

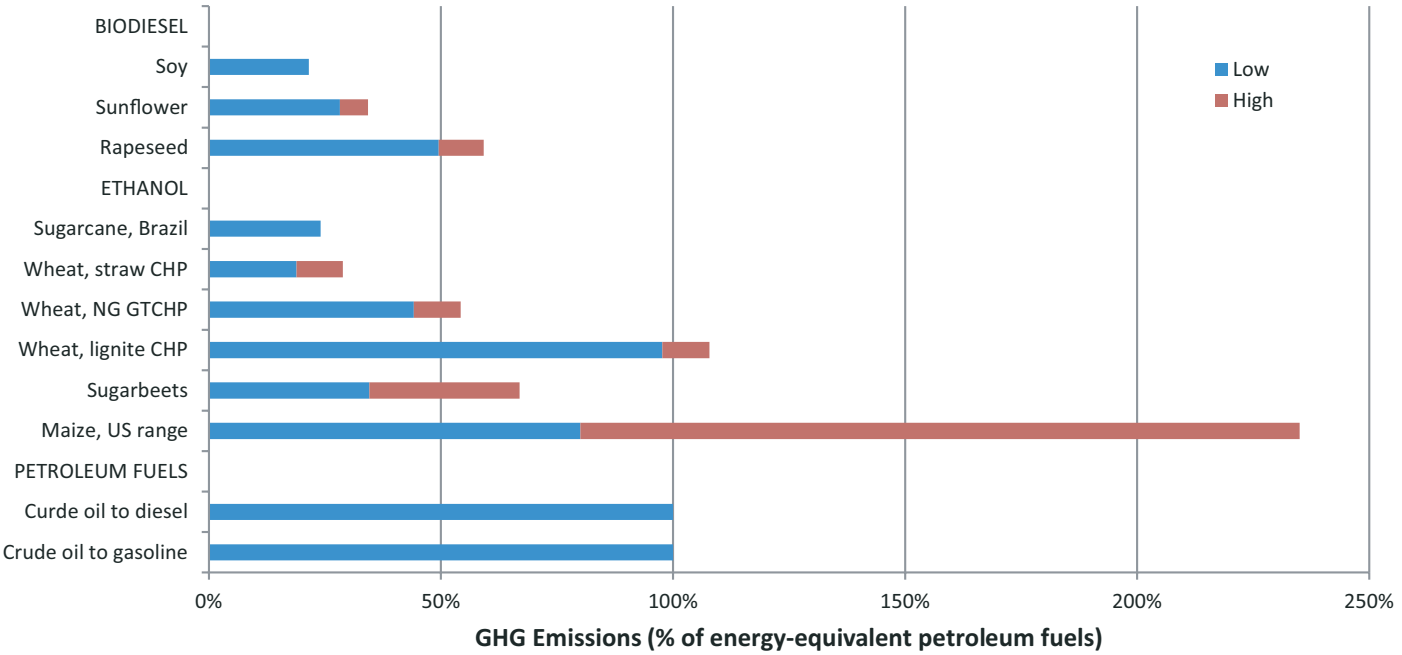

Figure 11.20 | Estimated life-cycle GHG emissions for first-generation biofuels, excluding any impacts of land use change. Source: based on CONCAWE et al., 2008; Pradhan et al., 2009; Sheehan et al., 1998b; Farrell et al., 2006; Macedo et al., 2008. The low and high values for maize ethanol are based on analysis by Shapouri et al. (2002) and Pimental and Patzek (2005), respectively, as reported by Farrell et al. (2006).

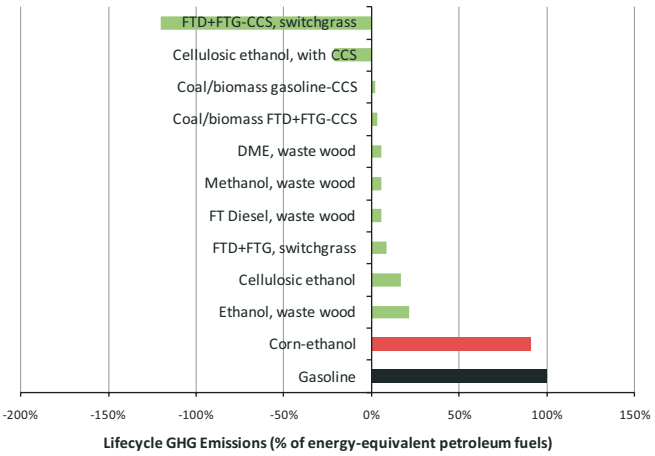

Figure 11.21 | Estimated life-cycle GHG emissions for second generation-biofuels, excluding any impacts of land use change. Estimates for fuels from waste wood are from CONCAWE et al. (2008). The corn-ethanol estimate represents the low estimate from Figure 11.20. The cellulosic ethanol estimates are based on Figure 12.22 in Chapter 12. The ethanol case with CCS assumes capture and storage of fermentation CO_2. Others are based on Table 12.15 in Chapter 12. FTD + FTG refers to synthetic diesel and gasoline made via Fischer-Tropsch synthesis. DME is dimethyl ether.

One additional interesting second-generation thermochemical route to fuels production is co-processing of biomass with coal at a single facility. Fuels such as Fisher-Tropsch Liquids, methanol to gasoline, and others can be made purely from coal in much the same manner as they would be made from biomass, but doing so leads to fuel cycle GHG emissions that could be about double those of the petroleum fuels displaced. If CCS were included as part of the facility design, net GHG emissions would be about the same as for petroleum fuels (see Chapter 12). By using CCS and co-processing an appropriate amount of biomass with the coal (so-called CBTL systems), net GHG emissions can be reduced to zero or less, since capture of photosynthetic carbon from the biomass provides negative GHG emissions to offset unavoidable positive emissions with coal (van Vliet et al., 2009; Larson et al., 2010).

Careful and detailed life-cycle assessments are needed to understand the gains to be made with different algal biofuel systems and thereby help guide future developments toward sustainable systems (IEA, 2010c). Kreutz (2011) has estimated the potential for GHG emissions reduction via reuse of coal power plant CO_2 to fertilize microalgae grown in ponds and converted to biodiesel. His analysis shows that with this approach the carbon mitigation potential is not sufficient to achieve deep GHG emissions reductions. As Kreutz states, "[u]sing the carbon twice fails to meet the objective of deep GHG emission reductions."

For bioelectricity, the life-cycle emissions are generally low, between about 10–50 g CO_2-eq/kWh, but also extremes like –1350 and +350 gCO_2-eq/kWh can be obtained depending on the technology and assumptions used (Chum et al., 2011). Negative emissions are achieved when biomass use is combined with CCS, allowing removal of CO_2 from the atmosphere by storing it underground.

11.2.7 Implementation Issues

A wide variety of existing and potential factors hinder the further deployment of bioenergy, related to supplies, technologies, and markets. Some essential supply side concerns relate to risks of biological production and the availability of residues. El Niño, drought, floods, fire, pests, and insect attacks affect production of biomass as well as of food. Some of these risks (fire, pests, insect attacks) can be reduced through proper management, but they cannot be eliminated. In general, diversity is the best mechanism to minimize these risks.

Concerning technologies, the main issues to be dealt with in an economic and environmentally sound manner are robustness of biomass conversion technologies to feedstock variability, the handling and storage of biomass feedstock, the commercialization of technologies with improved economics at small scale, the handling of co-products (e.g., ash, digestate) containing contaminants, and the need for flue gas cleansing meeting stringent limits on toxic emissions (e.g., NO_x, CO, particulates).

In terms of markets, the main risks and barriers are related to feedstock availability and price (representing 50–90% of the production costs of bioenergy), the competitiveness of different biomass conversion routes, the need for clarity and foresight in regulatory aspects such as planning regulation and emission standards, an unstable and unsupportive policy environment, and the interaction with other sectors – such as food and forestry – and the policies that affect them.

In the past few decades, bioenergy developments have been promoted and supported by governments of many countries through a wide variety of policy instruments. Typical examples for liquid biofuels include the Proálcool program launched in Brazil in 1975 to reduce dependence on imported oil; the Common Agricultural Policy in the EU, including production quotas for oilseed food crops as well as exemptions from certain taxes; and the US support included in several farm bills and state and federal incentives for ethanol production (Worldwatch Institute, 2006). Subsidies in one form or another to encourage consumption of first-generation biofuels amounted in 2006 to over US$6 billion in the United States and nearly US$5 billion in the European Union (FAO, 2008).

Successful policies to promote biomass for heat have focused on more centralized applications for heat or combined heat and power production in district heating and industry (Bauen et al., 2009). In the power sector, feed-in-tariffs have gradually become the most popular incentive. In addition, policies such as fiscal measures and soft loans have been supportive (Global Bioenergy Partnership, 2007). Quota systems have so far been less successful (van der Linden et al., 2005). Priority grid access for renewables is applied in most countries where bioenergy technologies have been successfully deployed (Sawin, 2004a).

As discussed by Chum et al. (2011), the main drivers behind governmental support for the bioenergy sector have been concerns about energy security and climate change as well as the desire to support the farm sector through increased demand for agricultural products (FAO, 2008). An estimated 69 countries had one or several biomass support policies in place in 2009 (REN21, 2010).

Concerns about the effects of these policies on food prices, questions about the GHG emission savings of biofuels, and doubts about the environmental sustainability of bioenergy have also seen countries rethinking their policies and targets for biofuels blending (IEA, 2009a). In addition, uncoordinated targets for renewables and biofuels without an overall biomass strategy may enhance competition for biomass between the power and transportation sectors (Bringezu et al., 2009). Some national targets will require increased imports, thus contributing to competition for biomass globally. An overall strategy would have to consider all types of use, especially for food and non-fiber biomass (Chum et al., 2011; see also Chapter 20).

11.3 Hydropower

11.3.1 Introduction

Hydropower is a form of renewable energy derived from moving water. It has been applied to generate mechanical power, at watermills for example, for several centuries, and has been used to generate electric power for more than 100 years. Hydropower projects may be usefully categorized by the way they harness water to generate power:

- Hydrokinetic – a project that places in a watercourse devices capable of generating electrical power from the flow of water;
- Run of river – a project that uses a watercourse to pass water through a power plant, with limited storage;
- Reservoir – a project that impounds a watercourse for storage, forming a reservoir, for release through a power plant;
- Pumped storage – a project that pumps water from a lower level to a reservoir at a higher elevation for storage in a cyclical fashion, for release through a power plant at times of high demand.

It should be noted that water is also used for power generation through other means, such as ocean energy (see Section 11.9), and water is used as a medium to drive turbines in thermal power stations or to produce hydrogen.

Hydropower plants are able to operate in isolation, but most of them are connected to a transmission network. The maximum output of individual units ranges from 0.1 kW (models) to 852 MW (Three Gorges power station, China). Three Gorges is nearing its full capacity of 22.5 GW and

is producing around 84 TWh/yr. By comparison, Itaipu power station, on the border between Brazil and Paraguay, generated a record of 95 TWh in 2008, with an installed capacity of 14 GW. This reflects the different operating regimes between the two stations, with Three Gorges fulfilling flood-control and navigational functions in addition to the generation of power. It is common for hydropower facilities, especially of the reservoir type, to serve multiple purposes.

11.3.2 Potential of Hydropower

The theoretical, technical, and economic potentials of hydropower for electricity production were presented in the *World Energy Assessment* (UNDP et al., 2000). An update of those figures is presented in Chapter 7. The main results are as follows:

- The gross theoretical potential for electricity production can be estimated at 40–55 x 10^3 TWh/yr (about 150–200 EJ_e/yr).
- The technically feasible potential can be estimated at 14–17 x 10^3 TWh/yr (about 50–60 EJ_e/yr).
- The potential used at present is about 3.0–3.2 x 10^3 TWh/yr (about 11 EJ_e/yr).
- The unexploited economic potential with production costs between US¢2–8/kWh can be estimated at about 5 x 10^3 TWh/yr (about 18 EJ_e/yr); at production costs ranging from US¢2–20/kWh, this figure would be about 11–14 x 10^3 TWh/yr (40–50 EJ_e/yr).

Climate change may have an impact on the potential of hydropower and the availability of hydro capacity in particular river basins, but it is unlikely to affect the global totals (see Section 11.3.3).

Recent energy scenario studies suggest that in 2050 the potential used could have increased to 18–35 EJ_e/yr (Greenpeace and EREC, 2007; IEA, 2008b; 2009a). This figure translates into savings on primary energy use through conventional power generation of 36–70 EJ/yr in 2050, assuming a significant improvement in the average conversion efficiency of fossil-fueled power plants from about 35% to 50% in the period 2010–2050.

11.3.3 Market Developments

In 2008 and 2009, hydropower provided about 3100±100 TWh, nearly 16% of the world's electricity generation, which was more than 80% of renewable energy-sourced electricity generation (US EIA, 2011; BP, 2011). This figure translates to fossil fuel savings in conventional power production equivalent to about 32 EJ/yr (assuming a conversion efficiency of 35%) or about 6% of global primary energy use. Hydropower is currently generating electricity in some 160 countries, using more than 11,000 stations with around 27,000 generating units (Taylor, 2010).

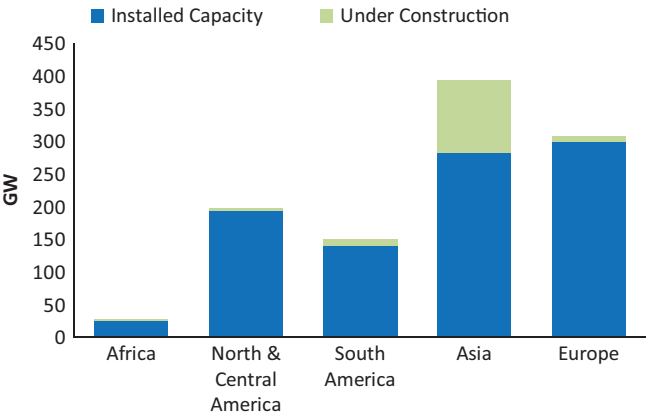

Figure 11.22 | Global installed hydropower capacity, by region, in 2009, including capacity under construction. Source: based on IHA, 2010a.

11.3.3.1 Installed Capacity and Capacity under Construction

Global installed capacity estimates for 2007 range from 860 to 950 GW (IHA, 2010a). According to REN21, global installed capacity can be estimated at about 920 GW in 2007, 950 GW in 2008, 980 GW in 2009, and 1010 GW in 2010 (REN21, 2009; 2010; 2011). Included in these figures are hydropower projects with less than 10 MW installed capacity (about 60 GW in 2009). A regional breakdown of installed capacity and capacity under construction for 2009 is presented in Figure 11.22. In 2009, 32% of the global capacity was installed in Asia, 29% in Europe, 20% in North and Central America, 16% in South America, and 3% in Africa.

According to regular surveys of hydro equipment suppliers by the International Hydropower Association (IHA), 2007 and 2008 were record years in the history of hydropower deployment. From 2005–2009 approximately 135 GW of additional capacity were commissioned, an average of 27 GW/yr, indicating a growth rate of 3% a year. It would appear realistic to assume at least this rate of development will continue into the foreseeable future. For smaller-scale hydro (<10 MW), the growth rate is estimated at about 9% a year.

11.3.3.2 Regional Developments

Hydropower is undergoing rapid development in Asia and Latin America in line with the remarkable growth of these regions. Aside from the recent economic transformations, other factors contributing to growth there include using hydropower to further stimulate economic growth, improve energy and water security, and mitigate and adapt to climate

Table 11.15 | Estimated changes in hydropower generation due to climate change by 2050.

Region	Installed capacity in 2005 [GW]	Generated electricity in 2005 [TWh/yr]	Change by 2050 [TWh/yr]
Africa	22	90	0.0
Asia	246	996	2.7
Europe	177	517	–0.8
North America	161	655	0.3
South America	119	661	0.3
Oceania	13	40	0.0
TOTAL	737	2931	2.5

Source: Hamududu and Killingtveit, 2010.

change. Despite high levels of existing deployment in North America and Europe, these regions also continue to show sizable growth. These developments are in sharp contrast to sub-Saharan Africa, a region with proportionally the lowest deployment to potential (less than 10% of its technical potential). Governance, institutional capacity, and financing rather than the lack of available resource remain major impediments to hydropower development in this region.

11.3.3.3 Potential Impacts of Climate Change on Hydropower

Table 11.15 presents the potential impacts of climate change on hydropower. Projected power generation in 2050 is compared with 2005 based on 12 different climate models. These suggest that losses in some areas will be offset by gains in others, resulting in a largely unchanged or slightly improved global picture of hydropower availability in 2050.

Further work is required to ascertain the impacts of climate change on existing hydropower infrastructure and future development. At present these are uncertain, but it seems clear that climate change will alter the hydrologic cycle at the river basin level. Although this does not change the amount of water in the global hydrologic cycle, changes, some of them significant, are anticipated in the spatial and temporal facets of precipitation and glacial discharge, which will vary from river basin to river basin. The changes this may bring to flows in some catchments could affect hydropower availability, particularly if reservoir storage is managed poorly or if there is limited storage capacity (run of river). Overall, it may be that the positive and negative impacts of climate change balance each other out if the value of water storage is appreciated in forward planning, e.g., by increasing capacity or adding spillways.

Pressure on scarce water resources coupled with a changing hydrologic cycle also increases the importance of hydropower's water storage capabilities. The impetus for developing reservoir projects grows if it is appreciated that water storage also provides energy storage and ancillary service capabilities.

11.3.4 Hydropower Technology Developments

Hydroelectricity generation is generally regarded as a proven, mature technology. For example, conventional turbines have reached 96% efficiency. Yet advances in the technology are still being made.

11.3.4.1 Technology Improvements

Inside the powerhouse, improvements include abrasion-resistant turbines, variable speed technology, and fish-friendly equipment. Also beyond conventional project types, developments in ultra-low head technology and hydrokinetic turbines show promise, especially for existing non-hydropower facilities, such as water reservoirs, weirs, barrages, canals, and falls. Outside the powerhouse, improvements include tunnel boring by machine, roller compacted concrete dams, and use of geomembranes, allowing potential civil works cost savings.

Further efficiencies are expected to be made through modernization and up-rating of aging hydropower stations. Most of the current generation capacity will require refurbishment within the next 30 years. (On average, major refurbishment of generation equipment and machinery is required every 40 years or so.) Consequently, these are ongoing benefits.

11.3.4.2 System Integration

The role that hydro will play in future energy networks is also changing. Most of the early hydropower projects were developed to provide continuous supply (base load) to the power system. This pattern will continue in countries where hydropower provides a significant share of power generation. As other electricity generation technologies have developed, however, the role of hydropower has evolved to encompass a supporting service. Given its unique abilities to store energy and move quickly to full capacity from standstill, it has assumed importance in peak loading when demand requires it.

As other renewable energy use expands on national grids, these abilities on the part of hydropower will assume greater importance: some renewable energies tend to supply electricity on a variable basis (solar photovoltaics, for instance, and wind). By matching these with hydropower, synergies develop from hydro's capacity to supply power on demand, which allows renewable variability to be balanced, as well as matching supply with demand.

The variable nature of some renewables, as well as the costs associated with matching output at times of reduced demand with fossil fuels, geothermal, and nuclear thermal generation options (resulting in these being kept running through periods of low demand), means that there is often excess power in a grid in times of low usage. This has created an increasingly important role for pumped storage hydro through the recycling of stored water.

11.3.4.3 Pumped Storage

Pumped storage facilities make use of the energy of water pumped from a lower level to a reservoir at a higher elevation. The water is brought up to the reservoir when demand for power is low (and when there is excess capacity in the generation system, resulting in cheaper electricity), and it is stored for use to meet peaks in demand. It thus provides peak load capabilities, as well as being available to deal with the intermittency issues surrounding other renewable energies. In 2008, pumped storage capacity in operation worldwide has been estimated to be 127 GW (Ingram, 2009).

It is anticipated that the market for pumped storage will increase by 60% by 2014 (Ingram, 2009). However, as pumped storage is a net user of electricity (about 20% of the energy is lost in the cycle of pumping and generating), its viability depends on clear and predictable differentials in price between periods of low and peak demand.

11.3.5 Economic and Financial Aspects

Hydropower projects are very site-specific. This makes it difficult to predict the amount of engineering required, and therefore the final cost, until investigations are well advanced. In complicated cases, this can lead to sizable cost overruns during construction.

Projects typically have a high upfront capital cost and risk profile. But operation and maintenance costs are very low. (See Table 11.16.) The long life of projects, electro-mechanical equipment about 40 years and civil works about 80–100 years, means that once capital expenditure is amortized, electricity can be produced very economically. This gives hydropower projects an economic life cycle that is quite different from other energy options.

Development costs on hydropower plants may range from US$1000~5000/kW installed capacity. O&M costs can be estimated at US¢0.3–1/kWh. The capacity factor of hydropower plants may be between 30–80%, depending, among other factors, on the characteristics of the energy system within which the hydro power plant operates. Assuming an economic lifetime of the system of 40–80 years and a discount rate ranging from 5–10%, the levelized cost of energy may be between US¢1.5–12/kWh for larger-scale systems (>100 MW) and between US¢1.5–20/kWh for smaller-scale systems (<10 MW). (See Table 11.17.) Because the plant is usually sited far from the point of electricity use, investments may also be required for transmission, perhaps adding another US¢1/kWh.

While these characteristics make many hydropower projects economically viable from a public sector perspective, they do not necessarily translate into financial viability for the private sector. Figure 11.23 presents a range of electric utility and project experiences, comparing average energy tariffs required to make private hydropower financially viable with the average generation cost of most electric utilities. The figure shows a high hydropower tariff in the first 10–20 years because of the relatively high investment costs, but a low tariff when return of investments has been achieved.

Table 11.16 | Costs of Hydropower Development.

Project size (MW)	Development cost (US$ million/MW)	Operational cost (US$/MWh)
< 10	1 to > 5	3 to 10
10 to 100	1 to 3	3 to 7
> 100	1 to 2.5	3 to 7

Source: Taylor, 2008.

The main challenges for hydropower are therefore reducing risk and raising investor confidence, especially prior to project permitting. These challenges are compounded in the least developed countries, where international public financing (multilateral or regional development banks, for example, or bilateral development assistance) continues to play a strong role.

Given the capital cost and risk profile, there have been relatively few successful independent power producer projects above 100 MW (Trouille and Head, 2008). Most projects have required a substantial amount of state involvement to get off the ground. However, there are increasing pressures on the public sector to provide a favorable environment to attract private-sector capital. This is becoming important for hydropower developments in emerging markets. Brazil, for example, is actively using public-private partnerships to drive the development of its hydro capacity (Ray, 2009).

Financing, rather than resource availability, along with governance and institutional capacity, continue to inhibit the growth of hydropower in least developed countries. Given the role that hydropower can play not only in providing energy and water services but also in contributing to the sustainable development of these countries, it is vital that financing, governance, and institutional support mechanisms are adapted.

11.3.6 Sustainability Issues

The development of a hydropower project, whatever its scale, generates a variety of positive and negative effects and involves working with all stakeholders. With over 100 years of development experience, the effects of projects have been relatively well documented and studied. (See Box 11.1.) Modern construction of hydropower plants tries to include in the system design several approaches that minimize social and ecological impacts. Some of the most important impacts are changes in habitat, fish stocks and other species, sedimentation, water quality, and downstream flow regimes. Hydropower reservoirs may also create opportunities for ecological services, tourism, fisheries, irrigation, and secured water supply.

Of note are advances made in proactive avoidance and reduction of negative effects prior to construction of hydropower projects, particularly in the past 20 years in response to changing societal values, increased public scrutiny, and evolving environmental and social

Table 11.17 | Cost of electricity as a function of capacity factor, turnkey investment costs, discount rate, and O&M costs. The O&M costs are assumed as US¢0.3–0.7/kWh for larger-scale systems and as US¢0.3–1.0/kWh for smaller systems. The economic lifetime of a hydro system is assumed to be 40–80 years.

Capacity factor	Turnkey investment costs per kWe installed (*plant > 100 MW*)	Discount rate	
		5%	10%
	US$	US¢/kWh	
80%	1000	1.4–1.8	2.0–2.4
	3000	3.5–3.9	5.3–5.7
30%	1000	2.5–2.9	4.2–4.6
	3000	6.9–7.3	11.9–12.3
Capacity factor	**Turnkey investment costs per kWe installed (*plant < 10 MW*)**	**Discount rate**	
		5%	**10%**
	US$	**US¢/kWh**	
80%	1300	1.4–2.1	2.3–2.9
	5000	4.4–5.1	7.6–8.3
30%	1300	3.2–3.9	5.3–6.0
	5000	11.3–12.0	19.7–20.4

standards. Managing the positive and negative environmental, social, and economic effects of a given project at local, national, regional, and even international levels remains complex.

11.3.6.1 Sustainability Assessment Protocol

The hydropower sector has been actively addressing issues of sustainability for more than a decade through engagement with key stakeholders. This has led the International Hydropower Association to develop Sustainability Guidelines (2004) and a Sustainability Assessment Protocol (2006) to guide and measure the sustainability performance of a hydropower project from conception to operation. The Hydropower Sustainability Assessment Forum in 2008 was formed as a direct result of these efforts. The Forum contains key stakeholders: representatives of industrial and developing countries, environmental and social NGOs, commercial and development banks, and the hydropower industry. A 2010 Forum-reviewed version of the Protocol adopted by IHA has now moved into the implementation phase. It measures performance against relevant criteria over four stages of a project. (See Figure 11.24.)

The consensus among key stakeholders on how to measure project sustainability paves the way for improved sustainability performance and more informed decision-making on hydropower development, particularly in the policy and financial arenas.

11.3.6.2 GHG Status of Reservoir Hydropower

As a renewable energy source, hydropower is recognized as being both clean and a low-carbon technology. A life-cycle assessment (LCA)

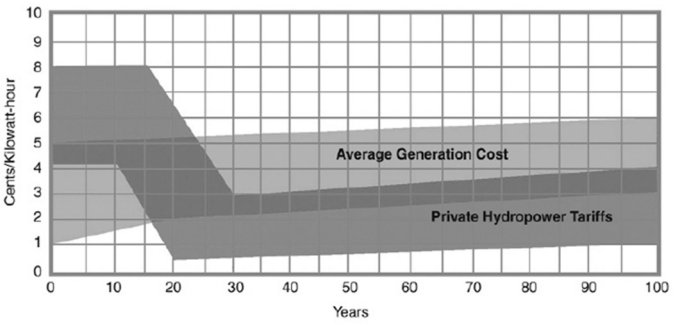

Figure 11.23 | Hydropower tariff versus average electricity generation costs in US_{2008}¢/kWh. Source: Trouille and Head, 2008.

published by the International Energy Agency in 2000 suggests that GHG emissions could range from 2–48 gCO_2-eq/kWh for reservoir type systems and from 1–18 gCO_2-eq/kWh for run-of-river systems (IEA, 2000). An overview published by the IPCC concludes that "the majority of lifecycle GHG emissions estimates for hydropower cluster between about 4–14 gCO_2-eq/kWh, but under certain scenarios there is the potential for much larger quantities of GHG emissions" (Kumar et al., 2011).

In conclusion, there is uncertainty and no consensus yet on these figures among experts (or, separate from the numbers, on LCA methodology for hydropower). In some circumstances freshwater reservoirs can produce highly elevated GHG emissions, a phenomenon that is the subject of ongoing research. Specific problems have included a lack of standard measurement techniques, limited reliable information from a sufficient variety of sources, and the lack of standard tools for assessing net GHG exchanges (Goldenfum, 2011).

The lack of scientific consensus has impeded progress in decision-making on carbon accounting and in carbon markets. For example, guidance is needed to support national GHG inventories, to develop methods (measurement and predictive modeling) of establishing the GHG footprint of new reservoirs (hydro, multipurpose, and non-hydro alike), and to quantify more precisely the carbon offsets of hydropower projects for GHG emissions trading. These circumstances led to the establishment of the UNESCO/IHA GHG Status of Freshwater Reservoirs Research Project in 2008 (Goldenfum, 2011). The project's main goals are:

- Developing, through a consensus-based, scientific approach, detailed measurement guidance for net GHG assessment
- Promoting scientifically rigorous field measurement campaigns and the evaluation of net emissions from a representative set of freshwater reservoirs throughout the world
- Building a standardized, credible set of data from these representative reservoirs

Box 11.1 | Sustainable Hydropower in Nepal

Source: IHA, 2005.

The Andhikhola Hydel & Rural Electrification Hydro Scheme in western Nepal was built in 1991 with technical and financial assistance from the Norwegian Development Agency.

A concrete gravity diversion weir on the Andhikhola River diverts water through a 1.3 km long tunnel and a 234 m vertical drop shaft. The 5 MW powerhouse is currently equipped with secondhand turbines previously used in Norway. The tunnel system also diverts water for irrigation. The opportunity was taken during construction to build Nepalese experience in tunneling technology as well as other areas of technical capability. Various elements of the scheme have demonstrated exceptional innovation to fit with aspects of capacity building, resource availability, and the remoteness of the site.

Some 100,000 people in the region now enjoy the benefits of an electricity supply for the first time. With the available power, more than 200 small enterprises have been established, creating employment for hundreds of people.

- Developing predictive modeling tools to assess the GHG status of unmonitored reservoirs and potential sites for new reservoirs
- Developing guidance and assessment tools for mitigation of GHG emissions at sites vulnerable to high net emissions.

The project has benefited from collaboration among some 160 researchers, scientists, and professionals working in the field, representing more than 100 institutions. In July 2010 the project met its first goal by publishing *GHG Measurement Guidelines for Freshwater Reservoirs*, which represents the state of the art in measurement guidance for net GHG assessment of reservoirs (Goldenfum, 2011).

11.3.7 Implementation Issues

Financing is by far the biggest obstacle for scaling up hydropower development. Barriers are especially high in the poorest countries. It is thus important for the public and private sectors to work together to reduce risk profiles and unlock finance.

A substantial opportunity to adapt is provided by the economic dimension of climate change policy. The important role that climate change financing can play is indicated by the Clean Development Mechanism (CDM): hydropower accounts for 30% of all registered CDM projects and 48% of all registered renewable energy projects (UNEP Risø, 2011). The additional income generated for projects is generally at levels below 5% of a project's internal rate of return, a stream of revenue not normally categorized as influential. Despite this, such revenues have strong impacts on overall project feasibility. An important factor is that this revenue will be in "hard currency" and can mitigate exchange rate risks for the developer. Further climate change policy and financing innovations to target the sustainable development of developing countries may increase the appetite for investment. For example, the addition of adaptation-driven multilateral and bilateral finance looks likely to emerge as a significant lever for further hydropower development.

Figure 11.24 | IHA Sustainability Assessment Protocol assessment tools and major decision points, with topics by section. Source: based on IHA, 2010b.

The sustainability performance of hydropower projects remains an ongoing challenge, but this is becoming more manageable with the efforts the sector continues to make at national, regional, and international levels, such as the Hydropower Sustainability Assessment Protocol.

The construction and operation of hydropower plants in transboundary river basins requires international cooperation to avoid conflicts over water – particularly as a changing hydrological cycle brought about by climate change is likely to increase pressure on water resources in some river basins.

As hydropower can cover base load and peak load demands, its integration into transmission systems can balance the output from variable systems such as wind and solar photovoltaics and can increase the economic value of produced electricity (US DOE, 2004).

In rural areas, smaller-scale hydropower may be used alone or connected to a mini-grid to provide electricity or mechanical power for local industrial, agricultural, and domestic uses. Depending on local circumstances, it can play a major role in rural electrification, as has been demonstrated in China and other developing countries. Although

support of these smaller-scale/rural, often financially challenged projects is desirable, the categorization of hydropower by size in policy and markets in an unsophisticated fashion can distort development outcomes.

11.4 Geothermal Energy

11.4.1 Introduction

Geothermal energy has been used for thousands of years for washing, bathing, and cooking. But it was only in the twentieth century that geothermal energy was harnessed on a large scale for space heating, electricity production, and industrial use. The first large municipal district heating service started in Iceland in the 1930s, and it now provides geothermal heat to about 99% of the 200,000 residents of Reykjavik.

The use of geothermal energy has increased rapidly since the 1970s. In the first decade of the new century, the globally installed direct use capacity tripled from 15 to nearly 50 GW_{th} whereas the installed capacity for electricity production increased from 8.0 to 10.7 GW_e.

11.4.2 Potential of Geothermal Energy

At present, geothermal energy is used by 78 countries for heating purposes (called "direct use") and by 24 countries for electricity production (Lund et al., 2010; Bertani, 2010). Table 11.18 presents the worldwide geothermal electric and direct-use capacity as well as the generated amount of heat and electricity in 2009, based on 70 country papers at the World Geothermal Congress 2010.

The figures for electric power capacity (MW_e) and annual generation values (GWh) appear to be fairly accurate. The direct-use figures are less reliable due to reporting errors and lack of data from some countries. Table 11.19 reports on geothermal energy use by continent.

The flow of heat from Earth's interior to its surface is 1400–1500 EJ/yr, with about 315 EJ/yr onshore (Stefansson, 2005; see also Chapter 7). The upper limit for the technical potential to use energy from geothermal resources is estimated at 50–60 TW_{th} (Stefansson, 2005). Part of these resources can be used to produce 1–2 TW_e electricity. Most resources, however, are suitable for direct use only, giving access to 22–44 TW_{th}. The technical potential for electricity production can be enhanced if the heat from hot dry rocks can be exploited using enhanced geothermal systems (EGS) technology. This may enlarge the technical potential for electricity production by about a factor of 5–10 (see, e.g., Tester et al., 2006). This may result in a total technical potential of about 700 EJ/yr; the economic potential in 2050 might be as high as 75 EJ/yr (see Chapter 7). The conversion efficiency for electricity generation is around 10% and for direct use nearly 100%.

11.4.3 Market Developments

In 1975 only 10 countries reported electrical production from or direct use of geothermal energy. By now the figure is 78 countries. At least another 10 countries are actively exploring for geothermal resources and are expected to be online by 2015 (Bertani, 2010; Lund and Bertani, 2010).

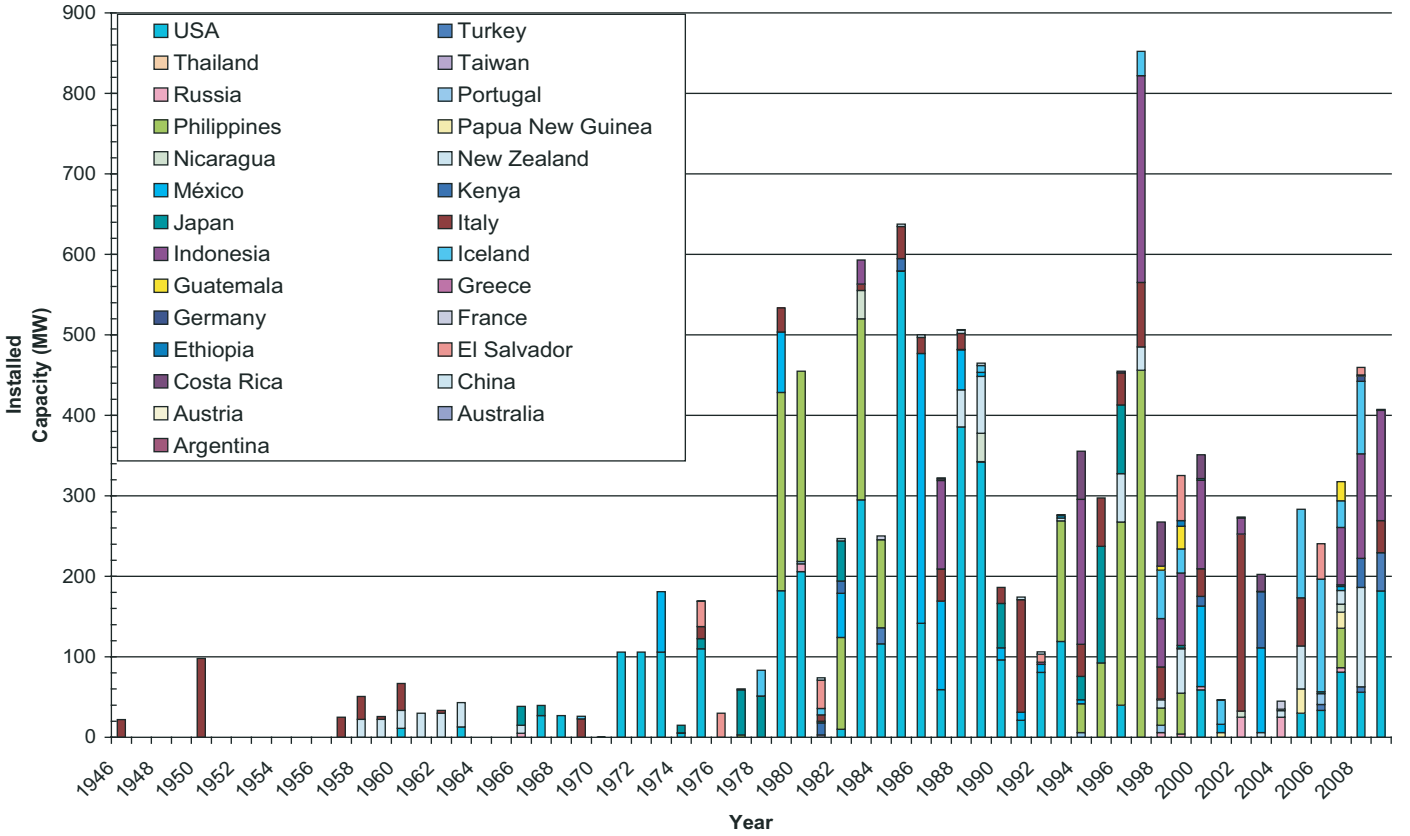

Figure 11.25 | Installed geothermal electricity capacity, 1946–2010, by country and in total. Source: data from Bertani, 2010.

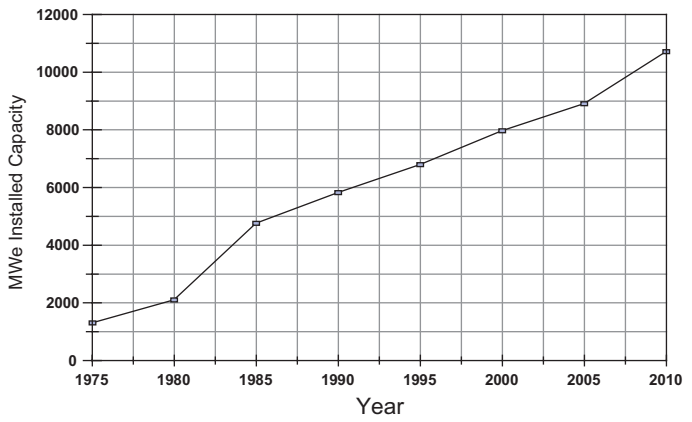

Figure 11.26 | Growth of the globally installed capacity of geothermal power production. Source: Bertani, 2010.

11.4.3.1 Geothermal Electricity Production

Use of high-temperature geothermal energy for electric power production started experimentally at Larderello, Italy, in 1904; the first commercial plant (250 kW_e) became available in 1913 and was connected to the electricity grid. In 1958, the Wairakei A station of 69 MWe came online in New Zealand. This was the first "wet steam" plant in the world. It was followed by plants using "dry steam" at Pathè, Mexico, in 1959 (3.5 MW_e); at The Geysers in the United States in 1960 (12 MW_e); and at Matsukawa in Japan in 1966 (23 MW_e). The first low-temperature plant using a binary (organic Rankine) cycle plant was opened in 1967 at Paratunka, Kamchatka, in Siberia (680 kW_e).

Figure 11.25 shows the annual installed capacity in the 27 countries that had initiated geothermal power production by 2010, starting in 1946. The worldwide installed capacity since 1975 is presented in Figure 11.26. The average growth rate between 1975 and 2010 has been 6.5% per year. Since 2005, major increases have occurred in El Salvador, Iceland, Indonesia, New Zealand, Turkey, and the United States.

The top 10 countries in terms of installed capacity of geothermal power plants in 2009 were the United States, The Philippines, Indonesia, Mexico, Italy, New Zealand, Iceland, Japan, El Salvador, and Kenya or Costa Rica. (See Figure 11.27.) If the criterion were the percentage contribution of geothermal plants to the total generating capacity of the country or region, however, the top 10 would be Lihir Island (Papua New Guinea), Tibet, San Miguel Island (Azores), El Salvador, Tuscany (Italy), Iceland, Kenya, the Philippines, Nicaragua, and Guadeloupe (Caribbean).

11.4.3.2 Direct Use of Geothermal Energy

Since 1975 the installed capacity of geothermal direct use has increased at an average rate of about 10% annually (see Figure 11.28). In the

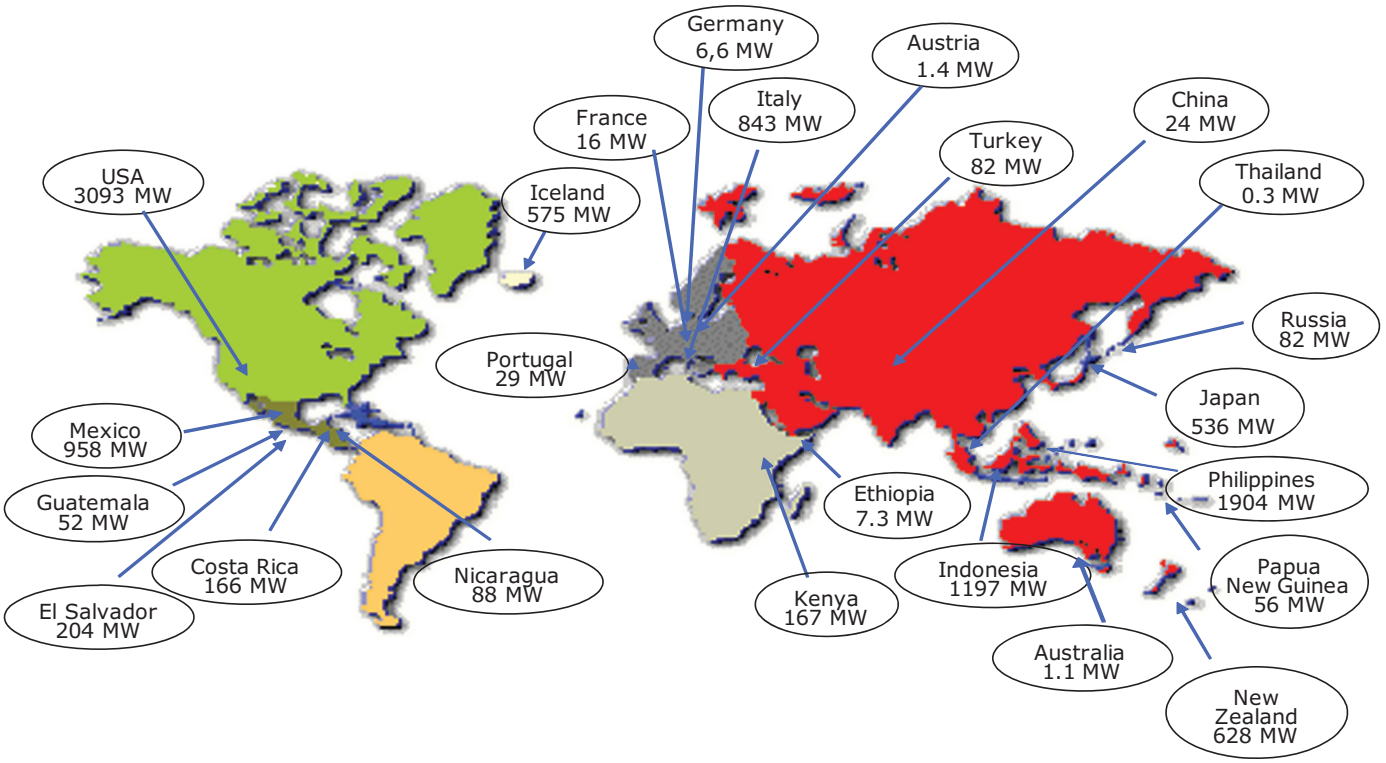

Figure 11.27 | Mapping of the 10.7 GW installed geothermal electric capacity in 2009. Source: data from Bertani, 2010.

period 2005–2009, heat production for direct use grew nearly 12% a year. Ground-source heat pumps (GHPs) alone have increased heat production about 20% per year in this period. This is due in part to the ability of geothermal heat pumps to use groundwater or ground-coupled temperatures anywhere in the world.

The annual savings achieved by geothermal energy use amounted to 36 million tons of fuel oil and 32 million tonnes of carbon emissions compared with power production from fuel oil (Lund et al., 2010).

In 2009, the top five countries with the largest installed direct-use capacity were the United States, China, Sweden, Norway, and Germany, accounting for about 63% of the total capacity worldwide. The five countries in 2009 with the largest direct use were China, the United States, Sweden, Turkey, and Japan, accounting for 55% of the world geothermal energy use.

Looking at the data in terms of the country's land area or population, however, the smaller countries dominate. In terms of GJ/km^2, the top five countries in 2009 were the Netherlands, Switzerland, Iceland, Norway, and Sweden. In terms of GJ/capita, the ranking was Iceland, Norway, Sweden, Denmark, and Switzerland. In Iceland, geothermal energy saves about US$100 million in imported oil (Lund et al., 2010).

The largest increases in direct use in terms of GJ/yr over the past five years were achieved in the United Kingdom, the Netherlands, South Korea, Norway, and Ireland, while the largest increases in installed

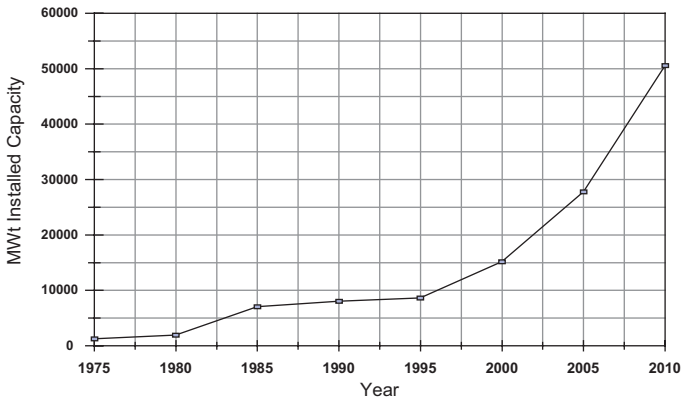

Figure 11.28 | Worldwide growth of installed capacity of geothermal direct use. Source: Lund et al., 2010.

capacity (MW_{th}) occurred in the United Kingdom, South Korea, Ireland, Spain, and the Netherlands, mainly due to an increased use of geothermal heat pumps.

In 1990 there were 14 countries reporting an installed capacity of over 100 MW_{th}. By 2000 this number had increased to 23, by 2005 it was 33, and by 2009 it reached 36. (See Box 11.2 for more details on some of these countries.)

Table 11.20 provides data on direct geothermal energy use in terms of installed capacity and thermal energy utilization for several recent years.

Box 11.2 | National Developments in Geothermal Direct Use as of 2009

- Iceland: Geothermal direct use meets 89% of the country's space heating needs.
- Japan: Over 2000 resorts, over 5000 public bath houses, and over 15,000 hotels visited by 15 million guests per year use natural hot springs.
- Tunisia: Geothermal heating of greenhouses has increased from 100 ha to 194 ha over the last five years.
- Turkey: Geothermal space heating has increased 40% in the five years, supplying 201,000 equivalent residences; 30% of the country will be heated with geothermal energy in the future.
- Switzerland: The country has installed 60,000 geothermal heat pumps; this is 1/km^2. Also, 2000 km of boreholes were drilled in 2009. Drain water from tunnels is used to heat nearby villages. Several geothermal projects have been developed to melt snow and ice on roads.
- United States: The country has installed 1 million geothermal heat pumps, mainly in the midwestern and eastern states, with about 12% annual growth. Around 100,000 to 120,000 units are installed per year.

Table 11.20 | Various geothermal direct-use categories worldwide, 1995–2009.

Direct-Use Category	Installed capacity [GW_{th}]				Thermal energy utilization [PJ/year]

Source: Lund et al., 2010.

The most recent use of low-grade geothermal energy is in the form of ground-source heat pumps that use the natural temperature of the Earth (between 5° and 30°C) to produce both heating and cooling with a limited amount of electric energy input. The first commercial building installation using a groundwater heat pump took place in Portland, Oregon, in 1946. Europe began using the technology around 1970. In 2009 heat pumps were the largest portion of the installed direct-use capacity (70%) and contributed 49% to the direct use of geothermal energy. The actual number of installed GHP units is around three million. Units are found in 43 countries, although they are mainly in the United States, Canada, and Europe (Lund et al., 2010).

11.4.3.3 Development of Enhanced Geothermal Systems

While conventional geothermal resources cover a wide range of uses for power production and direct uses in profitable conditions, a large part of the scientific and industrial community has been involved for more than 20 years in promoting enhanced geothermal systems (Ledru et al., 2007; Fridleifsson et al., 2008; Tester et al., 2006). The principle of EGS is simple: in the deep subsurface where temperatures are high enough for power generation (above 150°C), an extended fracture network is created or enlarged to act as new pathways. Water from the deep wells, or cold water from the surface, is circulated through this deep reservoir using injection and production wells and is then recovered as steam or hot water (Fridleifsson et al, 2008). These wells and further surface installations complete the circulation system. After using energy for power generation, the fluid can be cascaded for direct-use applications such as for district heating. EGS plants, once operational, can be expected to have great environmental benefits (such as zero CO_2 emissions).

The enhancement challenge is based on several conventional methods for exploring, developing, and exploiting geothermal resources that are not economically viable yet. The original idea calls for general

applicability, since the temperature increases with depth everywhere. But a number of basic problems still need to be solved; mainly, techniques need to be developed for creating, characterizing, and operating the deep fracture systems. Some environmental issues, like the chance of triggering seismicity and the availability of surface water, also need careful assessment and management (Bertani, 2009).

Targeted EGS demonstrations are under way in several places: Australia can claim a large-scale activity through a number of stock market-registered enterprises. A real boom can be observed: 19 companies are active in 140 leases (a total of 67,000 km^2 in four states), with an investment volume of US$650 million. The project developers plan to establish the first power plants (with a few MWe of capacity) in the coming years (Beardsmore, 2007). The EU project EGS Pilot Plant in Soultz-sous-Forêts, France, started in 1987 and has installed a power plant of 1.5 MW_e to use the enhanced fracture permeability at 200°C. In Landau, Germany, the first EGS-plant with a capacity of 2.5–2.9 MW_e went into operation in fall 2007 (Baumgärtner et al., 2007). Another approach is being made for deep sediments in the in-situ geothermal laboratory in Groß Schönebeck, Germany, using two research wells (Huenges et al., 2007).

One of the main future demonstration goals in EGS will be to see whether and how power plant size could be upscaled to several tens of MW_e. In the United States, the potential for EGS power generation is estimated at 1250 GW_e (based on a conservative 2% recovery factor). Assuming a capacity factor of 90%, this would correspond to 35.4 EJ/yr of electricity production (Tester et al., 2006).

11.4.3.4 New Developments: Drilling for Higher Temperatures

Production wells in high-temperature fields are commonly 1.5–2.5 km deep, and the production temperature is 250–340°C. The energy output from individual wells is highly variable, depending on the flow rate and the heat content of the fluid, but it is commonly in the range 5–10 MW_e and rarely over 15 MW_e per well.

It is well known from research on eroded high-temperature fields that much higher temperatures are found in the roots of the high-temperature systems. The International Iceland Deep Drilling Project is a long-term program to harness deep unconventional geothermal resources (Fridleifsson et al., 2007). Its aim is to produce electricity from natural supercritical hydrous fluids (at high temperature and pressure above the critical point where there is a phase change) from drillable depths. Producing supercritical fluids will require drilling wells that produce temperatures of 450–600°C. The current plan is to drill and test at least three 3.5–5 km deep boreholes in Iceland within the next few years. A deep well producing 0.67 m^3/sec steam (~2400 m^3/h) from a reservoir with a temperature significantly above 450°C could yield enough steam to generate 40–50 MW of electric power. This exceeds by an order of magnitude the power typically obtained from conventional geothermal wells (Fridleifsson et al. 2007).

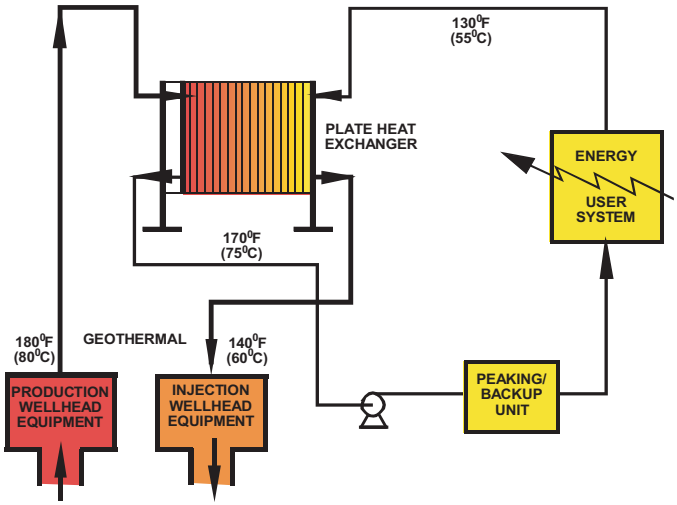

Figure 11.29 | Typical direct use geothermal heating system configuration. Source: based on Geo-Heat Center, 1998.

11.4.4 Geothermal Energy Technology Developments

11.4.4.1 Direct Use

The main advantage of using geothermal energy for direct use projects in the low- to intermediate-temperature range is that these resources are more widespread and exist in at least 80 countries at economic drilling depths. In addition, there are no conversion efficiency losses, and projects can use conventional water-well drilling and off-the-shelf heating and cooling equipment. Most projects can be online in less than a year. Projects can be on a small scale such as for an individual home, single greenhouse, or aquaculture pond, but they can also be a large-scale commercial operation such as for district heating/cooling, food and lumber drying, and mineral ore extraction.

It is often necessary to isolate the geothermal fluid from the user side to prevent corrosion and scaling. Care must be taken to prevent oxygen from entering the system (geothermal water normally is oxygen-free), and dissolved gases and minerals such a boron and arsenic must be removed or isolated, as they are harmful to plants and animals. Hydrogen sulfide, even in low concentrations, will cause problems with copper and solder and is harmful to humans. On the other hand, carbon dioxide, which often occurs in geothermal water, can be extracted and used for carbonated beverages or to enhance growth in greenhouses. The typical equipment for a direct-use system is illustrated in Figure 11.29; it includes downhole and circulation pumps, heat exchangers (normally the plate type), transmission and distribution lines (normally insulated pipes), heat extraction equipment, peaking or back-up plants (usually fossil-fuel-fired), and fluid disposal systems (injection wells). Geothermal energy can usually meet 80–90% of the annual heating or cooling demand, yet it is only sized for 50% of the peak load (Lund, 2005).

A well-known major example of geothermal direct-use is the district heating system in Reykjavik, Iceland; in 1930, some official buildings

and about 70 private houses received hot water from geothermal wells close to old thermal springs. The results were so encouraging that other geothermal fields were explored near the city. Now 52 wells produce 2400 liters/s of water at a temperature of 62–132°C. Later the municipal district heating agency added a high-temperature field about 27 km away. Today the geothermal water from the wells flows through pipelines to six large reservoir tanks and then to six storage tanks in downtown Reykjavik that hold 24 million liters. Nine pumping stations distribute the water to consumers.

Reykjavik Energy uses either a single or a double distribution system. In the double system, the used geothermal water from radiators runs back from the consumer to the pumping stations. There it is mixed with hotter geothermal water, which serves to cool the water to the proper 80°C before it is recirculated. In the single system, the backflow drains directly into the sewer system (Gunnlaugsson and Gíslason, 2003). The system has over 2000 km of pipelines and an installed capacity of 830 MW_{th}. A fossil fuel peaking station is used to increase the fluid temperature in extremely cold weather (Lund, 2005; Ragnarsson, 2010).

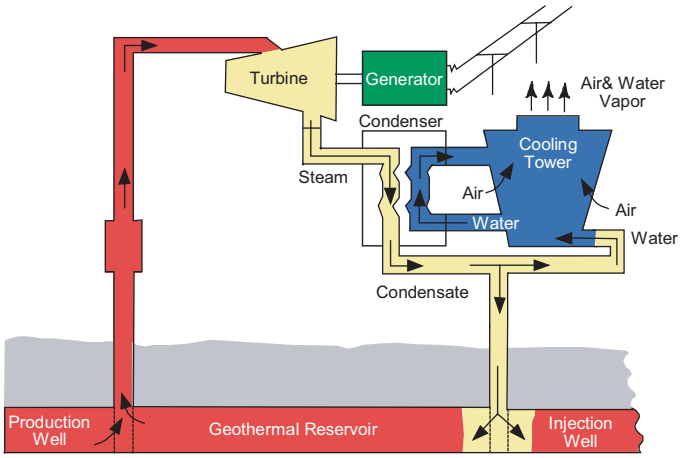

Figure 11.30 | Steam plant using a vapor or dry steam dominated geothermal resource. Source: modified from Lund, 2007.

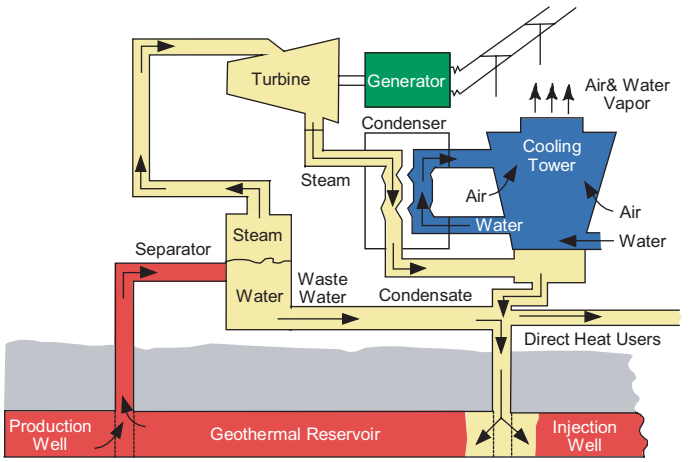

Figure 11.31 | Single-stage flash steam plant using a water-dominated geothermal resource with a separator to produce steam. Source: modified from Lund, 2007.

11.4.4.2 Geothermal Heat Pumps

Geothermal (ground-source) heat pumps use the relatively constant temperature of Earth to provide heating, cooling, and domestic hot water for homes, schools, government, and commercial buildings. A small amount of electricity input is required to run a compressor (approximately 25% of a normal baseboard electric heating system). However, the energy output is about four times the energy input in electricity form, described as the coefficient of performance (COP) of 4.0. These "machines" cause heat to flow "uphill" from a lower to a higher temperature location. "Pump" is used to describe the work done. The temperature difference is called "lift." The greater the lift, the greater the energy input required. The technology is not new, as Lord Kelvin developed the concept in 1852. GHPs gained commercial popularity in the 1960s and 1970s (Lund et al., 2003).

GHPs come in two basic configurations: ground-coupled (closed loop) systems, which are installed in the ground, and groundwater (open loop) systems, which are installed in wells and lakes. The type chosen depends on the soil and rock type at the installation, the land available, and whether a water well can be drilled economically or is already on-site. In the ground-coupled system, a closed loop of pipe, placed either horizontally (1–2 m deep) or vertically (50–70 m deep) is placed in the ground, and a water-antifreeze solution is circulated through the plastic pipes (high-density polyethylene) to either collect heat from the ground in the winter or reject heat to the ground in the summer (Rafferty, 2008). The open loop system uses groundwater or lake water directly in the heat exchanger and then discharges it into another well, into a stream or lake, or on the ground (say, for irrigation), depending on local laws.

The efficiency of GHP units is described by the coefficient of performance in the heating mode and by the energy efficiency ratio in the cooling mode (COP_h and COP_c, respectively, in Europe), which is the ratio of the output thermal energy divided by the input energy (electricity for the compressor). The higher the number, the better the efficiency. The ratio varies from three to six with present equipment. In comparison, an air-source heat pump has a COP of around two and depends on backup electrical energy to meet peak heating and cooling requirements (Lund et al., 2003; Curtis et al., 2005; Bertani, 2010).

11.4.4.3 Electric Power Generation

Geothermal power is generated by using steam or a hydrocarbon vapor to turn a turbine-generator set to produce electricity. A vapor-dominated (dry steam) resource (see Figure 11.30) can be used directly, but a hot water resource (see Figure 11.31) needs to be flashed by reducing the pressure to produce steam, normally in the 15–20% range. Some plants use double and triple flash to improve efficiency (IEA, 2010a). In the

Table 11.21 | Average capacity and electricity produced per plant category and the share of each category.

Type of plant	Average capacity per unit (MW)	Average electricity production per unit (GWh/yr)	Share in number of plants	Share in total capacity (MWe)	Share in electricity produced (GWh)
Binary plant	5	27	44%	4%	4%
Back Pressure plant	6	50	5%	5%	6%
Single Flash plant	31	199	27%	25%	26%
Double Flash plant	34	236	12%	28%	30%
Dry Steam plant	46	260	12%	38%	34%

Source: Bertani, 2010.

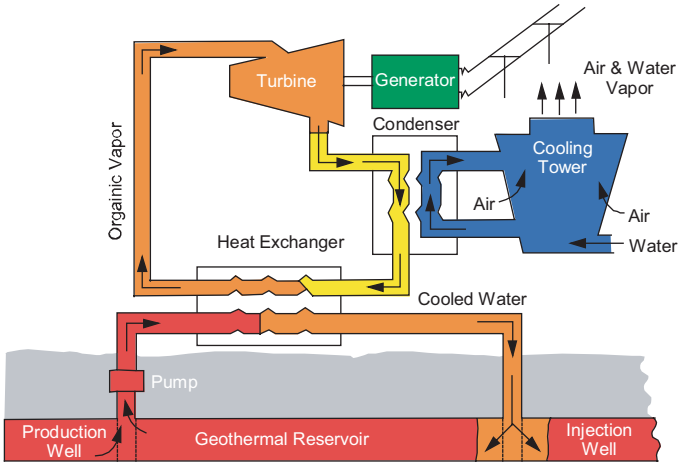

Figure 11.32 | Binary power or organic Rankine cycle plant using a low temperature geothermal resource and a secondary fluid of a low boiling-point hydrocarbon. Source: modified from Lund, 2007.

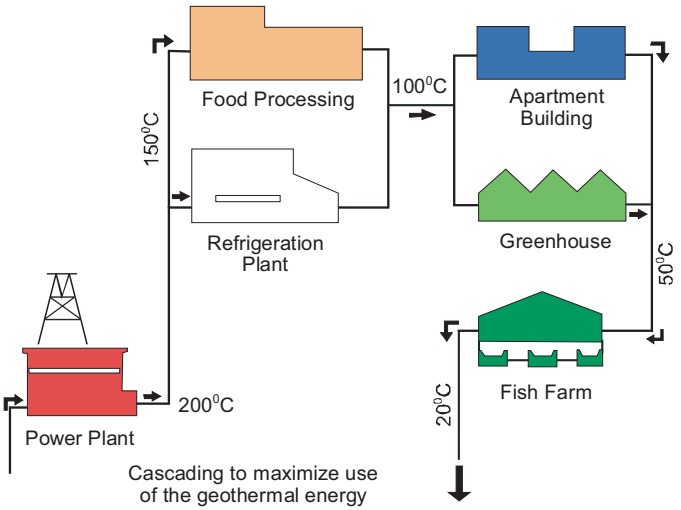

Figure 11.33 | Cascading the use of a geothermal resource for multiple applications. Source: Geo-Heat Center, 2003.

case of low-temperature resources, generally below 180°C, a secondary low boiling point fluid (typically a hydrocarbon) is needed to generate the vapor, resulting in a binary or organic Rankine cycle plant. (See Figure 11.32.)

Usually a wet or dry cooling tower is used to condense the vapor after it leaves the turbine to maximize the temperature and pressure drop between the incoming and outgoing vapor and thus increase the efficiency of the operation. Dry cooling is often used in arid areas where water resources are limited. Air cooling normally has lower efficiencies in summer months, when air temperatures are high and humidity is low.

The standard plant classifications are used here: *binary*, *back pressure*, *single flash*, *double flash*, and *dry steam* plant. Back pressure units (non-condensing) are used where condensing water is not available or based on economics to get the unit on line sooner. Table 11.21 indicates the share of each category in the total installed capacity, the electricity produced annually, and the total number of units. Average values per unit for installed capacity and annually produced electricity are also given. Hybrid plants using more than one form of energy are excluded from this overview, but their share is at present almost zero.

As indicated, there are three major families of plants: *small plants* (binary and back pressure plants) of about 5 MW per unit, *medium plants* (single and double flash plants) of around 30 MW per unit, and *big plants* (dry steam plants) of around 45 MW per unit or larger.

More recently, the use of combined heat and power plants has made low-temperature resources and deep drilling more economical. District heating using the spent water from a binary power plant can make a marginal project economical, as demonstrated at Neustadt-Glewe, Landau, and Bad Urach in Germany and at Bad Blumau in Austria. This was also found for high-temperature combined heat and power plants in Iceland (Geo-Heat Center, 2005). Options for cascading are shown in Figure 11.33, where the geothermal fluid is used for a number of applications at progressively lower temperatures to maximize energy use.

11.4.5 Economic and Financial Aspects

The economics of electricity production are influenced by drilling costs and resource development. The typical capital expenditure quota is 40% for reservoir and 60% for plant. The productivity of electricity per well is a

function of the thermodynamic characteristics of the reservoir fluid (phase and temperature). The higher the energy content of the reservoir fluid, the lower is the number of required wells; as a consequence, the reservoir typical capital expenditure quota is reduced. Single geothermal wells can produce from 1 to 5 MW_e, but sometimes even as high as 30 MW_e.

The cost of geothermal projects and the production of energy carriers vary considerably from site to site and from region to region, depending mainly on the depth, quality, quantity, and location of the resource. For any geothermal project, the costs can be divided into land acquisition or leasing; resource exploration and characterization; drilling and reservoir development; gathering and transmission pipelines; plant design and construction; energy or product transmission to consumers; operation and maintenance; the cost of financing, debt, and royalty payments; and costs related to permitting, legal, and institutional issues.

In this section, the levelized cost of energy is calculated for a number of applications, assuming a discount rate of 5–10%.

11.4.5.1 Electric Power Projects

Taking into account cost increases during 2006–2008, a new 50 MWe greenfield project costs in the range of US$2000–4000 per installed kW_e (see, e.g., Geothermal Task Force Report, 2006; Bromley et al., 2010). Thus, a 50 MWe plant is estimated to cost on average US$150 million. Of this, drilling would average US$1500/$kW_e$ or about US$2200/m for a 3 MW, 2000m deep well. Average well cost are estimated to vary from US$2–5 million, though it can approach US$9 million (Kagel, 2006).

A typical cost breakdown for a geothermal power project in the United States is as follows: exploration 5%, confirmation 5%, permitting 1%, drilling 23%, stream gathering 7%, power plant 54%, and transmission 4% (Hance, 2005). O&M costs can be estimated at 1.8–2.6US¢/kWh with an average of 2.2US¢/kWh in the United States (Owens, 2002; Hance 2005), but at 1.0–1.4US¢/kWh in New Zealand (Barnett and Quinlivan, 2009). The calculations here use an average value ranging from US_{2005}¢1.5–2.2/kWh.

At present, the capacity factor of geothermal power plants is worldwide on average 71–72% (Bertani, 2010). But new plants can achieve more than 90%. A value ranging from 70% to 90% is used here. The economic lifetime of the system is assumed to be 30 years. Based on these figures, an LCOE ranging from about US_{2005}¢3–9/kWh is found. (See Table 11.22)

In the United States, a federal production tax credit of US_{2005}¢1.8–2.1/kWh would just about offset the average O&M cost, increasing revenues and shortening the payback period. FITs, such as those provided in Germany, would also increase the income from the plant.

Smaller plants, around 5 MWe, are estimated to cost 20% more per installed kWe, while binary plants of the 5 MWe size cost approximately 30% more. Larger plants in the 100 MWe range can cost 10% less per installed kWe (Al-Dabbas, 2009). Water cooling versus air cooling is estimated to cost 15% more.

Table 11.22 | Cost of electricity as a function of capacity factor, turnkey investment costs, discount rate, and O&M costs. The O&M costs are assumed at ¢1.5–2.2/kWh. The assumed lifetime is 30 years.

Capacity factor	Turnkey investment costs/kWe	Discount rate	
		5%	10%
	US$	US_{2005}¢/kWh	
90%	2000	3.1–3.8	4.2–4.9
	4000	4.8–5.5	6.9–7.6
70%	2000	3.6–4.3	5.0–5.7
	4000	5.7–6.4	8.3–9.0

11.4.5.2 Direct-use Projects

Direct-use project costs have a wide range, depending on the specific use, the temperature and flow rate required, the associated O&M and labor costs, and the income from the product produced. In addition, new construction usually costs less than retrofitting older structures. Here, estimates are made for the following: individual space heat for a residence, a greenhouse project, district heating, and an industrial application. Well drilling and casing costs would vary from US$150–300/m for depths up to 500 m. Drilling cost will increase with depth and can approach US$500/m, but the cost can be highly non-linear with depth (Chad et al., 2006). These values are based on projects in the United States, and they can vary for other locations, depending on resource temperature and flow, labor and materials costs, and rig availability.

Individual space heating for a building of 200 square meters may have a load of 43MJ_{th}/h, requiring a generating capacity of 12 kW_{th}. Depending on the well depth and temperature of the resource, the system could cost US$10,000–25,000 in addition to the cost of land. This could result in total investment costs of about US$1600–4200/$kW_{th}$. The capacity factor is about 30%. Assuming an economic lifetime of 30 years and O&M costs of US¢2/kWh_{th}, the LCOE ranges between US¢6–19/kWh_{th}

Greenhouses are covered facilities costing approximately US$150/$m^2$. Thus, a commercial facility of 2.0 ha outdoors would cost US$3 million. The peak heating requirement is about 1.0 MJ/m^2. Thus an installed capacity of 5.6 MW_{th} is needed. The geothermal system may cost US$500–1000 per installed kW_{th}. With a capacity factor of 50%, this set-up would result in a geothermal heat use of 24.3 million kWh/yr. Pumping costs and other O&M for the geothermal system may be approximately US¢2/kWh. The economic lifetime is assumed to be 20 years. The LCOE ranges between US¢3–5/kWh_{th}.

District heating may be defined as the heating of two or more structures from a central heat source. Heat may be provided in the form of either steam or hot water and may be used to meet process, space, or domestic hot water requirements. The heat is distributed through a network of insulated pipes consisting of delivery and return mains. Thermal load density (heating load per unit of land area) is critical to the feasibility of district heating, as the distribution network may be the largest single capital expense, at approximately 35–75% of the entire project cost. Thus, high-rise buildings downtown are better candidates than single family residential areas. Generally, a thermal load density above 1.2 GJ/hr/ha or a favorability ratio of 2.5 GJ/ha/yr is recommended for district heating projects. Often fossil fuel peaking is used to meet the coldest period, rather than drilling additional wells or pumping more fluid, improving the efficiency and economics of the total system (Bloomquist et al., 1987). Biomass could also be used effectively for peaking.

One example cost for a district heating projects is found in Germany (Reif, 2008), where two geothermal wells are drilled to 3200m to provide a capacity of 35 MW_{th}, and 66 GWh_{th} a year of heat to customers (load factor of 0.22). The total cost of the project, including a fossil fuel peak heating load plant, was US$58.5 million broken down into the following components: 22.6% drilling, 1.7% pumps and accessories, 4.6% geothermal station and equipment, 1.7% peak-load heating plant, 42.4% distribution network, 14.4% service connections, 11.7% heat-transfer stations, and 0.9% land.

A smaller example is found in Elko, Nevada, in the United States (Bloomquist, 2004). The Elko Heat Company system was built in 1989 for US$1.4 million, which at today's costs would be approximately US$5 million; 15% was for resource assessment, 15% for drilling the production well (disposal is to a local river), 29% for the distribution system, 26% for retrofitting customer heating systems, and the remaining 15% for contract services and materials. The estimated capacity of the system is 3.8 MW_{th} and the energy provided to customers is 6.5 GWh_{th} a year. So the capacity factor is nearly 20%. In 2001, the annual operating revenue was US$184,270. The operating expenses were US$47,840, the maintenance US$19,105, and contract services and materials cost US$22,135. Translated to 2005 prices, this suggests O&M costs of US¢1.5/kWh_{th}.

From these two examples, investment costs ranging from US$1300–1700/$kW_{th}$ can be derived. However, lower figures are also possible, down to US$600/$kW_{th}$ (Lund et al., 2009). Assuming an economic lifetime of 30 years, an LCOE ranging from US_{2005}¢4–12/kWh_{th} can be calculated.

Industrial applications are more difficult to quantify, as they vary widely depending on the energy requirements and product produced (Goldstein et al., 2011). These plants normally require higher temperatures and often compete with power plant use. However, they do have a high load factor of 0.40–0.70, which improves the economics.

One recent study looked at an onion drying facility in Oregon (Geo-Heat Center, 2006). A single-line dryer handling 4500 kg/h of fresh onions

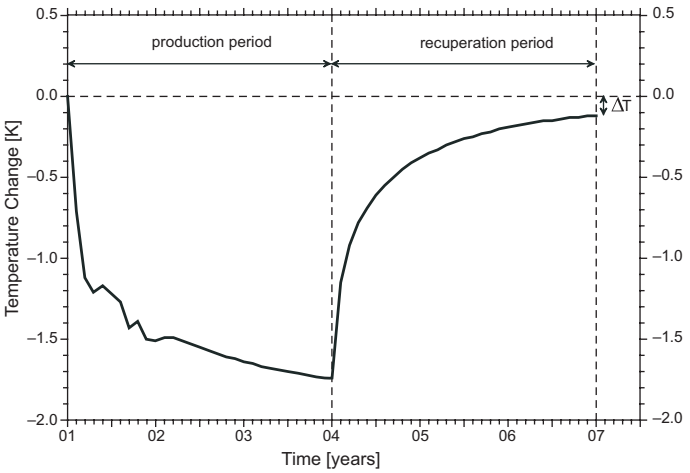

Figure 11.34 | Calculated ground temperature change at a depth of 50 m and at a distance of 1m from a 105 m long borehole heat exchanger over a production period and a recuperation period of 30 years each. Source: Eugster and Rybach, 2000.

for 24 hr/day over a season of 250 days (0.68 load factor) produces 900 kg/h of dried product. About 35 GJ/h (about 10 MWth) of direct use is required and 210 TJ would be the annual energy use, requiring a resource of at least 120°C at 57 liters per sec flow. The total cost for this facility would be US$13.3 million. The geothermal system including the wells may add US$3.6 million (US$360/kW_{th}). Assuming an economic lifetime of 20 years and US¢2/kWh_{th} O&M costs, the LCOE would be US¢2.5–2.7/kWh_{th}. As in practice higher investment costs are also found (up to US$1000/$kW_{th}$), an LCOE ranging from about US_{2005}¢2–4/kWh_{th} is calculated.

11.4.6 Sustainability Issues

Geothermal energy is generally classified as a renewable resource, where "renewable" describes a characteristic of the resource: the energy removed from the resource is continuously replaced by more energy on time scales similar to those required for energy removal (Stefansson, 2000). Consequently, geothermal energy use is not a "mining" process. Whether the exploitation of a geothermal source can be classified as "sustainable" depends on issues like the durability of energy supplies and environmental concerns.

11.4.6.1 Durability of Geothermal Energy Supplies

It appears natural to define the term "sustainable production" as production that can be maintained for a very long time. In Iceland, a reference period for a production well of 100–300 years has been proposed (Axelsson et al., 2005), while in New Zealand, production for more than 100 years is used as a criterion (Bromley et al., 2006). Much longer time scales, such as those comparable to the lifetimes of geothermal resources, are considered unrealistic in view of human endeavors. As geothermal heat is coming from the internal part of Earth and is related to natural

decay processes of radioactive isotopes, the flow of energy to Earth's surface of 1400–1500 EJ a year will continue for many million years.

The production of geothermal fluid/heat continuously creates a hydraulic/heat sink in the reservoir. This leads to pressure and temperature gradients, which in turn – after termination of production – generate fluid/heat inflow to re-establish the pre-production state. The regeneration of geothermal resources occurs over various time scales, depending on the type and size of the production system, the rate of extraction, and the attributes of the resource. Time scales for re-establishing the pre-production state following the cessation of production have been determined using numerical model simulations (for details, see Rybach and Mongillo, 2006; Axelsson et al., 2005). The results show that after production stops, recovery driven by natural forces like pressure and temperature gradients begins. This can be illustrated by the production and recuperation periods presented in Figure 11.34. The recovery typically shows an asymptotic behavior and theoretically takes an infinite amount of time to reach its original state. However, practical replenishment (for instance, 95%) will occur much earlier, generally on time scales of the same order as the lifetime of the geothermal production systems (Axelsson et al., 2002).

Examples of long-term production and use from high-temperature geothermal fields include Larderello in Italy for over 100 years (see, e.g., Cappetti, 2009) and The Geysers in northern California for almost 50 years – both of which generate electrical energy. In recent years, however, both fields have experienced reduced production – mainly due to not injecting all the spent fluid from the plants. Another example of what appears to be a sustainable use of a low-temperature geothermal field is the Reykir field (Mosfellssveit), which has been used for district heating of Reykjavik (Iceland) since 1943 (Gunnlaugsson and Gíslason, 2003).

11.4.6.2 Environmental Aspects

Geothermal fluids contain a variable quantity of gas (largely nitrogen) and carbon dioxide, plus some hydrogen sulfide and smaller proportions of ammonia, mercury, radon, and boron. The amounts depend on the geological conditions of different fields. Most of the chemicals are concentrated in the disposal water that is routinely reinjected into drill holes and thus not released into the environment. The concentration of the gases is usually not harmful, and they can be vented to the atmosphere. However, the technology for removing harmful non-condensable gases does exist, and these systems are installed at most geothermal power plants. Removing the hydrogen sulfide released from geothermal power plants is a requirement in, for example, the United States and Italy.

CO_2 emission from electricity production using high-temperature geothermal fields in the world is variable, but it is much lower than that for fossil fuel plants. Bertani and Thain (2002) reported on CO_2 emission data obtained in 2001 from 85 geothermal power plants operating in 11 countries. These plants had an operating capacity of about 6650 MWe, which constituted 85% of the world geothermal power plant capacity at the time. The collected data showed a wide spread – from 4 g/kWh to 740 g/kWh – with the weighted average being 122 g/kWh. This compares well with the US value reported by Bloomfield et al. (2003) of 91 g CO_2/kWh. A recent comprehensive literature review by IPCC of life cycle assessments for geothermal power plants, however, concluded that "lifecycle GHG emissions are less than 50 gCO_2-eq/kWh for flash steam plants and less than 80 gCO_2-eq/kWh for projected EGS plants" (Goldstein et al., 2011).

Where there is a high natural release of CO_2 from the geothermal fields prior to development, geothermal power development may also decrease this natural emission, as happened, for example, at the Larderello field in Italy. The GHG emissions from low-temperature geothermal resources are normally only a fraction of those from the high-temperature fields used for electricity production. The gas content of low-temperature water is in many cases minute, as in Reykjavik, where the CO_2 content is lower than that of the cold groundwater. In sedimentary basins, such as the Paris basin, the gas content may cause scaling if it is released. In such cases the geothermal fluid is kept under pressure within a closed circuit (the geothermal doublet) and reinjected into the reservoir without any de-gassing taking place.

No systematic collection has been made of data about GHG emissions from geothermal district heating systems. The CO_2 emissions from low-temperature geothermal water can be less than 1 gCO_2/kWh_{th} depending on the carbonate content of the water. As an example, for Reykjavik District Heating the emissions from low-temperature areas are about 0.00005 gCO_2/kWh_{th}. Data from geothermal district heating systems in China (Beijing, Tianjin, and Xianyang) are limited but also indicate emissions of less than 1 gCO_2/kWh_{th} (Gunnlaugsson, 2007). The district heating system in Klamath Falls, Oregon, has about zero emissions, as all the geothermal water is used and reinjected in a closed system. Life-cycle analyses, taking into account indirect emissions, show GHG emissions ranging from 14–58 gCO_2-eq/kWh_{th} (Kaltschmidt, 2000).

The GHG emission rates of geothermal heat pumps depend on the energy efficiency of the equipment as well as the fuel mix and the efficiency of electricity generation. In most cases, heat pumps are driven by auxiliary electric power, so the CO_2 emissions depend on the energy source for electricity generation. The average CO_2 emission associated with generation of electricity in Europe in 2005 has been estimated to be about 0.55 $kgCO_2$/kWh. With proper system design, the electrically driven geothermal heat pump reduces the CO_2 emissions of an oil-fired boiler by 45% and those of a natural-gas-fired boiler by 33% (ISEO, 2010). Based on life-cycle analysis, Kaltschmitt (2000) found emission rates for GHPs ranging from 180–200 gCO_2-eq/kWh_{th}. If the electricity that drives the heat pump is produced from a renewable energy source, the emission rate will be much smaller. The total CO_2 emission reduction potential of heat pumps has been estimated to be 1.2 Gt/yr, or about 6% of global emissions (ISEO, 2010).

There are also local environmental impacts related to land and water use and the operation of an energy system. In addition, there could be some specific phenomena such as discharges of gas other than CO_2. But these can be reduced strongly where gas injection is used and nearly eliminated when binary geothermal plants are installed for power generation. Since most direct-use projects use only hot water and the spent fluid injected, the polluting emissions are nearly eliminated.

The exploration of geothermal resources can also have impacts on outstanding natural features and landscapes. And geothermal systems using wells may have an impact on seismicity and ground vibrations and contribute to risks such as hydrothermal steam eruptions. Proper design and management as well as monitoring and control are needed to avoid or mitigate these risks. Recent exploratory work on EGS has produced small earthquakes (up to 3.4 on the Richter scale) that have caused local concerns. The mitigation of these earthquakes is currently under investigation.

11.4.7 Implementation Issues

The technology to produce electricity and generate heat for direct use is mature and can be applied cost effectively depending on local circumstances. New technology developments may enhance access to geothermal energy use. Getting access to geothermal energy fields may also require the construction of transmission capacity, adding to the total costs of energy supply. Other implementation issues could include siting and permitting delays, high capital costs, the concerns of local populations, and public perceptions and support, including lack of knowledge about benefits.

Geothermal power plants are operated in base load. Geothermal energy may fit well with the use of other renewable resources such as wind, solar, biomass, and hydro, offering the potential of a reliable and secured supply of heat and electricity. Given the barriers and constraints, enhanced deployment of geothermal energy use requires government policies, regulations, and initiatives, including incentives such as a FIT for geothermal pricing, as demonstrated by a number of countries (see, e.g., Rybach, 2010; REN21, 2010). Enhanced deployment also requires education, including training and outreach, along with improvements of the technology.

11.5 Wind Energy

11.5.1 Introduction

Wind energy has been used for thousands of years in a variety of applications, but it was largely overshadowed by other fuels for much of this time for a variety of technical, social, and economic reasons. The oil crises of the 1970s, however, renewed interest in wind energy technology for grid-connected electricity production, water pumping, and power supply in remote areas (WEC, 1994; UNDP et al., 2000). This section focuses on utility-scale, grid-connected wind technology deployed either on land or offshore.

Wind power capacity grew to meet nearly 2% of global electricity demand in 2009. Onshore wind is currently one of the most economical renewable energy generation technologies. In areas with good wind resources, generating electricity with wind turbines is already competitive. As a result, these installations have grown rapidly. Offshore wind projects are almost twice as capital-intensive as their land-based counterparts, but in Europe and Asia some countries have set aggressive goals for their deployment. The experience gained through this is expected to reduce costs and improve performance.

11.5.2 Potential of Wind Energy

Wind energy is broadly available but diffuse. There is a vast global wind resource that could be tapped (see Chapter 7) and provide carbon-free electricity. Figure 11.35 illustrates the global land-based wind resource at 50-m above ground level.

The *technical potential* of wind energy to fulfill energy needs is very large. Estimates range from about 20,000 TWh/yr (onshore only) to 125,000 TWh/yr (onshore and near-shore). The range suggests that wind could supply in principle anywhere from one to six times the 2009 global electricity production of about 20,000 TWh (IEA 2010b; BP, 2011). Although wind resource quality varies around the globe, there is sufficient potential in most regions to support high levels of wind energy generation. Wind resources are not a global barrier to expansion of the use of this technology in the coming decades.

It has been noted that local and global climate change could affect wind resources (IPCC, 2007b), although research in this area is nascent (Wiser et al., 2011). Climate change could have impacts on wind patterns locally, but it is unlikely to be a large enough magnitude to change the global technical potential of wind energy greatly (IPCC 2011).

The *economic potential* of harnessing wind energy is defined by capital investment, corresponding annual power production, competitiveness with other energy technologies, and policy measures. The *realizable (*or *implementation) potential* also depends on aspects such as access of a particular site to electricity markets through transmission lines; rules favorable to variable generation technologies; sufficient mitigation of visual, acoustic, and wildlife impacts; public acceptance; and maintenance costs. For a given site, the economic potential depends on the annual power production from wind technology, requiring knowledge of, for example, average wind speeds at heights above ground corresponding to wind turbine hubs, the statistical distribution of wind speeds throughout the year, turbulence intensity, and the impact of terrain features near the plant. Continued development of calculation models and increased availability of observational wind speed data are critical to optimizing the annual power production of

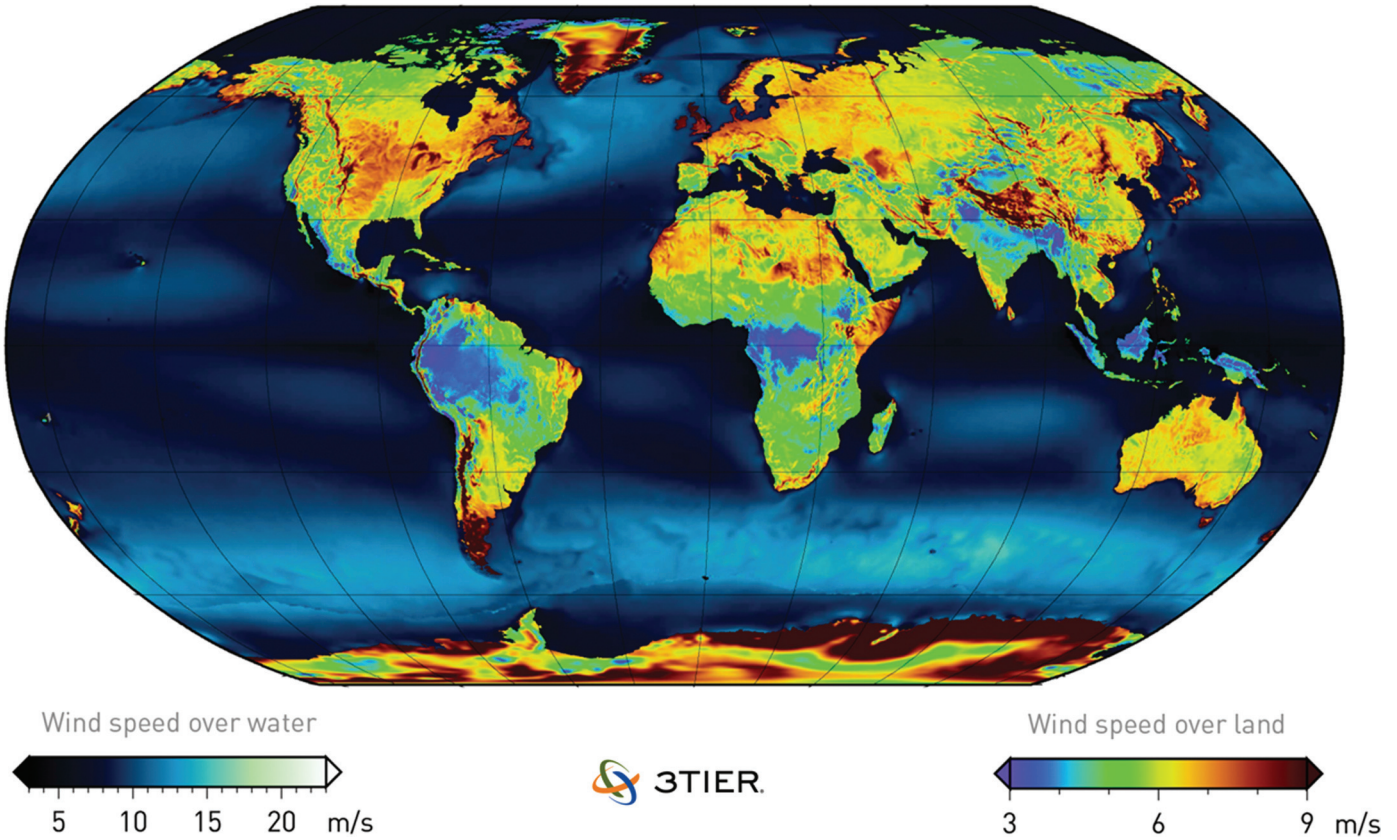

Figure 11.35 | Global wind resource. The red color represents the strongest wind and the blue color denotes the weakest wind resource. Source: 3 Tier, 2011. (c) 2011 3TIER, Inc.

wind turbines and assessing the economic potential of wind resources (IEA, 2010a).

Numerous studies and approaches have been used to develop scenarios for economic deployment of wind energy. The Global Wind Energy Council (GWEC) uses a simulation model to create scenarios for wind technology through 2050 based on different levels of political support (GWEC and Greenpeace, 2010a). GWEC poses three scenarios: Reference, Moderate, and Advanced. The Reference scenario is based on the IEA's *World Energy Outlook* 2009. The Moderate scenario accounts for all policy measures to support renewable energy either enacted or in planning stages. The Advanced scenario represents the extent to which the wind industry could grow in a base case "wind energy vision."

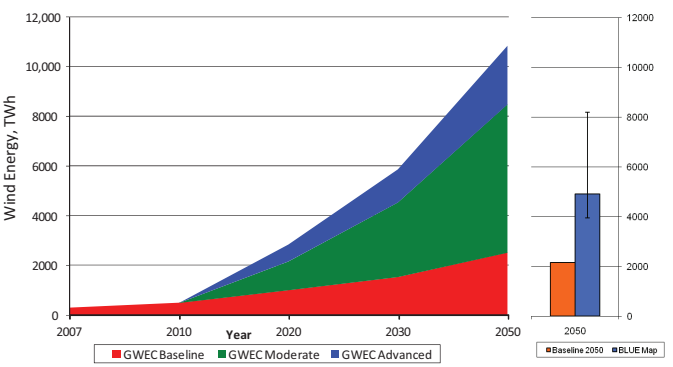

Figure 11.36 | Wind energy generation estimates from two studies (left panel: GWEC and Greenpeace, 2010a; right panel: IEA, 2010a).

A second estimate, developed by the IEA in *Energy Technology Perspectives* 2010 (ETP), uses an optimization model to create global energy scenarios based on different levels of commitment to carbon emission reduction (IEA, 2010a). It poses two scenarios, Baseline and BLUE Map. The Baseline scenario is based on the *World Energy Outlook* 2009 extrapolated to 2050 and assumes that no new policies are introduced. The BLUE Map scenario represents a reduction of CO_2 emissions to 50% below 2005 levels by 2050.

Figure 11.36 shows the estimated wind energy generation in 2050 for these two studies. The GWEC scenario projections include both onshore and offshore wind but do not estimate the proportion from each. The

error bar on the Blue Map scenario (4900 TWh/yr in 2050) represents the variation in wind energy generation estimates based on sensitivity runs.

These two studies suggest significant generation potential for wind technology, up to 10,000 TWh annually in the GWEC Advanced scenario. Wind generation as a percentage of total global electricity demand varies from 10% to 26% for the non-reference / non-baseline scenarios, depending on assumptions that influence projections of total electricity demand and the role of competing low-carbon generation technologies. These studies use different approaches to reach internally consistent scenarios. The GWEC simulation model focuses on wind industry growth potential based on historical expansion levels and considering growth rates, turbine rating and capacity factor, capital costs, and progress ratios. The IEA-ETP simulation model assesses wind technology contribution to projected electricity sector expansion relative to other generation technologies under various policy influences.

A third approach by Hoogwijk et al. (2004) explores the economic potential of onshore and offshore wind generation based on geographic location, exclusion areas for environmental and competing uses, wind speed estimates, wind technology generation estimates, and costs. This study finds that wind technology could generate an amount roughly equal to 2001 world electricity consumption, 16,000 TWh, at a cost of up to US_{2004}¢7/kWh.

Although all these studies use very different approaches, they demonstrate that economically feasible wind energy generation potential is significant. The cost of wind generation relative to other generation technologies becomes the ultimate driver.

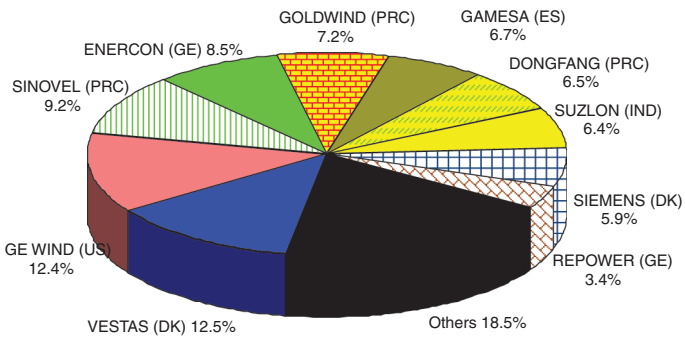

Figure 11.38 | Top 10 wind turbine suppliers, 2009. Source: based on BTM Consult, 2010.

11.5.3 Market Developments

The wind industry has enjoyed sustained global growth since 1990. Almost 160 GW of wind generation capacity were installed through 2009, generating nearly 350 TWh electricity annually. At the end of 2010, almost 200 GW was operating worldwide. In the period 2004–2009, cumulative installed capacity grew at an annual average rate of approximately 27%.

Europe is the global leader in terms of installed wind capacity (76 MW in 2009) but cumulative installations in Asian and American markets grew rapidly between 2008 and 2009 at 68% and 39% respectively. (See Figure 11.37.)

European countries such as Denmark, Germany, and Spain led growth in the late 1990s. The United States and China became the fastest-growing markets from 2005 to 2010. India has moved into the top 10 wind markets. By the end of 2010, the highest installed wind capacity was found in China (45 GW), followed by the United States (40 GW), Germany (27 MW), Spain (20 GW), and India (13 GW) (GWEC, 2011).

The wind industry remains highly concentrated: just six countries are home to the top 10 wind turbine suppliers in 2009 (see Figure 11.38) – all from Europe, North America, or Asia.

While the industry was previously dominated by small independent project developers, electric utilities and large independent power producers are increasingly investing in wind projects. This is leading to increasing globalization and competitiveness in the wind turbine supply chain (BTM Consult, 2010). In 2009, investments in wind power installations totaled nearly US_{2009}52 billion; direct employment in the wind energy sector has been roughly estimated at 600,000 jobs (GWEC and Greenpeace, 2010a).

In Europe and the United States, wind has become a major source of capacity additions to the electric sector. Between 2000 and 2009, wind capacity additions were second only to natural gas and were ahead of coal. In 2009, 39% of all capacity additions in both the United States and the European Union came from wind power. (See Figure 11.39.)

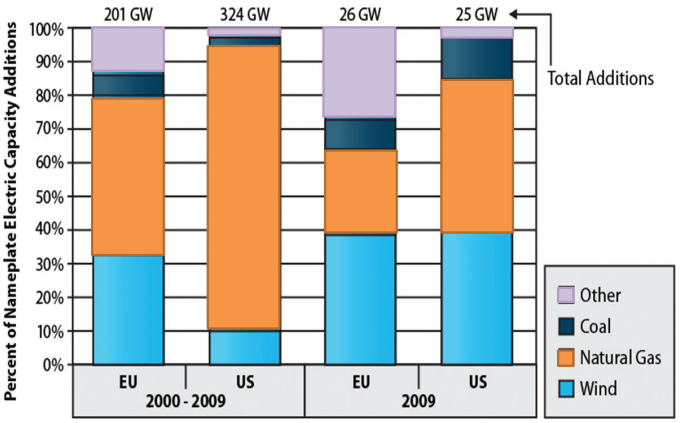

Figure 11.39 | Relative contribution of generation types to capacity additions in the United States and the European Union, 2000–2009 and 2009. Source: Wiser and Bolinger, 2010; EWEA, 2010.

By the end of 2009, the wind industry had developed 38 offshore projects in nine European countries, bringing total capacity to above 2000 MW. Annual installations grew to 577 MW in 2009, up 54% from 2008 (EWEA, 2010). The European Wind Energy Association (EWEA) estimates that the 2056 MW of capacity installed at year-end 2009 will generate more than 7 TWh of electricity annually. The development of offshore wind projects has so far been concentrated in Europe, but 2010 saw the first Chinese project commissioned and the final permitting of the Cape Wind project in the United States (Musial and Ram, 2010).

11.5.3.1 Role of Wind Turbine Standards

The development of a suite of international standards for wind turbines has been a major contributor to the evolving market for wind turbine technology over the past 15 years. The International Electrotechnical Commission (IEC) is a global organization that prepares and publishes international standards for electrical, electronic, and related technologies (IEC, 2010). These standards serve as the basis for national standards and as a reference when drafting international tenders and contracts. The standards cover wind turbine systems and subsystems, such as mechanical and internal electrical systems, support structures, and control and protection systems.

11.5.3.2 The Near-term Market Future

Near-term forecasts indicate continued rapid growth of the global wind industry from the current level of 160 GW. The Global Wind Energy Council forecasts a cumulative installed capacity (onshore and offshore) of 409 GW by 2015, meeting about 4% of global electricity demand (up from 2% in 2009) (GWEC and Greenpeace, 2010b). This equates to an investment of more than US_{2005}225 billion. BTM Consult reaches a similar but slightly more aggressive forecast for the period, predicting that wind will achieve 447 GW by 2014 (BTM Consult, 2010).

Prospects for growth in the offshore wind market are considerable. EWEA (2010) foresees European offshore wind installations growing to 150 GW by 2030, depending on the policies implemented. The US DOE and the US Department of the Interior have adopted a strategy to realize 54 GW of offshore wind in the United States by 2030 (US DOE, 2011a). In Europe at the end of 2009, some 3500 MW of offshore wind was under construction, 16,000 MW had received final permits, and 100,000 MW had been proposed (EWEA, 2010).

11.5.3.3 Small Wind Turbines

There is also a market for small-scale wind turbines with capacities in the hundreds of watts up to 100 kW range. In rural areas they are used for battery charging and in stand-alone hybrid electricity systems. It has been estimated that annual global installations of small wind turbines may approach 40 MW (AWEA, 2009). In addition, probably more than 1 million water-pumping wind turbines (wind pumps) manufactured in developing countries supply water to livestock (UNDP et al., 2000).

11.5.4 Wind Energy Technology Development

11.5.4.1 Onshore Wind Turbine Technology: Current Status

Commercial-scale wind turbines have largely coalesced around a horizontal-axis design with three pitch-regulated blades that capture the wind resource upwind of the tower and have a diameter of 60–120m. The rotor and blades are attached to a hub and main shaft through which mechanical energy is transferred to a gearbox (depending on the design) and finally to a variable speed generator, where the energy is converted to electricity. These components are contained in a housing made of fiberglass, called a nacelle, which protects components from the elements. The nacelle is mounted on a 50–120m tower to allow the rotor to capture higher-quality wind resources than found near the ground.

Wind turbines are typically grouped together into wind power plants (wind projects, wind farms) for the commercial production of electricity (as opposed to community or residential electricity production). The electricity generated is aggregated at an on-site substation and then exported to the utility system grid. Modern onshore wind projects typically range in size from 25 to 400 MW, though the largest plant currently operating has more than 800 MW of capacity.

During the past 25 years, average wind turbine ratings have grown almost linearly since the introduction of 50 kW turbines in the early 1980s. Current commercial machines are rated at 1.5–3 MW for land-based turbines, offshore turbines as large as 5 MW are being deployed, and larger machines are on the drawing boards of several manufactures. Wind turbine designers in the last two decades have continually predicted that the current generation of turbines had grown as large as

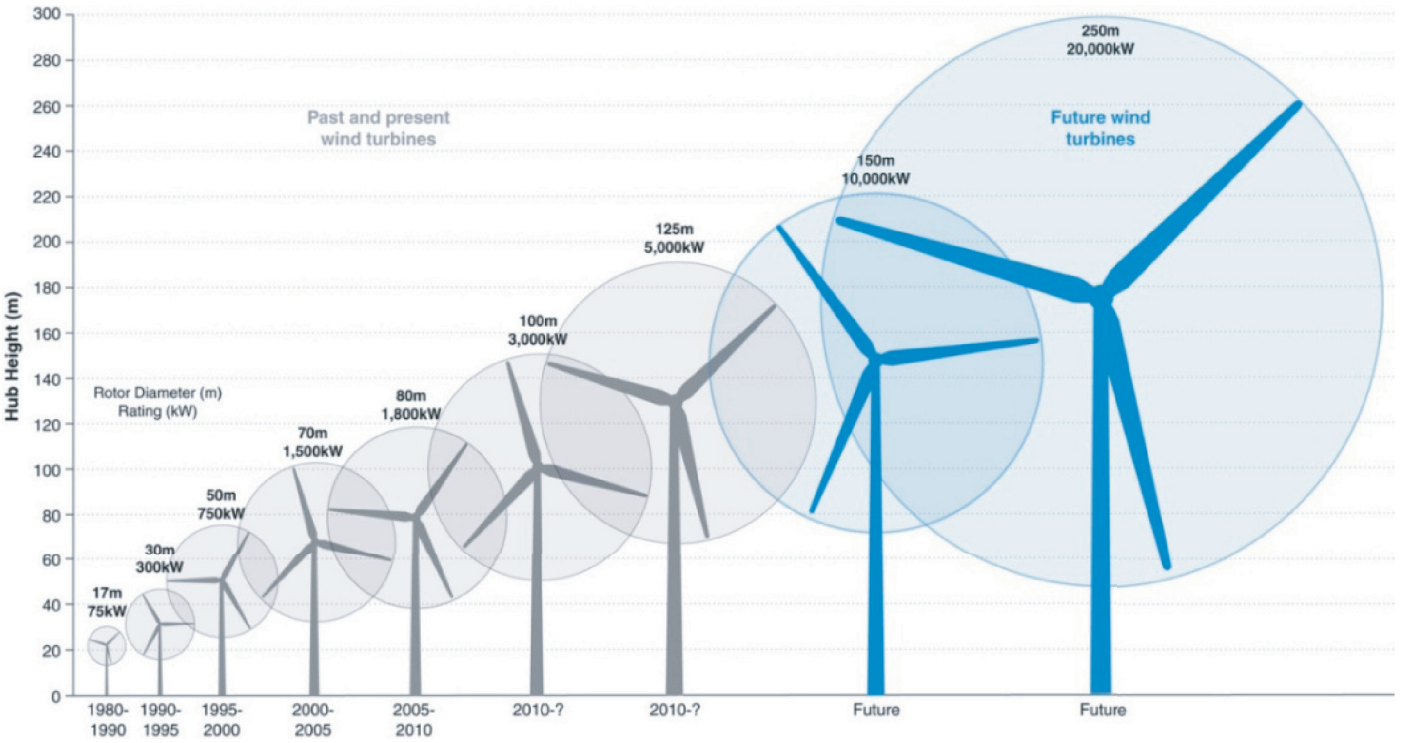

Figure 11.40 | Development and size growth (rotor diameter) of wind turbines since 1980. Source: courtesy of NREL.

they would ever be. But with each new generation of turbines, size has increased linearly and resulted in a reduction in life-cycle cost of energy. This impressive evolution of wind turbine technology is illustrated in Figure 11.40.

11.5.4.2 Potential Future Land-based Turbine Technology Improvements

The long-term drive to develop larger turbines stems from a desire to increase power production (by tapping higher-quality wind resources with larger rotors and towers), reduce investment costs per unit of capacity, and reduce operation and maintenance costs per unit of capacity. Increased size also leads to the consideration of wind turbines as energy plants – which is important to large-scale implementation – and to the introduction of more sophisticated technologies such as smart-blade designs.

There are constraints to this continued growth, however (see, e.g., Thresher et al., 2008a). In general, it costs more to build a larger turbine. The primary argument for a size limit for wind turbines is based on the "square-cube law." Roughly stated, it says that "as a wind turbine rotor increases in size, its energy output increases with the rotor-swept area (the diameter squared), while the volume of material required, and therefore its mass and cost, increases as the cube of the diameter." Consequently, at some size the cost for a larger turbine will grow faster than the resulting energy output and revenue, making scaling unattractive on economic terms. Engineers have successfully skirted this law by optimizing design characteristics for a given turbine size and removing material or by using material more efficiently to trim weight and cost (Burton et al., 2001).

Constraints in transporting very large blades, towers, and nacelles over land also can pose limiting factors to wind-turbine growth. An additional constraint is the cost and availability of cranes that are capable of lifting components into place. If designers are unable to address these problems, future land-based turbines are likely to be redesigns of 2–5MW turbines, with an emphasis on greater efficiency and reliability. Transportation to offshore sites is not limited by size, and offshore wind energy is a major driver of the development of larger turbines.

Both the European Technology Platform for Wind Energy (TPWind, 2008) and the US DOE (WindPACT, 1999; US DOE, 2008a) have identified a broad array of wind energy R&D activities that have the potential to improve the cost and performance of wind technology significantly. Potential improvements are summarized in Table 11.23, which also shows the manufacturing learning-curve effect generated by several doublings of turbine manufacturing output expected. The impact on capital cost reduction is assumed to range from zero in a worst-case scenario to the historic level in a best-case scenario, with the most likely outcome halfway in between. The most probable scenario is a sizable (~ 45%) increase in capacity factor with a modest (~ 10%) drop in capital cost (Thresher et al., 2008a).

Thus although no "big breakthrough" is on the horizon for land-based wind technology, many evolutionary R&D steps can cumulatively bring

Table 11.23 | Areas of potential wind energy technology improvements.[a]

Technical Area	Potential Advances	Increments from Baseline (Best/Expected/Least)	
		Annual Electricity Production per kW (%)	Turbine Investment Cost per kW (%)
Advanced Tower Concepts	* Taller towers in difficult locations * New materials and/or processes * Advanced structures/foundations * Self-erecting, initial or for service	+11/**+11**/+11	+8/**+12**/+20
Advanced (Enlarged) Rotors	* Advanced materials * Improved structural-aero design * Active controls * Passive controls * Higher tip speed/lower acoustics	+35/**+25**/+10	-6/**-3**/+3
Reduced Energy Losses and Improved Availability	* Reduced blade soiling losses * Damage-tolerant sensors * Robust control systems * Prognostic maintenance	+7/**+5**/0	0/**0**/0
Advanced Drive Trains (Gearboxes and Generators and Power Electronics)	* Fewer gear stages or direct drive * Medium/low-speed generators * Distributed gearbox topologies * Permanent-magnet generators * Medium-voltage equipment * Advanced gear tooth profiles * New circuit topologies * New semiconductor devices * New materials (GaAs, SiC)	+8/**+4**/0	-11/**-6**/+1
Manufacturing Learning	* Sustained, incremental design and process improvements * Large-scale manufacturing * Reduced design loads	0/**0**/0	-27/**-13**/-3

[a] The baseline for these estimates was a 2002 turbine system in the United States. There have already been sizable improvements in capacity factor since 2002, from just over 30% to almost 35%, while investment costs have increased due to large increases in commodity costs in conjunction with a drop in the value of the US dollar. Therefore, working from a 2008 baseline, a more-modest increase in capacity factor could be expected, but the 10% investment cost reduction is still quite possible, if not conservative, particularly from the higher 2008 starting point. The table does not consider any changes in the overall wind turbine design concept (e.g., two-bladed turbines).

Source: US DOE, 2008a.

about a 30–40% improvement in the cost effectiveness of this wind technology over the next two decades.

11.5.4.3 Offshore Wind Turbine Technology: Current Status

The typical offshore wind turbine to date has essentially been a marinized version of the standard land-based turbine installed in shallow water, with some system redesigns to account for ocean conditions (Musial and Ram, 2010). Modifications include upgrades to the support structure to address added loading from waves, pressurized nacelles and environmental controls to prevent corrosive sea air from degrading critical drive train and electrical components, and personnel access platforms to facilitate maintenance and provide emergency shelter (Thresher et al., 2008b). Offshore turbines must also have corrosion protection systems at the sea interface and high-grade marine coatings on most exterior components. For marine navigational safety, turbine arrays are equipped with warning lights, vivid markers on tower bases, and fog signals. To minimize expensive servicing, offshore turbines can be equipped with, for example, enhanced condition monitoring systems, automatic bearing lubrication systems, and on-board service cranes – all of which exceed the standard for land-based designs (Thresher et al., 2008b).

Today's offshore turbines range in capacity from 2 to 5 MW and typically are represented by architectures that include a three-bladed horizontal-axis upwind rotor, nominally 80–126m in diameter. The drivetrain topology consists of a modular three-stage hybrid planetary-helical gearbox that steps up to generator speeds between 1000 and 1800 rpm, which is generally run with variable speed torque control, although there is some evidence that direct drive generators might offer a smaller, lighter, cheaper, and more reliable alternative. Tower heights offshore are generally less than those of land-based turbines because wind-shear profiles are less steep, tempering the energy capture gains sought with increased elevation. Lower offshore tower heights also reduce the potential for overturning – an important consideration for floating platforms (Thresher et al., 2008b).

The offshore foundation systems differ substantially from land-based turbines. Offshore wind turbines installed to date have used three main

foundation designs: monopile, gravity base, and multipile. Monopile and multipile foundation technologies require specialized installation vessels to drive piles into the seabed. Gravity bases can simply be towed to the site, where they are filled with ballast and sunk carefully onto each site. Once the foundation is prepared, the turbine is installed using a specialized crane ship or barge. Mobilization of the infrastructure and logistical support for a large offshore wind farm is a significant portion of the cost (Thresher et al., 2008b).

In 2009, some 88% of offshore turbines were installed on monopiles, 8% on gravity bases, and 3% on multipiles (EWEA, 2009). The choice of foundation technology is largely governed by project economics. Monopiles and gravity bases are the most cost-effective technologies for turbines rated lower than 5 MW and installed in shallow water (less than 30m). It is expected that it will be cost-prohibitive to use these technologies with larger turbines or transitional depths (30–60m). So the use of multipiles is expected to expand considerably.

11.5.4.4 Potential Future Offshore Turbine Technology Improvements

Three pathways for offshore technology represent progressive levels of complexity and development that will lead to cost reductions and greater deployment potential (Thresher et al., 2008b). The first path is to lower costs and remove deployment barriers for *shallow-water technology* in water depths of 0–30m, where technology has already been deployed and proven. The second path is *transitional depth technology*, which is needed for depths where current technology no longer works, up to the point where floating systems are more economical. This technology deals mostly with substructures that will be adapted from existing offshore oil and gas practices. The third path is to develop technology for *deep-water* depths of 60–900m. This could use floating systems, which will require a higher level of R&D to optimize turbines that are lightweight and can survive additional tower motion on anchored, buoyant platforms. Deep-water designs would open up major areas to wind energy development where the turbines would not be visible from shore and where competition with other human activities would be minimal. Such platforms would allow mass production of all system components, introducing a major new opportunity for cost reduction. At this time, all three of these development pathways are being explored.

The European *UpWind* research project (Hjuler Jensen, 2007) envisions offshore wind turbines growing in scale to 8–10 MW and having rotor diameters greater than 120m, which is a challenge to design, build, install, and operate at sea. The project, established to address this multitude of engineering challenges, addresses these technical areas: aerodynamics and aero-elasticity, rotor structure, and materials; foundations and support structure; controls systems; remote sensing; condition monitoring; flow; electrical grid; and management. The *UpWind* project is also designed to address systems integration topics like integrated system design, standards, metrology (measurement), training and education, innovative rotor systems, electricity transmission and conversion, smart rotor blades, and system up-scaling.

In general, offshore wind technology is expected to gain improvements similar to those envisioned for land-based wind turbines (as outlined in Table 11.23) but at a much larger machine scale and in a more hostile operating environment. Clearly the researchers must design larger and lighter rotors.

11.5.4.5 Future Underlying Science Challenges

The very significant wind energy technology improvements and related cost reductions currently achieved have been enabled by the application of improved engineering analysis and design techniques and by testing each new wind turbine component and system. However, wind energy technology has matured to a point where it will be difficult to sustain this rapid rate of improvement without a major advance in understanding of the basic physical processes underlying wind energy science and engineering. There are fundamental knowledge barriers to further progress in virtually all aspects of wind energy engineering: scientists' understanding of atmospheric flows, unsteady aerodynamics and stall, turbine dynamics and stability, and turbine wake flows and related array effects. Even climate effects might be caused locally by the large-scale use of wind energy, both onshore and offshore (Thresher et al, 2008a).

Research in these focus areas has developed in relative isolation from the others. Continued progress in wind energy technology will require interdisciplinary reunification, especially with the atmospheric sciences, to exploit previously untapped synergies. Also, experiments and observations need to be applied in a coordinated fashion with computation and theory. The use of high-penetration wind energy deployment requires an unprecedented ability to characterize the operation of large wind turbines deployed in gigawatt-scale wind plants (Thresher et al, 2008a).

11.5.5 Economic and Financial Aspects

11.5.5.1 Present Wind Energy Costs

Capital costs for wind projects have declined dramatically since the 1980s. Figure 11.41 shows historic installed capital costs for wind projects in the United States and Denmark from 1982 to 2009. Improved design methods and experience with installations as well as upscaling of turbine technology contributed to the decreases observed until 2002/2003. Since 2004, however, capital costs have increased, driven by turbine performance improvements, rising commodity prices, currency fluctuations, high demand for turbines, supply chain constraints, higher labor costs, and increased margins for original equipment manufactures, developers, and component suppliers. Milborrow (2010) reports that the global average capital costs for onshore wind projects installed in 2009 ranged from US$1400–2100/kW, with an average of $US_{2005}$$1750/kW.

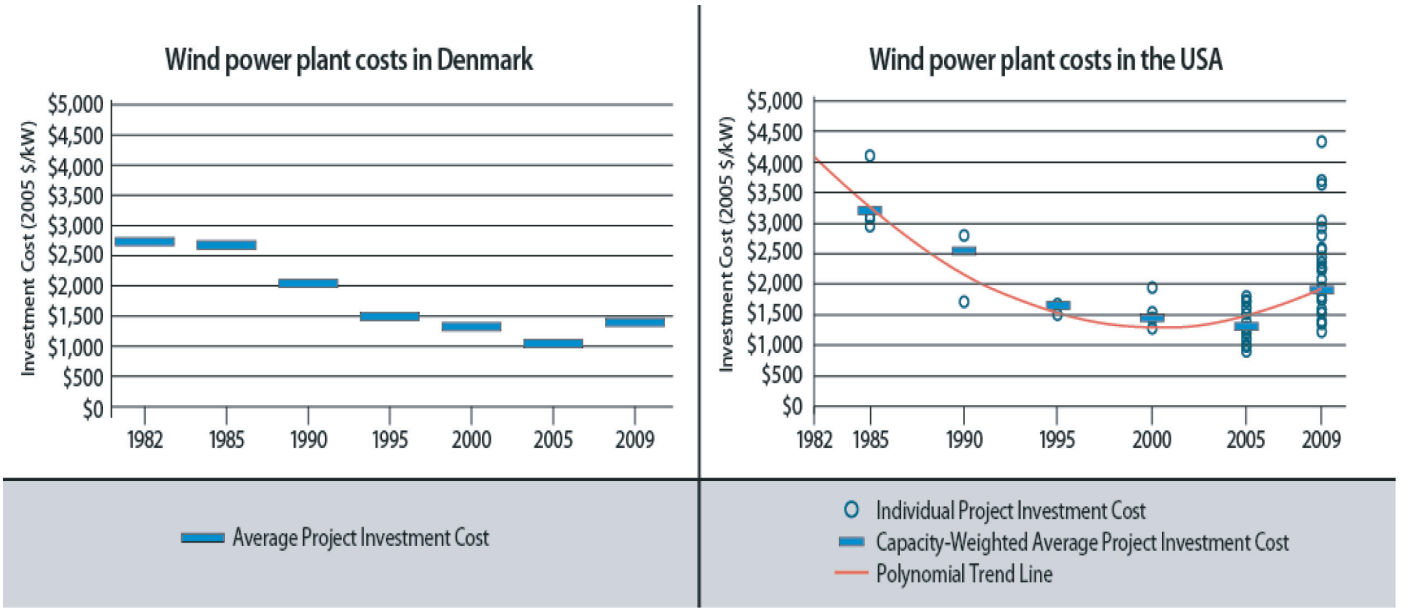

Figure 11.41a, b | Installed Wind Project Costs over time in Denmark and the United States. Source: Denmark: Nielson et al., 2010; United States: Wiser and Bolinger, 2010.

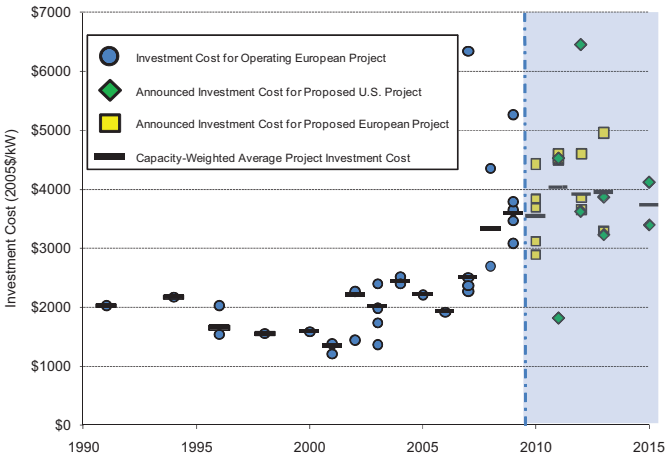

Figure 11.42 | Capital costs for installed and announced offshore wind projects. Source: Musial and Ram, 2010. Courtesy of NREL.

Wiser and Bolinger (2010) report a slightly higher average capital cost in the United States of US$1900/kW. Capital costs for Chinese projects are substantially lower, with an average in the range of US$1000–1300/kW as a result of low-cost turbines supplied by Chinese manufacturers (Li and Ma, 2009; Li, 2010). Some of the cost pressures (supply chain, commodity prices) appear to be easing, leading to expectations that capital costs will decrease over time (Wiser and Bolinger, 2010).

Capital costs for offshore projects are far less certain due to the relative immaturity of the technology. Figure 11.42 shows the capital costs for installed and announced offshore wind projects from 1990 to 2015. Offshore wind project capital costs rose from about US$1300/kW to current levels of US$3000–6000/kW, driven by similar factors as land-based wind capital costs.

But these increases were exacerbated by sector-specific factors, including a lack of competition in the market for offshore wind turbines (two manufactures had a 90% market share in 2009), limited availability of specialized installation vessels, complexity of siting projects in deeper water and farther from shore, and increasingly robust turbine designs necessitated by a better understanding of technical risks (Musial and Ram, 2010). While the near-term trend for offshore wind capital costs is uncertain, there is a positive sign in that the supply chain is becoming more competitive. In 2010, some 21 manufactures announced 29 different wind turbine models for the offshore market (EWEA, 2011).

Power prices for onshore wind energy have risen considerably since the low reached in 2002 and 2003. Wiser and Bolinger (2010) estimate that prices for electricity generated by onshore wind projects built in 2009 range from about US¢4–8/kWh, with a capacity-weighted average of about US¢6/kWh. (The price for projects in the United States reflects the value of state and federal incentives available to wind projects, such as the federal Production Tax Credit, worth US$20/MWh, and the Investment Tax Credit/Cash Grant, worth 30% of installed capital cost.) This is double the average price of projects built in 2002 and 2003 and 20% higher than the average price of projects built in 2008. The authors attribute increasing prices to elevated capital costs and lower project capacity factors. EWEA (2009) reports unsubsidized levelized costs of energy ranging from US¢6–13/kWh.

Offshore wind power prices are much less well understood than land-based prices due to a lack of available data and the substantial spike in capital costs between 2004 and 2009. EWEA (2009) calculated unsubsidized LCOE for 10 European projects installed between 2001 and 2008, resulting in a range of US_{2005}¢7–11/kWh. Mott MacDonald (2010) estimates that the LCOE for offshore wind projects installed between

Table 11.24 | Cost of electricity as a function of capacity factor, turnkey investment costs, discount rate, and O&M costs. The O&M costs are assumed at US¢1–2/kWh onshore and US¢2–4/kWh offshore. The economic lifetime is 30 years.

Capacity factor	Turnkey investment costs per kWe (*onshore*)	Discount rate	
		5%	10%
	$US_{2005}$$	US_{2005}¢/kWh	
35%	1200	3.5–4.5	5.1–6.1
	2100	5.5–6.5	8.3–9.3
20%	1200	5.4–6.4	8.2–9.2
	2100	8.7–9.7	13.5–14.5
Capacity factor	**Turnkey investment costs per kWe (*offshore*)**	**Discount rate**	
		5%	**10%**
	$US_{2005}$$	**US_{2005}¢/kWh**	
45%	3000	7.0–9.0	10.1–12.1
	6000	11.8–13.8	18.1–20.1
35%	3000	8.4–10.4	12.4–14.4
	6000	14.7–16.7	22.8–24.8

2010 and 2020 will range from US¢15–26/kWh. These estimates of LCOE differ considerably, based on assumptions about the capital cost of offshore wind projects: EWEA uses a range of US$1500–3300/kW, while Mott Mac Donald uses US$4356–6825/kWh.

The performance of wind power plants varies with the wind resource of the site, the technology deployed, and maintenance. Globally, individual project capacity factors range from a low of about 20% to a high of 50%. Average capacity factors have been estimated for Germany at about 21% (BTM Consult, 2010), China at 23% (Li, 2010), India at 20% (Goyal, 2010), and the United States at 30% (Wiser and Bolinger, 2010). Offshore turbines installed to date have had a more narrow range of capacity factors, from 35–45% (Lemming et al., 2009), but in the United Kingdom initially also about 30% was found (UKERC, 2010).

The O&M costs for wind projects onshore are estimated to range at present from about US¢1–2/kWh, while those for offshore plants are about US¢2–4/kWh (EWEA, 2009; Lemming et al., 2009; IEA, 2009b, 2010a; Milborrow, 2010; UKERC, 2010; Wiser and Bolinger, 2010).

From these figures it can be calculated, assuming an economic lifetime of the investment of 30 years, that the electricity production costs (the LCOE) range from about US¢4–15US¢/kWh for onshore wind and from US¢7–25/kWh for offshore wind. (See Table 11.24.) Assuming a lifetime of 20 years, the lowest figure increases by about US¢1/kWh.

11.5.5.2 Estimates of Future Wind Energy Costs

Estimating future wind technology costs is difficult, and various approaches have been used. Potential future cost reductions have been shown through "bottom-up" engineering models through reduced capital cost and increased energy capture of –10% and 45%, respectively. Another methodology for the calculation of future cost reduction potential is learning curve analysis, which calculates a learning rate defined as the cost reduction that occurs with each doubling of deployment.

Learning rates for wind technology summarized for IEA over different time periods range from 8–17% for capital costs and from 18–32% for electricity production costs (IEA, 2010a). The IEA study assumed a learning rate of 7% would result in cost-competitive onshore wind technology by 2020–2025, representing a capital cost reduction of 25%. A learning rate of 9% for offshore wind technology would reach a cost-competitive level by 2030–2035, representing a capital cost reduction of 38%. The IEA study assumed that global average capacity factors would increase from current averages of 20% offshore and 38% onshore to 30% and 40% respectively.

11.5.5.3 System Integration Consideration and Costs

Electric systems have historically linked large, centralized generators to consumers. Wind resources are dispersed and often located some distance from electricity customers. Integration of large amounts of wind-generated electricity will depend on the degree to which electric networks and markets evolve to accommodate variable dispersed generation technologies. Power systems are designed to handle variability, and wind generation adds to that. Experience has shown a number of ways to mitigate this: aggregation of wind generation over large geographic areas to reduce the system-level variability; forecasting methodologies implemented in control rooms to reduce operational impacts and costs; and more flexibility in the system to increase the potential for integrating wind energy. Methods to increase flexibility include additional flexible capacity in the generation mix (such as gas turbines, pumped hydro storage, or other storage technologies), increases in the size of balancing areas, trades closer to real-time (short gate-closure), and encouragement of demand-side flexibility. (See also Section 11.10).

Costs associated with managing wind variability are small at low penetrations. As wind penetration increases, these increase. Additional system balancing costs vary widely across markets, depending on plant mix and fuel costs among other factors. Recent estimates of balancing costs range from US¢0.1–0.5/kWh for wind energy penetrations between 10% and 20% (IEA-Wind, 2010). Expansion of the transmission system to remote wind resources and reinforcing the grid will also add costs. In the United States, the transmission cost to achieve 20% of projected US electricity demand from wind generation in 2030 was estimated to add US$150–290/kW to the investment cost of wind plants (US DOE, 2008a). Estimates by system operators in Germany, the United Kingdom, the Netherlands, and Portugal are of approximately US$70–170/kW of wind capacity to reach penetration levels between 15–25% (IEA-Wind, 2010).

System-level costs related to balancing or transmission expansion are borne by different entities based on the operation practices of a particular electric system. As electric systems expand to meet growing demand, including the characteristics of variable generation in the planning and design stages will enable higher penetrations of wind and other renewable technologies.

11.5.6 Sustainability Issues

This section covers sustainability issues outlined by the National Research Council of the National Academies of Sciences in the United States in *Environmental Impacts of Wind-Energy Projects* (NRC, 2007).

There are a number of life-cycle analysis studies of wind turbines. The most extensive is the ExternE study on the externalities of all energy sources. There is general agreement that a modern wind turbine system has an energy payback period of less than half a year (Wiser et al., 2011). Calculated life-cycle GHG emissions for wind range generally from about 8–20 gCO_2-eq/kWh (ExternE, 1995; Tester et al., 2005; Wiser et al., 2011). It should, however, be noted that substantial penetrations of wind energy into the grid will enhance the need for backup power and/or storage and reduce the conversion efficiency of backup plants, adding to these emissions (Gross and Hepponstall, 2008).

In terms of human health and well-being, concerns are related to noise and shadow flicker caused by the turbine blades passing through the sun and creating a flickering light shadow effect that is visually annoying. The loudest noises at a wind farm are generally emitted during construction and are similar for all construction projects. Operating wind turbines are now designed to meet a maximum noise output according to the IEC Standards (IEC, 2010). A shadow flicker analysis for close neighbors is done by the developers during the layout of the wind farm. At that time turbines can be moved to eliminate the possibility of turbine rotor shadows impinging on any close residences.

Aesthetic impacts are generally handled using techniques like an opinion survey of local inhabitants and organizations that are found in or that use the area, to determine the least visually intrusive layout for the wind farm and thereby gain general public acceptance. Responsible wind developers have established methods for gaining acceptance, and they attempt to make the projects a real economic benefit to the local residents and to minimize the visual impacts (see also Wolsink, 2007).

Regarding cultural impacts, the concern is to avoid possible intrusion on important historical, sacred, or archeological sites and to preclude possible litigation.

The economic and fiscal impacts on the local inhabitants are generally felt to be beneficial. Jobs are created locally, and the tax base is often increased along with the monetary benefits associated with direct payments to landowners who allow turbines on their property.

Turbines are sited with an eye to any possible interference with microwave communications systems and electromagnetic interference. Television interference has not been much of a problem since the widespread use of cable and dish satellite TV broadcasting. Interference between wind facilities and radar is real. If the radar unit cannot perform its intended functions, the effects must be mitigated. This can involve blocking the interference using a software fix or moving the turbines. Sometimes the radar unit must be moved or additional radar units added to the system (NWCC, 2006).

The environmental issues for wind technology concern the impacts of facilities on wildlife and wildlife habitat, including wildlife fatalities and habitat loss and modification, as well as animal displacement and fragmentation both for onshore and offshore wind facilities. This impact on wildlife can be direct (for example, fatalities or reduced reproduction) or indirect (such as habitat loss or behavioral displacement). The largest impacts to date are on flying animals, such as birds and bats. At the current level of deployment, land-based wind energy does not appear to have a significant impact on bird fatalities compared with other sources of fatalities, such as collisions with buildings and communication towers as well as predation by cats.

The general conclusion from site monitoring in the United States indicates that the average fatality rate is approximately three birds per MW annually, with about 70% of the fatalities being passerines (song birds) (Wildlife Society, 2007; NRC, 2007). Bat fatalities have been reported at land-based facilities either anecdotally or by post-construction monitoring. The highest fatalities have been recorded at wind farms located on ridges in eastern deciduous forests of the United States. Recent reports showing greater bat fatalities in the open prairie regions of southern Alberta, Canada, and in mixed agricultural and forested lands in New York suggest that the impacts on bats could be higher than currently assumed. Bats are long-lived and have low reproductive rates, so their ability to recover from population declines is limited. This increases the risk of local population extinctions and the loss of species biodiversity (Wildlife Society, 2007). Similar observations are found in Europe. In general, the variability of fatalities between facilities is quite high.

Commercial offshore wind energy facilities require a relatively large expanse of seabed floor for foundations and related structures to fix (or anchor) the structures and for deployment of interconnection cabling. These facilities will cause a degree of physical disturbance to the sea and surrounding seabed, with possible ecological responses (Gill, 2005). Therefore ecologists have expressed concerns about the impact on benthic communities, fisheries resources, marine mammals, sea turtles, and birds. The available studies on possible impacts are, however, limited (Minerals Management Service, 2007). In spite of the limited data available from existing studies, current results show limited negative direct impacts.

As with onshore wind farms, the collision of birds and bats with offshore wind turbine rotors is a major environmental and public concern. Radar studies at offshore Nysted wind farm in Denmark indicate that the

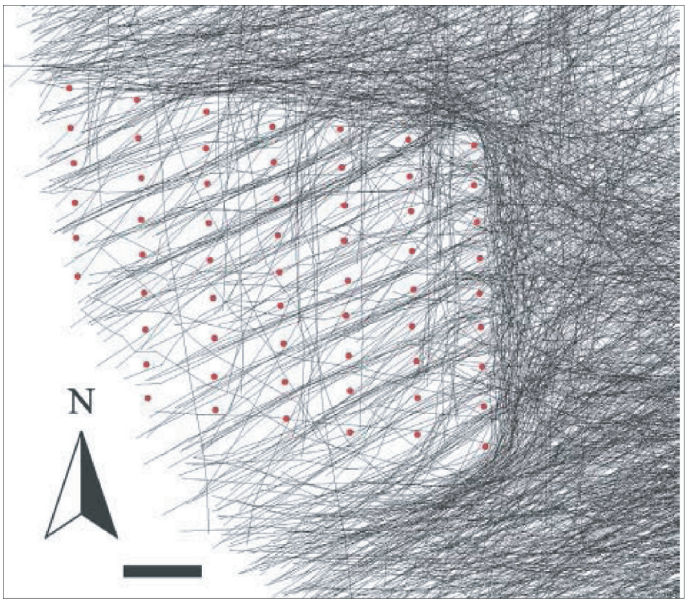

Figure 11.43 | Westerly orientated flight trajectories during the initial operation of the wind farm at Nysted off the southern coast of Denmark. Black lines show the trajectories of water bird flocks and the red dots are the wind turbine locations. The black bar is 1000 m. Source: Desholm and Kahlert, 2005.

diurnal percentage of flocks entering the wind farm area decrease significantly (by a factor of 4.5) from preconstruction to operational conditions (Desholm and Kahlert, 2005). At night about 14% of a flock entered the area of operating turbines, but only 6.5% of those flew within 50m of an operating turbine. During the day these numbers declined to 12.3% and 4.5% respectively. Radar trajectories of water bird flocks flying through the wind farm area are shown in Figure 11.43. It illustrates that water birds avoid wind farms, which reduces the risk of collisions.

11.5.7 Implementation Issues

11.5.7.1 Regional Deployment

The deployment of wind technology has historically been concentrated in Europe, North America, India, and China. High penetration scenarios such as GWEC's advanced scenario of about 2300 GW by 2030 require more diverse geographic deployment. In the advanced scenario, GWEC projects that regions other than Europe, North America, and China will account for 30% of cumulative wind capacity compared with 17% in the reference scenario (GWEC and Greenpeace, 2010a). Enabling the spread of the technology to other regions poses challenges and opportunities for the global industry.

11.5.7.2 Supply Chain Issues

Due to rapid increases in annual installations, from 2005 to 2008 the wind industry suffered acute shortages in the supply of gearboxes, bearings, and skilled labor. In addition, the offshore industry supply chain experienced a shortage in specialized ports and installation vessels. These factors increased delivery time for turbines and installation time for offshore projects, and they generally drove costs upward. The industry has largely addressed these issues through investment in new manufacturing capacity, the globalization of the supply chain, and the widespread expansion of firms supplying the market. The supply chain does not appear to offer any insurmountable barriers despite the high level of annual installations required in high penetration scenarios.

11.5.7.3 Economics

Deployment will depend on the economic attractiveness of wind technologies balanced against competing technologies under prevailing market conditions. Onshore wind is competitive with conventional generation technologies in areas with strong wind resources. The cost of generating offshore wind power far exceeds market prices for electricity in most regions. While costs are expected to be reduced, near-term deployment of offshore wind technology will remain highly dependent upon policy. This presents a substantial barrier to achieving the high penetration scenarios that suggest that 18–32% of total capacity installed by 2050 may come from offshore (Lemming et al., 2009; IEA, 2010a).

11.5.7.4 Transmission and Integration

Studies have shown that electric systems can integrate 20% wind generation with relatively modest integration costs and without encountering insurmountable technical barriers (US DOE, 2008a; European Commission, 2010; IEA-Wind, 2010). System impacts for deployment above 20% are less well understood but could be addressed through structural changes in the electric market, including better forecasting techniques, increasing fidelity of dispatching procedures, flexible deployment of other generating plants, demand response measures, increased international coordination and interconnection (like the Supergrid and other proposals in Europe (FOSG, 2010; EEGI, 2010)), "smart grids," deployment of storage technologies (including electric transport system), and wind curtailment. (See Section 11.10.) The costs of integration and of maintaining electric system reliability will increase with higher levels of penetration and at some point are likely to constrain further deployment on economic terms. Substantial investments in transmission will be required to deliver power from both onshore and offshore wind plants to load centers. New transmission is required in even the low to moderate penetration scenarios and will limit wind energy deployment if not built.

11.5.7.5 Social and Environmental Concerns

Concerns about the social and environmental impacts of wind power plants – including bird and bat collision fatalities, habitat and ecosystem modifications, visibility, acoustics, competing uses, and radar interference – could limit the deployment of wind technology. These concerns

are likely to become more acute as wind technology reaches higher levels of penetration. The wind industry can limit concerns over social and environmental impacts by seeking to understand the nature and magnitude of these impacts, developing mitigation strategies, and educating the public on the results of these efforts (Wolsink, 2007; Minerals Management Survey, 2007). Advanced deployment scenarios might require that regulators adopt a more streamlined permitting process for wind projects.

11.5.7.6 Policies

In the last two decades, an increasing number of countries have developed and implemented policy measures to promote renewables, including wind (REN21, 2010). Financial support for R&D, establishment of generation or capacity targets based on Renewable Portfolio Standards (RPS) or Obligations, and FITs have been used successfully. Additional measures sometimes include tax incentives, regulation of GHG emissions, bidding overseen by government, appropriate administrative procedures for wind farm planning, priority access to transmission grids, and transmission grid expansion. (See section 11.12.)

11.6 Photovoltaic Solar Energy

11.6.1 Introduction

Photovoltaic solar energy is the direct conversion of sunlight into electricity. The basic building block of a PV system is the solar module, which consists of a number of solar cells. Solar cells and modules come in many different forms that vary greatly in performance and degree of maturity. Applications range from consumer products (milliwatts) and small-scale systems for rural use (tens or hundreds of watts) to building-integrated systems (kilowatts) and large-scale power plants (megawatts and soon up to gigawatts). The PV market – and hence, the PV industry – is developing rapidly as a result of market support programs in a number of countries. So far, self-sustained markets are modest in size, but this may well change during this decade.

11.6.2 Potential of PV Solar Energy

The theoretical potential of solar energy is huge, as expressed in the popular statement that the amount of sunlight hitting Earth in one hour equals the total annual primary energy use worldwide. (See also Chapter 7.) However, this impressive fact has little practical significance. Therefore, it is important to consider the technical and realizable potentials.

11.6.2.1 Technical and Economic Potentials

The technical potential of solar energy is estimated to be between 1600 and 50,000 exajoules (EJ) a year (UNDP et al., 2000), with the wide range expressing the very different assumptions made in the analyses. Higher figures are mentioned too, however (see Chapter 7; also Figure 11.3). Even though the lower limit exceeds the current and estimated future worldwide energy use, there is no consensus on the economic potential of solar energy in general and of PV in particular because of the many technical, economic, and societal aspects at play.

11.6.2.2 PV Roadmaps and Scenarios

At the end of 2009, the installed solar PV capacity was 24–25 gigawatts peak (GWp), consisting of 21 GWp of grid-connected systems and 3–4 GWp of off-grid systems (REN21, 2010; IEA-PVPS, 2010; Jäger-Waldau, 2010). This generated 30–35 terawatt-hours (TWh) a year.[6] In 2010, another 16–17 GWp were added (versus about 7 MW in 2009), bringing the total installed capacity worldwide to roughly 40 GWp, producing some 50 TWh a year (EPIA, 2011).

In the 2010 IEA *PV Technology Roadmap*, the share of PV in global electricity consumption in 2050 is estimated at 11% (4600 TWh/yr) and the installed capacity at 3.2 TWp. Higher projections of the installed capacities can also be found. In *Solar Generation 6*, Greenpeace and the European Photovoltaic Industry Association project up to 4.7 TWp (6800 TWh) for 2050 (Greenpeace and EPIA, 2010). A study on very large-scale use of PV and concentrating solar power (in combination with compressed air energy storage) in the United States suggests that the combined contribution to electricity consumption could be as high as 69% in 2050; this would correspond to 35% of primary energy use, a share that could increase to 90% in 2100 (Fthenakis et al., 2009).

Komoto et al. (2009) prepared a detailed analysis of the potential of large-scale PV systems in sunbelt (desert) regions of the world. For six major regions, they determined a total potential of 465 TWp, allowing 750,000 TWh of solar electricity generation per year (2700 EJ_e/yr). In an ambitious scenario, the total installed PV capacity could be 10 TWp in 2050 and 133 TWp in 2100, of which 2 TWp and then 67 TWp would be in the form of very large-scale systems (the remainder would be urban and rural systems).

11.6.2.3 Potential of PV in the Built Environment

Because PV is a highly modular technology and does not involve moving parts, it can be integrated into buildings (roofs and facades) and infrastructure objects such as noise barriers, railways, and roads. This makes PV a suitable technology for use in urban and industrial areas. A number of studies have shown that the potential expressed as the fraction of

6 Because about half of the installations are still in Germany, which has relatively low insolation, the ratio between electricity generated and power installed will increase as the market share of "sunny" countries increases (from 1.25 to at least 1.5 kWh/Wp per year).

solar electricity from roofs and facades to the total electricity consumption per country varies from 20% to 60%, mainly depending on the electricity consumption per capita and the insolation level (IEA-PVPS, 2002; Lehmann et al., 2003). This assumes a rather conservative 10% energy conversion efficiency of the PV system. Future generations of PV modules may well cover a significantly higher fraction of the demand.

11.6.3 Market Developments

The market for PV systems can be divided into two main categories and several subcategories:

- *Grid-connected PV systems* – can be building-integrated and building-adapted systems (distributed systems), ground-based systems (power plants), and others (such as systems on sound barriers).
- *Off-grid / stand-alone PV systems* – can be solar cells integrated in consumer products, professional systems (e.g., telecom), rural PV systems, mini-grid systems, and others.

The market can also be divided according to the type of ownership, such as households, housing corporations, industries, companies, utilities, and institutional investors.

11.6.3.1 PV Market Deployment

Figure 11.44 shows the evolution of grid-connected and off-grid PV systems from 1995 to 2009. The total cumulative installed capacity has increased by about 30% per year on average. For grid-connected systems alone, the average growth was 50% a year.

Table 11.25 presents the cumulative installed PV capacity by country at the end of 2010, showing the leading positions of Germany (50%), Spain (11%) and Japan (10%) (see also REN21, 2011). On a per capita basis, Italy also belongs to the lead. These leading positions have been achieved in various ways (see IEA-PVPS, 2010; 2011). Japan has been a pioneer in market development and saw steady market growth until 2005, after which the market stabilized for a few years as a result of changes in market incentives; in 2009, Japan caught up again. Spain only recently joined the leaders, with an explosive (and unsustainable) growth of the Spanish market by 500% in 2008; but in 2009, the market fell back to pre-2006 levels due to drastically reduced market incentives. Germany is the only country with a substantial and steadily growing market through 2010.

The global PV market depends at present on market support policies in a very small number of countries. For sustainable and yet rapid growth, it is essential that the global market relies on more countries. Thus it is noteworthy that the group of countries with significant PV markets is growing, with Italy, France, and the United States as important examples. A

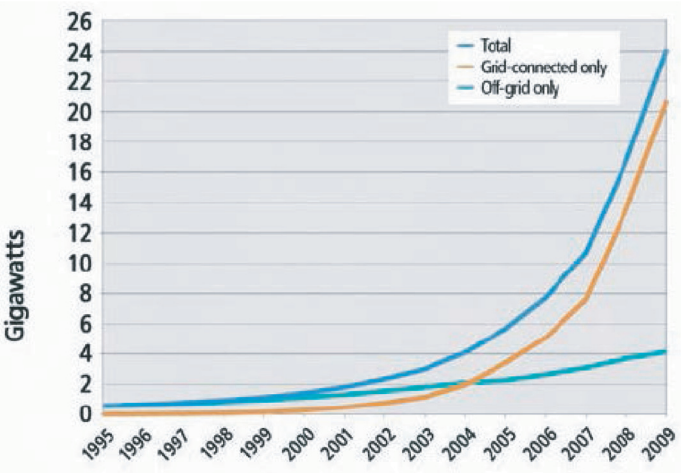

Figure 11.44 | Cumulative installed PV capacity, 1995–2009. In 2010 the total installed capacity was 40 GW (REN21, 2011). Source: REN21, 2010.

key question is how fast new markets will develop in, for example, China and India and countries in sunbelt regions, such as northern Africa.

Although currently the global market for PV systems depends heavily on various market support schemes, this situation is expected to change rapidly as system prices – and therefore, electricity generation costs – continue to decrease. In its *PV Roadmap*, the IEA distinguishes three levels of competitiveness (IEA, 2010). In the first level, the current situation, PV is only competitive in selected applications and regions of the world. In the second level, PV generation costs are lower than retail electricity prices. This is expected to happen between 2012 and 2030 almost everywhere. In the third level, PV electricity can compete with wholesale prices of electricity and, after that, with bulk power generation costs in a number of markets. This is expected to occur from 2020 onward. This scenario agrees with other major studies, such as the *Implementation Plan* of the European Photovoltaic Technology Platform (EPTP, 2009) and the Japanese *Roadmap PV2030+* of New Energy and Industrial Technology Development Organization (NEDO) (NEDO, 2009; Aratani, 2009).

11.6.3.2 Development of PV Industry

Figure 11.45 shows the growth of PV cell and module production in different regions. Manufacturers are located throughout the world, with recent rapid industry expansion in Asia. Table 11.26 shows the number of jobs in the PV sector, including R&D, as of the end of 2009. While the total number of PV-related jobs there is close to 200,000, China, Taiwan, and other Asian countries are not included in this list. So the real total is much higher (especially industry-related jobs, not deployment-related jobs).

The 2010 global turnover of the PV sector is roughly estimated to be US_{2010}100 billion. This number includes the value of turnkey system installations as well as investments in new production capacity and R&D. Although turnkey system prices are decreasing, market expansion

Table 11.25 | Cumulative installed PV capacity by country and application type, by the end of 2010. (Only the countries participating in the International Energy Agency-Photovoltaic Power Systems Programme (IEA-PVPS) are shown)

is so rapid that the related turnover is increasing rapidly. Investments in expansion of manufacturing capacity increase even more rapidly than market volumes, in view of expected PV market growth.

11.6.4 PV Technology Development

The discovery of the photovoltaic effect is usually attributed to Edmond Becquerel (Becquerel, 1839). Practical applications for power generation, however, have only come within reach after the successful development in the early 1950s of methods for well-controlled processing of semiconductor silicon, the material that most solar cells are still made of. The research group at Bell Laboratories in the United States played a key role in this development (Perlin, 1999). Many people immediately saw the great potential of PV for large-scale use, but the number and size of applications remained very modest until the 1980s. An exception was the use of PV to power satellites, which began successfully in 1958 and has remained their standard power source.

11.6.4.1 Basic Principles of Operation

The photovoltaic effect is based on a two-step process (see Figure 11.46), summarized by Sinke (2009) as follows:

- The absorption of light (consisting of light particles, or photons) in a suitable (usually semiconductor) material, by which negatively charged electrons are excited and mobilized. The excited electrons leave behind positively charged "missing electrons," called holes, which can also move through the material.

- The spatial separation (collection) of generated electrons and holes at a selective interface, which leads to a buildup of negative charge on one side of the interface and positive charge on the other side. As a result of this charge separation, a voltage (an electrical potential difference) builds up over the interface. In most solar cells, the selective interface (junction) is formed by stacking two different semiconductor layers—either different forms of the same semiconductor (in homojunction cells) or two different semiconductors (in heterojunction cells).

The key feature of a semiconductor junction is that it has a built-in electric field, which pushes/pulls electrons to one side and holes to the other side. When the two sides of the junction are contacted and an electrical circuit is formed, a current can flow (i.e., electrons can flow from one side of the device to the other). The combination of a voltage and a current represents electric power. When the solar cell is illuminated, electrons and holes are generated and collected continuously and the cell can thus generate power.

11.6.4.2 Features of Sunlight and Solar Cell Efficiency Limits

The total annual amount of solar energy per unit area (the insolation) varies over Earth's surface and roughly ranges from 700 kWh/m^2 in polar regions to 2800 kWh/m^2 in selected dry desert areas for horizontal planes (Šúri, 2006).[7] When comparing the insolation on optimally inclined surfaces, the range becomes smaller, with the lower values increasing to roughly 900 kWh/m^2. In other words, the global range of electricity production potentials per m^2 of fixed, optimally inclined surface area roughly spans a factor of three.

The maximum intensity of sunlight is about 1 kW/m^2 everywhere. The differences in insolation primarily result from varying time fractions with low light levels (seasonal, but also daily variations). Whereas daily variations are inherent to the use of sunlight, the magnitude of seasonal variations in the daily (or weekly or monthly) amount of solar energy received may have important implications for system design and implementation.

Sunlight consists of a wide range of colors (from infrared to ultraviolet) and corresponding photon energies that make up the solar spectrum. The shape of the spectrum and the total intensity of the light depend on the position of the observer with respect to the sun and on atmospheric conditions. When the sun is exactly overhead and the sky is clear, the spectrum is "Air Mass 1," which means that the sunlight has passed through Earth's atmosphere in the shortest possible path: it has crossed "1 air mass."[8] Upon passing through the atmosphere, some light is absorbed and some light is scattered, leading to characteristic features in the spectrum shape. When the sun is incident at another angle, the

7 High-quality, extensive information on insolation in Europe and Africa can be found at sunbird.jrc.it/pvgis/, which also gives links to databases covering other regions of the world. An excellent source of US information is rredc.nrel.gov/solar/old_data/nsrdb/redbook/atlas/.

8 Actually, definitions are much stricter than described here; see, e.g., rredc.nrel.gov/solar/spectra.

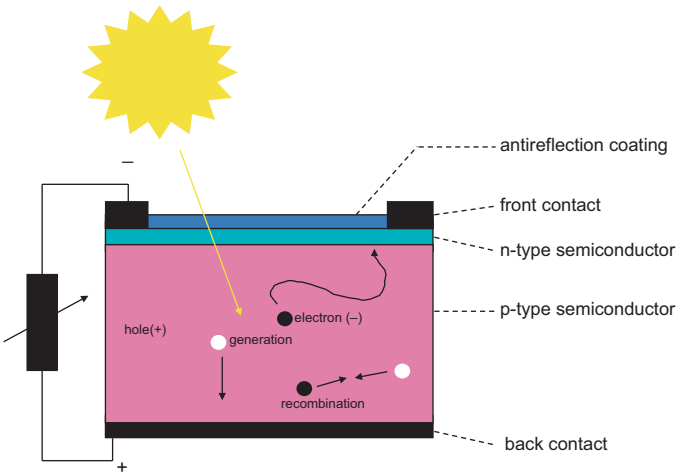

Figure 11.46 | Schematic cross-section of a solar cell.

Air Mass number changes accordingly. For measurement purposes, Air Mass 1.5 is often taken as a reference, where the path of light is at an angle through 1.5 times the thickness of the atmosphere.

The efficiency (η) of solar cells is defined as the maximum power output of the cell ($P_{max,electrical}$) divided by the power input in the form of light (P_{light}). For reasons of easy and fair comparison, efficiency values are normally defined and measured under Standard Test Conditions (STC): Air Mass 1.5 spectrum (AM1.5), 1 kW/m^2 light intensity, and 25°C operating temperature, although other standardized conditions are also useful and necessary for certain types of cells and modules, especially concentrators.

The rated power of PV cells, modules, and systems is expressed in terms of watt-peak (Wp), which is the power produced at STC. The efficiency of cells, and hence, of modules and systems, depends in part on operating conditions. Therefore, the average efficiency over a year differs from the STC efficiency. In most cases, the average value is lower. In particular, higher operating temperatures, lower light intensities, and different light spectra lead to deviations from STC efficiency. To calculate the electricity yield, the rated power has to be multiplied by the equivalent number of hours of full sun (e.g., per year) and corrected for the effects of non-STC conditions.

Semiconductors can be characterized by their light absorption behavior. Each semiconductor has a specific threshold energy above which photons can be absorbed and below which the material is basically transparent. This threshold energy is the so-called bandgap energy, the minimum energy it takes to free an electron from its original position in the crystal lattice of the material.[9] The bandgap energy varies substantially from one semiconductor to another and determines which part of the solar spectrum can be absorbed. Low-bandgap materials absorb more of the solar spectrum than high-bandgap materials and can thus, in principle, generate more current. However, the output voltage of a solar cell is also related to the bandgap: the higher the bandgap, the higher the voltage (at least for ideal devices). This implies that to achieve maximum efficiency, it is important to choose an optimum bandgap.

In any cell made of a single semiconductor (i.e., one bandgap), there are large spectral losses. Part of the spectrum cannot be absorbed at all and the rest can only be partially used. The combined spectral losses add to more than 50% even for the optimum bandgap and perfect material. In addition to the spectral losses, any cell suffers from some fundamental losses – for example, those related to electrons and holes recombining. For cells made from one type of material and operating under natural, unconcentrated sunlight, the efficiency is therefore limited to a maximum of about 30%. The best single-material solar cells made so far have an efficiency of 25–26% (Green et al., 2010), indicating that these devices are already close to perfect. Commercial solar cells and modules have significantly lower efficiencies, as discussed in the next sections.

Two common strategies to move the efficiency beyond the limit are to use multiple materials (bandgaps) for light absorption and to use concentrated sunlight. By stacking solar cells with different absorption characteristics, it is possible to achieve better coverage of the solar spectrum and to reduce the spectral losses. These are called multijunction, multigap, multilayer, or tandem solar cells. By using concentrated sunlight (up to 1000x), the effects of recombination of electrons and holes can be reduced and the output voltage can be increased. This requires a dedicated device design, because the currents generated by concentrated sunlight are large, and significant amounts of heat need to be extracted. The combination of these two approaches pushes the fundamental efficiency limit up to 75% (Green, 2003).

9 The bandgap energy and also photon energies are usually expressed in electron-volts (eV)—the energy an electron takes up when it passes through a 1-volt (V) potential difference: 1.6 10–^{19} joule (J). The eV is a convenient unit in relation to the behavior of single electrons, such as light absorption. Bandgap energies are typically between a few tenths of an eV and a few eV. Solar photon energies are in the same range.

Table 11.27 | Overview of PV technologies, PV conversion concepts, and PV efficiency boosters.

State of Development	Category	Technology Type
Commercial	Flat-plate	Wafer-based crystalline silicon (mono-crystalline, cast multi-crystalline, ribbon)
		Thin-film silicon (amorphous, nano- and microcrystalline)
		Thin-film cadmium telluride (CdTe)
		Thin-film copper-indium/gallium-diselenide/sulfide (CIGSS)
	Concentrator	Silicon-based
		Compound (III-V) semiconductor-based
Emerging (typically advanced laboratory or pilot production)	Flat-plate	Polymer cells and modules
		Dye-sensitized cells and modules
		Alternative forms of inorganic thin films (e.g., printed CIGSS) and hybrid materials
	Concentrator (low concentration)	Luminescent concentrators using silicon or compound semiconductor cells
Novel concepts (laboratory only – research or proof-of-principle phase)	Not yet known	Intermediate-band semiconductors ("intrinsic multijunction materials")
		Spectrum converters ("external efficiency boosters")
		Various electronic and optical applications of quantum dots (e.g., "all-silicon tandems")
		Plasmonic structures for light management
		Hot-carrier devices

Source: EPTP, 2007.

There is growing interest in achieving such efficiencies through "third-generation photovoltaics." Some of these concepts offer fundamental efficiency limits of 75–85% (Green, 2003); however, they are all in a very early stage of development.

11.6.4.3 Practical Solar Cells and Modules

Solar modules are commonly divided into two categories:

- Flat-plate modules, in which the active cell area is roughly equal to the light-harvesting area.
- Concentrator modules, in which a small-area solar cell is illuminated by sunlight collected on a (much) larger area. These modules have a lens or mirror to focus sunlight onto the solar cell.

Concentrator modules need to track the sun because the light must come from a well-defined angle to produce a high-quality focus on the cell. For similar reasons, concentrator modules only use the direct (not the diffuse) part of the sunlight. Therefore, they work best in regions where the fraction of direct radiation is high, typically countries with an insolation of 1500 kWh/m^2/yr or more. Low-concentration-factor modules that do not require tracking have also been developed; "flat-plate concentrators" or "luminescent concentrators" fall in this category (see, e.g., Currie et al., 2008).

For flat-plate modules, it has been calculated that the performance gain of two-axis tracking compared with using an optimal but fixed orientation ranges from 10% to more than 40%, depending on the geographical location (Huld et al., 2008; Komoto et al., 2009).

It is also common to categorize cell and module technologies according to the active material(s) – the semiconductors – used for the solar cells. At the highest level, the technologies can be divided into wafer-based technologies and thin-film technologies.

Although the term "wafer-based" usually refers to flat-plate technologies, concentrator cells may also be (and usually are) wafer-based. The wafer may be silicon, germanium, or gallium arsenide, although the latter two are only for concentrator applications. In the discussion here, "wafer-based" is used only regarding silicon technology. The individual cells produced from wafers are electrically connected before or on encapsulation in a module.

In the case of thin-film technologies, the cells are deposited on a substrate (glass or metal foil) or a superstrate (glass) in the form of a very thin layer. Typical thicknesses are on the order of 1 micrometer (10^{-6} meter).

In the framework of a Strategic Research Agenda (EPTP, 2007), the European Photovoltaic Technology Platform prepared an overview of the present state of the art and expected future developments in cell and module technologies. The technology categories and types are summarized in Table 11.27.

Figure 11.47 presents the historic development of record laboratory cell efficiencies for a selection of technologies and concepts mentioned in Table 11.27. The figure shows gradually increasing efficiencies for most technologies, with occasionally more rapid increases and a few cases of saturation (indicated by termination of trend lines).

While Figure 11.47 shows record efficiencies for small-area laboratory cells (typically 1 cm^2), efficiencies for large-area commercial module

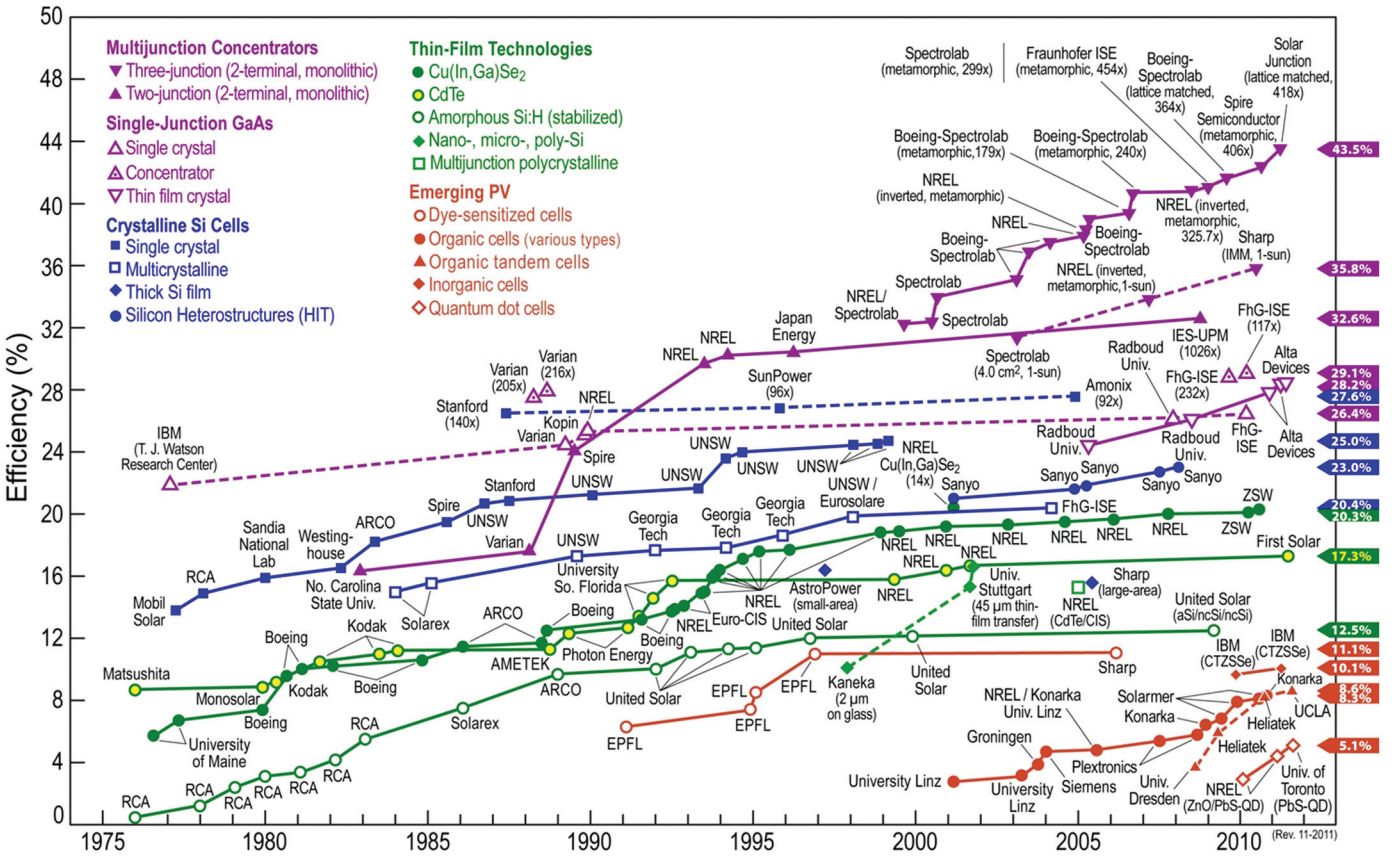

Figure 11.47 | Trends in conversion efficiencies for various laboratory solar cell technologies. Source: Kazmerski, 2011. Courtesy of NREL.

efficiencies (typically 1 m^2) are significantly lower. Efficiencies of currently available most commercial modules and the possible efficiency evolution of improved, as well as new, technologies are presented in Figure 11.48. The figure shows a gradual but robust increase for all existing technologies and the emergence of new technologies (aimed at very high efficiencies or at very low manufacturing costs) in the course of this decade.

11.6.4.4 PV Systems and Systems Terminology

Complete PV systems consist of modules (also referred to as panels) that contain solar cells, and the so-called balance-of-systems (BOS). The BOS mainly comprises electronic components, cabling, support structures, and, if applicable, electricity storage, optics and sun trackers, and/or site preparation. The BOS costs also include labor costs for turnkey installation.

PV systems are often divided into grid-connected systems, whether integrated or ground-based, and stand-alone (or autonomous) systems. PV systems feeding into or connected to a mini-grid fall in between these categories.

Systems consist of modules that are electrically connected in series and/or in parallel. Modules connected in series are called a string. A number of strings connected in parallel are called an array or sub-array. A number of arrays that function together are called a system or subsystem. To be able to quantify the performance of grid-connected PV systems and to allow comparisons with other electricity-generating technologies, the following terms and definitions are helpful:

- *System power:* The nominal (nameplate, rated) power of PV cells, modules, and systems is expressed in watt-peak – the power produced under STC. The power of complete systems is often simply expressed as the sum of the powers of the individual modules that make up the systems, although the actual direct-current (DC) power of many modules connected in series and in parallel will never equal the sum of the individual powers.

- *Performance ratio:* The (dimensionless) Performance Ratio (PR) of a PV system is defined as the average alternating-current (AC) system efficiency divided by the STC module efficiency. The PR is usually taken as the average over a year. In the PR, the effects on efficiency of very different factors are taken together. Most important are module mismatch, cabling and inverter (DC/AC conversion) losses, and

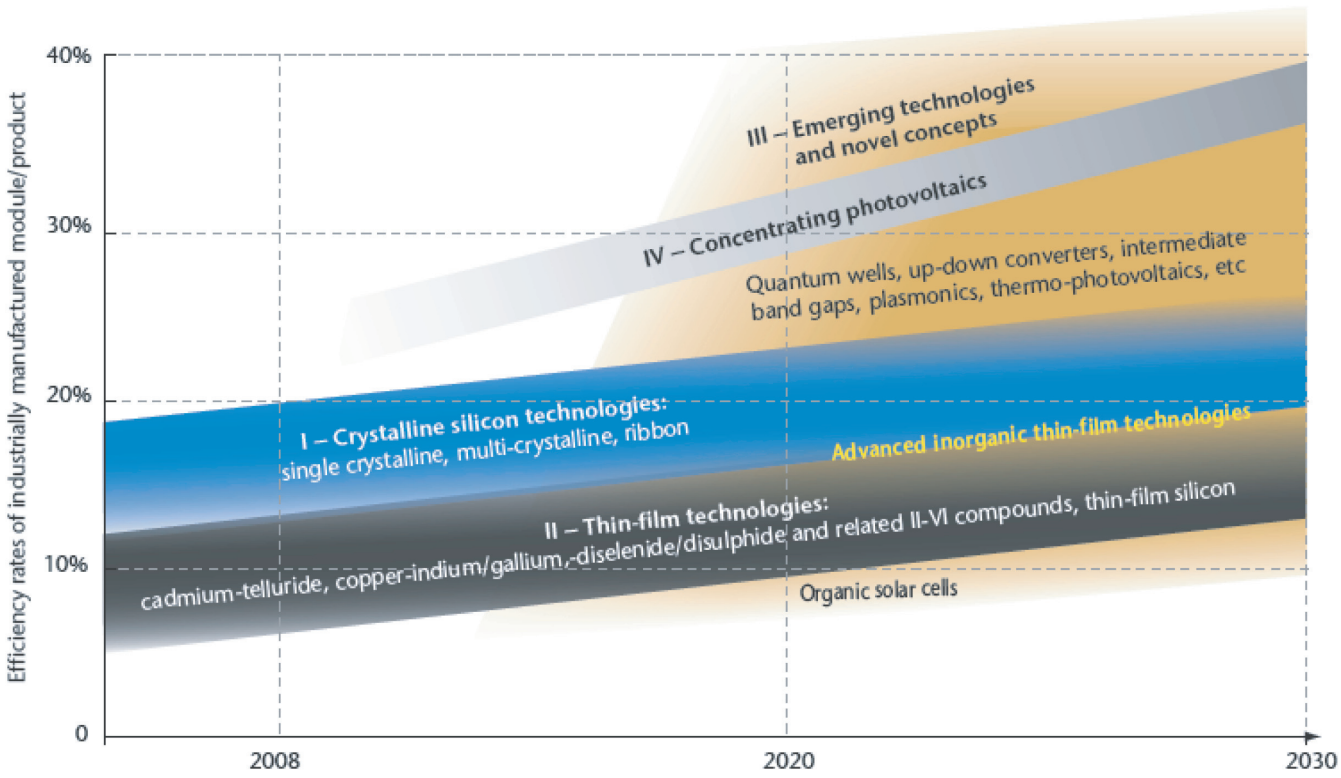

Figure 11.48 | State of the art and possible development of commercial PV module efficiencies. Source: IEA, 2010d. ©OECD/International Energy Agency 2011.

cell/module operating temperatures, as well as light intensities, light spectra, and angles of incidence that deviate from standard conditions. Also, system outages, if they occur, influence the PR. Typical PR values for recent well-functioning systems are in the range of 0.70~0.85 (IEA-PVPS, 2007). With improvements, the PR may have a modest upward potential to 0.9 ultimately.

- *PV system performance in practice:* Extensive data on the performance of PV systems in different countries are collected in the framework of IEA-PVPS Task 2 (IEA-PVPS, 2007; Nordmann, 2008). From 1991 to 2005, the typical system PR improved significantly – from 0.64 to 0.74 – as a result of, among other reasons, higher inverter efficiencies and fewer and shorter system outages and more accurate module rating. This increase does not appear to be saturated yet. In 2005, the best systems had a PR in the range of 0.80 to 0.85.

- *Capacity factor:* The (dimensionless) Capacity Factor (CF) of a PV system is determined by the insolation (in the plane of the modules) at the location of the system and the system PR. It is defined as (N × PR) / 8760, in which 8760 is the number of hours in a year and N is the equivalent number of full-sun hours in a year. N is equivalent to the insolation (in kWh/m^2/yr) divided by the intensity of full sun (1 kW/m^2). It is noted that the numeric value of N is equal to the insolation, because on Earth, "full sun" can defined as 1 kW/m^2. Taking the most relevant range of insolation values (in the plane of the modules) as 1000–2500 kWh/m^2/yr and the range of PRs as 0.75–0.85, the global range of CFs becomes 0.08–0.21, with upward potential to 0.23. It is important to note that these values refer to systems without sun tracking. If tracking is applied, the CF of systems in high-insolation regions may ultimately reach values around 0.30. The CF is a particularly useful parameter when comparing different electricity generation technologies.

- *Specific electricity yield:* The specific final AC electricity Yield (Y_f) of a system is defined as the annual AC electricity output of the system (P × N × PR) divided by the system power (P). The global range of Y_f values is 750 to 2100 kWh/kWp/yr, with upward potential to 2250 kWh/kWp/yr, excluding yield gains by sun tracking. With tracking, however, which is especially likely to be applied for all ground-based desert systems, Y_f could go up to almost 3000 kWh/kWp/yr.

Stand-alone systems (Luque, 2003) come in a wide variety of types and sizes (powers), ranging from mini systems integrated in consumer products with a typical power well below 1 Wp, through solar home systems for use in rural areas with a power in the order of 100 Wp, to larger systems for industrial use and village electrification above 1 kWp. They may also be combined with other electricity generators such as wind turbines in a hybrid system.

Although the market share of stand-alone systems is small and decreasing, their value for the user is often very high. This is because these systems are generally the user's only source of electricity, and the

alternatives are either more expensive or less convenient. It is difficult to define a simple set of performance indicators as in the case of grid-connected systems. The performance of stand-alone systems, however, can also be measured in terms of their availability – that is, the fraction of time they are able to supply the electricity needed by the user.

11.6.5 Economic and Financial Aspects

Although PV modules are the most visible part of PV systems, the economics of PV obviously depends on the price and performance of complete, turnkey systems. The price of a turnkey PV system is the sum of the price of the modules and of the BOS; it also contains labor costs, such as those related to engineering and installation.

11.6.5.1 Module Price Development

The price evolution of PV modules can be described well by a price-experience or "learning" curve, in which the average selling price (ASP) is plotted on a double-logarithmic scale as a function of cumulative production (van Sark et al., 2008; Hoffmann et al., 2009). Figure 11.49 presents data for 1980–2008. The straight line indicates the price decrease as a fixed percentage for each doubling of the cumulative production (or shipments). The progress ratio is defined as 100% minus this percentage.

The figure shows that the ASP of crystalline silicon modules (the main technology in this period) decreased by about 20% for each doubling of the cumulatively shipped volume. The curve also shows the effect on prices of the temporary silicon feedstock shortage in the early 2000s, due to rapid market expansion. By 2010, prices had largely returned to the historic trend line, as the shortage had been solved. By December 2009, prices were falling below $2/Wp in some instances (REN21, 2010). Note that the curve shows prices, not costs. The black dot in the figure shows that the price level for thin-film modules was comparable to that of crystalline silicon modules at its lowest point, albeit at a much lower cumulative production volume. This underscores the strength of thin-film technologies as low-cost options.

Although it is not possible to simply extrapolate the curve to higher cumulative production volumes (and thus, implicitly, into the future), the potential for further cost reductions by technology development and economies of scale is still substantial for both crystalline silicon (Sinke et al., 2009; Swanson, 2006) and thin-film technologies (Hoffmann et al., 2009).

11.6.5.2 Value of Higher Module Efficiency

Turnkey system prices of installed systems are a better indicator of the competitive position of PV than module prices as such. Because the BOS component of system prices consists of a power-related part (such as the inverter) and an area-related part (such as the mounting or support structure), module efficiency has an influence on system price (US$/Wp). This could be turned around to say that for an equal turnkey system price, higher efficiency modules are generally allowed to be somewhat more expensive than lower efficiency modules. For example, assume an area-related BOS price of US$100/m^2 and a power-related BOS price of US$0.50/Wp. Then a turnkey system price of US$3/Wp may allow a module price of US$1.50/Wp when the conversion efficiency of the module would be 10%, but US$2/Wp when the module efficiency would be 20%. In this specific example, the "value" of 20% over 10% efficiency is thus US$0.5/Wp.

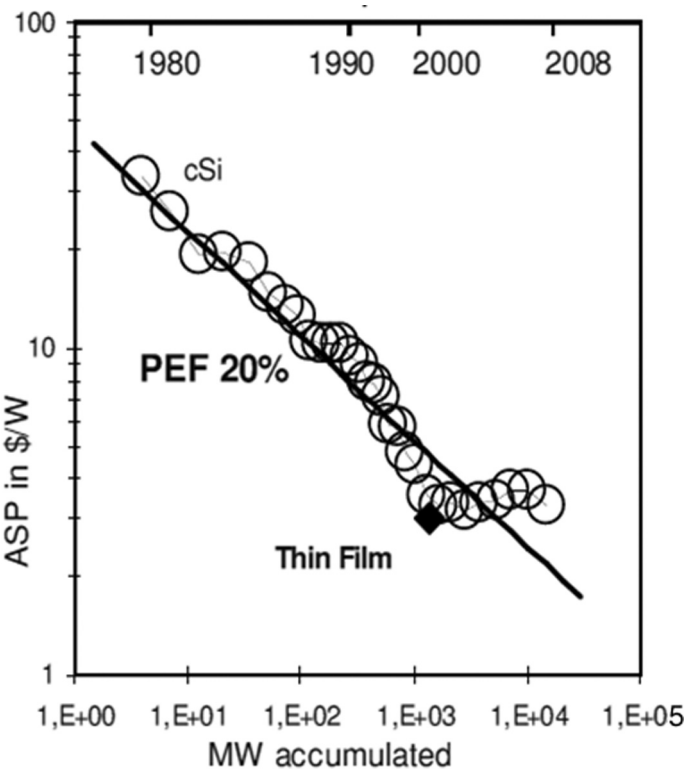

Figure 11.49 | PV module experience curves showing the average selling price (ASP) of modules in US_{2008} as a function of the cumulative module production. Note that the Progress Ration (or PEF: Price Experience Factor) is about 20%. See text for further explanation of the curve. Source: Hoffmann et al., 2009.

11.6.5.3 PV System Price Development

System prices vary much more than module prices do because of the wide variety of system types and sizes, country-to-country differences in experience and installation practice, and other factors. For systems that can be compared, a European study has indicated that the BOS part of system prices may follow an experience curve with a progress ratio similar to that of modules, although the uncertainties are much larger (Schaeffer et al., 2004). Moreover, it is uncertain whether this trend can be maintained over the long term, because drastic possibilities for price reduction are perhaps less obvious for BOS than for modules. Therefore

Table 11.28 | Turnkey investment costs of PV systems and corresponding (rounded) levelized electricity generation costs for 2009, 2020, and 2050.

Typical Irradiation on Fixed Optimally Oriented Plane (kWh/m²/yr)	Capacity Factor (and Corresponding Annual Yield in kWh/kWp)	Typical Turn-key Investment Costs (US_{2005}/kWp)	Cost of Electricity (¢/kWh)	
			Discount rate	
			5%	10%
Current (2009)				
1000	9% (790)	4500 (typical range 3500–5000)	46.1	68.5
2000 / 1500 (without / with sun tracking)	18% (1580)		23.1	34.2
2300 (with sun tracking)	27% (2370)		15.4	22.8
2020				
1000	9% (790)	2000 (possible range < 1500–2500)	19.0	29.4
2000 / 1500 (without / with sun tracking)	18% (1580)		9.5	14.7
2300 (with sun tracking)	27% (2370)		6.3	9.8
Long-Term (2050)				
1000	9% (790)	900 (possible range ~ 700–1200)	8.6	13.2
2000 / 1500 (without / with sun tracking)	18% (1580)		4.3	6.6
2300 (with sun tracking)	27% (2370)		2.9	4.4

it has been argued that the progress ratio for BOS on the longer term may be 85% or 90%, rather than 80% as for modules.

The evolution of system prices is monitored by IEA-PVPS (see, e.g., IEA-PVPS, 2010). The 2009 turnkey system prices of larger grid-connected systems were roughly in the range of US_{2009}3.5–7.5/Wp in major markets – with the lower end of the range being characteristic for systems installed in countries with a well-developed and competitive market. For off-grid systems this range was US_{2009}7–22/Wp (IEA-PVPS, 2010).

Turnkey system price can be translated into electricity generation costs using the levelized cost of energy method. Although the calculation involved is rather straightforward (see, e.g., EPTP, 2010), it requires assumptions and estimates of parameters that may not be made in a straightforward manner. More precisely, in addition to the turnkey investment price, values are needed for the O&M costs (normally expressed as a percentage of the investment per year), system economic lifetime (depreciation/amortization period), cost of capital, and specific electricity yield (kWh per year per watt-peak of system power). However, it is difficult to "standardize" the parameters used in the calculation because they may vary substantially depending on, among other items, the type of technology and system, geographical location, and type of ownership.

Table 11.27 gives 2009 and (target) 2020 and long-term turnkey investment costs and corresponding levelized electricity generation costs. Indicative turnkey investment costs (in mature markets), O&M costs, and depreciation times are taken from the IEA-PVPS *Trends Report* (IEA-PVPS, 2010) and IEA *PV Technology Roadmap* (IEA, 2010d). It is noted, however, that more aggressive cost reduction targets can also be found in the literature – see, for instance, the US DOE's SunShot Initiative, which mentions a target of US$1/Wp to be reached even before 2020 (US DOE, 2011b).

In Table 11.28, the capacity factor ranges indicated roughly correspond to low-, medium-, and high-insolation regions of the world, assuming a performance ratio of 80% and sun tracking for high-insolation regions. Gains of sun tracking are indicative and vary per region (see section 11.6.4.4 and Huld et al., 2008). In the calculations, annual O&M costs were assumed as 1% of the investment costs. The system lifetime assumed is 25 years in 2009, 30 years in 2020, and 40 years in 2050. Note that the table is primarily meant to show trends and typical numbers; in practice, other figures are found (IEA-PVPS, 2010).

11.6.5.4 Grid and Investment Parity

PV will gradually reach various levels of competitiveness (IEA, 2010d; Greenpeace and EPIA, 2008; Breyer, 2010). (See Figure 11.50.) For grid-connected systems, which compete with electricity from the grid, these levels are usually referred to as "grid parity" (e.g., with consumer

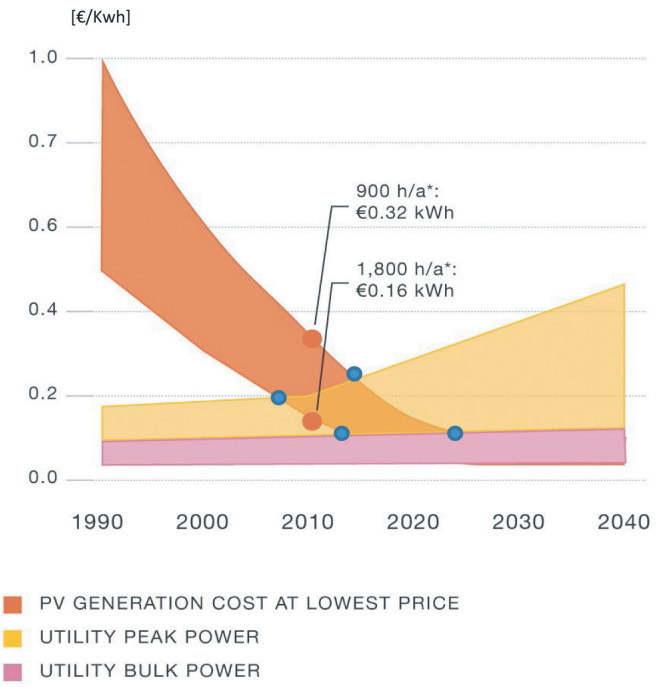

Figure 11.50 | Schematic representation of grid parity points (in blue, see text). *h/a: Hours of sun per annum, 900 h/a corresponds to northern countries of Europe. 1800 h/a corresponds to southern countries of Europe. Source: European Photovoltaic Industry Association/Greenpeace International, 2011.

prices and wholesale prices respectively). The concept of "grid parity" is based on a comparison of LCOE and electricity prices in a specific year. The concept of grid parity does not take into account the expected increase of conventional electricity prices; therefore "investment parity" or "dynamic grid parity" has been proposed (EPIA, 2009) as a more useful concept in relation to decision-making. In this case, the life-cycle costs of PV electricity generation are compared with the anticipated total value of avoided electricity purchase and revenues of sales over the relevant period (such as 15, 20, or 25 years).

Note that in the direct comparison between PV generation costs and electricity prices, other costs and benefits are not taken into account. Specifically, the comparison does not take into account costs for grid transport, backup power, or storage (even though these need not be attributed exclusively to PV). Nor does it take into account benefits such as avoided carbon dioxide emissions and (passive or active) grid support. Therefore, the point of grid parity is useful only as a rough indicator of the competitive position of PV.

11.6.6 Sustainability Issues

PV technology may inherently be renewable, but it is not automatically sustainable. The sustainability of PV systems depends on, among other considerations, equivalent CO_2 emissions, the use of hazardous and non-Earth-abundant elements and materials, and possibilities for recycling. The equivalent CO_2 emissions are related to the energy needed for manufacturing and installation (often expressed in terms of the energy payback time) and the fuel mix for generation of electricity used in PV manufacturing.

To date, most attention has focused on the energy payback time of PV systems and the equivalent CO_2 emissions of PV electricity generation. Figure 11.51 shows the energy payback time of PV technologies (including recycling) when applied in reasonably sunny regions (in-plane irradiation of 1700 kWh/m^2/yr) (De Wild-Scholten, 2010). Energy payback times are all well below 2 years and even below 1.5 years for thin-film technologies, which is to be compared with a service lifetime of PV systems of 25 years or more. The energy payback times are expected to decrease further substantially as the technology develops (EPTP, 2009).

The equivalent CO_2 emissions per kWh produced with PV electricity are 16 gCO_2-eq/kWh at an in-plane insolation of 1700 kWh/m^2/yr for the best current PV systems (de Wild-Scholten, 2010). Based on a review of life-cycle analysis studies, Arvizu et al. (2011) conclude that "the majority of lifecycle GHG emission estimates cluster between about 30–80 gCO_2-eq/kWh." It is expected that this value may be reduced to 10 g or less, along with shortening of the energy payback time and transformations in the energy system, decreasing the indirect emissions (Reich et al., 2011). These values refer to equivalent emissions directly related to the PV plants. High degrees of penetration of PV necessitate modifications on a system level (e.g., adding backup power, small- or large-scale storage, smart grids) to accommodate the power generated by PV. These modifications may lead to increased – or, in specific cases, decreased – overall emissions.

Recently, the rapidly increasing production volumes and high prices of a wide range of materials have drawn attention to the use of non-Earth-abundant elements such as silver, indium, and tellurium in PV cells and modules. Multi-gigawatt-scale or even terawatt-scale manufacturing of specific PV technologies is only possible at very low cost when materials constraint can be avoided. This has led to research on alternatives for active and passive parts of PV cells and modules. Examples are copper- and carbon-based conductors instead of silver in wafer-silicon cells and zinc-tin instead of indium in the light absorber of CIGS modules.

For many years, there has been a debate about the use of hazardous materials in PV modules, particularly Cadmium telluride (CdTe). CdTe is the biggest thin-film PV technology in the market today, and take-back and recycling systems have been developed and implemented. Moreover, CdTe is a very stable compound. Therefore, it has been argued that CdTe can be used in a safe and sustainable way (Raugei, 2010).

Companies in the PV sector joined forces in 2007 and founded the PV Cycle Association. It aims to "implement the photovoltaic industry's commitment to set up a voluntary take back and recycling program for

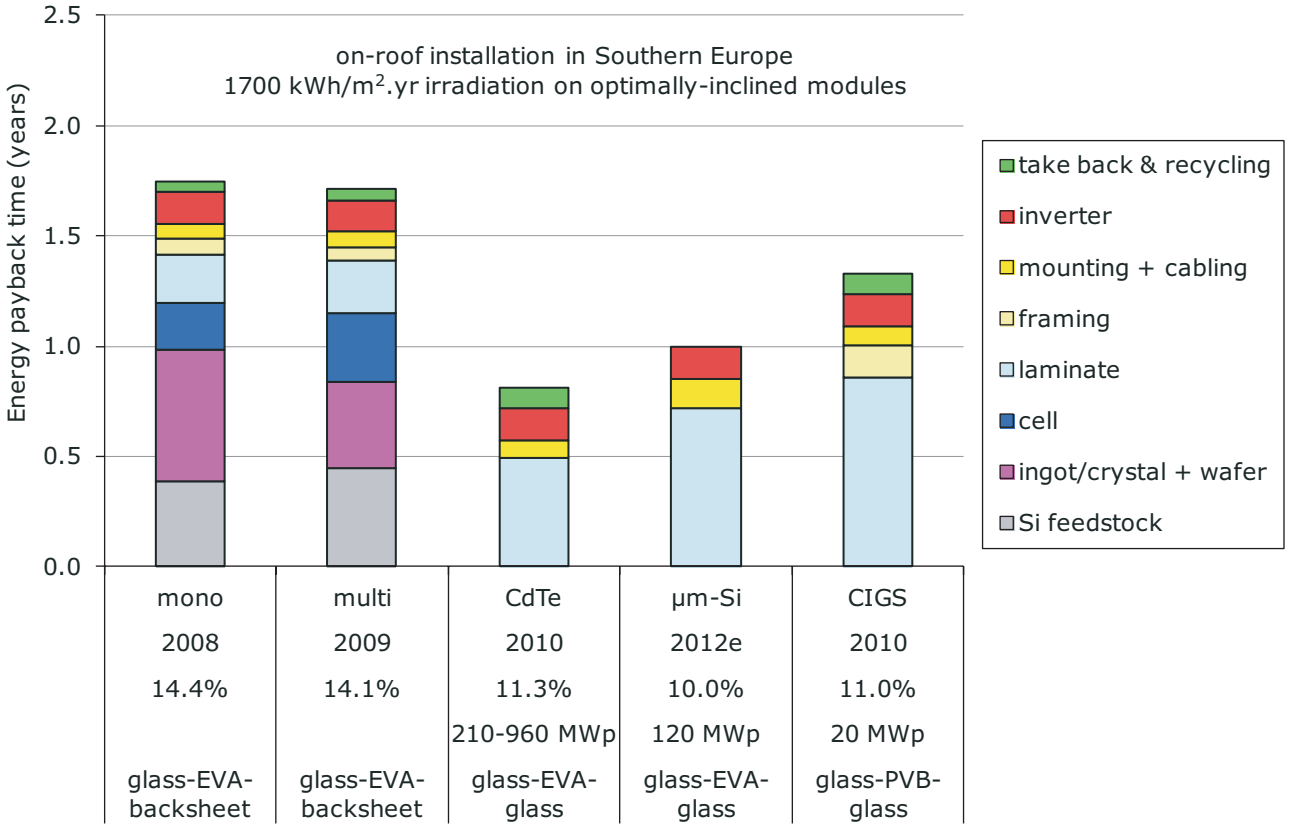

Figure 11.51 | Energy payback time (EPBT) of on-roof PV systems for an in-plane irradiation of 1700 kWh/m²/yr. Source: de Wild-Scholten, 2011.

end-of-life-modules and to take responsibility for PV modules throughout their entire value chain" (PV Cycle, undated). In 2010, there were about 40 full members.

11.6.7 Implementation Issues

The main issues to be addressed in relation to very large-scale deployment of PV are the cost of electricity generation and grid integration. In the long term, materials availability also needs to be considered. In addition, a range of less fundamental issues to be addressed include the development of dedicated products for building integration and standardization.

The cost of electricity is generally considered to be the key driver for PV deployment, but grid integration is certainly a key enabler (FVEE, 2010). Grid integration is not a problem today, with the exception of some local constraints. However, ambitious deployment scenarios may bring PV into the regime where grid adaptations are necessary (Braun, 2009). The framework of the Grand Solar Plan (Fthenakis et al., 2009) in the United States illustrates how very large volumes may be integrated into the electricity system by choosing a portfolio approach—in particular, by combining PV with concentrating solar power and compressed air energy storage.

Large-scale deployment of PV, and thus high levels of penetration into the grids, requires sufficient grid flexibility to enable integration of the varying output of PV systems and to provide the backup power needed when the sun does not shine. This can be achieved by introducing a proper portfolio approach – that is, combining PV with other generators such as wind energy, biomass, natural-gas-fired plants, and hydropower – and demand-side management (FVEE, 2010). In addition, storage will become important on small and large scales (including, for instance, the capacity available in electric vehicles) and for different time scales (day-night; summer-winter).

11.7 High-Temperature Solar Thermal Energy

11.7.1 Introduction

High-temperature solar thermal technologies, also referred to as concentrating solar thermal, use mirrors that reflect and concentrate sunlight onto receivers. The receivers convert the solar energy to thermal energy, which is used in a steam turbine or heat engine to drive an electric generator. These concentrating solar power (CSP) systems might also allow the production of chemical fuels for transportation, storage, and industrial processes (Meier and Steinfeld, 2010). CSP systems perform best in regions having a high direct-normal component of solar radiation.

Table 11.29 | Potential growth of cumulative CSP capacities until 2050

Name of Scenario and Year	Installed CSP Capacity [GW_e]				
	2000	2015	2020	2030	2050
CSP Global Outlook 2009 (Reference scenario)	0.35	4	7	13	18
CSP Global Outlook 2009 (Moderate Scenario)	0.35	24	69	231	831

The primary advantage of CSP is its potential for integrating thermal storage, which would allow dispatchable power generation. Dispatchable CSP electricity can have a higher value than variable renewable energy technologies (Madaeni et al., 2011). The four main types of CSP systems are parabolic trough, power tower, dish/engine, and linear Fresnel reflector. Systems that use concentrators to focus sunlight onto high-efficiency solar cells for utility-scale electricity generation are discussed in section 11.6.

11.7.2 Potential of High-Temperature Solar Thermal Energy

CSP requires significant levels of direct-normal irradiance, which generally occurs in semiarid areas between 15° and 40° north or south latitude. Closer to the equator the humidity is generally too high, and at higher-latitude regions there is usually too much cloud cover. A threshold of 1800–2000 kWh/m^2/yr is often considered suitable for CSP development. The regions with the best resource potential are the Mediterranean, North Africa, Middle East, South Africa, portions of southern Asia, Australia, Chile, the southwestern United States, and Mexico.

By the end of 2010, more than 1.1 GW of grid-connected CSP plants were installed worldwide, generating 2.9 TWh of electricity a year (REN21, 2011). The installed capacity in 2009 was 610 MW, generating 1.6 TWh a year.

The *Global CSP Outlook 2009* – developed jointly by SolarPACES, the European Solar Thermal Electricity Association, and Greenpeace International – used an advanced industry development scenario, with high levels of energy efficiency, to project future electricity demands. The study estimates that CSP could meet up to 7% of the world's power needs by 2030 and 25% by 2050. The global CSP capacity for 2050 could be 1500 GW with annual energy output of 7800 TWh. More moderate assumptions for future market development put combined solar power capacity at around 830 GW by 2050, with annual deployments of 41 GW. This would meet 3.0–3.6% of global electricity demand in 2030 and 8.5–11.8% in 2050 (Greenpeace et al., 2009).

A recent analysis of CSP potential in the United States projects capacity of 11,000 GW in Arizona, California, Colorado, Nevada, New Mexico, Texas, and Utah by 2030 (Mehos et al., 2009). Another study projects up to 30 GW of parabolic trough systems with thermal storage could be deployed in this region by 2030 (Blair et al., 2006). Capacity in the Middle East and North Africa is projected to be 390 GW by 2050 by the German Aerospace Center. That study concludes that with the high capacity factors resulting from integration of CSP with thermal storage, this capacity could provide about half this region's electricity (German Aerospace Institute, 2005). The trends and potential for CSP capacities from recent studies are shown in Tables 11.29 and 11.30.

In 2010, IEA published a technology roadmap for CSP, which foresees a potential generation of 4000 TWh in 2050, contributing 10% to global electricity production (IEA, 2010e). CSP electricity production and consumption predicted in the roadmap is shown in Figure 11.52. The roadmap authors expect North America to be the largest producing region, followed by Africa, India, and the Middle East. Africa would be by far the largest exporter of electricity, and Europe the largest importer. The Middle East and North Africa considered together, however, would produce almost as much electricity as the United States and Mexico (IEA, 2010e).

11.7.3 Market Developments

The number of CSP plants built or planned each year has increased since 2004. The size of new plants has increased from several megawatts to hundreds of megawatts. By the close of 2010, CSP generation was able to meet intermediate-load demand, particularly in plants that have thermal energy storage. As the amount of storage increases, CSP could become cost-competitive in the base-load electricity market if the generation cost of conventional fossil base-load technologies includes a carbon cost.

Between 1985 and 1991, about 354 MW of solar parabolic trough technology were deployed in southern California, and most of these plants are still in commercial operation. CSP technology is most economically viable in large-scale installations. In the 1990s, world energy prices dropped and remained relatively low. Low prices and the lack of incentives discouraged additional large installations.

The emerging demand for cuts in GHG emissions, as well as the need to decrease dependence on fossil fuels, may improve the market outlook for CSP. Worldwide, interest in CSP is increasing in the United States, Spain, and the Middle East-North Africa. Figure 11.53 shows the development of CSP from 1985 to 2008 and the estimated CSP project pipeline, by country, for 2009–2014.

Table 11.30 | Potential growth of electricity generated by CSP until 2050.

Name of Scenario and Year	Electricity production by CSP [TWh/yr]

At the end of 2010, most of the 1.1 GW of grid-connected CSP plants worldwide used parabolic trough technology (about 39 MW used power-tower technology). Tables 11.31 and 11.32 provide details about these plants in the United States, Europe, Asia, and North Africa. The tables also show that more than 100 CSP projects were in the planning phase at the close of 2010. Contracts specify when the projects must start delivering electricity between 2010 and 2014.

In the United States, 500 MW of CSP were in operation at the end of 2010, with more than 9 GW on hold with signed power purchase agreements. A 64 MW parabolic trough plant came online in 2007 in Nevada, and a 75 MW plant began operating in 2010 in Florida. A 5 MW power tower and a 5 MW Linear Fresnel project came online in 2009 in California. The US federal solar investment tax credit, which allows developers and utilities to offset 30% of plant costs, was extended through the end of 2016. Companies may use a 30% federal grant in lieu of the tax credit and can also apply for a federally backed loan guarantee. These policies are expected to stimulate plans for and construction of CSP plants in the United States in the next several years.

In Europe, Asia, and North Africa, about 655 MW were in operation at the end of 2010, and more than 7 GW of CSP capacity were under construction or are being developed over the next several years. In Spain, more than 400 MW of commercial CSP projects were operational, and about 2000 MW have provisional registration. Spanish Royal Decree 436/2004 (dated 12 March 2004) guaranteed a FIT of €0.27/kWh for 25 years. In the *Plan de Energías Renovables en España* (2005 to 2010), a total capacity of 500 MW was foreseen. Royal Decree 661/2007 raised the cap to 500 MW and allowed the tariff to float, adjusting with the market price. In response, developers in Spain have identified projects well beyond the 500 MW cap, and the government must reassess the number of projects to support. Recent projects in Spain include the 11 MW PS10 power tower plant in 2007, the 20 MW PS20 tower in 2009, and the 50 MW parabolic trough system, with 7.5 hours of storage, in 2008. Several additional plants came online in 2009 and 2010.

Since 2000, the CSP industry grew from a negligible activity to one that has more than 1400 MW of generation commissioned or under construction in 2009 worldwide. In 2006, two or three companies were in a position to build for commercial-scale plants. In 2009, more than 10 companies were active in building or preparing for such plants. These companies range from large organizations with international construction and project management expertise who have acquired rights to specific technologies to start-up companies using their own technology (IHS EER, 2009; Arvizu et al, 2011).

The CSP industry provides employment in countries with growing capacities. About 50–60% of the cost of CSP projects is for equipment leading to manufacturing jobs (Stoddard et al., 2006). In the United States, the National Renewable Energy Laboratory (NREL) estimates that realizing 4000 MW of CSP would require domestic investment of US$13 billion. Such an investment would create 145,000 jobs in construction and engineering and 3000 direct permanent jobs for operation and maintenance (Stoddard et al., 2006). Similar numbers would be likely in other regions of the world.

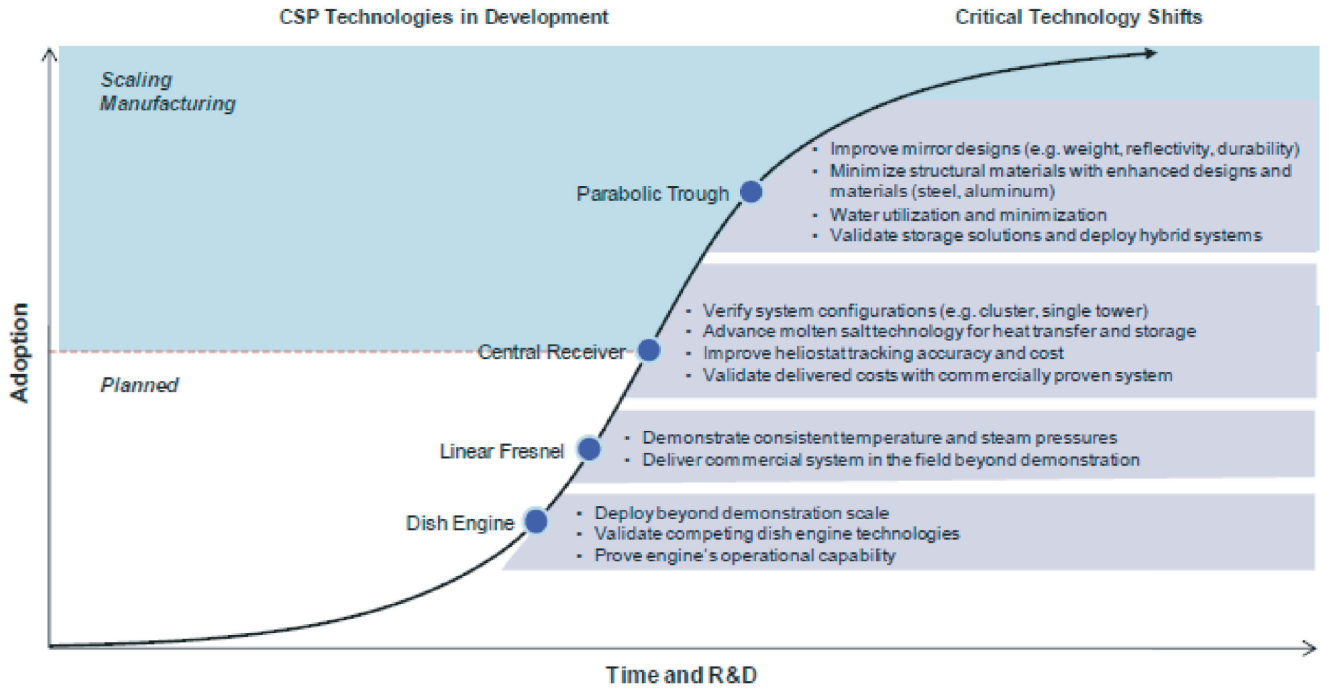

Figure 11.54 | CSP technology curve and evolutionary changes. Source: IHS EER, 2009.

11.7.4 CSP Technology Development

Four main CSP technologies, with different levels of maturity, are discussed in this section (Sargent and Lundy, 2009). (See Figure 11.54.)

11.7.4.1 Status of CSP technologies

A *parabolic trough system* has long parallel rows of trough-like reflectors – typically, glass mirrors. Controllers make the reflectors follow the sun as it moves from east to west by rotating them along their axes. Each trough focuses the sun's energy on a thermal receiver or heat-collection element located along its focal line. A heat-transfer fluid – typically oil at temperatures as high as 390°C – is circulated through the heat-collection element. Then the hot fluid is pumped to a central power-block area, where it passes through a series of heat exchangers. Superheated steam is created at 370°C and 100 bar. Once past the steam generator, parabolic trough plants behave just like conventional steam plants. The steam is used to drive a conventional steam-Rankine turbine generator, and the plant can store heat or use additional heat from fossil fuels to generate electricity when the sun is not shining. The annual solar-to-electric efficiency of parabolic trough plants is approximately 15%, a figure that includes losses due to non-normal solar incidence, part-load operation, and plant availability throughout the year.

The first commercial trough/oil CSP plants were installed and commissioned between 1985 and 1991 in the United States. Nine plants with a combined 354 MW capacity were built by Luz, and they continue operation with new owners. In 2007, the next commercial plant was built and owned by Acciona. This 64 MW Nevada Solar One uses aluminum rather than steel troughs.

With the increasing interest in CSP construction, strong competition is emerging among companies in the supply chain for components and construction. However, in 2010 only Schott and Solel were capable of supplying several 100 MW/yr of the large evacuated tubes (heat-collection elements) designed specifically for use in trough/oil systems for power generation (Arvizu et al., 2011). The trough concentrator requires know-how in both structure and thermally sagged glass mirrors. Companies are offering new trough designs and considering alternatives to conventional rear-silvered glass (such as new polymer-based reflective films). But the essential technology remains unchanged (Arvizu et al., 2011).

Commercial systems today are limited by the maximum operating temperature of the heat-transfer fluid – synthetic oil with a maximum temperature of 390°C. Direct steam generation in troughs may allow trough systems to operate at higher temperatures, and this concept is being demonstrated. In other designs, molten salt has the potential advantage of operating at higher temperatures than steam systems and allows for integration with direct two-tank salt storage systems similar to those used for molten-salt tower configurations. In 2010, the Italian utility ENEA began operating a small prototype molten salt trough plant in Sicily. A disadvantage of this concept is the potential for the salt freezing in the solar field and the need to design a system to recover from such an event.

Figure 11.55 | PS10 and PS20 power towers in Spain (left) and a power tower solar thermal power plant in the California desert (right). Source: Left photo courtesy of Abengoa Solar.

In a *power tower system* (also called a central-receiver system), a field of two-axis tracking mirrors, called heliostats, reflect solar energy onto a receiver mounted on a central tower. (See Figure 11.55.) To maintain the beam of concentrated sunlight on the receiver at all times, each heliostat must track a position in the sky that is midway between the receiver and the sun. A heat-transfer fluid heated in the receiver is used to generate steam that runs a conventional turbine to generate electricity. Some power towers use water and steam directly as the heat transfer fluid. Central-receiver systems typically operate at higher temperatures than parabolic troughs, with superheated steam temperatures of 550°C for proposed steam and molten-salt systems. As with parabolic troughs, central-receiver systems can be integrated with thermal storage; the amount of storage available depends on the heat transfer fluid used in the receiver. Direct-steam receivers offer limited storage capacities, typically less than one hour, due to the high costs associated with storing high-temperature steam.

Power tower systems based on molten-salt receivers integrated with thermal storage have been demonstrated on the pilot scale. Because molten-salt receivers have superior heat-transfer and energy-storage capabilities, annual efficiencies are projected to be higher than for oil-based parabolic trough systems. In early 2011, a commercial unit was under construction in Spain, and several commercial units were under development in the United States.

Power tower systems are just entering the market on a commercial scale, and this should open the way for new industry participants and a diversity of system designs. Primary design choices include the heliostat ($1m^2$ to $>100m^2$), receiver (cavity or external), and heat transfer fluid type (steam, molten salt, or air). The high concentration of solar energy associated with tower systems allows heat transfer fluid operating temperatures as high as 1000°C, as for example in the air heat-transfer fluids for solar Brayton cycles. So far, there is little consensus on the best approach for achieving low cost, high performance, and high market value in power tower systems.

A *dish/engine system* tracks the sun and focuses solar energy into a cavity receiver; the receiver absorbs the energy and transfers it to the heat engine/generator that generates electric power. Dish/engine systems have demonstrated peak efficiencies greater than 30%, and the projected annual conversion efficiency is 24% (Arvizu et al., 2011). Effort is going into developing a commercial product using Stirling engines as the power-conversion device, although Brayton engines are also an alternative. The technology may be able to take advantage of existing know-how such as on the Stirling engine mass-produced through the automotive industry.

A *linear Fresnel reflector (LFR) system* uses a series of flat or shallow-curvature mirrors to focus light onto a linear receiver located at the focal point of the mirror array. Linear Fresnel systems could have lower capital cost than systems with parabolic mirrors because the mirrors are flat and located close to the ground. But they have also lower operating efficiencies than parabolic trough systems (Häberle et al., 2002). Because no large-scale commercial Fresnel-based systems are in operation at present, it is unclear whether the lower upfront capital cost will offset the efficiency problem.

Research on Linear Fresnel reflector systems has used steam as the heat-transfer fluid. A significant disadvantage of steam-based systems is their current incompatibility with long-term (>1 hour) thermal storage. The US DOE (US DOE 2008b) is supporting development of a linear Fresnel reflector system that uses molten salt as a heat-transfer fluid. As with parabolic troughs, the freezing of the salt in the field is still a primary concern. However, unlike parabolic trough systems, the linear Fresnel reflector receiver is stationary, so engineering freeze protection should be much more straightforward.

11.7.4.2 Thermal Storage

Thermal storage is an important attribute of CSP. Even 30 minutes to 1 hour of full-load storage can reduce the impact of thermal transients (such as clouds) on the plant and of electrical transients to the grid. Thermal storage can result in significantly higher energy and capacity value over equivalent systems without storage.

Spain is the first country to incorporate thermal storage into commercial installations. Parabolic trough plants such as Andasol 1 in Spain have been designed for 7.5 hours of full-load storage. This allows operation well into the evening, when peak demand can occur and tariffs are high. Several parabolic trough plants in Spain use molten-salt storage. (See Figure 11.56) Depending on the electricity market, storage can be increased up to 16 hours to allow 24-hour-a-day electricity generation.

Power towers operate at high temperatures and can charge and store molten salt more efficiently and less expensively than other CSP systems. The 17 MW GEMASOLAR power tower being developed in Spain is designed to operate 6500 hours a year – a 74% capacity factor. A 100 MW plant in Nevada in the southwest United States with 10 hours of molten-salt thermal storage has a signed power purchase agreement.

With thermal storage, the heat from the solar field is stored prior to reaching the turbine. Storage media include molten salt, steam accumulators (for short-term storage only), solid ceramic particles, high-temperature phase-change materials, graphite, and high-temperature concrete (Gil et al., 2010; Medrano et al., 2010). Figure 11.57 shows that thermal storage allows the CSP plant to dispatch power to meet demand after sunset.

Significant R&D is under way to develop thermal storage technologies that are compatible with the steam-based heat-transfer fluids for power tower, parabolic trough, and linear Fresnel systems. Storage systems using phase-change materials are more thermodynamically compatible with the latent energy associated with evaporation and condensation of steam. The intrinsic nature of phase-change systems results in decreased storage volumes, thereby reducing materials costs.

11.7.4.3 Power Cycles

In general, thermodynamic cycles will perform more efficiently at higher temperatures. The solar collectors providing the thermal energy must perform efficiently at these higher temperatures. Development to optimize the linkage between solar collectors and higher-temperature thermodynamic cycles is under way (Arvizu et al., 2011). The most commonly used power block is the steam turbine (Rankine cycle), which is most efficient and cost-effective in large capacities. Parabolic trough plants using oil as the heat-transfer fluid limit steam-turbine temperatures to 370°C and turbine cycle efficiencies to around 37%. This leads to design-point solar-to-electric efficiencies of 24% and annual average efficiency of 15% (Arvizu et al., 2011). To increase efficiency, alternatives to using oil as the heat transfer fluid – such as producing steam directly in the receiver or using molten salts – are being developed for parabolic troughs. Power towers and dishes/engine systems can reach the upper limits of existing fluids (around 600°C for current molten salts) for advanced steam-turbine cycles. Power towers can also provide the temperatures needed for higher-efficiency cycles (Arvizu et al., 2011).

11.7.4.4 Solar Thermal Hydrogen Production

The global use of hydrogen, mainly as feedstock in industrial processes, was estimated to be around 5 EJ/yr in 2004 (IEA, 2005). In 2050, in a carbon-constrained world, the demand for hydrogen as an energy carrier might be as large as 11–44 EJ/yr (IEA, 2008b; European Commission, 2006). It would be used in the transport sector and for stationary applications. High-temperature solar thermal energy can be used in several ways to produce the hydrogen (see, for example, Pregger et al., 2009).

One commercially available route is splitting water molecules into hydrogen and oxygen using electricity from a CSP plant: $2H_2O \rightarrow 2H_2 + O_2$. Another approach, solar thermal high-temperature electrolysis, splits water into pure oxygen and hydrogen at about 700–1000°C. Splitting water is possible using very high temperature heat (2300–2600°C) produced by solar power towers. Yet another option is cracking methane using solar heat: $CH_4 \rightarrow C + 2H_2$. Solar heat (1200–2000°C) can also be used to assist in steam reforming methane: $CH_4 + H_2O \rightarrow CO + 3H_2$, followed by a water-gas shift reaction: $CO + H_2O \rightarrow CO_2 + H_2$. The hydrogen can be blended with natural gas in existing pipelines and distribution networks. Capture and storage of the CO_2 (see Chapter 13) can be applied to largely prevent its emission into the atmosphere. According to the IEA-CSP roadmap, this technology will be used in the Middle East, Central Asia, and the US Southwest starting in 2030 (IEA, 2010e).

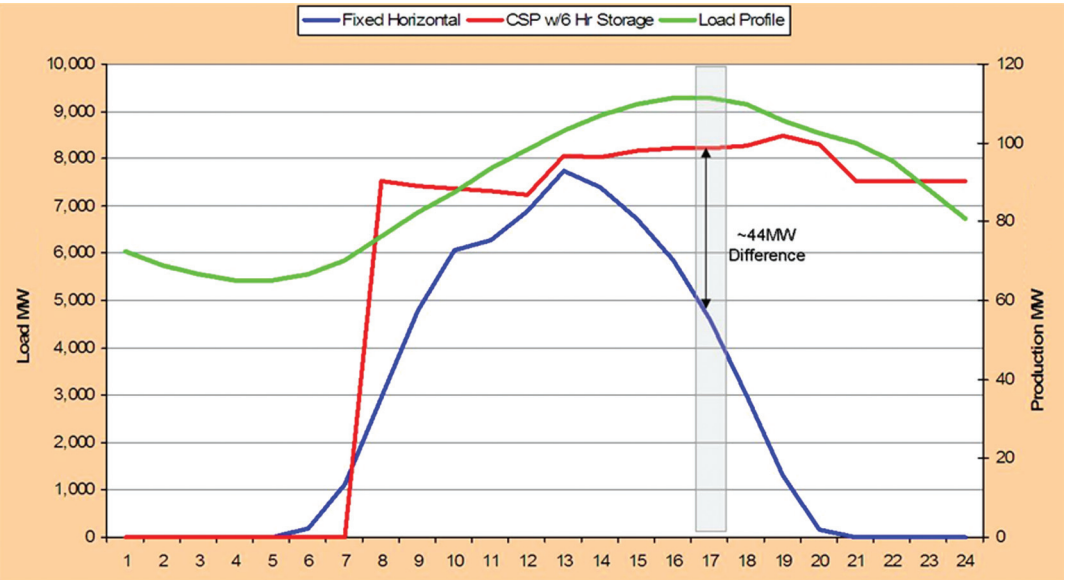

Figure 11.57 | Customer load profile (green) and power production profile of a CSP system with storage (red) and a non-tracking PV system (blue) over 24 hours. Source: Courtesy of Arizona Public Service.

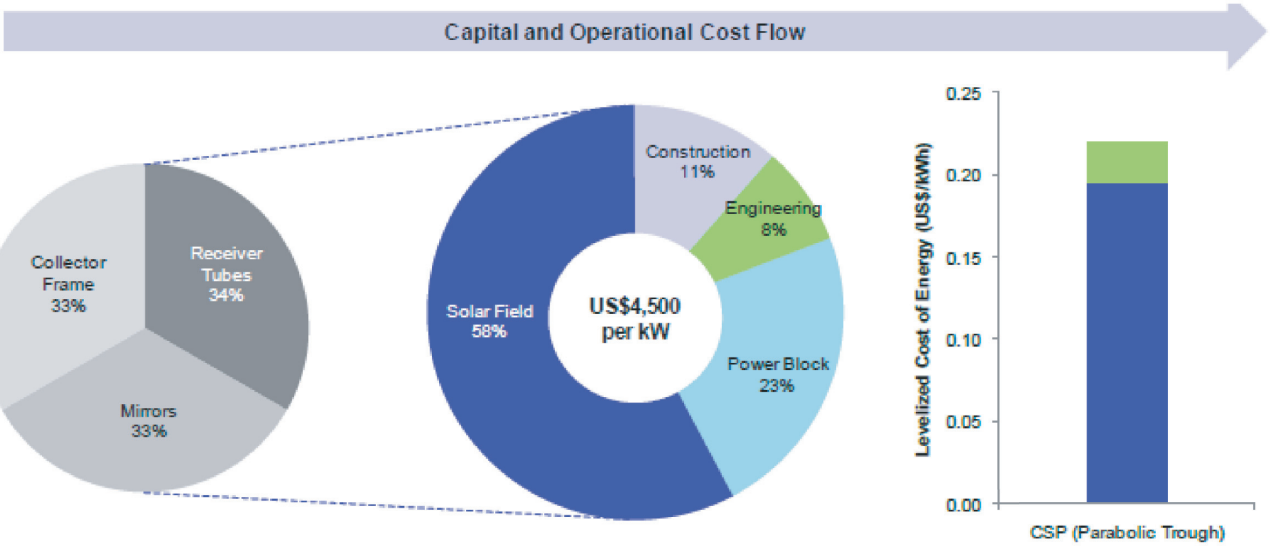

Figure 11.58 | Capital cost breakdown for parabolic trough plant. Source: IHS EER, 2009.

Thermo-chemical production of hydrogen is in the early development stages. An example is the Solzinc process, developed in Israel, using solar heat at a temperature above 1200°C to decompose zinc oxide. The zinc is subsequently combined with water and transformed back to zinc oxide, producing hydrogen: $Zn + H_2O \rightarrow ZnO + H_2$.

Because of the high costs involved and the current high conversion losses (cumulative up to 80–90%), R&D is needed to substantially improve the performance and competitiveness of solar hydrogen systems. Hydrogen production using fossil fuels is expected to remain the cheapest hydrogen source until at least 2030 (Pregger et al., 2009).

11.7.5 Economic and Financial Aspects

CSP must compete with electricity generation rates in utility markets rather than end-use electricity rates in residential or commercial markets. The levelized cost of energy for a CSP plant is calculated using the plant's upfront capital costs and its projected operating and maintenance costs, annual generation of electricity, finances, and lifetime.

In 2007, the installed cost of the 64 MW Nevada Solar One plant was US$260 million. The installed costs for parabolic trough CSP plants were US$4200/kW for a 100 MW system without thermal storage and

US$4900/kW for the same system with six hours of thermal storage. O&M fees for the system have been estimated at US¢1–3/kWh or more (US DOE, 2010a; IEA, 2010e).

An analysis by Lazard (2009) of CSP capital costs shows a range from US$4500–6300/kW, with parabolic troughs representing the low end and power towers representing the high end. In the IEA's technology roadmap (IEA, 2010e), the estimated capital costs range from US$4200–8400/kW. A breakdown of the estimated capital cost is presented in Figure 11.58. Land costs generally add less than 3%.

In 2010, the cost of installing a 100 MW CSP parabolic trough plant was estimated at US$4900/kW for a system without thermal storage and US$8400/kW for the same system with six hours of thermal storage (Turchi, 2010). The increased cost projected for current plants is primarily due to an increase in raw material costs (such as steel, concrete, and sodium/potassium nitrate salts) that occurred prior to the worldwide economic downturn at the end of 2007. Since 2008, costs have remained relatively steady, although a global recovery would likely put upward pressure on material costs.

The levelized cost of energy can be calculated from the estimated installation and O&M costs. The LCOE presented here assumes little or no storage, a capacity factor of 30–40%, a discount rate of 5% and 10%, an economic lifetime of 30 years, and average O&M costs of US¢2/kWh. The LCOE ranges from US¢10–20/kWh if total investment costs were US$4500/kW and from US¢15–30/kWh for investments of US$7000/kW. (See Table 11.33.) Similar LCOE figures were found for systems with 12-hour heat storage.

A recent analysis supported by the US DOE projected cost reductions for parabolic troughs based on advances in collector design, economies of scale for larger plants, and the use of molten salt as the heat transfer fluid. The capital cost for a trough system with 12 hours of storage is projected to be US$6500/kW in 2020. The same study projected a capital cost for an advanced tower system with 12 hours of storage to be US$5900/kW in 2025 (Turchi, 2010). The lowest energy cost in the long-term may be US¢5–7/kWh. This would result from technical learning, material improvements, and increased system performance (see, for example, IEA, 2010e).

Table 11.33 | Cost of electricity as a function of capacity factor, turnkey investment costs, discount rate, and O&M costs. The O&M costs are assumed to be US¢2/kWh; the lifetime is assumed to be 30 years.

Capacity factor	Present turnkey investment costs per kW_e (*without storage*)	Discount rate	
		5%	10%
	$US_{2005}$$	US¢/kWh	
40%	4500	10.3	15.6
	7000	15.0	23.2
30%	4500	13.1	20.2
	7000	19.3	30.2
Capacity factor	**Future turnkey investment costs per kW_e (*with 12 hour storage*)**	**Discount rate**	
		5%	**10%**
	$US_{2005}$$	**US¢/kWh**	
65%	8000	11.2	16.9
	10,000	13.4	20.6
50%	8000	13.9	21.3
	10,000	16.8	26.2

11.7.6 Sustainability Issues

The environmental impacts of CSP considered here include land use, water use, and environmental emissions, and they depend on the technology used. Solar thermal power plants require relatively large areas of land – up to 8 km^2 for a 250 MW plant with six hours of storage. The acreage is often in desert regions, where plant construction and operation may affect sensitive habitats (Pregger et al., 2009).

CSP plants use a continuous supply of water for steam generation, cooling, and cleaning the solar mirrors. For Rankine cycle systems, a water source for cooling is desirable to achieve higher turbine efficiencies. Where water is limited, air cooling or a combination of wet/dry hybrid cooling can eliminate up to 90% of the water usage (Kutscher, 2009). Such approaches for steam-generating CSP plants reduce electricity produced by 2–10%, depending on geographic location, electricity pricing, and water costs. Dry cooling performs least efficiently during the summer months, when solar energy is most abundant and when the plants should have the greatest output to meet the higher electricity demand (WorleyParsons Group, 2009).

Most environmental emissions from CSP plants occur during the manufacturing of plant components that are produced with fossil fuels. Compared with the life-cycle emissions of fossil-fueled power plants, CSP power plants generate significantly lower levels of greenhouse gases and other emissions (Pehnt, 2006). Studies conducted by NREL concluded that a 4000 MW solar power plant could offset 300 tons of nitrogen oxide, 180 tons of carbon monoxide, and 7.6 million tons of carbon dioxide (Western Governors' Association, 2006; also cf. Greenpeace et al., 2009). Another study by NREL provides a life-cycle assessment indicating that a reference 100 MW parabolic trough plant with six hours of storage would generate GHG emissions estimated at 26 gCO_2-eq/kWh (Burkhardt et al., 2010). In life-cycle studies, several assumptions have to be made, such as the fuel mix in the power sector. Consequently, somewhat lower figures can be found in the literature. The indicated reference plant would also cumulatively demand 0.43 MJ/kWh of energy and consume 4.7 L/kWh of water.

According to the IPCC Special Report on *Renewable Energy Sources and Climate Change Mitigation*, most estimates of life-cycle GHG emissions fall between 14–32 gCO_2-eq/kWh for parabolic trough,

power tower, dish/engine, and linear Fresnel reflector systems, whereas the energy payback time of CSP systems can be as low as five months (Arvizu et al., 2011). According to the *CSP Global Outlook 2009* (Greenpeace et al., 2009) results presented in Table 11.29, the moderate scenario will provide annual savings of 148 million metric tonnes of CO_2 in 2020, rising to 2.1 gigatonnes (Gt) annually by 2050. The cumulative savings would account for about 0.6 $GtCO_2$ by 2020 and 28 Gt by 2050.

11.7.7 Implementation Issues

The barriers and challenges to implementation include issues related to cost, land access, water use, transmission of electricity, system integration, and policy development.

11.7.7.1 Land Access

Land generally represents a minor portion of the cost of the whole CSP plant. However, aesthetic and environmental issues may cause a "not in my backyard" response to news of potential CSP development. When seeking to acquire private or public lands, developers may encounter difficulties such as high costs and permitting delays.

A 100 MW CSP plant would require 200–400 hectares, depending on the technology and the degree of storage integrated into the plant. The land should ideally have less than a 1% grade and no more than a 2% grade, particularly for parabolic trough and linear Fresnel reflector systems. Land for development must be near transmission lines and roads and should not be in an environmentally sensitive area. Although the mirror area covers only 25–35% of the land, the arid nature of a solar plant site will mean it is not suitable for other agricultural pursuits (Arvizu et al., 2011).

11.7.7.2 Transmission

Utility-scale CSP plants (50–300 MW_e) must be linked to the transmission network, so developing the grid infrastructure is critical to the widespread implementation of CSP.

North European countries are studying the installation of long transmission lines to get power from CSP plants in Southern Europe and North Africa. The DESERTEC Foundation has proposed using solar thermal power plants throughout the Sahara Desert to send power to Europe via a super grid running from Iceland to the Arabian Peninsula and from the Baltic Sea to the west coast of Africa (DESERTEC Foundation, 2011). (See Figure 11.59.)

In the United States, the Energy Policy Act of 2005 directed DOE to analyze the state of transmission capacity across the country and to identify areas requiring improvements. In the southwestern and western United States, many power lines operate at or near capacity, and bringing the power from remote locations to cities can be difficult. After conducting several studies to determine the impact of renewable on the US power transmission system, DOE concluded it was in the national interest to create an energy highway to allow power to travel more easily from the West Coast to the East Coast. In October 2007, DOE designated two national transmission corridors as the first step to a national power transmission system. The solar industry petitioned the Federal Energy Regulatory Commission (FERC) to clear any transmission bottlenecks to "greening the grid." In late July 2008, FERC granted the California Independent System Operator Corporation (a nonprofit organization charged with managing the flow of electricity in California's wholesale power grid) the ability to open the grid to renewable energy in California.

11.7.7.3 System Integration

CSP can be combined with fossil fuel or biomass plants in so-called integrated solar combined cycle plants to conserve fuel at relatively low cost. These plants are being built in Algeria, Australia, Egypt, Iran, Italy, and the United States (IEA, 2010e). Solar-augment of existing fossil power plants offers a lower-cost and lower-risk alternative to stand-alone CSP plant construction. A recent study found the potential in the southern half of the United States for over 11 GW_e of parabolic trough and over 21 GW_e of power tower capacity that could be added to coal-fired and natural gas combined-cycle plants whether existing, under construction, or planned (Turchi et al., 2011).

Combined with storage, CSP can enhance the reliability of power production and even offer base-load capacity. Consequently, CSP can contribute to grid flexibility and accommodate a larger share of variable energy sources in electricity systems. Losses in thermal storage cycles are much smaller than in other existing electricity storage technologies, such as pumped hydro and batteries (IEA, 2010e).

11.7.7.4 Policies

A number of countries are subsidizing R&D to increase the performance of CSP and reduce costs. Policy measures such as tax credits, emission trading schemes, and feed-in-tariffs help to create markets for CSP and achieve cost competitiveness. In recent years Spain has been the most active market in CSP development as a result of Royal Decrees enacted in 2004 and 2007 offering long-term and profitable FITs for solar thermal electricity. By contrast, the US market is driven primarily by Renewable Portfolio Standards, which require utilities to purchase a specified fraction of electricity generation from renewable energy facilities – sometimes with a specific "set-aside" requiring generation from solar. Combined with attractive federal tax incentives for solar installations, the United States represents a burgeoning near-term CSP market (see also Section 11.12).

11.8 Low-Temperature Solar Energy

11.8.1 Introduction

Low-temperature solar energy technologies, with operating temperatures up to 100° C, are perhaps the simplest way to use solar resources. These systems can be active or passive. In active conversion systems, heat from a solar collector is transported to the end process by a heat transfer system. In passive systems, no active components are needed to use the solar resource for heating or lighting (UNDP et al., 2000). This section is focused mainly on active systems that convert sunlight to thermal energy for water heating, space heating, space cooling, cooking, and crop drying.

11.8.2 Potential of Low-Temperature Solar Energy

Solar thermal energy use varies greatly by country and region depending on the maturity of the market, policy incentives, and available solar resource. The total installed capacity has been estimated at 152 GW_{th} in 2008 and 180 GW_{th} in 2009 (Weiss and Mauthner, 2010; REN21, 2010). Table 11.34 provides a breakdown for different countries for 2008. China has the most capacity, with 87.5 GW_{th}, followed by Europe (28.5 GW_{th}), the United States and Canada (15.1 GW_{th}), and Japan (4.4 GW_{th}). The energy yield from solar collectors in 2008 worldwide was about 110 TWh_{th} (395 PJ) (Weiss and Mauthner, 2010), and in 2009 it was about 130 TWh (470 PJ) – saving about 0.5 EJ of primary fossil fuel consumption.

Figure 11.60 shows solar heating capacity in 2008 and the types of collectors used in the 10 leading countries. China, the world leader in total capacity, uses more evacuated tube liquid collectors than any other country. The United States uses a high percentage of unglazed liquid collectors (for solar pool heating). Australia also uses many unglazed collectors, whereas glazed liquid collectors are the leading technology in other countries.

IEA developed an energy scenario in which energy-related CO_2 emissions in 2050 are 50% below today's level. In this scenario, called BLUE MAP, world solar thermal capacity growth is 8%/yr (IEA, 2010a). This trend

Table 11.34 | Total low-temperature solar heating capacity in operation, end of 2008.

Source: based on data from Weiss and Mauthner, 2010.

would result in about 4000 GW_{th} installed capacity by 2050. Assuming an average capacity factor of 8%, solar thermal systems would yield 2800 TWh_{th} a year (10 EJ a year). Since 2004, the actual increase in capacity has been 19%/yr.

In the United States alone, the technical potential of solar water heating (SWH) has been estimated at 300 TWh_{th} (about 1 EJ) of primary energy savings per year, equivalent to an annual CO_2 emissions reduction of 50–75 million metric tons. For US consumers, this could save more than US$8 billion per year in retail energy costs. Natural gas is used to heat a large fraction of hot water in the United States. It is used directly in gas water heaters or indirectly in electric water heaters, where the electricity is generated using natural gas as the marginal fuel (Denholm, 2007).

In Europe, the European Solar Thermal Technology Platform formulated a target that in the long term 50% of the heating demand should be covered by solar thermal, while accounting for 100% of the heating and cooling demands in new buildings (ESTTP, 2008).

Low-temperature solar heat is also considered an excellent option for crop drying. Its low, even temperatures do not harm delicate foods and are as effective as fired heating methods. Solar crop drying can be used for coffee, tea, beans, rice, fruit, cocoa, spices, rubber, and timber.

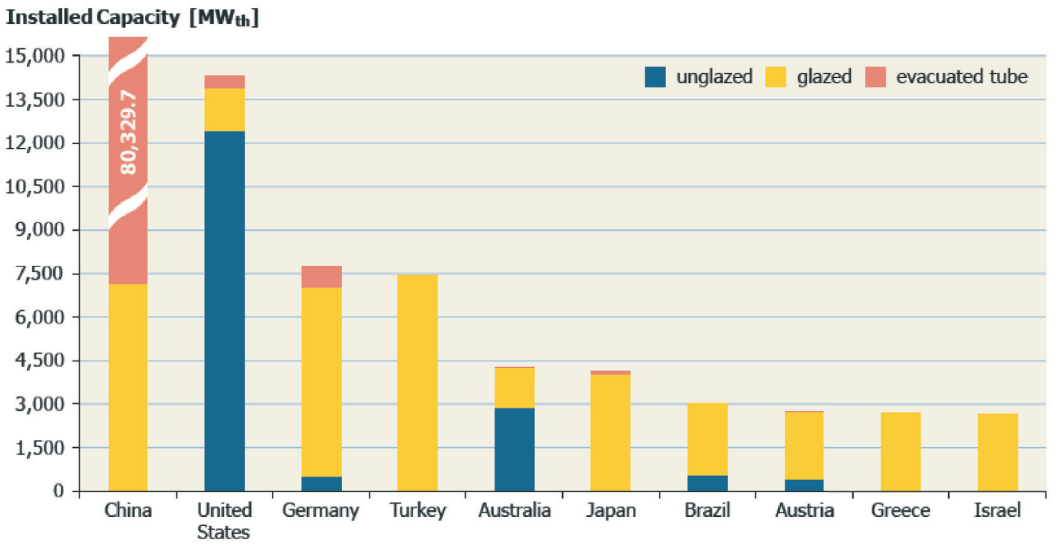

Figure 11.60 | Total capacity of solar collectors, 2008, in top 10 countries. Source: Weiss and Mauthner, 2010.

Expanding its use could displace between 300 and 900 PJ annually. This estimate is based on displacing fuel-fired dryers for crops operating at temperatures below 50°C. The use of solar energy for these markets is largely undeveloped (IEA-SHC, 2009).

In 2004, the organization Solar Cookers International ranked India, China, Pakistan, Ethiopia, and Nigeria as countries with the highest potential for solar cooking. The study considered annual solar radiation, the percentage of the country with forests, estimated populations in 2020, and the estimated share of the population within each country with both good solar insolation and fuel scarcity. In India, 80 concentrating systems of different capacities cover 25,000 m^2 of dish area. The world's largest system, at Shirdi, cooks food for 20,000 people every day (Solar Cookers International, 2009).

11.8.3 Market Developments

Since the early 1990s the solar thermal energy market has been growing. Installed capacity of flat plate and evacuated collectors increased by about a factor of four from 2000 to 2008. (See Figure 11.61.) China is the world's largest market today.

In 2008, 29 GW_{th} (41.5 million m^2) of solar collectors were installed worldwide. The average annual increase between 2004 and 2008 was 19%, but between 2007 and 2008 the increase was 43%. Some markets for glazed collectors (flat-plate and evacuated tube collectors) in Europe had growth of 62% in one year. In the United States and Canada, growth was nearly 42%, and in Australia and New Zealand, nearly 40%. New installations in China increased in 2008 by about 35%.

By the end of 2008, nearly 217 million m^2 of collector area were in operation in the 53 countries tracked by the IEA (Weiss and Mauthner, 2010). These countries represent about 61% of the world's population. The installed capacity in these countries represents an estimated 85–90% of the solar thermal market worldwide. Note that 217 million m^2 is equivalent to the installed capacity of 152 GW_{th} already mentioned, using an average conversion factor of 0.7 kW_{th}/m^2.

In China, Europe, and Japan, flat-plate and evacuated tube collectors are used mainly to provide hot water and space heating, while in the United States and Canada, swimming pool heating with unglazed polymer collectors is the dominant application.

Solar water heating offers the least-cost option in certain locales. This is the case in China, which is experiencing a boom in sales of these systems.

Figure 11.62 shows the regional distribution of glazed flat-plate and evacuated tube liquid low-temperature solar energy systems at the end of 2008. Most systems produce domestic hot water for single and multi-family houses. Only in Europe do combination systems for solar space heating and water heating account for a measureable number of low-temperature solar energy applications.

Although growing fast, especially in Europe, the market for solar cooling systems is still small. The IEA Solar Heating and Cooling Program has identified over 450 solar cooling systems in Europe and 30 in North America (Wiemken, 2009).

The most glazed flat-plate and evacuated tube collectors are found in Cyprus (527 kW_{th} per 1000 inhabitants), followed by Israel (371), Austria (285), Greece (253), Barbedos (203) and Jordan (102) (Weiss und Mauthner, 2010). Currently, glazed flat-plate collector manufactures are producing about 27 million m^2 of solar collectors per year (Epp, 2009).

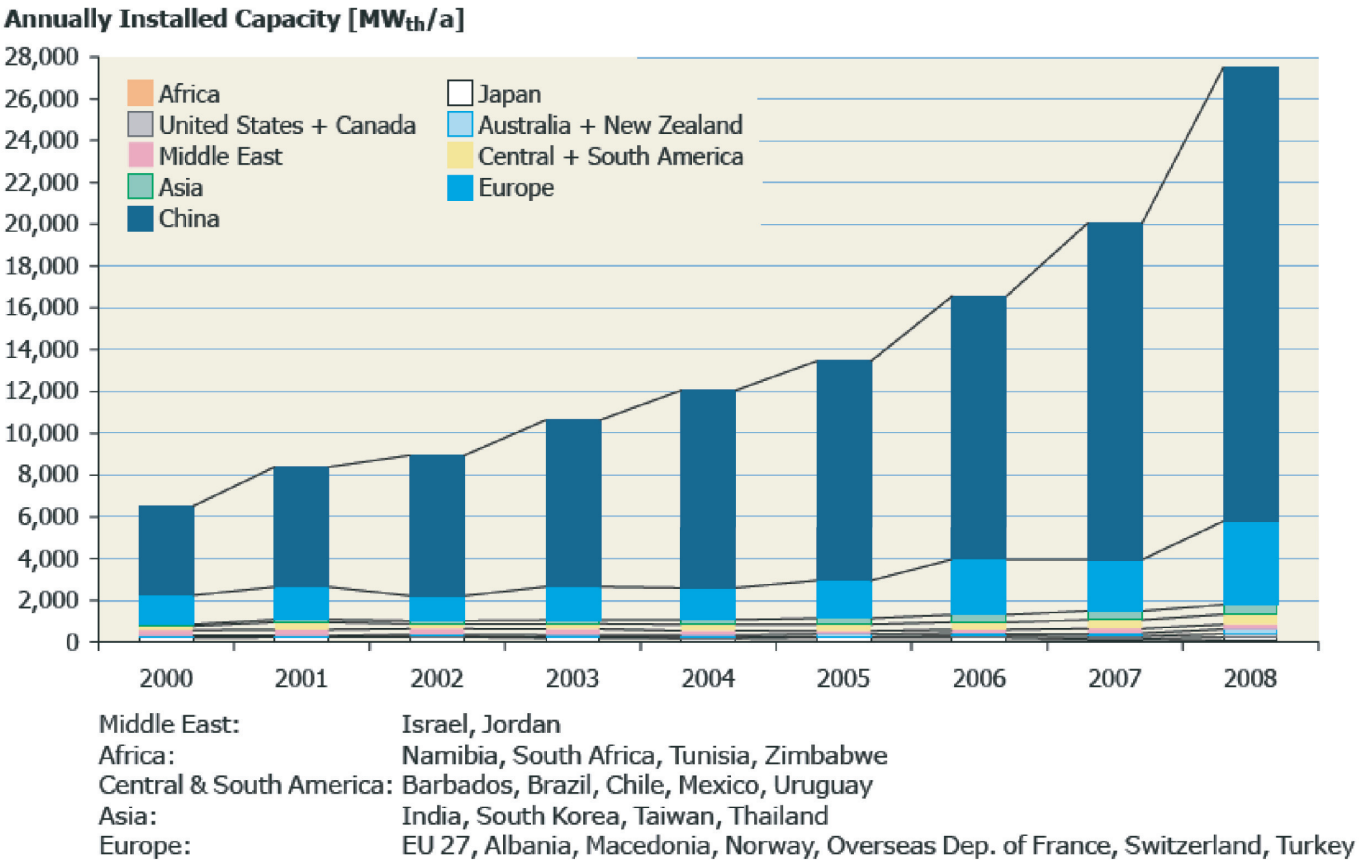

Figure 11.61 | Annual installed capacity of flat-plate and evacuated tube collectors, 2000–2008, total and per region. Source: Weiss and Mauthner, 2010.

The IEA Solar Heating and Cooling Programme has identified promising applications and sectors for solar heat in industrial processes as follows (Vannoni et al., 2008):

- cleaning, primarily in food processes, but also for process equipment and metal treatment plants (galvanizing, anodizing, and painting);
- commercial laundries;
- car washes;
- drying requirements after cleaning in both the food and chemical industries;
- pasteurization and sterilization for the food and biochemistry sectors; and
- preheating of boiler feed water.

Local sourcing, local jobs, and local sales are hallmarks of low-temperature solar technologies. According to detailed country reports for 2007, production, installation, and maintenance of solar thermal plants created 200,000 jobs worldwide (Weiss and Mauthner, 2010).

11.8.4 Low-temperature Solar Energy Technology Development

The working temperature ranges for the active solar thermal technologies used for water heating, space heating, space cooling, pool heating, crop drying, and cooking and the typical types of solar collectors used in these application are shown in Figure 11.63 (For concentrating technologies to generate high-temperature heat, see section 11.7.)

Most active solar energy technologies have four basic components:

- Solar thermal collector(s) – flat-plate and evacuated tube collectors are the most typical
- Storage system – in order to meet the thermal energy demand when solar radiation is not available
- Heat transfer system – piping and valves for liquids and ducts and dampers for air; pumps, fans, and heat exchangers, if necessary
- Control system – to manage the collection, storage, and distribution of thermal energy.

11.8.4.1 Solar Water Heating

Solar water heating (SWH) is the most widely used application of low-temperature solar heat. Conventional collectors use either flat-plate and evacuated tube approaches. A flat-plate collector is an insulated metal box with a dark, heat-absorbing metal plate inside and a cover of glass or plastic. Sunlight passes through the cover and heats up the dark absorber plate. The heat is transferred to a liquid (usually water or propylene glycol) flowing through pipes inside the absorber plate. In areas with freezing temperatures, liquid collectors must contain anti-freeze or have a system to drain the water when the temperature drops. Evacuated tube systems have a row of glass tubes that contain small metal pipes with heat transfer fluid that act as heat absorbers. This type of collector has higher temperature differences between the ambient air and the collector fluid, leading to higher operating efficiency than flat-plate collectors at cold outdoor temperatures.

Active SWH systems use a circulating pump, sometimes powered by a small solar electric panel, to circulate fluid through the heating system. Passive systems rely on water pressure, the buoyancy of warm liquids, and gravity to move the heat-transfer fluid through the system. (See Figure 11.64.) Tables 11.35 and 11.36 show characteristics of SWH systems and combination solar space heating and water heating systems for single-family and multi-family residences in three regions of the world.

SWH technologies have improved significantly in the last 20 years. Areas that can be improved further include the following:

- Increase durability and reliability while reducing costs. Identify and develop low-cost polymer materials, predict degradation from optical and mechanical processes, develop protective coatings, and improve active system components such as electronic sensors and controls.
- Improve freeze protection. Expand the geographic range of SWH markets from systems primarily made of low-cost polymers.
- Standardize SWH system components. Develop easy-to-assemble systems that incorporate standardized, packaged sets of subsystems and components (pumps, valves, controls, and tanks).

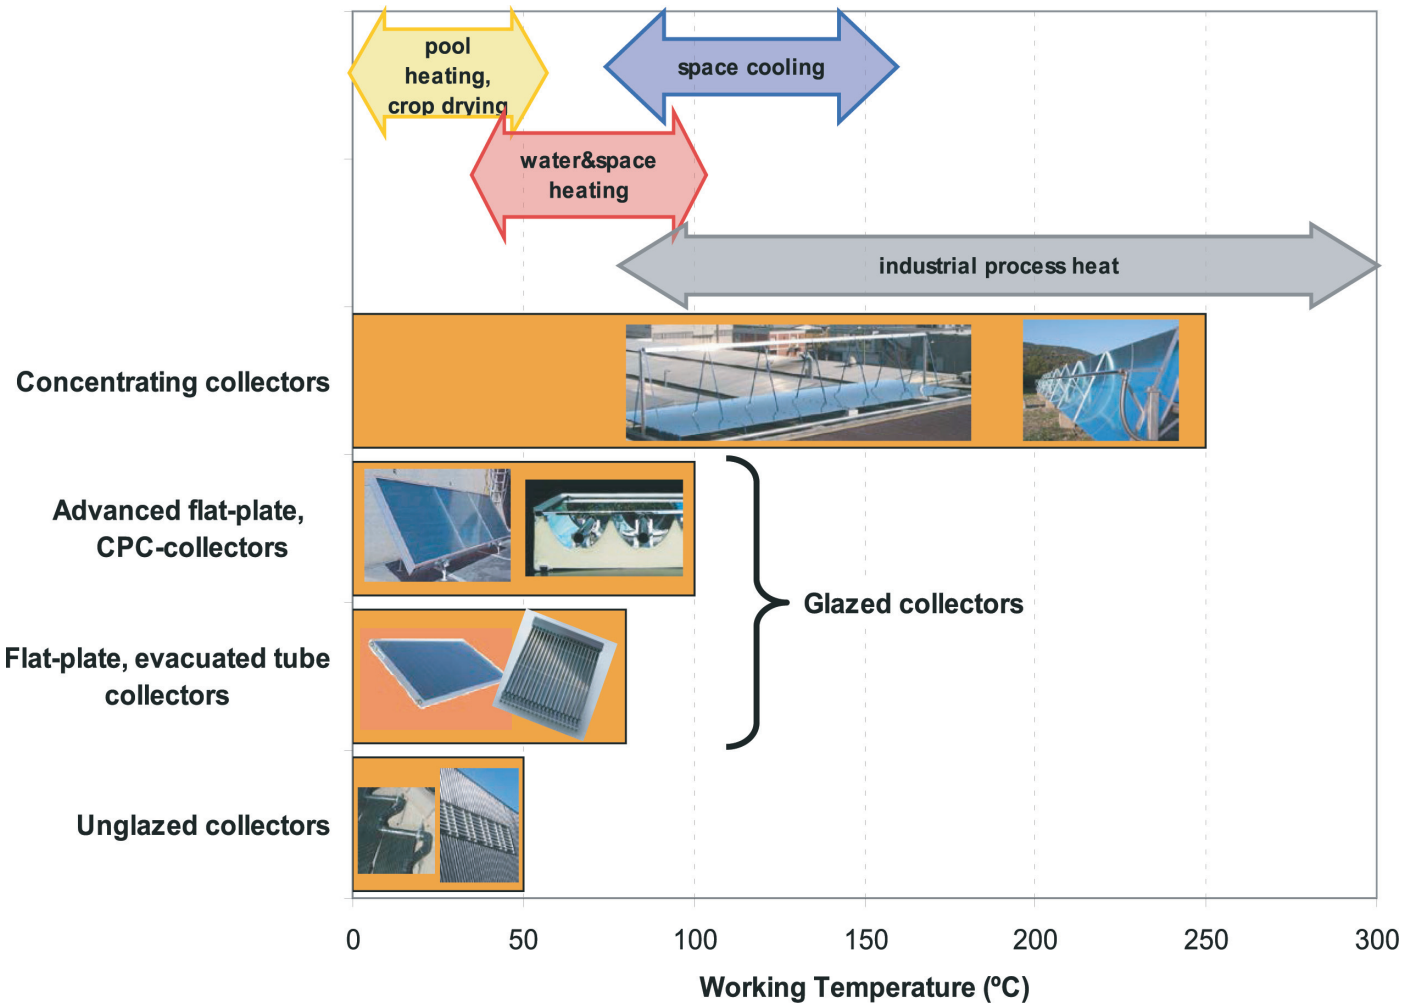

Figure 11.63 | Active solar thermal technologies, collectors, and working temperature ranges. Source: IEA-CERT, 2011. Courtesy of ORNL.

- Develop "combination" technologies and integrate SWH into buildings. Combine solar thermal technologies with other water-heating and building-system technologies.

11.8.4.2 Large Solar Water Heating Systems

Solar thermal systems can provide heat and hot water for direct use. They can also provide preheated water to boilers that generate steam. Large water heating systems can be used by hotels, hospitals, homes for the elderly, and public institutions such as correctional facilities. Other markets for large water heating systems are fertilizer and chemical factories, textile mills, dairies, and food-processing units. Large (MW-scale) solar thermal systems in the low temperature range are used for district heating and for cooling and low/medium temperature process heating.

11.8.4.3 Solar Space Heating

Active solar space heating systems for residential and commercial buildings use a solar collector to heat liquid or air. Thermal energy is transferred directly to an interior space or to a storage area for later use. Liquid-based heating systems are used when storage is desired. Solar-heated air is typically used for ventilation air heating. For example, the transpired solar collector draws air through the perforations of a solar absorber, warming the air in the process. This heated air is used directly in the building, or it may serve as pre-warmed air for a conventional heating/ventilation system.

Space heating often uses liquid-based systems that heat ordinary water or an antifreeze solution such as glycol, depending on the climate. The hot liquid may be used in a fan coil, a hydronic system, or a radiant floor system. R&D activities are under way to improve the performance, cost, and reliability of solar collectors and associated thermal-storage systems.

Solar-assisted heat pump systems are being installed in Europe. Four main components interact in these combined solar and heat pump systems:

- solar collectors: glazed, evacuated, or unglazed;
- a heat pump: air source, water source, or ground source;

Table 11.35 | Characteristics of a typical single-family solar water heating system and combination solar space and water heating system, 2007.

	OECD Europe	OECD North America	OECD Pacific
Water heating: typical size (kW^{th})	2.8–4.2	2.6–4.2	2.1–4.2

- controls that determine how the other components interact.

11.8.4.4 Solar Space Cooling

Space cooling is the newest building application of solar thermal energy. Solar cooling systems can reduce summer peak demand on electricity grids. In addition to the four basic components of a typical solar thermal system, a space cooling system also requires a heat rejection system such as a wet cooling tower or a dry condenser.

Thermally driven cooling uses either a closed cycle for sensible cooling or an open sorption cycle for latent cooling. Closed cycles include absorption cooling, adsorption cooling, and ejector cooling. Absorption cooling systems use working fluids such as water paired with ammonia or solutions of certain salts such as lithium bromide. Closed adsorption cooling systems use solids such as silica gel paired with water. Absorption chillers that use thermal energy from natural gas or other fossil fuels provided the first space cooling before the advent of electric vapor compression cooling equipment. However, smaller-scale absorption chillers designed to operate at temperatures more suitable for solar thermal systems are now under development in Europe and China.

In hot, humid climates, removing moisture from the conditioned air is a key factor in space cooling. In an open sorption cooling cycle, solar

thermal energy can be used in the regeneration phase to dry either solid or liquid desiccant material that has absorbed moisture. Depending on the desiccant material, flat-plate or evacuated tube collectors can be used to provide the regeneration energy. Liquid desiccant systems that work well below 80°C are under development.

11.8.4.5 Solar Pool Heating

Solar pool heating for homes is the largest use of solar thermal energy in the United States. Hotels, municipal governments, and other commercial customers are also starting to adopt this technology. Solar pool heating systems use the pool-filtration system to pump water from the pool to a solar collector. The sun heats the water as it flows through the collector, and the heated water is returned directly to the pool. Solar pool heating collectors are usually unglazed, operate at a slightly warmer temperature than the surrounding air, and are in general made from polymers.

11.8.4.6 Solar Cooking

Solar cookers can cook food, boil water, and pasteurize food or water. Simple solar cookers use diffuse sunlight. Even a simple insulated box with a transparent lid can produce temperatures in the range of 50–100°C. More complex designs use reflectors in dish or trough concentrators to produce temperatures up to 300°C using direct sunlight. In countries where firewood is traditionally used for cooking, solar cookers can slow deforestation and decrease indoor and outdoor air pollution from wood smoke.

11.8.4.7 Solar Crop Drying

Drying agricultural products uses large quantities of low temperature heat usually supplied by burning firewood or fossil fuels, such as diesel and propane. In many cases, air-based solar collectors could provide the needed heat. In Finland, Norway, and Switzerland, this technology is used to dry hay.

The IEA Solar Heating and Cooling Programme (IEA-SHC, 2009) sponsored a project in India to demonstrate a solar air preheating system to help dry coir pith, a byproduct manufactured from coconut shells marketed as an absorbent substitute for potting soil. The coir pith is pressed to reduce moisture content and then final drying takes place in a fluidized bed burner. Solar energy is used to preheat air to the burner. Perforated transpired collector panels on the roof draw air through the small openings heating it to 20°C above ambient. The air is then ducted to the burner, where the temperature is raised to the required 105°C to feed the dryers. After three years of operation, the solar heating system displaced 14% of the heating fuel, which resulted in a two-year payback.

11.8.4.8 Passive Solar Energy

Applying passive solar design principles to new buildings can reduce energy demands for heating, cooling, ventilation, and lighting. A successful solar building design integrates individual building components to achieve optimal energy performance. Computer simulations can help designers understand and quantify the interactions among the various components and systems. It has been estimated that 13% of the heat demand of buildings could be met by passive solar energy use. For optimized buildings, this figure could reach 30% without major investments (Brouwer and Bosselaar, 1999).

The key to passive solar design is the building envelope – the interface between the interior of the building and the outdoor environment. Energy pathways through the building envelope include the roof, walls, windows, air infiltrations, thermal storage, and insulation. Numerous advances are being made within these various components (Kutscher, 2007; Walker et al., 2003):

- New roofing materials with pigments can reflect more heat than conventional materials. Preventing heat from entering a building through the roof can help to reduce the amount of energy needed to cool the interior space.
- New wall designs can help control heat loss by reducing the amount of framing and optimizing insulating materials, such as structural insulated panels and insulated concrete forms. When retrofitting existing buildings, new insulating fabrics can be hung or applied to interior walls to control indoor temperatures.
- High-quality windows address the three main energy paths: radiant energy, heat conduction through the frame, and air leakage around the window's components. Low-emissivity window coatings increase the window's R-value by reducing the flow of infrared energy out of the building; other low-emissivity coatings can block infrared energy from entering the window to reduce the cooling load.
- Passive daylighting is combined with very efficient lighting systems to meet additional lighting needs. In daylight design, windows provide adequate interior illumination while minimizing glare and controlling interior temperatures. Building designs can also include clerestory windows, skylights, light tubes, and light shelves to bring light into the deeper recesses of buildings. Energy use can be offset both directly by replacing artificial lighting or indirectly by reducing cooling loads.
- Sunshine can heat a space passively through direct solar gain, where the sun shines into a building and warms materials in the space such as bricks, concrete, or adobe. These materials store thermal energy as they are heated during the day and release their heat to warm the space at night. A Trombe wall, separated from the outdoors by a glass wall, is designed to absorb solar heat and release it into the interior

Table 11.37 | Cost of energy for a single-family solar thermal system as a function of capacity factor, turnkey investment costs, and discount rate. The O&M costs are assumed at US¢2/kWh for a capacity factor of 10–12% and US¢4/kWh for 5–6%. Lifetime is 20 years.

Capacity factor	Turnkey investment costs per kWth (*water heating*)	Discount rate	
		5%	10%
	$US_{2005}$$	US¢/kWh	
12%	1100	10.4	14.2
	2200	18.7	26.5
6%	1100	20.8	28.5
	2200	37.5	53.0
Capacity factor	**Turnkey investment costs per kWth (*space and water heating*)**	**Discount rate**	
		5%	10%
	$US_{2005}$$	US¢/kWh	
10%	1100	12.0	16.7
	2200	22.1	31.4
5%	1100	24.1	33.4
	2200	44.2	62.8

of a building. The future may see special phase-change materials used for thermal storage and molecular or nanocomposite materials. Ventilation takes place during periods of cool outside temperatures.

11.8.5 Economic and Financial Aspects

Active low-temperature solar technologies require an auxiliary energy source. In solar water heating systems, 20–70% of the demand is met by solar, and in combined solar water and space heating systems, the figure is 20–60% (IEA-CERT, 2011). However, when thermal energy storage is included, this percentage will increase.

Solar has a first cost to the user that must be amortized over the years of service. Based on the data in Tables 11.35 and 11.36, the levelized cost of energy for these systems can be calculated. This calculation assumes discount rates of 5% and 10%, an economic system lifetime of 20 years, and O&M costs ranging from US¢1–4/kWh_{th}, depending on the system and the capacity factor achieved. (See Tables 11.37 and 11.38) The energy costs range from US¢10–63/kWh_{th} for single-family systems and from US¢8–55/kWh_{th} for multi-family systems. In the long term, further improvements in the performance and investment costs may reduce the energy cost by a factor of two (ESTTP, 2008). Solar thermal systems in developing countries cost US¢2–3/kWh_{th} because they are simple thermosiphon systems and usually without freeze-protection (IEA-CERT, 2011).

11.8.6 Sustainability Issues

Low-temperature solar energy technologies have the potential to displace burning wood and fossil fuels. Solar water heating and solar cooking technologies can conserve local biomass and reduce the burden of collecting firewood. They can purify water and mitigate the health impacts of cooking with wood, which creates smoky indoor environments. They can reduce costly diesel fuel use and pollution of the local environment. Low-cost solar crop drying added to the local infrastructure can produce feed for livestock and bring more protein into the diet.

Solar technologies emit no CO_2 while operating. The CO_2 emissions attributed to these technologies come mostly from the energy expended in producing the raw materials, fabricating the products, and transporting and installing them. Displacing combustion with solar thermal heat can offset considerable amounts of CO_2 (Arvizu, 2008), as the energy payback time of a thermosiphon type solar collector and storage system could be 1.3–4.0 years (Harvey, 2006). Worldwide, the energy yield of solar collectors in 2008 roughly translated to an oil equivalent of over 12 million metric tons and an annual CO_2 emissions reduction of 39 million metric tons (Weiss and Mauthner, 2010). Under the IEA BLUE Map scenario, the total installed worldwide solar thermal capacity in 2050 could reduce CO_2 emissions by roughly 450 million metric tons (IEA-CERT, 2011).

11.8.7 Implementation Issues

Barriers to the widespread use of solar thermal systems include initial costs, financing problems, policy uncertainty, and consumer and institutional ignorance (IEA-CERT, 2011). Key barriers to wider use of solar crop drying are lack of information about the cost-effectiveness of these systems, about their technical details, and about practical experience (IEA-SHC, 2009).

Table 11.38 | Cost of energy for a multi-family solar thermal system as a function of capacity factor, turnkey investment costs, and discount rate. The O&M costs are assumed at US¢1/kWh for a capacity factor of 10–12% and US¢2/kWh for 5–6%. Lifetime is 20 years.

Capacity factor	Turnkey investment costs per kWth (*water heating*)	Discount rate	
		5%	10%
	US_{2005}	US¢/kWh	
12%	950	8.2	11.6
	2000	16.2	23.3
6%	950	16.5	23.2
	2000	32.5	46.6
Capacity factor	**Turnkey investment costs per kWth (*space and water heating*)**	**Discount rate**	
		5%	**10%**
	US_{2005}	US¢/kWh	
10%	950	9.7	13.7
	2000	19.3	27.3
5%	950	19.4	27.4
	2000	38.5	55.4

Incentive programs and policies that include environmental mandates can help reduce economic and other barriers. These actions may be taken at the local, regional, national, or international level – from a desire for a city to be "green," to a state or province mandating air quality levels, to a country striving to meet the guidelines of the Kyoto Protocol (Arvizu, 2008). Tax credits for companies and consumers, a carbon tax on fossil fuel use, and renewable energy portfolio mandates designed for utilities are a few examples of policies and practices that encourage use of solar technologies (Johansson and Turkenburg, 2004; REN21, 2010). (See also section 11.12.) Legislation can be very effective. For example, in 1980 the Israeli government required solar water heaters in all new homes (except tall buildings with insufficient roof area). In Israel, 85% of households now use solar thermal systems. Spain also introduced a national solar thermal obligation for new buildings in 2006 (ESTIF, 2007).

In the (draft) *Roadmap for Energy Efficiency in Buildings*, focusing on heating and cooling (IEA-CERT, 2011), the following areas are identified for policy support:

- Increased technology R&D, significant demonstration programs, and development beyond the present best available technologies;
- Improved information for consumers and robust metrics for analyzing the energy savings, CO_2 emission savings, and financial benefits of heating and cooling technologies;
- Market transformation policies to overcome the current low uptake of many low/zero carbon heating and cooling technologies;
- International cooperation to maximize the benefits of policy intervention as well as the transfer of technical knowledge between countries;
- The creation of strong partnerships for the promotion of efficient and low/zero carbon heating and cooling technologies.

11.9 Ocean Energy

11.9.1 Introduction

In principle, the oceans represent one of the largest renewable energy resources on earth. Energy is stored in the seas as kinetic energy from the motion of waves and currents and as thermal energy from the sun. Energy can be extracted from the mixing of fresh and salt water ("salinity gradient energy") where rivers run into the sea. Ocean water can be used for cooling purposes, and oceans can be used to produce marine biomass for energy services (as discussed in section 11.2).

Most ocean energy resources are diffuse and far from where they are needed. Yet energy from the oceans can be captured for practical use (Turkenburg et al., 2000). Tidal energy can be extracted where extreme tidal ranges or currents exist. Wave energy can be exploited where a higher-than-average wave climate occurs. Ocean thermal energy conversion (OTEC) can be achieved where the temperature difference between surface waters and water near the seabed is sufficient. Using ocean water to cool power plants or buildings is feasible when the distance between source and end user is short. These requirements tend to

limit the use of the ocean resource to certain areas of coastline where the resource and a market for the energy are within reach.

Many techniques have been proposed to exploit this resource to generate electricity, produce fuels, provide cooling, and make potable water. Virtually all of them, however, are still at the early development or demonstration stage.

11.9.2 Potential of Ocean Energy Technologies

The main ocean energy resources considered here are tidal head energy, tidal current energy, ocean current energy, wave energy, ocean thermal energy, and salinity gradient energy.

Tidal head energy: Tidal head (or barrage) energy makes use of the potential energy from the difference in height between high and low tides. The output of a tidal head plant is entirely predictable. The largest tidal heads can be found in estuaries in Canada (Bay of Fundy), the United Kingdom (Severn Estuary), France (Baie du Mont Saint Michel), and India (Gulf of Cambay). The global potential of tidal head energy is estimated at 3 TW, with about 1 TW being available at comparable shallow waters (Charlier et al, 1993). The capacity factor for these plants varies from 22–29%. Consequently, the theoretical potential of tidal head energy can be estimated at about 2500 TWh/yr (9 EJ_e/yr). The technical potential is estimated at about 1,000 TWh/yr (3.6 EJ_e/yr) (see Chapter 7).

Tidal current and ocean current energy. Tidal current energy makes use of the kinetic energy of water in a tide. Ocean currents are generated by winds and by differences in water temperature and salinity. In most places, the movements of seawater are too slow to permit practical energy exploitation. Water velocity can be increased by a reduction in cross-section of the flow area. This happens in straits, around the ends of headlands, in estuaries, and in other narrowing topographical features (Turkenburg et al., 2000). As with wind energy, a cube law governs instantaneous power to fluid velocity. An average peak marine current of 2.5 mps (5 knots), which is not unusual, translates to a power flux of about 8 kW/m^2. Potential sites must have flows exceeding 1.5 mps for a reasonable period (Fraenkel, 1999; IT Power, 1996).

Estimates of the tidal current energy resource have been made for the European Union, Asia, the United Kingdom, and Canada (CEC, 1996; CEC, 1998; UK-DTI, 2004; Cornett, 2006). Sites have also been identified in Japan, New Zealand, and South America. In Europe, about 100 locations have been identified where power production from tidal current energy may become attractive, offering a potential electricity supply of 48 TWh/yr (compared with European electricity demand of about 5000 TWh/yr in 2010). Countries with promising sites include France, Greece, Ireland, Italy, and the United Kingdom (CEC, 1996). In China, 14 GW of tidal current power installations might be possible (Wang and Lu, 2009). This would translate to 50 TWh/yr, assuming a high capacity factor of about 40% (Harvey, 2010).

Assessments for open ocean current flows have also been made (see, e.g., Leaman et al., 1987). Potential locations have been identified in South Africa, East Asia, Australia, and North America, including the Florida current of the Gulf Stream, 15–30 km off the coast. Ocean currents offer the potential of a relatively high capacity factor of 70–80% (Boud, 2002). The theoretical potential of ocean current energy has been estimated at about 6000 TWh/yr (Sörensen and Weinstein, 2008). The technical potential could be 1000–2000 TWh/yr and maybe more, depending on assumptions made.

Wave energy: Wave energy is generated by friction transfers from wind energy passing over the ocean. The energy density of waves is substantial: a wave 1.5 m high has a capacity of about 10 kW/m of wave front. The greatest wave power densities occur off northwestern Europe, western Canada and Alaska, and southern South America and Australia (Harvey, 2010). Energy fluxes of up to 75 kW/m have been found off the coast of Ireland and Scotland (Clément et al., 2002).

The global theoretical potential of wave energy has been estimated at 8000–80,000 TWh/yr (Harvey, 2010). Another study has proposed approximately 30,000 TWh/yr (108 EJ_e/yr) (Mørk et al., 2010). In Chapter 7, the technical potential is estimated at about 20,000 TWh/yr (72 EJ_e/yr).

The wave energy potential that can be harnessed in practice has been estimated at 260 TWh/yr in the United States and at 120–200 TWh/yr in Europe (Boud, 2002; Harvey, 2010). Wave energy is variable in time, resulting in capacity factors of 25–35%, depending on the location. However, the available wave energy can be predicted accurately 24–48 hours in advance (Harvey, 2010).

Ocean thermal energy: Using some form of heat engine to exploit natural temperature differences in the ocean has been discussed and investigated for many decades (Boyle, 1996). To deliver a feasible system, technically and economically, as large a temperature difference as possible is required. A temperature difference of about 20°C is required for OTEC. A few tropical regions with very deep water (a depth of 1 km or so) have this characteristic. In a recent assessment, a global technical potential of about 40,000 TWh/yr (144 EJ_e/yr) was calculated (Nihous, 2007). However, in another study the technical potential was assessed at 10,000 TWh/yr (Harvey, 2010). An even earlier assessment presented an estimate of 30,000–90,000 TWh/yr (108–324 EJ_e/yr) (Charlier and Justus, 1999).

Deep water from the ocean can also be used to cool buildings in coastal areas, especially in the tropics (see, e.g., Makai Ocean Engineering, 2010). The technology is called seawater air conditioning (SWAC). No estimates could be found about the technical potential of this technology.

Salinity gradient energy: Mixing salt water and fresh water releases latent heat that can be converted to work when a river runs into the sea (Pattle, 1954). According to Norman (1976), cited by Post (2009), "the tremendous energy flux available in the natural salination of fresh water

is graphically illustrated if one imagines that every stream and river in the world is terminated at its mouth by a waterfall 225 meter high," which is the potential energy equivalent of the latent heat from mixing fresh water with seawater. In a recent study, the theoretical potential of this technology was calculated at 1.7 TW/yr, or about 50 EJ/yr (Post, 2009). For most continents, the theoretical potential is about 300 GW (nearly 10 EJ_e/yr); only Europe (94 GW, or 3 EJ_e/yr) and Australia (30 GW, or 1 EJ_e/yr) have significantly lower potentials.

The global technical potential of salinity gradient energy can be estimated at 1 TW (Post, 2009). Assuming a capacity factor of 80–90%, this would translate to about 7500 TWh/yr (27 EJ_e/yr). In another publication the technical potential was estimated at about 150–170 GW_e (van den Ende and Groeman, 2007); this capacity could generate about 1200 TWh/y (4.3 EJ_e/yr). However, citing Statkraft of Norway, Criscione (2010) suggests that by 2030 the deployment of this energy source could already be 1600–1700 TWh/yr.

11.9.3 Market Developments

The world is only beginning deployment of ocean energy conversion systems. Not many systems are operational and most activities are undertaken by research institutes and small and medium-size enterprises, mainly in Canada, Norway, the United Kingdom, and the United States (Kahn et al., 2009; Harvey, 2010). Other countries involved include Australia, China, Denmark, France, India, Ireland, Japan, the Netherlands, and Sweden. Most of these countries participate in the IEA Ocean Energy Systems Implementing Agreement (IEA-OES-IA).

The 2010 annual report of IEA-OES-IA (2011) indicates that at the end of that year the installed power, reported by member countries, was 2 MW for wave energy, 4 MW of tidal stream, and 259 MW of tidal barrage energy. Consequently, the total installed capacity for ocean energy in 2009 and 2010 was less than 300 MW, mainly tidal head capacity, generating about 0.5 TWh/yr.

Tidal head energy: Tidal head energy has been exploited on a small scale for centuries using water mills. In France, the 240 MW La Rance scheme, built in the 1960s, is a large modern version. It uses bulb turbines like those applied in river-based hydro-electric projects. These turbines can pump to increase storage and produce about 0.5 TWh/yr (Andre, 1976; Kerr, 2007). A 254 MW plant at Lake Sihwa on the western coast of South Korea was expected to become operational in 2011. In addition, a handful of smaller plants have been built in Canada, China, and Russia (Cavanagh et al., 1993; Strange et al., 1994; Kerr, 2007). About 43 GW of tidal range capacity is under investigation, with an estimated electricity production potential of 63 TWh/yr (Kerr, 2007).

Tidal and ocean current energy: Large-scale energy generation from currents requires a totally submerged turbine, which may look like a wind turbine, adapted for harsh marine conditions. It can have a horizontal or a vertical axis. About a dozen devices are in the RD&D phase. A 1.2 MW grid-connected system, called SeaGen, has been built by Marine Current Turbines and has been in operation in Northern Ireland since 2008. It is accredited as an official UK power station. Marine Current Turbines's earlier Seaflow 200 kW prototype operated from 2003 to 2009 in the Bristol Channel at the Devon coast (Willis, 2010). Other devices include the Hammerfest Strøm 300 kW turbine in Norway, installed in 2004; the TGL 500 kW device of Rolls Royce in the United Kingdom, installed in 2010; and the Verdant Energy array of 6 x 35 kW (small) turbines in East River, New York, that operated between 2005 and 2008.

Wave energy: The development of wave energy through 2007 was supported by Australia, Canada, Chile, China, India, Ireland, Japan, New Zealand, Norway, Portugal, Russia, Sweden, the United Kingdom, and the United States. In the last 5–10 years, the wave energy converters introduced by several companies include the Limpet (operational in Scotland since 2000) of Voith Hydro Wavegen, the PowerBuoy of OPT, the Oyster of Aquamarine Power, the Wave Energy Converter of Pelamis Wave Power, the Archimedes Waveswing of AWS Ocean Energy, and the Wave Energy Converters of Oceanlinx.

Ocean thermal energy: The first OTEC plant (using a low-pressure turbine) was a 22 kW device built in 1940 in Cuba. Some later attempts off the coast of Brazil and the Ivory Coast were initiated but failed. OTEC technology has been developed in the United States since 1974 (Hawaii) and in Japan since 2004. In the United States, prototype plants with rated capacities of 50 kW up to 1 MW were tested around 1980. A 210 kW system was tested from 1993 to 1998. Several small-scale power plants, including a 30 kW hybrid OTEC prototype plant, have been built in Japan. Unfortunately, Pacific Ocean storms knocked out a number of pioneering installations. OTEC systems have a very long pipe extending to deep water, making the system vulnerable to damage from rough seas. This vulnerability and the high system costs may explain why in 2006 only one ongoing project could be identified. It was in operation near the coast of India and developed by the Institute of Ocean Energy in Japan. Almost all the major US OTEC experiments have taken place at the Natural Energy Laboratory of Hawaii Authority (NELHA). In 2010, a 1.2 MW demonstration plant was under construction (Harvey, 2010). About one-third of the capacity will be used to run the pumps and the system, which would result in a net production of 800 kilowatts.

In Hawaii, cold seawater is also being used to air-condition buildings. This technology is applied to cool buildings of NELHA, which saves the laboratory nearly $4000 per month in electricity costs. The system requires much less maintenance than traditional compressor systems (State of Hawaii, 2010). Similar projects have been developed or are being developed in Sweden and elsewhere (IEA-DHC, 2002; IEA, 2009c; Makai Ocean Engineering, 2010).

Salinity gradient energy: Two technologies to extract energy from mixing fresh water and salt water, using quite different physical principles, are in the prototype stage. The Pressure Retarded Osmosis technology has

been under investigation by Statkraft of Norway since 1997 (Scråmestø et al., 2009). The Reversed Electro Dialysis technology has been investigated by Wetsus Institute of the Netherlands since about 2004 (Post, 2009).

Ocean energy in future energy scenario studies: Because of the early stage of development, ocean energy is projected to have a minor role in most energy scenarios for 2030–2050. Potential contributions in 2050 range from 25–600 TWh/yr. The European Renewable Energy Council and Greenpeace International, however, project a figure of 1900 TWh in 2050 (Krewitt et al., 2009; EREC & Greenpeace, 2010; IEA 2010a).

11.9.4 Ocean Energy Technology Developments

A recent study identified 135 ocean energy technologies that have been under development since the 1990s (Khan and Bhuyan, 2009). Within constrained funding environments, and due to the difficult operating environment and resource diversity, maturity of various ocean energy technologies has been relatively slow. (See Figure 11.65.)

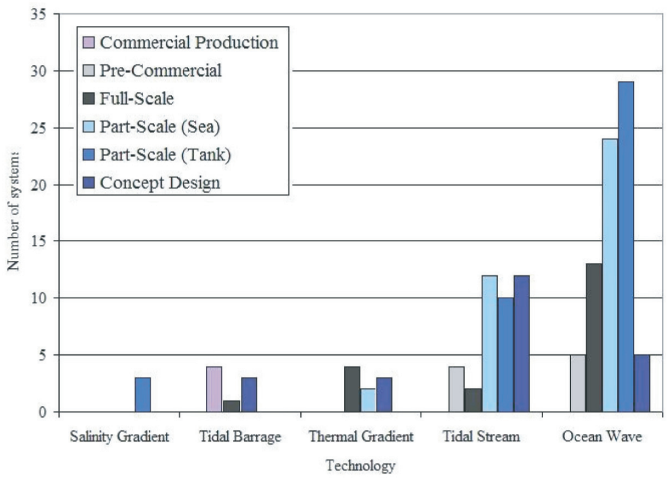

Figure 11.65 | Number of ocean energy conversion schemes and their maturity. Source: Kahn and Bhuyan, 2009.

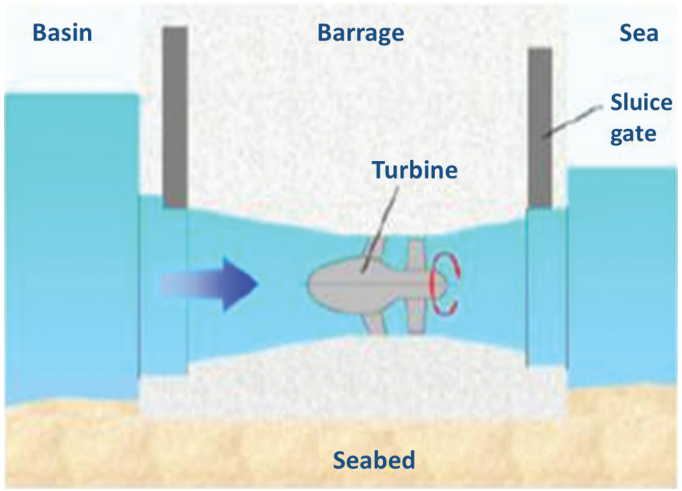

Figure 11.66 | Tidal barrage type of energy device. Source: Sørensen and Weinstein, 2008.

Tidal head energy technology: Tidal head energy conversion technology uses similar technology to conventional low-head hydro-electric systems and therefore is considered mature. At present it is used in estuaries where a basin is created by means of a barrage. (See Figure 11.66) The high tide fills the basin and the impounded water is held behind the barrage until the receding tide creates a suitable head. The water is then released through the hydroelectric converter until the rising tide reduces the head to a minimum operating point. This sequence is repeated with the tides (Strange et al., 1994). In this approach, called "ebb generation," power production on both ebb and flood is also possible. To obtain continuity of supply, plant configurations and operating routines of greater complexity are needed, including linked and paired basins (Strange et al., 1994). Single-basin plants deliver one or two intermittent pulses of energy per tide. The pulses recur at a period of 12 hours and 25 minutes. Consequently, the capacity (or load) factor of the plant is limited to 25–35%. Recent studies also investigated options to produce electricity using artificial basins offshore (called tidal lagoons). Increased output can be obtained by using the turbines as pumps using external power to increase the water level and therefore the generating head (Strange et al., 1994). Turbine and generator system configurations include the bulb, the Straflow, and the tubular turbine (Harvey, 2010).

Tidal and ocean current energy technology: Marine current energy machines work very much like underwater wind turbines; the physical principles of kinetic energy conversion are directly analogous in moving water or air. Currents are complicated by short-term variations in both velocity and direction, caused by turbulence and velocity shear effects. In particular, surface currents move much faster than the currents deeper down, to the extent that the majority of the energy in most locations with strong currents is in the upper half of the water column. Full understanding is needed about how variation in velocity combined with waves from any direction will affect structural strength and power-conversion mechanisms (Salter et al., 2006).

The density of water is some 850 times higher than that of air at normal atmospheric pressure, so a water current turbine can be considerably smaller than an equivalent powered wind turbine. When applied to convert tidal current energy, which is a bi-directional flow, the turbine should be able to respond to reversing flow directions. This is not an issue when converting energy from ocean currents, which are generally unidirectional.

The biggest problem with underwater kinetic energy conversion systems stems from the very large forces generated by taking momentum from such a dense medium. Although the literature tends to focus on rotor

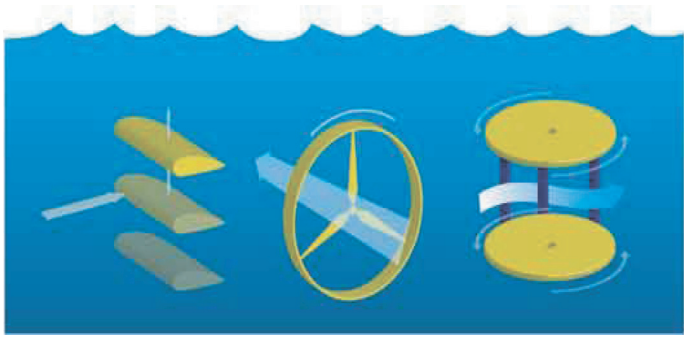

Figure 11.67 | Three technologies to convert ocean current energy: reciprocating hydrofoil (left), horizontal axis turbine (middle), vertical axis turbine (right). Source: DP Energy, 2010.

concepts, the overwhelming problem in engineering a large system to extract kinetic energy from moving water, whether it is waves or currents, is the strength needed both to react to very large forces and to be anchored securely to the seabed. Typically a tidal turbine experiences thrust forces amounting to around 100 tonnes per MW with a rated current of about 2.5m/s (typical), whereas a wind turbine will experience about one third of this force per MW.

Tidal turbine developers are following in the footsteps of wind turbine developers 30 years ago by experimenting with a variety of rotor types: axial-flow turbines, cross-flow turbines, and reciprocating devices. (See Figure 11.67.) When using axial-flow or cross-flow turbines, horizontal axis as well as vertical axis configurations can be applied and shrouds can be used to increase the flow velocity through the turbine. A reciprocating device uses the flow of water to produce the lift or drag of an oscillating part transverse to the flow direction. The mechanical energy from this oscillation can be used to generate electricity. It seems probable that the pros and cons of these different rotor types will be similar in water to those in air, notably that the open axial flow rotor is more efficient, more controllable, and more cost-effective than any other. This is why virtually 100% of commercial wind turbines (and the majority of low-head hydro turbines too) use pitch regulated axial flow rotors.

Although in an early stage of development, experiments have been conducted with prototypes in the open sea in the United Kingdom. At least one system (Marine Current Turbines's 1.2 MW SeaGen) has reached the commercial stage, is an accredited UK power station, and will be replicated in larger numbers in the near future.

Wave energy technology: At least 50 wave-energy devices are under development (US DOE, 2009; Khan and Bhuyan, 2009). One group is devices operating on the shoreline, near-shore, or offshore. Another group is installations located at the water surface versus installations located at a depth of about 5–15 m (Sørensen and Weinstein, 2008). In a third group, technologies are divided according to the mechanism applied: oscillating water column devices, surge devices, heaving float devices, heaving and pitching float devices, and pitching devices. (See Figure 11.68.) Each mechanism reacts to the waves in a different way. For example, surge devices often have a flap that is pushed back and forth by the waves; heaving float devices move up and down as the wave passes and activate either a pump or a generator to extract energy; pitching devices rock usually fore and aft and generally react one floatation device against another, often compressing hydraulic fluid in the process to drive a generator.

To increase confidence in wave energy, demonstrations are needed that wave devices can survive the worst climate (wind, temperature) and ocean conditions (saltwater corrosion, fouling, heavy storms, seawater pollution) and perform as expected. Less expensive installation methods are needed, along with test platforms so that large numbers of components and subassemblies can be operated in parallel.

Ocean thermal energy technology: The three main concepts of OTEC are all based on the Rankine (steam/vapor) cycle: an open cycle system, a closed cycle system, and a combination of these two. The open cycle concept quickly evaporates warm seawater to vapor (at reduced pressure) and draws it though a turbine by condensing the vapor with cold seawater. The closed cycle system uses warm seawater to boil a low-temperature fluid, such as ammonia or propane. (See Figure 11.69.) That vapor is then drawn through a turbine by being condensed in a heat exchanger with cold seawater and recycled back to the boiler by a pump (Turkenburg et al., 2000). Closed cycle systems offer in principle a better conversion efficiency and a smaller turbine. The hybrid system flash evaporates warm seawater, and the generated steam is used as a heat source for a closed cycle.

Offshore OTEC is technically difficult because of the need to pipe large volumes of water from the sea bed to a floating system and the need for huge areas of heat exchanger. Other operational challenges include storm resistance, corrosion, maintenance of vacuum, and fouling. Transmitting power from a device floating in deep water to the shore is also an issue, because of the costs involved. As a result, OTEC technology has yet to mature to commercial and economic viability.

Seawater air-conditioning systems can be applied to produce chilled water. Such systems pipe cold water from the deep ocean to the shore. The cold (1–7°C) water, which is denser than warm water, is pumped from a depth of 600–1000 meters, and the return system water is 8–12°C (IEA-DHC, 2002; IEA, 2009c). Using a heat exchanger, the cold can be made available to air condition hotels, offices, and other buildings, reducing the energy use for air conditioning by 90% (Van Wijk, 2010). The cold can also be used to condense water vapor for irrigation purposes and to produce potable water. The capacity of a SWAC system can be many MW. Commercial production is feasible, especially in regions where a high capacity factor can be achieved.

Salinity gradient energy technology: In a Pressure Retarded Osmosis system – also called osmotic power system – a semi-permeable membrane is placed between a salt solution (seawater) and fresh water (Post,

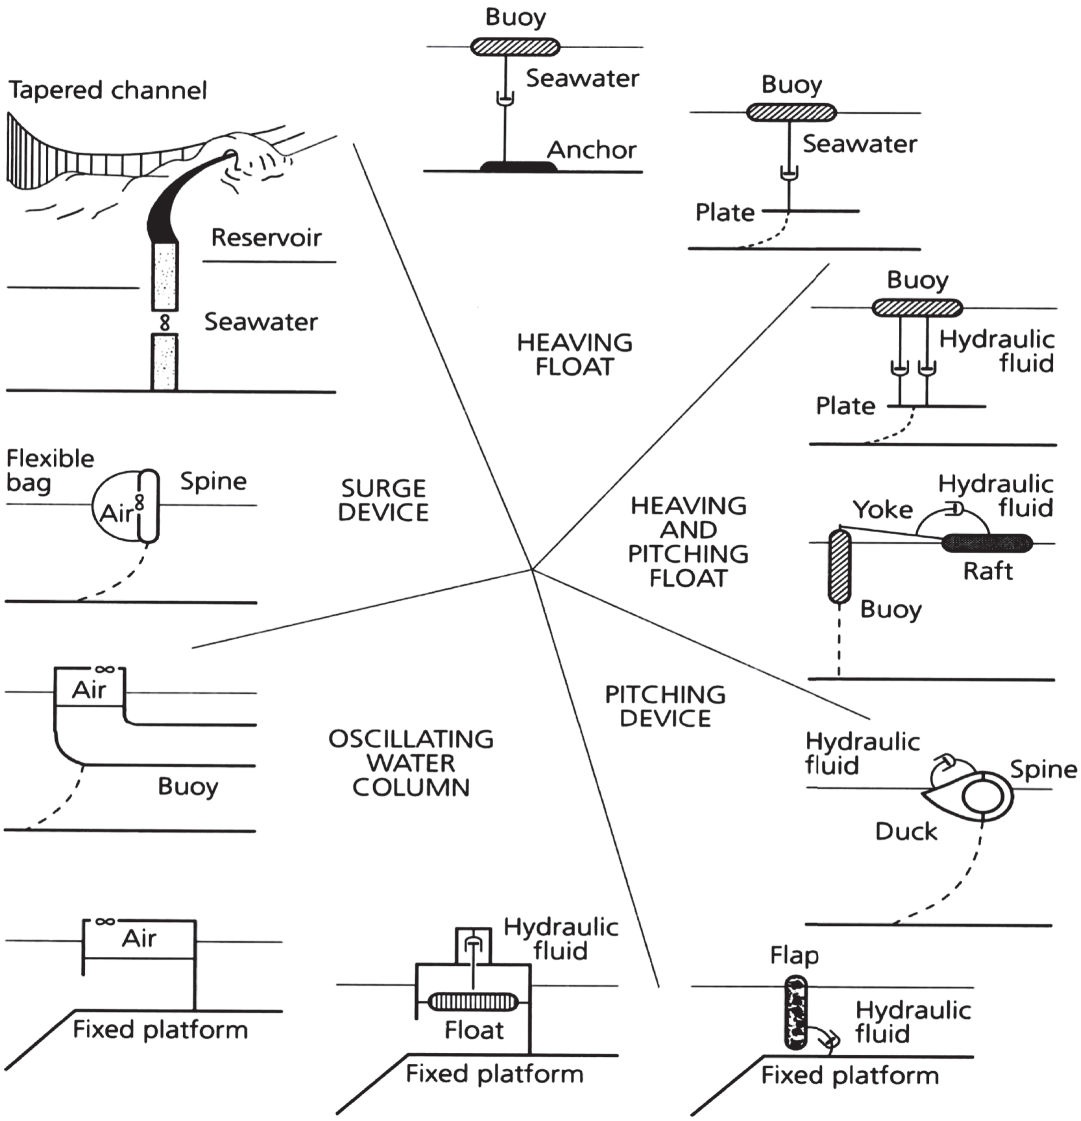

Figure 11.68 | Schematic representation of five mechanisms and 11 devices to use wave energy. Source: Cavanagh et al.,1993.

2009). The membrane allows the solvent (the water) to permeate, but it acts as a barrier to the dissolved salts. The chemical potential difference between the solutions causes transport of water from the diluted salt solution to the more concentrated salt solution. This transport results in a pressurization of the volume of transported water, which can be used to generate electricity in a turbine. The great difference in osmotic pressure (equal to a 240 m head) between fresh water and seawater is used. A first pilot plant based on this technology was commissioned by Statkraft in Norway in 2009 (Post, 2009).

A Reversed Electro Dialysis system is essentially a salt battery. A number of cation and anion-exchange membranes are stacked in an alternating pattern between a cathode and an anode to create an electrical battery. The compartments between the membranes are alternately filled with a concentrated salt solution and a diluted salt solution. The salinity gradient results in a potential difference (80 millivolt for sea water and river water) over each membrane. The potential difference between the outer compartments of the membrane stack is the sum of the potential difference over each membrane. First prototypes of this technology have been tested at the Wetsus Institute in the Netherlands (Post, 2009).

These technologies are still at an early stage of experimentation, and at present it is unclear whether they can be made sufficiently efficient to become commercially and economically viable.

11.9.5 Economic and Financial Aspects

Most ocean energy technologies are in the RD&D phase. Their development is driven by governmental R&D funding and policy objectives. Consequently, only preliminary cost figures can be presented, with a high degree of uncertainty.

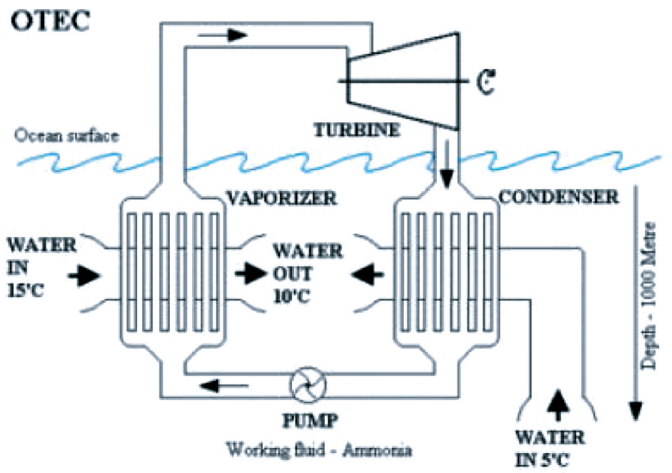

Figure 11.69 | A closed cycle OTEC power plant. Source: Sørensen and Weinstein, 2008.

When calculating the cost per kWh, the assumptions are a discount rate ranging from 5–10%, annual O&M costs equivalent to 1% of the initial investment costs, and an economic lifetime of the system ranging from 30–40 years (depending on the technology involved). It should be noted that if the technical lifetime of a system is much longer than the economic lifetime – as is the case with tidal barrage systems – the kWh production costs will in general be substantially lower in the long term. Due to anticipated technical learning, it can be expected that future electricity production costs will come down by a factor of two or more for most of these technologies. An overview of the kWh cost calculations is presented in Table 11.39.

It must be noted that corrosion issues and fouling can have a large impact on O&M costs and the capacity factor of the conversion system. Seawater is bad for electronic circuitry as well as for other parts of the system. Failure of the simplest, cheapest components can cause outage for long periods of time because bad weather, for example, can hinder and delay even minor repairs.

Tidal head electricity: Big barrage systems, have been estimated to have investment costs of US_{2005}4000–6000/kW (Turkenburg et al., 2000; IEA-ETSAP, 2010) and a capacity factor of 25–30%, with resulting production costs of electricity of US¢10–31/kWh. The 254 MW Sihwa scheme under construction in South Korea is the only other large tidal barrage to be installed after the French La Rance scheme of the 1960s. The system is based on an existing barrage built primarily for flood control purposes, which thereby reduced its capital costs to the marginal cost of adding turbines and generating plant. Economic estimates, however, are not available. The Severn Barrage in the United Kingdom, which was assessed in 2010 for the UK government, would have been rated at 7000 MW and cost over US$30 billion; it was rejected for governmental support primarily because it was evaluated to be uneconomical.

Tidal and ocean current electricity: Tidal and marine turbines are modular devices that may have individual power outputs in the 1–5 MW range and that are designed for build-out into arrays or "farms." Therefore they can be built up incrementally into large projects eventually, allowing quicker start to the repayments compared with big barrage systems.

It is estimated that the initial investments for open ocean current energy systems may range from US_{2005}7000–14,000/kW. Assuming a capacity factor of these systems of 70%, the initial kWh production costs would be US¢9–27/kWh. For tidal current systems, the initial investment costs will probably be lower, such as US$5000–10,000/kW. However, the capacity factor will also be less: maybe about 35%. This would result in a kWh cost of US¢12–38/kWh. It should be noted that higher initial investment costs are mentioned in the literature than assumed here, up to US$14,000/kW (Callaghan, 2006; IEA-ETSAP, 2010).

Wave power electricity: Wave power devices tend to be heavier than wind ones, because for a given power output they need to handle much larger forces, demanding more structural material. This gives wave energy a disadvantage if cost predictions are based on weight. Plants can run steadily for days, even weeks at a time. But because energy comes in pulses at twice the wave frequency, and wave amplitudes follow the Gaussian distribution, there are large power peaks – 10 or more times the mean values. Assuming present investment costs ranging from US_{2005}6000–16,000/kW (Turkenburg et al., 2000; Callaghan, 2006; IEA-ETSAP, 2010) and a capacity factor of 25–35%, the initial electricity production cost could be US¢15–85/kWh. It is projected that energy generated by wave energy installations can reach an average price below about US¢13/kWh in the longer term (Sørensen and Weinstein, 2008). Harvey (2010) gives a longer term figure of US¢10–14/kWh.

OTEC electricity: Investment costs of initial commercial plants have been estimated at US$6000–12,000/kW (see, e.g., Vega, 2002; Cooper et al., 2009). Assuming a capacity factor of 70%, this would result in production costs of US¢8–23/kWh.

Salient gradient electricity: No cost estimates have been completed for this technology, and thus no figures for the investment and kWh costs can be presented. It is estimated that the investment costs per kW will be substantially higher than for other mature renewable energy technologies, but this is compensated by the expected high capacity factor (80–90%).

It should be noted that the cost figures presented in Table 11.39 are higher than expected about 10 years ago, when the World Energy Assessment was published (Turkenburg et al., 2000). The main reasons are a steep increase in the overall investment costs and lack of technological learning, reflecting the relatively immature nature of these technologies.

Table 11.39 | Production cost of electricity as a function of capacity factor, turnkey investment costs, and discount rate. For all technologies, the annual O&M costs are assumed to be equivalent to 1% of the turnkey investment costs. The economic lifetime is assumed to be 40 years for tidal range, and 30 years for other systems.

Tidal head electricity (economic lifetime 40 years)			
Capacity factor	**Turnkey investment costs (US_{2005})**	**Discount rate**	
		5%	**10%**
30%	$4000/kW	10.4¢/kWh	17.0¢/kWh
	$6000/kW	15.5¢/kWh	25.6¢/kWh
25%	$4000/kW	12.4¢/kWh	20.5¢/kWh
	$6000/kW	18.6¢/kWh	30.7¢/kWh
Tidal current electricity (economic lifetime 30 years)			
Capacity factor	**Turnkey investment costs (US_{2005})**	**Discount rate**	
		5%	**10%**
35%	$5000/kW	12.3¢/kWh	19.0¢/kWh
	$10,000/kW	24.5¢/kWh	37.8¢/kWh
Ocean current electricity (economic lifetime 30 years)			
Capacity factor	**Turnkey investment costs (US_{2005})**	**Discount rate**	
		5%	**10%**
70%	$7000/kW	8.6¢/kWh	13.2¢/kWh
	$14,000/kW	17.1¢/kWh	26.5¢/kWh
Wave electricity (economic lifetime 30 years)			
Capacity factor	**Turnkey investment costs (US_{2005})**	**Discount rate**	
		5%	**10%**
35%	$6,000/kW	14.6¢/kWh	22.7¢/kWh
	$16,000/kW	39.1¢/kWh	60.5¢/kWh
25%	$6000/kW	20.5¢/kWh	31.8¢/kWh
	$16,000/kW	54.8¢/kWh	84.7¢/kWh
OTEC electricity (economic lifetime 30 years)			
Capacity factor	**Turnkey investment costs (US_{2005})**	**Discount rate**	
		5%	**10%**
70%	$6000/kW	7.9¢/kWh	11.3¢/kWh
	$12,000/kW	14.6¢/kWh	22.8¢/kWh

11.9.6 Sustainability Issues

All ocean energy technologies are able to support local energy supplies with almost no environmental emissions to the atmosphere during operation. Consequently, using ocean energy would contribute to reducing GHG emissions as well as acidification and other environmental problems associated with conventional energy use. Further development and deployment of these technologies can also contribute to regional and local economic development and employment. In coastal regions, the marine energy industry could create 10–20 jobs/MW (Sørensen and Weinstein, 2008).

Life-cycle assessments of tidal and wave energy conversion systems indicate GHG emissions ranging from about 15–50 gCO_2-eq/kWh and an energy payback time ranging from about 1–2.5 years (Raventós et al., 2010).

Locally ocean energy systems could also have some negative impacts that should be minimized. Tidal head energy systems, for example, when located in estuaries, will have an impact on currents and on sediment transport and deposits. Current subjects of investigation include the impacts of construction of the barrage on local biodiversity, of a large human-made seawater

lake behind the barrage, and of offshore tidal lagoon systems on fishing, fish, bird breeding, and feeding. Wave energy systems will have a visual impact when large arrays of floating devices are installed near shore.

Current energy devices are expected to have limited environmental impact. Underwater noise and vibrations can be a concern as well as impacts on fishing activities. To avoid accidents with surface vessels, these devices must be installed deep enough (resulting, however, in a lower energy yield) or be made to be surface-piercing and hence visible to shipping. For OTEC devices that use closed-circuit hydraulics, spills of working fluids or leakage is a subject for investigation.

The corrosive effects of seawater as well as debris and fouling are having an impact on the durability and performance of ocean energy systems and are issues of concern.

11.9.7 Implementation Issues

A major issue is the nascent stage of development of most ocean energy technologies, the high investments costs per kW, and the need to reduce these costs through R&D and learning by doing. Therefore government support is needed to bring promising technologies from the R&D phase to the stage of prototype and pilot plant developments. A drawback then could be the large diversity of technologies investigated. A barrier for early deployment can also be the remote location of most ocean energy systems, increasing installation costs but also the need to develop or adjust infrastructures to connect these systems to the grid. Yet some synergies may be found when also deploying wind turbines offshore. And the high predictability of energy supplies from these sources reduces system integration challenges. An advantage of tidal barrage systems can be the possible integration with energy storage (pumped hydro) to enlarge the flexibility in electricity supplies.

At a country level, high-quality resource assessment and inclusion of these technologies into energy development and planning portfolios is needed. Of the few countries that have completed these initial steps, the United Kingdom has set a target of 2 GW ocean capacity installed by 2020 (UKERC, 2008). Following this model, a strategy to commercialize and deploy ocean energy technologies should cover in principle all aspects of the innovation chain for emerging technologies, ranging from R&D and capacity building to, for example, the manufacturing of systems, the development of standards, and financial arrangements to facilitate high-volume deployment.

11.10 System Integration

11.10.1 Introduction

At present, only a handful of countries have non-traditional renewable penetration above 10% (with a few above 30%). A number of studies suggest that this figure could steeply increase in the coming decades (see, e.g., Krewitt et al., 2009b; IEA, 2010a; ECF, 2010; Sims et al., 2011; see also Chapter 17). Because of the partly fluctuating nature of some renewable energy sources, ranging from minutes to annual seasons, a key challenge will be to match load and supply of energy properly.

Experience demonstrates that large shares of variable renewables are possible if appropriate measures are taken to support system integration. The common and historical use of hydroelectricity – in some countries providing more than 50% of the overall electricity supply – is an excellent example of how annual seasonal variation can be successfully managed. In 2007, about 20% of the Danish electricity demand was met by wind energy (IEA, 2008a), with instantaneous penetration levels exceeding 100% of electricity demand in the west. Only a few years earlier, such an achievement was considered impossible (IEA, 2008c).

The current energy supply system is capable of dealing with significant variability in demand by combining "base load," "middle load," and "peak load" power plants. With a growing contribution from renewable energies, the concept of base versus peak load power plants will become increasingly obsolete. The goal will be to guarantee firm capacity and supplies from a variety of energy technologies and sources such that a reliable and environmentally sound supply is achieved at competitive costs. Innovative ways to pool various decentralized renewable energy sources – such as energy storage options, advanced infrastructures (like "smart grids," "virtual power plants," and "microgrids"), and long-distance energy transport between supply and demand clusters (FOSG, 2010; ENTSO-E, 2010) – are required to integrate especially variable renewable energy sources into low-carbon energy supply systems (see, e.g., ECF, 2010; Sims et al., 2011).

A distinction can be made between renewables being dispatchable (having a high potential to deliver when needed) and variable (having a low potential to deliver on each moment). Hydropower, biomass energy, geothermal energy, and ocean energy options like OTEC are dispatchable renewables. Solar energy, wind energy, and ocean energy options like tidal range are variable renewables.

The integration of variable renewables into energy systems, which is most challenging, is the focus of this section, especially their integration into larger-scale electricity and thermal heating and cooling systems. Some aspects of integrating biofuels in liquid fuel transportation systems are discussed in Section 11.2. Integrating energy systems is discussed in Chapter 15.

11.10.2 Integration of Renewables into Electricity Supply Systems

Normally, electricity systems consist of a number of power plants (units) that generate electricity to fulfill load demands and a transmission and distribution system that can deliver the generated electricity

to customers. Two concepts are of special importance: unit commitment and load dispatch. When a unit is running, it is committed. It does not need to be generating power, but all the implications of its start-up have been accepted by the system operator. After carrying out the commitment procedure, the operator has to organize the dispatch of the load to all the running units. These procedures are essentially optimization problems. Solving these problems can be difficult, especially when high levels of renewable energy sources and energy storage are incorporated (Van Wijk and Turkenburg, 1992). The unit commitment problem can be defined as "commit the units in an order such that total fuel and start-up costs of the system are minimized;" the load dispatch problem is to "dispatch the load and the spinning reserve to all committed units, such that the total fuel costs are minimized." Spinning reserve has to be available to cover power shortages caused by sudden outages of units or sudden sharp increases in the load (Van Wijk and Turkenburg, 1992).

Penetration of dispatchable renewables can take advantage of complementarity along the different periods of the year. In particular, biomass is harvested during part of the year to take advantage of its energy content and the better logistic facility. Harvesting time usually is coupled with bioenergy production, at least to reduce storage feedstock costs. On the other hand, hydroelectricity availability peaks during the rainy season and quite often at this time water supply exceeds demand or generation installed capacity. In some regions the harvest period for bioenergy feedstock occurs mainly during the low rain period, providing synergism of significant economic value, mainly when bioelectricity is one of the final energy forms obtained from biomass.

Deep penetration of variable renewables reduces the consumption of conventional fuels and the associated production of waste and emissions to the atmosphere. It also reduces somewhat the need for conventional power plants, because of the capacity credit of wind turbines and solar systems. However, it may also force dispatchable plants to contribute more to the spinning reserve and to operate in partial load, reducing conversion efficiencies and increasing fuel consumption. Enough backup power should be available to guarantee security of supply when solar or wind energy is not available. And there should be enough flexibility in the system to meet the variations in load and in availability of wind and solar resources. Finally, the transmission and distribution system should be able to cope with increases in distributed electricity generation associated with the use of renewables.

11.10.2.1 Distributed Electricity Generation

In conventional grid structures, electricity is fed into the grid at high voltage levels by relatively few large power stations and is brought to the customer via several intermediate grid levels. As generation becomes more widely distributed, the number of electricity sources increases and the direction of flow can be reversed. The distribution grids assume the function of transporting electricity in different (bidirectional) directions and become service providers between generators and consumers. Central power stations will continue to exist, but in addition there will be a large number of smaller, distributed systems. This change requires investments in many high-voltage distribution lines when the supply comes from MW-size power plants and in coordination of the operation of a large number of systems in the electricity distribution and transportation networks, facilitated by adequate information and communication technologies (Degner et al., 2006). Current grids are not designed to allow major amounts of electricity to be fed into the distribution grid. However, several solutions are under development to solve this, including converter technologies that also provide ancillary services to the grid and control schemes that enable a high penetration of distributed generation. These approaches are integral to the development of so-called Smart Grids.

As defined by the European Technology Platform for Electricity Networks of the Future (also called Smart Grids ETP), "a Smart Grid is an electricity network that can intelligently integrate the actions of all users connected to it—generators, consumers and those that do both—in order to efficiently deliver sustainable, economic and secure electricity supplies." A Smart Grid "employs innovative products and services together with intelligent monitoring, control, communication, and self-healing technologies to better facilitate the connection and operation of generators of all sizes and technologies, to allow consumers to play a part in optimizing the operation of the system, to provide consumers with greater information and choice of supply, to significantly reduce the environmental impact of the whole electricity supply system, and to deliver enhanced levels of reliability and security of supply" (Smart Grids ETP, 2010).

Quality of supply, power quality, grid control and stability, safety and protection, and standardization are considered the main challenges for a major deployment of decentralized generation. Scheepers et al. (2007) listed a number of ways to address these challenges:

- Active management of distribution systems to increase the accommodation of distributed generation (DG); typical examples are voltage control in rural systems and fault level control in urban systems through network switching;
- Development of intelligent networks where technological innovations on power equipment and information and communication technologies are combined to allow a more efficient use of distribution network capacities;
- Further development of the microgrid concept, based on the assumption that large numbers of micro-generators, connected to the network, can be used to reduce the requirement for transmission and high-voltage distribution assets;
- Pooling small (renewable energy) generators to create a virtual plant, either for the purpose of trading electrical energy or to provide system support services.

Microgrids are low-voltage or medium-voltage distribution systems with distributed generators, storage devices, and controllable loads. They are operated connected to the main power network or isolated from the main grid (Hatziargyriou, et al., 2007; Hatziargyriou, 2008; Microgrids, 2011). From the grid's point of view, a microgrid can be regarded as a controlled entity that can be operated as a single aggregated load or generator and, given attractive remuneration, as a small source of power.

Many system operators regard distributed generation as an additional complexity and thus fear additional costs (Scheepers et al., 2007). Nevertheless, distributed generation also offers potential benefits to electric system planning and operation. (See Table 11.40). However, the regulatory context is of key importance for deployment of distributed generation (Coll-Mayor et al., 2007).

Table 11.40 | Potential benefits of distributed generation.

Potential Benefit	Explanation
System reliability	DG can add to supply diversity. A distributed network of smaller sources may also provide a greater level of adequacy than a centralized system with fewer large sources. Reliability can also be enhanced if islanding is planned in case of faults.
Reduction in peak power requirements	Reduction in peak load can displace or defer capital investment, as the need for more expensive power plants is reduced.
Ancillary services	DG can provide ancillary services, particularly those that are needed locally, such as reactive power, voltage control, and local black start.
Power quality	DG can address power quality problems, particularly when the systems involve energy storage, power electronics, and power conditioning equipment. However, large-scale introduction of DG may also lead to instability of the voltage profile.
T&D capacity	DG can reduce transmission and distribution requirements and can contribute to reduced grid losses. On-site production of energy carriers can result in savings in T&D costs.

11.10.2.2 Forecasting the Short-term Availability of Wind and Solar Energy

The availability of renewable energy resources, especially wind and solar, can vary dramatically (Holltinen et al., 2007). Technical options like load management, energy storage, and improved interconnection of grids help match supply and demand, but good information on the availability of renewable energy sources in space and time is required to apply these options optimally.

The challenge with variable renewable energy at present "is not so much its variability, but rather its predictability" (IEA, 2008). To facilitate system integration and to reduce related costs, it is necessary to predict the available variable power hours or days ahead as accurately as possible. Sophisticated wind forecasting tools are available today, and interest in forecasting solar radiation is rising in parallel to the market uptake of PV systems and concentrating solar thermal power plants. But predictability is not the only issue to be solved. Reliability is also important. Long periods of low wind or sun, even if predicted accurately, require the power system to meet demand by running other capacity or importing electricity from elsewhere, which imposes additional cost.

There are two main approaches for wind power prediction (Jursa and Rohrig, 2008). One uses physical models of wind farms to determine the relationship between weather data from a numerical weather prediction model and the power output of the wind farm. The other is a mathematical modeling approach, in which statistical or artificial intelligence methods, such as neural networks, are used to model the relationship between weather prediction data and power output from historical data sets. This is currently used by several transmission system operators in three European countries. Artificial neural networks provide a time series of the instantaneous and expected wind power for a control zone for up to 96 hours in advance (Rohrig and Lange, 2008). Use of this system in Germany to make predictions a day ahead resulted in errors of around 5% (root mean square error, in percent of the installed capacity) for the entire German system. In addition, short-term (15 minutes to 8 hours ahead) high-resolution forecasts of wind power generation are generated, taking into account data from online wind power measurements of representative sites. A number of short-term prediction tools, both physical and statistical, are currently in use in Denmark, Germany, United States, Spain, Ireland, and Greece (Costa et al., 2008).

The difference between the forecasted and instantaneous wind power production can be minimized with advanced control strategies of wind farms. Pooling of geographically distributed large wind farms in a portfolio of one supplier allows optimized control of variable generation. This minimizes imbalance penalties.

Solar forecasting is not yet as mature as wind forecasting, but several models are under development. In general there are two approaches: short-term forecasting (a few hours ahead) and medium-term forecasting (up to two days ahead) (Heinemann et al., 2006). Short-term forecasting can be based on satellite data about solar irradiation and an algorithm calculating the motion of clouds. This approach improves considerably the prediction accuracy with respect to assuming persistency (that is, irradiation at hour h is identical to that at hour h-1). When forecasting one hour ahead, a relative root mean square error of about 30% can be obtained for an area of 31x45 km^2, while for a six-hour forecast this error increases to 40–50% (Heinemann et al., 2006). Medium-term forecasting can be performed using weather forecasts, with a three-hour temporal and a 0.25°x0.25° spatial resolution. Lorenz et al. (2009) have shown that the relative root mean square error could be 36% for a single location in Germany for a one-day-ahead forecast. Taking the whole of Germany, this error would reduce to 13%.

Table 11.41 | Storage options in electricity systems.

Scale	Response time	Typical discharge times	Storage technologies	Applications
Very large scale	> 15 min	days to weeks	Hydrogen storage systems	Reserve power compensating for long-lasting unavailability of wind energy
Large scale	< 15 min	hours to days	Compressed air storage Hydrogen storage systems Pumped hydro	Secondary reserve Minute reserve Load leveling
Medium scale	1–30 sec[a] 15 min[b]	minutes to hours	Batteries (Li-ion, lead-acid, NiCd) High-temperature batteries Zinc-bromine batteries Redox-flow batteries	Load leveling Peak shaving

[a] Primary reserve.

[b] Secondary and minute reserve.

11.10.2.3 Energy Storage Options

Energy storage in an electricity system allows generation to be decoupled from demand. Storage can also improve the economic efficiency and use of the entire system (Ummels et al., 2008). The broad range of available electricity storage technologies differ with respect to capacity, duty cycle, response time to full power, and load following capability.

Managing seasonal variation on electricity supply from hydro sources uses well-known storage procedures based in large water reservoirs able to keep above the average river flows due to either the rainy season or ice melting annual period, mainly in countries/regions with large penetration of this renewable source. Table 11.41 provides a summary of storage technologies appropriate for short periods compared with annual seasons and their typical applications.

Recent developments in electricity storage (see, e.g., Chen et al., 2009; Ibrahim et al., 2008; Meiwes, 2009) include the following:

- Adiabatic compressed air energy storage (CAES) incorporates compression heat into the expansion process and thus does not need additional fuel. The efficiency for adiabatic CAES is up to 70%.
- Lithium-ion batteries, with an efficiency of 90–95%, have become an important storage technology in portable applications.
- Redox-flow batteries allow the electrolyte to be stored in large tanks, making redox-flow batteries well-suited for large-scale applications. The system efficiency is in the range of 60–75%.

Hydrogen is considered a suitable storage option for fluctuating renewable electricity. The achievable energy density of compressed hydrogen is more than one order of magnitude higher than the one of compressed air. The storage of compressed hydrogen in salt caverns is currently the only technology with a technical potential for single storage systems in the 100 GWh range (Kleimaier et al., 2008) and for long (seasonal) storage periods. Different electrolyser technologies are under development to produce hydrogen from electricity. The most efficient conversion back to electricity can be achieved in combined-cycle power plants or in fuel cells. Round-trip efficiencies are expected to be in the range of 35–40% (Kleimaier et al., 2008), but a demonstration project in Norway shows 10–20% (Ulleberg et al., 2010).

The economic performance of a storage system depends on operating conditions and system costs, which can vary depending on required volume, conversion and generation capacities, and response times.

Figure 11.70 shows life-cycle costs for two storage applications: longer-term storage (500 MW, 100 GWh, 200 hour full load, ~1.5 cycle/month) and load-leveling (1 GW, 8 GWh, 8 hour full load, 1 cycle/day) (Kleimaier et al., 2008; Meiwes, 2009). For each storage option, Figure 11.70 shows a range of costs that spans from a low value representing "achievable costs expected within 10 years" to a high value of present (2008) costs. The life-cycle costs have been calculated assuming 8% interest rate and investment cost for the storage system, including necessary auxiliary units, power converters, and interfaces to the grid (Leonard et al., 2008). Component replacement has also been included, as well as the electricity price needed to cover losses. In both storage applications, pumped hydro systems are reported to be the most economic option, assuming appropriate geographic conditions. For long-term storage, hydrogen benefits from low volume-related costs due to its high energy density compared with adiabatic CAES. For load leveling, however, compressed air appears viable.

Battery technologies also can be used for load leveling, but costs are in the range of US_{2008}¢6.5–10/kWh up to more than US_{2008}¢30/kWh, depending on the technology used, and thus are well above the costs shown in Figure 11.70.

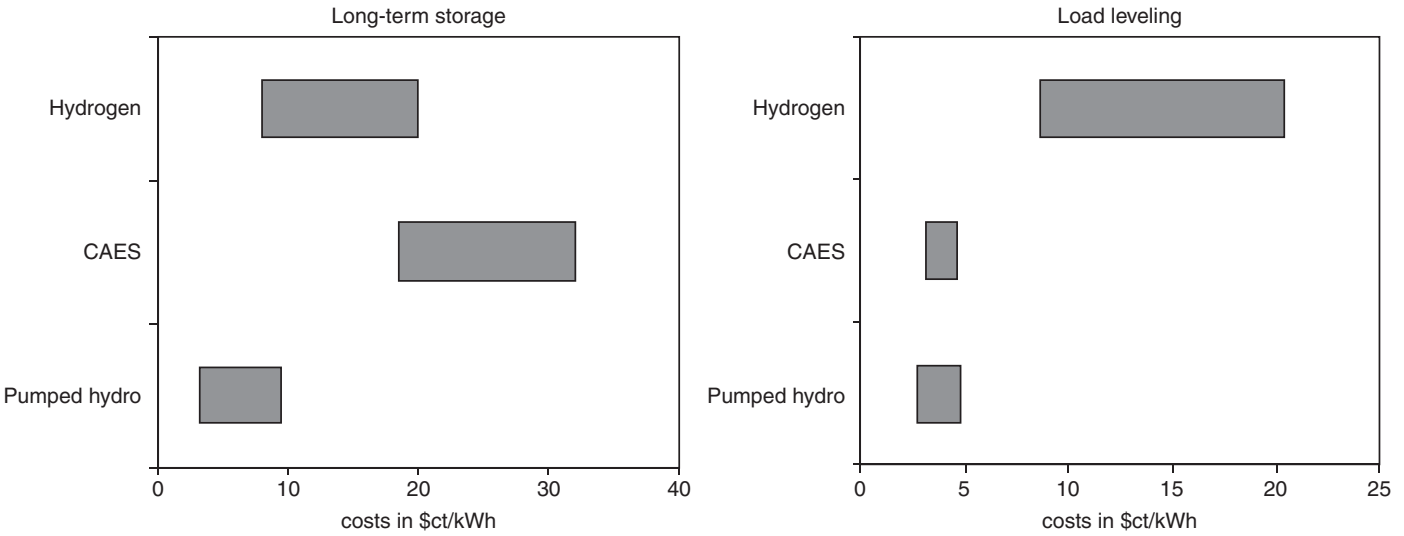

Figure 11.70 | Electricity storage costs for different storage options (US_{2008} ¢t/kWh). Source: Kleimaier et al., 2008; Leonard et al., 2008; Meiwes, 2009.

11.10.2.4 Vehicle-to-Grid Options

Because of the partly complementary nature of the electric power system and the light vehicle fleet, "vehicle-to-grid" (V2G) technologies may improve the ability of the electricity grid and the transportation system to integrate larger proportions of fluctuating renewables. The basic concept of vehicle-to-grid power is that electric vehicles (EVs) – including battery electric vehicles, fuel cell vehicles, and plug-in hybrids – can not only be charged by the grid but also can provide electricity and other services to the grid while parked. Each vehicle must have a connection to the grid for electrical energy flow, options for communication with the grid operators, and on-board control and metering devices. Figure 11.71 schematically illustrates the integration of electric vehicles and solar and wind technologies into an electricity supply system (Kempton and Tomić, 2005a).

Lund and Kempton (2008) show that wind electricity shares of more than 50% in the Danish power system lead to substantial excess wind power production, which reduces the revenues from wind electricity generation. The introduction of electric vehicles can reduce excess production. It can also improve the ability of power systems to integrate large proportions of wind power.

While the capital costs of power plants are high and thus motivate high use, personal vehicles are cheap per unit of power and are used only about 5% of the time for transportation, making them potentially available 95% of time for a secondary function (Kempton and Tomić, 2005a). Because vehicles have limited storage capacity and higher per kWh cost of energy than power plants, the generation of bulk power will not be the main business case for V2G concepts. V2G systems can, however, be competitive in providing spinning reserve and regulation capacity (Kempton and Tomić, 2005b; Dallinger, 2009).

11.10.2.5 Long-distance Electricity Transmission

While energy storage decouples supply and demand in time, transmission can decouple supply and demand in space. Transmission allows the pooling of different renewable energy sources, even on a transcontinental level (DESERTEC Foundation, 2011). Transmission distances have been limited because conventional alternating current transmission technology is suited to transmitting electricity only about 500 km. However, newer high voltage direct current (HVDC) technology can be used to link areas with large renewable resources to demand centers, thus facilitating the provision of dispatchable renewable bulk electricity over a larger distance (see Figures 11.71 and 11.72).

One of the advantages of HVDC is the low cost – in the range of US_{2005}¢0.7–2/kWh (for 700 TWh, 150 GW, 3000 km) – for transmission of very high power over very long distances (Asplund, 2007; Trieb and Müller-Steinhagen, 2007). The total losses for point-to-point transfer of power over 3000 km may be on the order of 5%. The loss rate increases with each injection/extraction point along the line (Klimstra and Hotakainen, 2011). Today's HVDC schemes have a maximum power of 3000 MW and a transmission distance of around 1000 km. Unlike with alternating current cables, there are no physical limitations on the distance or power level for underground or submarine HVDC cables. HVDC can be used to transfer power from wind parks offshore and to strengthen the electricity grid in areas where overhead lines are not feasible. Maximizing implementation of HVDC, however, will require international coordination and cooperation on a master plan for developing and optimizing super-grids for long-distance transmission. Technical limitations exist that need to be addressed, as well as some regulatory obstacles and economic concerns (Van Hertem and Ghandhari, 2010).

11.10.2.6 German Renewable Energy Combined Power Plant Demonstration Project

Following a 2006 German energy summit, leading German manufacturers of renewable energy technologies announced that they would prove the feasibility of a secure and constant provision of power using renewable energies only. The goal of the project was to demonstrate that the demand for electric power can be met fully by combining different forms of renewable electricity generation.

The so-called renewable energy Combined Power Plant (Combi-Plant) links and controls 36 wind (12.6 MW), solar PV (5.5 MW), biogas CHP (4 MW), and pumped hydro (1 MW) installations throughout Germany (Mackensen et al., 2008). (See Figure 11.73.) The plant is scaled to meet 1/10,000 of the electricity demand in Germany. This corresponds to the annual electricity requirements of a small town with around 12,000 households.

A central control unit is the core of the Combi-Plant. A control algorithm determines the optimum energy mix at any given point in time. Biogas and hydropower are used to balance fluctuations in wind and solar resources.

The Combi-Plant has been in operation since July 2007, and several months of real world operation were used to calibrate tools that control the plant. Figure 11.74 shows the simulated generation mix based on electricity demand data for 2006. Mackensen et al. (2008) conclude that the Combi-Plant is able to meet electricity demand entirely from renewable energy sources. The use of biogas, in particular, plays a central role in controlling the Combi-Plant by covering peak loads and balancing the natural fluctuations in wind and solar energy (Mackensen et al., 2008).

11.10.3 Renewables in Heating and Cooling

Heating and cooling demands from the industrial, commercial, and domestic sectors constitute around 40–50% of global final energy demand (IEA, 2007). Although there is a large potential for renewables in this sector, the use of renewables for heating and cooling generally receives less attention than electricity generation or the production of biofuels for transportation.

Solar thermal, biomass energy, and geothermal heat can provide various categories and scales of heating and cooling services. (See Table 11.42.)

A key challenge is to match seasonal variations in demand and supply. The increasing use of renewable energies for heating and cooling – but also the intensified use of waste heat from industrial processes, the expansion of combined heat and power generation, and the growing demand for air conditioning – calls for more sophisticated interaction between energy demand and supply options.

A fully autonomous energy supply for buildings using locally available sources is feasible. In most regions, however, an independent off-grid supply system causes oversizing of the capacity to produce energy carriers from renewables, in order to overcome the seasonal mismatch of demand and supply. In areas with an existing infrastructure, bringing together a variety of demand and supply options may facilitate the cost-effective integration of renewables, as complementary supply and demand patterns can help reduce system requirements.

The design, costs, and operation strategies of integrated renewable heating and cooling systems depend on local conditions – that is, the availability of renewable resources and the demand for heating and cooling services as a function of time.

11.10.3.1 Renewables in District Heating and Cooling Systems

The potential of renewable heating can be fully exploited primarily in settlement areas having a district heating system, in which centralized

plants create and distribute heat to residential and commercial customers. These systems are considered more efficient than distributed systems, such as boiler systems. Temperatures provided by them are typically 80–90°C, with about 45–60°C in the return system.

Figure 11.75 shows that world district heating supplies are about 10–11 EJ a year. District heating meets much of the heat demand of the residential, service, and other sectors in Iceland (94%), Russia (63%), Sweden (55%), Lithuania (50%), Finland (49%), and Poland (47%) (Euroheat & Power, 2007). The energy source can be fossil fuels, waste heat, biomass, geothermal energy, and (partly) solar thermal energy.

In the case of deep geothermal heat, a large demand is required to compensate for high drilling costs. In most cases, such a demand is only present in district heating networks. Selling waste heat might be crucial for the economic performance of geothermal electricity production, and that is possible only if large consumers or networks of consumers are available. It should be noted, however, that heating and cooling of buildings can also be achieved by applying heat pumps and using near-surface geothermal energy (see Section 11.4). Moreover, improving the building envelope to reduce heating and cooling needs will influence the competitiveness of district heating systems.

As with deep geothermal heat sources, the scale provided by district heating systems is a prerequisite for the economical integration of large-scale solar thermal systems with seasonal storage. In this case, large scale assumes solar meets 50% or more of the total heat demand. The energy gained by the solar collectors can be delivered via a collecting network to the heating central (see, e.g., Bodmann et al., 2005). From there, heat either can be supplied directly to the consumer or, in summer, stored for use in autumn and winter. A gas or biomass boiler can cover the remaining heat demand. A key component in such a system is the seasonal heat storage.

A district cooling system distributes cold from a central source to multiple buildings through a network of underground pipes. The distribution medium in this case is usually chilled water, which is typically generated by compressor-driven chillers, absorption chillers, or other sources like ambient cooling or "free cooling" from deep lakes, rivers, aquifers, or oceans. The temperature of the supply system is normally 1–7°C, while

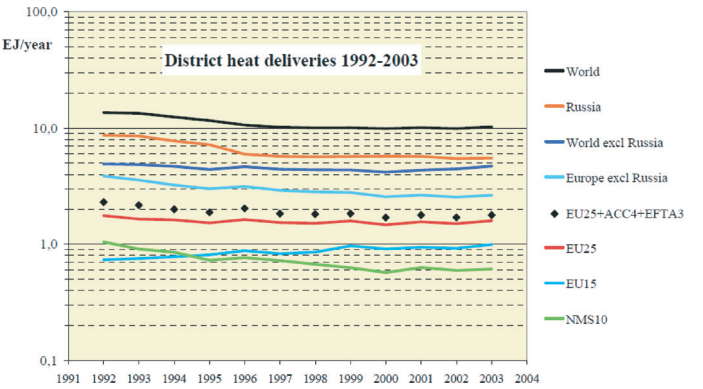

Figure 11.75 | Development of district heat in various parts of the world, 1992–2003. Source: Ecoheatcool, 2005–2006.

the return system is at 8–12°C (IEA-DHC, 2002; IEA, 2009). Cold water from the sea or a lake is applied in a number of projects in Sweden and other countries (see Section 11.9).

11.10.3.2 Thermal Energy Storage Options

The capacity of thermal storage systems ranges from a few kWh up to a GWh, the storage time from minutes to months, and the temperature from –20°C up to 1000°C. Capacity depends in part on the storage materials – solid, water, oil, salt, air – each of which has its own mechanism to store thermal energy. In household applications, water is almost exclusively the medium to store heat.

Storage systems may also rely on sorptive heat storage or latent heat storage (using so-called phase change materials). Both of these options allow thermal storage for an almost unlimited period of time but are at present in early development (Sharma et al., 2009).

The development of very large systems for seasonal heat storage has shown considerable progress in the last few decades. Various demonstration plants have been built. Four different storage types have been developed (Bauer et al., 2007, 2010; Mangold, 2007):

- *Hot water heat storage* has the widest range of possibilities, as it is independent of geological conditions and can be used in small

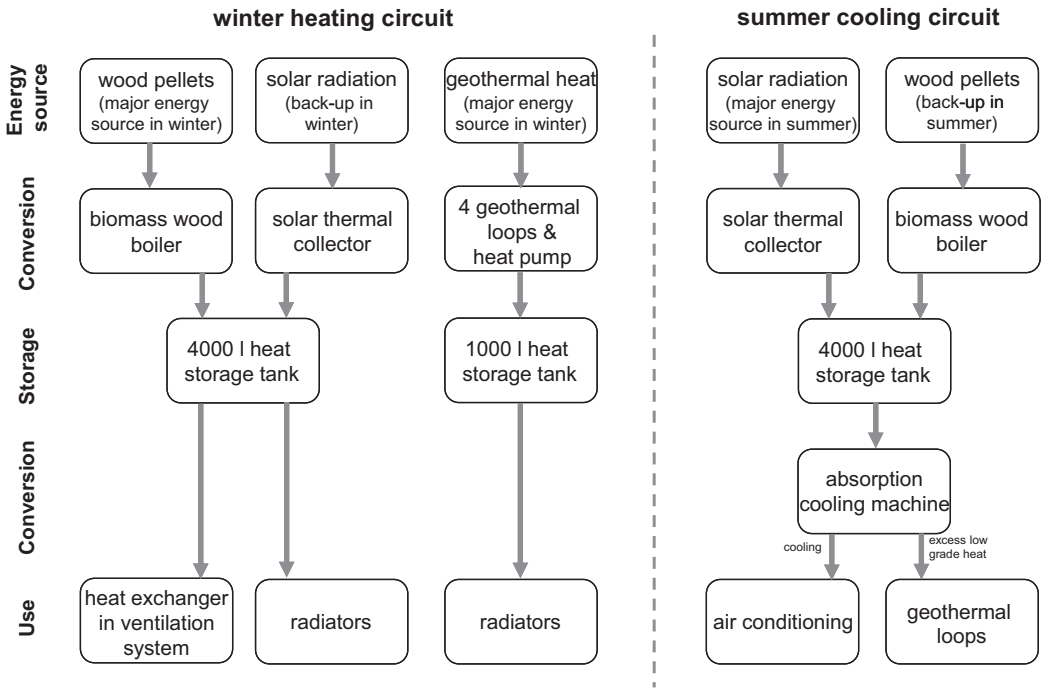

Figure 11.76 | Renewable heating and cooling system in the Renewable Energy House, Brussels, Belgium. Source: adopted from EREC, 2008.

amounts, such as heat storage for a period of days. It consists of a water-filled containment of steel-enforced concrete, which is partly submerged into the ground.

- *Gravel/water heat storage* consists of a pit sealed with a water-proof synthetic foil, filled by a storage medium of gravel and water.
- Using *borehole thermal energy storage*, heat is conducted via U-tube probes directly into water-saturated soil. These polybutane tubes are inserted into bore holes with a diameter of 10–20cm, which are 20–100m deep. The operational behavior is slow, as heat transport within the store occurs mainly by conduction.
- *Aquifer heat storage* uses natural layers of underground water to store heat. Water is taken out of the aquifer through well boreholes, heated, and then pumped back into the store through another borehole.

The suitability of a storage system depends on local geological and hydro-geological conditions.

Both ice and chilled water storage are used in district cooling plants. Chilled water storage systems are generally limited to a temperature of 4°C due to density considerations. Ice-based storage systems can achieve temperatures of 0.5–1°C. The cool storage is most commonly sized to shift part of the cooling load, which allows the chillers to be sized closer to the average than the peak load (IEA-DHC, 2002). An alternative can be to store cold underground or in aquifers. In Europe, this technology is most widely applied in Sweden (Norden, 2006).

11.10.3.3 Two System Integration Case Studies

The Renewable Energy House in central Brussels is an office building with meeting facilities of approximately 2.800 m². The plan for refurbishing the 140-year-old building was designed to reduce the annual energy use for heating, ventilation, and air conditioning by 50% compared with a reference building and to cover energy demand for heating and cooling with 100% renewable energy sources (EREC, 2008). Key elements of the system, illustrated in Figure 11.76, are two biomass wood pellet boilers (85 kW + 15 kW), 60 m² solar thermal collectors (30 m² evacuated tube collectors, 30 m² flat plate collectors), four geothermal energy loops (115m deep) exploited by a 24 kW ground source heat pump in winter and used as a "cooling tower" by the thermally driven cooling machine in summer, and a thermally driven absorption cooling machine (35 kW cooling capacity at 7–12°C).

In winter, the heating system mainly relies on the biomass pellet boilers and the geothermal system. The solar system and the biomass boilers heat the same storage tank, while the geothermal system operates on a separate circuit. The core of the cooling system is the thermally driven absorption cooling machine, which is powered from relatively low temperature solar heat (85°C) and a small amount of electrical power for the control and pumping circuits. Because solar radiation and cooling demands coincide, the solar thermal system provides most of the heat required for cooling. The solar system is backed up on cloudy days by the biomass boiler. The geothermal borehole loops absorb the low-grade excess heat from the cooling machine, thus serving as a seasonal heat storage system in the winter.

In Crailsheim, Germany, a former military area is currently being transferred into a new residential area in which more than half of the total heat demand will be covered by solar energy. A prerequisite for achieving such high solar shares is the use of a seasonal heat storage facility. The new residential area consists of former military barracks, a school and a sports hall equipped with 700 m² of solar collectors, and new single-family buildings. The residential area is separated from a commercial area by a noise protection wall, which houses the main part of the solar collectors. The first phase of the project focuses on 260 housing units with an expected total annual heat demand of 4100 MWh. The total solar collector area is 7300 m². A borehole thermal energy storage system with 80 boreholes at a depth of 55m provides seasonal storage. In a second phase, the residential area is extended by 210 housing units. The total collector area will then be around 10,000 m², and the seasonal storage system will consist of 160 boreholes. The solar system is separated into diurnal and seasonal parts. Solar heat costs are estimated to be around US_{2005}¢15/kWh (Mangold and Schmidt, 2006; Mangold 2007).

11.10.4 The Way Forward

Various studies on the integration of renewables into electricity grids focus on the challenges it poses and inform strategies on how to proceed. A number of studies have assessed the impacts of up to 35% renewables in the western and eastern grid areas of the United States (EnerNex, 2010; IEEE, 2009; Piwko et al., 2010). The main findings were that renewable energy represents a near-term, leveragable opportunity, provided that issues like siting, access to transmission, and systems operations are well addressed (Piwko et al., 2010). Renewable energy penetration on the order of 30–35% (30% wind, 5% solar) is operationally feasible, assuming significant changes to current operating practice (NERC, 2008; Arent, 2010). NERC (2008) made several specific recommendations:

- Diversify supply technologies across a large geographical region to leverage resource diversity.
- Use advanced control technology to address ramping, supply surplus, and voltage control.
- Ensure access to and the installation of new transmission lines.
- Add flexible resources, such as demand response, V2G systems, and storage capacity.
- Improve the measurement and forecasting of variable generation.
- Use more-comprehensive system-level planning.
- Enlarge balancing areas to increase access to larger pools of generation and demand options.

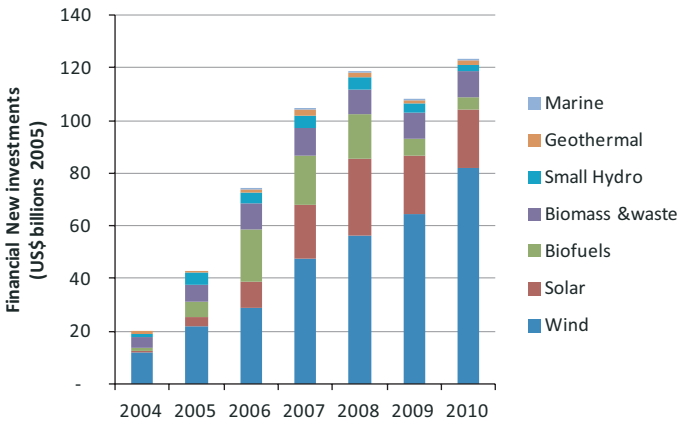

Figure 11.77 | Financial New Investments in New Renewable Energy, 2004–2010 ($US_{2005}$$ bn). Note that investments in larger-scale hydropower (>50MW) are excluded. Source: UNEP and BNEF, 2011.

Recent investigations are focusing on system-level solutions, in which information technology-enabled power management, advanced forecasting, adaptive and shiftable loads, and advances in energy storage go hand in hand in moving toward power systems with a larger share, possibly a majority, of renewable generation (Denholm et al., 2010; US DOE, 2010b; Krewitt et al., 2009a; Sterner, 2009).

Another important development is the European Electricity Grid Initiative, which is aiming in vision and strategy to enable high penetration rates of renewables (EEGI, 2010) through the integration of national networks into a market-based pan-European network.

11.11 Financial and Investment Issues

11.11.1 Introduction

This section provides information on developments in financing renewable energy for the period 2004–2010. A breakdown of global transactions in non-hydro renewables in 2010 is also shown. The section then describes trends in public policies and public finance mechanisms that aim to stimulate private investments in renewables. From the results, it is clear that – in terms of investments – renewables have become a mainstream energy option.

11.11.2 Commercial Financing

The renewable energy sector has mostly seen increasing levels of financing in the past 10 years. Figure 11.77 shows the trend for financial new investments in new renewables (excluding large hydropower, governmental and corporate R&D, small projects, and solar water heaters) for the period 2004–2010, with a breakdown for different technologies. Between 2004 and 2010 financial new investment increased six-fold to

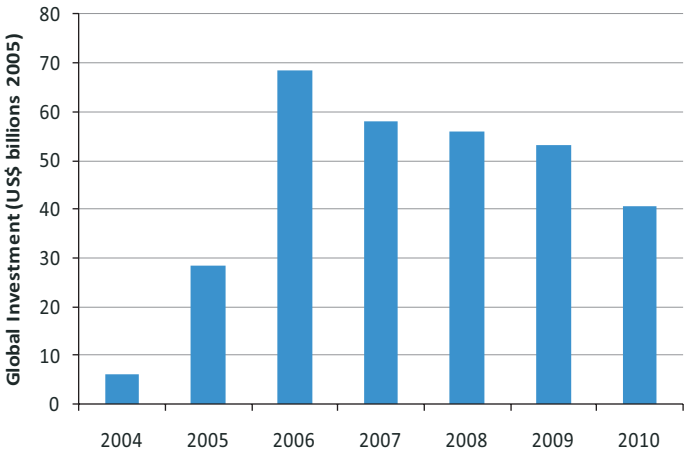

Figure 11.78 | Investments in larger-scale hydropower, 2004–2010 ($US_{2005}$$ bn). Source: based on International Journal of Hydropower and Dams Annual Directory, 2004; 2005; 2006; 2007; 2008; 2009, estimating US$1500/MW average cost of new plant and UNEP and BNEF (2011) for the 2010 value.

$US_{2005}$$123 billion, indicating a compound annual growth rate of 36% (UNEP and BNEF, 2011).[10]

Figure 11.78 shows similar investment data for larger-scale hydroelectricity generating capacity for the period 2004–2010. Reporting investment figures in hydropower on a year by year basis is not easy due to the relatively long building time of hydro developments. Generating capacity can also be added at established dams, and progress on both activities is rarely reported annually.

Government and corporate R&D and small projects totaled $US_{2005}$$59 billion in 2010, while investments in solar water heater were estimated at $US_{2005}$$9 billion (UNEP and BNEF, 2011). Including estimated new investments in larger-scale hydropower of $US_{2005}$$40 billion, the total new investment in renewables in 2010 was about $US_{2005}$$230 billion.

A regional breakdown of financial new investments in renewables for the period 2004–2010 is presented in Figure 11.79. It shows strong increases in total investments in Asia and Oceania but stagnation in 2008–2010 in North America, Europe, and South America.

Figure 11.80 provides a breakdown of the total investment of $US_{2005}$$182 billion in 2010 by different financing type: venture capital investments ($2 billion), corporate and governmental R&D support ($3 billion and $5 billion, respectively), private equity investments ($3 billion), public equity investments ($13 billion), asset finance ($110 billion), and investment in small distributed capacity ($52 billion).

10 For conversion of current value US$ to $US_{2005}$$ throughout this section the international time series of USDA www.ers.usda.gov/Data/Macroeconomics/ was used (downloaded in August 2011). In $US_{2010}$$ Financial new investment was $143bn, plus $68bn in Governmental and corporate R&D and Small projects and an estimated 10bn$ decentralized and small scale investment in solar water heater.

Different forms of financing are used for technology development and commercialization, equipment manufacture and scale-up, project construction, and re-financing and sale of companies (mergers and acquisitions, or M&A). This last category is not shown in the Figures since it does not represent new investment in the sector but rather a recycling of funds between early investors and those that later buy them out. The trends in financing along this continuum represent successive steps in the innovation process and provide indicators of the sector's current and expected growth as follows (see also Mitchell et al, 2011):

- Trends in technology investment indicate the mid- to long-term expectations for the sector – investments are being made in new technology developments that will only begin to pay off several years down the road.
- Trends in manufacturing investment indicate near-term expectations for the sector – essentially, that market demand will be sufficient to justify new manufacturing capacity.
- Trends in new project investment indicate current sector activity – that is, the number of new renewable energy plants being constructed.
- Trends in industry mergers and acquisitions indicate the overall maturity of the sector, since increasing refinancing activity over time shows that larger, more conventional investors are entering the sector, buying up successful early investments from first movers.

Each of these trends is discussed in the following sections.

Table 11.43 provides information about the variety of financing types, arranged by phase of technology development. An important catalyst that will influence these trends is the price of fossil fuels, particularly oil and gas. As "easy oil" becomes scarce, the dependence on fossil fuel imports increases and environmental emissions decrease; renewable energy investments in all four dimensions are also expected to increase (see, e.g., REN21, 2010). However, the availability and pricing of natural gas present competitive challenges to the attractiveness of investing in renewable energy technologies.

11.11.2.1 Financing Technology Development and Commercialization

While governments fund most of the basic R&D, and large corporations fund applied or "lab-bench" R&D, venture capitalists begin to play a role once technologies are ready to move from the lab-bench to the early market deployment phase (Mitchell et al., 2011). According to Moore and Wüstenhagen (2004), venture capitalists have initially been slow to pick up on the emerging opportunities in the energy technology sector, with renewable energies accounting for only 1–3% of venture capital investment in most countries in the early 2000s. Since 2002, however, venture

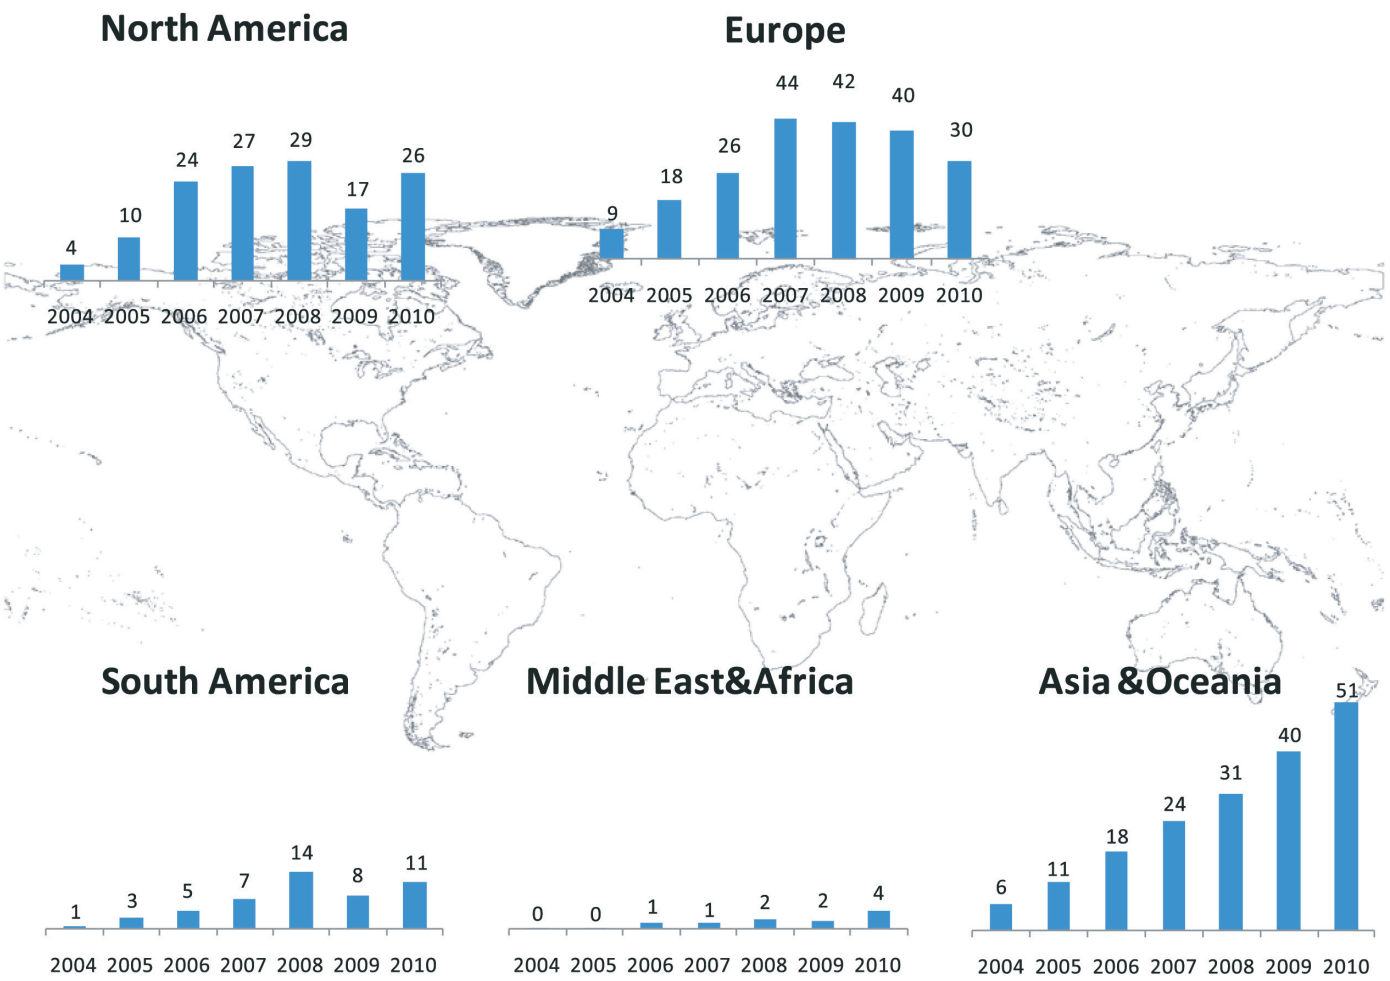

Figure 11.79 | New financial investments in renewable energy, by region, 2004–2010 (US$$_{2005}$bn). New investment volume adjusts for reinvested equity; total values include estimates for undisclosed deals. This comparison does not include small-scale distributed energy projects or larger-scale hydropower investments. Source: UNEP and BNEF, 2011.

capital investment in RE technology firms has increased markedly. Venture capital into RE companies grew from about US$_{2005}$400 million in 2004 to US$_{2005}$2.2 billion in 2010, representing a compound annual growth rate of 33% (UNEP and BNEF, 2011). This growth trend in technology investment has been an indicator that the finance community expects continued growth in the RE sector. Downturns such as those experienced in 2008/2009 may slow or reverse the trend in the short term, but in the longer term an increasing engagement of financial investors is foreseen in RE technology development (UNEP and BNEF, 2010; 2011).

11.11.2.2 Financing Equipment Manufacturing and Scale-up

Once a technology has passed the demonstration phase, the capital needed to set up manufacturing facilities will usually come initially from private equity investors (those financing un-listed companies) and subsequently from public equity investors buying shares of companies listed on public stock markets (Mitchell et al., 2011). Private and public equity investment in RE grew from about US$1 billion in 2004 to US$16 billion in 2010, representing a compound annual growth rate of 68% (UNEP and BNEF, 2011).

As discussed in Mitchell et al. (2011), in 2008 and 2009 the trading prices of shares in publicly listed companies on the global stock markets in general dropped sharply from the peaks of 2007, but RE shares fared worse due to the initial energy price collapse and the fact that investors shunned stocks with any sort of technology or execution risk, particularly those with high capital requirements (UNEP and BNEF, 2010). By 2010, even with the overall financing picture for renewables much improved, the prices of publicly traded stocks remained depressed largely due to concerns over changes in subsidy regimes and the lower profit margins that manufacturers were earning in many countries (UNEP and BNEF, 2010).

11.11.2.3 Financing Project Construction

Financing construction of renewable energy generating facilities involves a mix of equity investment from the owners and loans from the banks

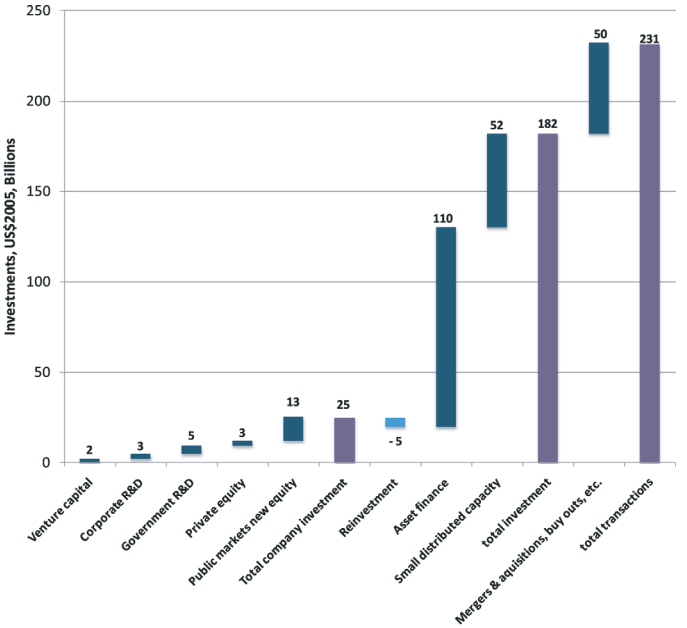

Figure 11.80 | Global Transactions in Renewable Energy in 2010 (US_{2005} bn). Includes all investments as well as acquisition. Source: UNEP and BNEF, 2011.

(private debt) or capital markets (public debt raised through bond offerings). The share of equity and debt in a project typically ranges from 20/80 to 50/50, depending on the project context and the overall market conditions. Both types of finance are combined into the term "asset finance," which represents all forms of financing secured for renewable energy projects (Mitchell et al., 2011).

Asset financing to this sector grew from US_{2005}18 billion in 2004 to US_{2005}110 billion in 2010, representing a compound annual growth rate of 35% (UNEP and BNEF, 2011). In recent years capital flows available to RE projects have become more mainstream and have broadened, meaning that the industry has access to a far wider range of financial sources and products than it did around 2004/2005 (UNEP and BNEF, 2011). For instance the largest component of total renewable energy capital flows today is through project finance investment (Deutsche Bank, 2010a,b), an approach that mobilizes large flows of private-sector investment in infrastructure (Mitchell et al., 2011).

11.11.2.4 Financing Small-scale Technology Deployment

Consumer loans, micro-finance, and leasing are some of the instruments that banks offer to households and other end-users to finance the purchase of small-scale technologies. (See Box 11.3) But most investment in such systems comes from the end-user themselves, usually through purchases made on a cash basis. UNEP and BNEF (2011) estimates that US_{2005}52 billion was invested in 2010 in small-scale RE projects ("small distributed capacity"), up from US_{2005}9 billion in 2004, representing a compound growth rate of 34%.

Table 11.43 | Overview of financing types arranged by phase of technology development.

Development Phase	Financing Types
R&D	Public and corporate R&D support to (further) develop technology is provided through a range of funding instruments.
Technology Commercialization	Venture capital is a type of private equity capital typically provided for early-stage, high-potential technology companies in the interest of generating a return on investment through a trade sale of the company or an eventual listing on a public stock exchange.
Equipment Manufacturing and Scale-up	Private equity investment is capital provided by investors and funds directly into private companies often for setting up a manufacturing operation or other business activity. (This can also apply to project construction.) Public equity investment is capital provided by investors into publicly listed companies most commonly for expanding manufacturing operations or other business activities, or to construct projects. (This can also apply to project construction.)
Project Construction	Asset finance is a consolidated term that describes all money invested in generation projects, whether from internal company balance sheets, from debt finance, or from equity finance. Project finance is debt obligations (loans) provided by banks to distinct, single-purpose companies, whose energy sales are usually guaranteed by power off-take agreements. Often known as off-balance sheet or non-recourse finance, since the financiers rely mostly on the certainty of project cash flows to pay back the loan. Corporate finance is debt obligations provided by banks to companies using "on-balance sheet" assets as collateral. Most mature companies have access to corporate finance but have constraints on their debt ratio and therefore must rationalize each additional loan with other capital needs. Bonds are debt obligations issued by corporations directly to the capital markets to raise financing for expanding a business or to finance one or several projects.
Small-scale Technology Deployment	Small and medium-size enterprise finance is realized in different forms – such as consumer loans, micro-finance, and leasing – and is generally provided to help companies set up the required sales and service infrastructure.
Carbon Mitigation	Carbon finance can be in the form of loans or investment obtained from some banks or investors in return for future carbon revenue streams. Examples include the CDM and JI under the Kyoto Protocol.
Refinancing and Sale of Companies	Mergers & acquisitions involve the sale and refinancing of existing companies and projects by new corporate buyers.

An interesting development, especially with decentralized solar technologies, is the advent of new small-scale financing approaches. In industrial countries, solar equipment manufacturers in the United States have led the way, realizing that they could help overcome capital-cost barriers by acting as financial intermediaries. One of the main financing tools used is the third-party power purchase agreement, which by some estimates drove 60% of the solar capacity installed in California in 2007 (Deutsche Bank, 2010a). Under a third-party power purchase agreement, a third party designs, builds, owns, operates, and maintains

Box 11.3 | End-user Financing for Small-scale Renewables

Many developing countries have rural electrification programs today, and an increasing number of these rely on renewables and distributed financing models to provide access in off-grid areas. Besides electrification, many other clean energy systems and services are being installed with a range of end-user finance approaches.

For example, in Tunisia UNEP has jointly run the Prosol Solar Water Heating Programme with the energy agency and electric utility, helping realize over 95,000 household installations through bank financing made via customer utility bills. UNEP has also run a loan program with two of India's largest banking groups, Canara Bank and Syndicate Bank, helping to kick-start the consumer credit market there for solar home system financing. More than 19,000 homes where financed over three years, and the market continues to grow, with other banks now beginning to lend. Today UNEP has 20 such small-scale end-user finance programs operating in the developing world.

Source: Haselip et al; 2011

the solar systems and sells back solar-generated electricity to the end-user. This model removes the burden of significant upfront costs from the end-user and also allows the solar contractor, who has significantly greater expertise than the end-user, to assume the responsibility for system installation and maintenance (UNEP, 2008).

11.11.2.5 Financing Carbon Mitigation

The carbon markets include a range of instruments used to monetize the CO_2 offset value of climate mitigation projects. According to the World Bank (2009), the primary carbon markets associated with actual emission reductions – the CDM, joint implementation (JI), and voluntary transactions – decreased from US$8.2 billion in 2007 to US$7.2 billion in 2008.

According to the UNEP Risø CDM Pipeline Analysis (UNEP Risø, 2011), renewable energy projects now account for the majority of CDM projects, with 60% of all validated and registered CDM projects, 35% of expected certified emissions reductions (CERs) by 2012, and 13% of CERs issued to date. The low share of CERs issued is mostly due to the very large industrial gas mitigation projects that have been small in number but quick to build, accounting for 75% of CERs issued to date.

The Risø CDM Pipeline Analysis has also calculated the total underlying investment associated with building the proposed 4968 carbon mitigation projects that have reached at least the CDM validation stage in 2010. Of the US$60 billion of total projected investment, US$39 billion (65%) is for renewable energy projects.

11.11.2.6 Refinancing and the Sale of Companies

In 2010, about $US_{2005}$$50 billion worth of mergers and acquisitions took place involving the refinancing and sale of renewable energy companies and projects, up from about $US_{2005}$$6.5 billion in 2004, for 41% compound annual growth (UNEP and BNEF, 2011). M&A transactions usually involve the sale of generating assets or project pipelines or of companies that develop or manufacture technologies and services. Increasing M&A activity in the short term is a sign of industry consolidation, as larger companies buy out smaller, less well capitalized competitors. In the longer term, growing M&A activity indicates the increasing mainstreaming of the sector, as larger entrants prefer to buy their way in rather than developing businesses from the ground up (Mitchell et al., 2011).

11.11.3 Linking Policy and Investments

Policies and their design play an important role in improving the economics of renewable energy systems, and as such they can be central to catalyzing private finance and influencing longer-term investment flows. Stern (2009) has proposed that governments have a role to play in reducing the cost of capital and improving access to it by mitigating the key risks associated with renewable energy investments, particularly non-commercial risks that cannot be directly controlled by the private sector. FITs, for instance, have been found to be particularly effective for mobilizing commercial investment (REN21, 2010). They enhance the possibility of project financing, as the guaranteed cash flow increases the willingness of banks to lend money (Deutsche Bank, 2010a; Couture 2010).

Private-sector investment decisions are underpinned by an assessment of risk and return. Financiers want to make a return proportional to the risk they undertake; the greater the risk, the higher the expected return (Justice, 2009). Expectations about the level of risk that will be taken, and the returns required, vary with different financial institutions. A policy framework to induce investment will need to be designed to reduce risks and enable attractive returns and to be stable over a time frame relevant to the investment. To be fully effective, or "investment grade,"

a policy needs to cover all the factors that are relevant to a particular investment or project (Hamilton, 2009).

11.11.4 Public Financing

The most important role of governments may be to create an enabling environment (a "policy framework") to achieve accepted policy objectives. For many countries, however, creating enabling policies on their own may be insufficient to mobilize the many types of investment needed to move a technology from innovation to deployment to market transformation. Public funding and related interventions may therefore be needed to bring down market barriers, bridge gaps, and share risks with the private sector (UNEP, 2008a).

Public finance mechanisms (PFMs) have a twofold objective: to directly mobilize or leverage commercial investment into renewable energy projects and to indirectly create scaled-up and commercially sustainable markets for these technologies. To make the best use of public funding, it is essential that both these outcomes are sought when designing and implementing such mechanisms. For example, direct short-term benefits should not create market distortions that indirectly hinder the growth of sustainable long-term markets (UNEP, 2008a).

There is a growing body of experience with the use of PFMs for promoting investments in renewable energy deployment. Their role is to help commercial financiers act within a national policy framework, filling gaps and sharing risks where the private sector is initially unwilling or unable to act on its own (UNEP, 2008a).

According to UNEP (2008a), the following are the most common types of PFMs used to mobilize investment in climate change mitigation broadly, all of which are relevant to the renewable energy sector:

- credit lines to local commercial financial institutions for providing debt financing (loans) to projects;
- guarantees to share with local commercial financial institutions and sponsors the risks of providing financing to projects and companies;
- debt financing provided directly to projects;
- loan softening programs, to mobilize domestic sources of capital;
- financing of private equity funds that invest risk capital in companies and projects;
- equity financing provided directly to companies and projects; and
- grants and contingent grants to share elevated project development, transaction, or capital costs.

Using these mechanisms to facilitate access to finance is necessary, but access alone is seldom sufficient for getting clean energy or other low-carbon technologies deployed and scaled up (UNEP, 2008a). Successful mechanisms typically combine access to finance with technical assistance programs designed to help prepare projects for investment and build capacity.

Many finance facilities were created but did not disburse funds because they failed to find and generate sufficient demand for the financing (UNEP, 2008a). Successful public funding mechanisms actively reach back into the project development cycle to find and prepare projects for investment; that is, they work on both the supply and the demand sides of the financing equation. Strategies to generate a flow of well-prepared projects for financing can involve partnerships with many market actors, such as utilities, equipment suppliers and project developers, end-user associations, and government authorities (UNEP, 2008a).

11.11.5 Renewables as a Mainstream Energy Option

Whether renewables can now be considered a mainstream energy option can be best seen by examining the power sector (Usher, 2008). In total, and excluding large-scale hydropower (above 50 MW), about US_{2005}170 billion was invested in new renewable power generation plants in 2010, compared with about US_{2005}200 billion for fossil-fueled power plants (UNEP and BNEF, 2011). This is about the same as more than half of Spain's total electricity generating capacity. So this is not only about success in Germany, Spain, Denmark, and a few other countries; it is becoming a global phenomenon.

As shown in Figure 11.1, new renewables still represented only about 8% of global power capacity and about 4.5% of global electricity generation in 2010. According to UNEP and BNEF (2011), new renewables accounted for about one-third (about 60 GW) of total global electricity capacity installed in 2010, whereas all renewables accounted for about 47% (84 GW) of net power additions worldwide. REN21 (2011), however, estimates the net power additions worldwide at 194 GW in 2010, with renewables accounting for approximately half (about 96 GW).

More will be needed to meet the challenges ahead. In August 2007, the Secretariat of the United Nations Framework Convention on Climate Change published *Investment and Financial Flows to Address Climate Change*, which estimated that US$200–210 billion in additional investment will be required annually by 2030 to meet global GHG emissions reduction targets (UNFCCC, 2007). The technical paper concluded that although the lion's share of this investment will need to come from the private sector, substantial public funding will be required to mobilize and leverage the needed private capital (UNEP, 2008a).

11.12 Policy Instruments and Measures

11.12.1 Introduction

Increased use of renewable energy technologies (RETs) can address a broad range of goals, including energy security, economic development, and emission reductions. For this to occur, policy measures have been used to overcome the barriers within the current energy system that prevent wider uptake of renewables. In addition to continued R&D aimed at performance improvements, cost reductions, and system integration, a key issue is how to accelerate the deployment of renewable energy so that deep penetration of renewables into the energy system can be achieved quickly.

This section considers some of the key market failures in developing and deploying renewable energy, the policies in place to overcome them, the need to encourage technological and social innovation, and the appropriate frameworks for investment. It also explores positive links between renewable energy and other policies, such as climate change policies and water policies. (Chapters 22 to 25 provide more in-depth analysis of energy policies in general.)

11.12.2 Need for Policy Intervention and Policy Frameworks

The overall supply and use of energy within the global marketplace does not currently reflect the importance of energy's role in relation to economic, social, and environmental goals. Brown and Chandler (2008) evaluated more than 300 policies and measures grouped into nine categories of "deployment activities": tax policy and other financial incentives; technology demonstrations; codes and standards; coalitions and partnerships; international cooperation; market conditioning, including government procurement; education, labeling, and information dissemination; legislative act of regulation; and risk mitigation. The comprehensive taxonomy underscores how many different policies can affect the innovation value chain related to the reduction of GHGs (and many specific to renewable energy) and the importance of choosing policies that will have the intended impacts (Mitchell et al., 2011).

Given the enormous size and momentum of the current global energy system, in combination with capital intensity and technology lock-in, new technologies such as renewables face significant market barriers. To address these, policy measures should ideally enable not just a level playing field where renewables can compete fairly with other forms of energy; they should also support RE development so that they can overcome the additional hurdles to their deployment that result from inertia to change the incumbent socioeconomic-technical system (see, e.g., Hughes, 1983).

11.12.2.1 Market Failures

While competitive markets operate effectively for many goods and services, a number of failures need to be addressed in relation to energy. A central concern is the way that markets currently favor conventional forms of energy by not fully incorporating the externalities they are responsible for and by continuing to subsidize them, thereby making it harder to incorporate new technologies, new entrants, and new services in the energy system. This both distorts the market and creates barriers for RE (Johansson and Turkenburg, 2004; Mitchell, 2008).

The negative externalities of using fossil fuels include impacts on the environment, health, safety, and security (Johansson and Turkenburg, 2004; Bosello et al., 2006). Similarly, the potential benefits that renewables can offer – such as increased energy security, access to energy, reduced economic impact volatility, climate change mitigation, and new manufacturing and employment opportunities – are also often not accounted for when evaluating the return on investment.

These issues are exacerbated by ongoing subsidies for fossil fuels. Global fossil fuel subsidy levels have been estimated at between US_{2005}170–317 billion – and even as high as US_{2005}516 billion (IEA, 2010f), compared with US_{2005}15.5 billion for renewable energy (UNEP and BNEF, 2008).

11.12.2.2 Failures in the Innovation System

Innovation is central to the development and deployment of new and existing energy technologies. Innovation can be considered as a chain in which technologies move through a number of stages from basic R&D to full commercialization, as well as encouragement for social innovation. (Social innovation concerns the ability of people and institutions to be able to change the way they do things so as to adapt and support the emergence and deployment of RE technologies; Kok et al., 2002).Technologically, this comprises both a supply push from the R&D side of the chain and a demand pull from the market as a technology approaches commercialization.

As technologies advance through these stages, there are both performance improvements and cost reductions (Grubb, 2004). At each stage of the chain, policy instruments may enable (or deter) the appropriate funding to be available – through either public or private means. Figure 11.81 provides an overview of the innovation chain. It shows the need for a seamless linking of policies to provide basic and applied R&D funds early on through to market expansion-type policies later on.

As discussed in Chapter 24, however, innovation is a complex, non-linear process that involves dynamic feedback among the actors, organizations, and networks that include market mechanisms and the flow of knowledge (see also Foxon et al., 2007). As Grubb (2004) describes, the playing field is not level in terms of the introduction of new technologies

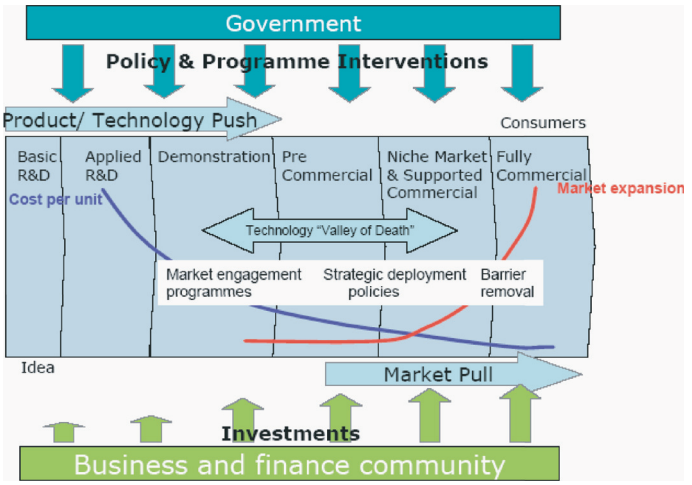

Figure 11.81 | Overview of Innovation System. Source: Grubb, 2004.

due to the nature of large energy systems, which are capital-intensive with long life spans that therefore do not encourage innovation and rapid technology turnover.

Incumbent energy technologies are also mature in terms of their cost and the infrastructure, skills, and knowledge that accompany them (Johansson and Turkenburg, 2004). This results in "lock-in" of technologies and institutions, which favors the energy incumbents and creates a range of barriers for RETs. Some technologies can become stuck along the way. This occurs from a range of risks that relate to the technology itself not performing, market uncertainty, concerns of regulation, and the issues with the system itself, such as lock-in (Turkenburg, 2002). These risks and uncertainties can make it difficult to secure the necessary investment to get a technology through the technology "valley of death."

Policies to address these risks and market failures can also encourage a balanced approach to funding across the innovation chain: one that focuses on research, development, and demonstration as well as deployment phases and that helps reduce the risk that technologies will become stuck (Turkenburg, 2002; Watson, 2008; Foxon et al., 2007).

11.12.2.3 Failures Related to Investment

It is clear that RETs face a number of factors that make it harder for them to compete based solely on costs:

- capital intensity, scale, and resource risk;
- a discounted value to traditional utility operators;
- real or perceived technology risk;
- the absence of full-cost accounting for environmental impacts on a level playing field; and
- a lack of recognition of the long-term value owing to reduced variable fuel cost exposure.

These issues have a negative impact on attractiveness for investors by extending the time frame for returns or by increasing risk and expected rate of return. These risks can be reduced by using public-sector financial or market instruments such as guarantees in terms of market access, market size, and price security (Johansson and Turkenburg, 2004; Mitchell, 2008; Baker et al., 2009).

Support for technological innovation can help create a positive environment for development, demonstration, and commercial deployment investment (Foxon et al., 2007). In contrast, there are many examples of the impact of inconsistent and unsustained policies on renewable energy in terms of creating uncertainty, damaging commercial interest, preventing manufacturing, and creating boom-and-bust markets (Sawin, 2004b). The result is market instability, an increasing perception of risk, and a loss of investor confidence, which can affect development of individual technologies.

11.12.3 Policy Approaches for Renewable Energy

A wide range of regulatory, fiscal, and voluntary policies have been introduced globally to promote renewable energy. These serve a range of technology-specific objectives, including innovation, early-stage development and commercialization, manufacturing, and market deployment, as well as wider political goals such as new manufacturing bases for a technology, local and global environmental stewardship, and economic prosperity. These policies all help to reduce risk and encourage RET development and are generally used in combination. (See Table 11.44).

Using a portfolio of policies helps to control total costs and increase successful innovation and commercialization, providing the policies complement each other (Foxon et al., 2007). The means of using financial instruments are described in section 11.11. To get renewable technologies through the "valley of death," it is important to note that (IEA, 2008b):

- market growth results from the use of combinations of policies;
- long-term, predictable policies are important;
- multi-level involvement and support from national to local actors is important; and
- each policy mechanism evolves as experience with it increases.

Policy approaches for RE intend to address the innovation chain both technologically and socially, to pull technologies to the marketplace and

Table 11.44 | Summary of renewable energy policies.

Policy	Definition	End-use Sector		
		Electricity	Heat/Cooling	Transport
Regulatory Policies				
Targets	A voluntary or mandated amount of RE, usually a percentage of total energy supply	X	X	X
Access-related Policies				
Net metering	Allows a two-way flow of electricity between generator and distribution company and also payment for the electricity supplied to the grid	X		
Priority access to network	Allows RE supplies unhindered access to network for remuneration	X	X	
Priority dispatch	Ensures RE is integrated into energy system before supplies from other sources	X	X	
Quota-driven Policies				
Obligation, mandates, Renewable Portfolio Standards	Set a minimum percentage of energy to be provided by RE sources	X	X	X
Tendering/bidding	Public authorities organize tenders for a given quota of RE supplies and ensure payment	X		
Tradable certificates	A tool for trading and meeting RE obligations	X	X	
Price-driven Policies				
Feed-in tariff (FIT)	Guarantees RE supplies with priority access, dispatch, and a fixed price per unit payment (sometimes declining) delivered for a fixed number of years	X	X	X
Premium payment	Guarantees RE supplies an additional payment on top of their energy market price or end-use value	X	X	
Quality-driven Policies				
Green energy purchasing		X	X	
Green labeling	Usually government-sponsored labeling that guarantees that energy products meet certain criteria to facilitate voluntary green energy purchasing	X	X	X
Fiscal Policies				
Accelerated depreciation	Allows for reduction in tax burden	X	X	X
Investment grants, subsidies, and rebates	One-time direct payments usually from government but also from other actors, such as utilities	X	X	X
Renewable energy conversion payments	Direct payment by government per unit of energy extracted from RE sources	X	X	
Investment tax credit	Provides investor/owner with an annual tax credit related to investment amount	X	X	X
Other Public Policies				
Research and development	Funds for early innovation	X	X	X
Public procurement	Public entities preferentially purchasing RE or RE equipment	X	X	X
Information Dissemination and Capacity Building	Communications campaigns, training, and certification	X	X	X

commercialize them, and to improve the financial attractiveness and investment opportunities of RE.

Of the market pull policies, two are most common: policies that set a price to be paid for RE and that ensure connection to the grid and offtake (i.e., FITs) and policies that set an obligation to buy but not necessarily an obligation on price (often known as a quota or obligation mechanism but also referred to as a Renewable Portfolio Standard or Renewable Fuel Standard (RFS) and sometimes as a Renewable Electricity Standard). So far, FITs have been for electricity only, although some countries, such as the United Kingdom, are now considering how to provide them for heat (DECC, 2009). Quotas have so far been used for electricity, heat, and transport. Biofuel mandates are now a common occurrence globally.

Table 11.45 indicates the number of countries that have introduced policies to promote renewable, which is increasing nearly across the board.

Table 11.45 | Recent development of the implementation of Renewable Energy policy instruments.

Policy instrument	End 2005	End 2007	End 2009	End 2010
Countries with policy targets	55	66	80	96
States / provinces / countries with FITs	41	56	80	87
States / provinces / countries with RPS policies	38	44	51	63
States / provinces / countries with biofuels mandates	38	53	64	60

11.12.3.1 Innovation-driven

R&D is the policy instrument intended to meet the early requirements of the innovation chain. However, support needs to be balanced across this innovation chain (IEA, 2008b) because learning through doing or utilization can focus R&D beneficially (Neij, 2008; Junginger et al., 2010).

Research and development is generally targeted to both increase performance and reduce costs of newer technologies. New forms of collaboration between researchers, such as joint road mapping (NEDO, 2009) or the Scholarships for Excellence program (BIS, 2010), may also lead to increased and targeted innovation. Investments in energy R&D are low within total national R&D budgets (UNEP, 2008b), and only a small part of those budgets is directed toward renewables (IEA, 2010g).

Changing energy behaviors is not simple, but it is critical to reduce overall energy use and enable the widespread adoption and application of renewable energy. There is often a gap between support for RE in opinion polls and buying, investing, or enabling RE projects to gain planning permission (Devine-Wright, 2005). Increasingly, policies are being implemented that are intended to support RE but also to change people's attitudes and behaviors. For example, the United Kingdom has a Low Carbon Challenge program that has supported 25 communities implementing RE but that also has used the process to educate communities and individuals about reducing GHG emissions (DECC, 2010).

11.12.3.2 Price-driven

The most widely used price-based policy is the FIT. Other RE price policies are premium payments, which are often set as a percentage or an amount over an electricity price (for example, Spain offers the choice between an amount over the retail price (Lucas Porta, 2009). While beneficial, premium payment structures are more risky because the price of electricity moves up and down, so investors may not be sure about the payment they will receive.

FITs guarantee a price for the sale of qualified (such as renewably generated) electricity and allow the supply of investment to determine the resulting volume or capacity. FIT rules differ by country, but a "standard" electricity FIT includes an obligation to connect the renewable project to the grid, its priority dispatch (see section 11.10), and the purchase of any electricity generated at a fixed minimum price (which is generally above the market level for a set time period). In addition, the payment usually declines over time according to a rate known at the time of initial contracting, to take account of technological learning and maturity (Couture et al., 2010). This approach minimizes the risk of investment and, if designed appropriately, should provide attractive risk-adjusted returns on investment.

FITs were first introduced in the United States in the late 1970s and since then have become the most widely adopted class of promotional policy globally. Much of the growth in their use has been within the last decade as some countries enact new policies and others adjust and refine existing tariffs. Their popularity is linked to their ability (if well designed and implemented) to offer sufficient rates of return over the economic life of the technology at low risk (Klessman et al., 2010). To date, FITs have had a large impact on the development and deployment of wind, PV, biomass, and small hydro (REN21, 2010). The transaction costs involved with FITs are lower than those of quotas (Mitchell et al., 2006). This means that the number and diversity of actors taking up the opportunity of an FIT are far greater than with quota mechanisms, which in turn has a number of other positive benefits, such as new market entrants and reduced excess profits (Jacobsson et al., 2009). However, the payment and cost structure for FITs, as exemplified by recent restructuring in Germany and Spain, have raised concerns over FIT design and best practices (Kreycik et al., 2011, Coture et al., 2010).

11.12.3.3 Quantity-driven

Renewable Portfolio Standards set an obligation for renewable capacity or volume such as a percent of electricity or share of fuels, and the market determines the price at which this is achieved. This obligation often increases over time toward a set total or date, and the requirement to meet it can be placed on producers, distributors, or consumers (Sawin, 2004a,b). Most RPS policies require a renewable power share of 5–20% by a set date, generally 10–20 years ahead. Such targets translate into expected future investments, but the means of achieving it are often flexible (REN21, 2008).

For electricity generation, quota systems can be based on obligation or certificate mechanisms in which investors, generators, or utilities have to achieve specific targets and are penalized if they do not. Credits are created through the generation of renewable electricity such as green

certificates, green labels, or renewable energy credits. To meet the obligation, it is possible to generate renewable electricity, enter into a contract with others to do so, or buy a valid credit in the marketplace. Quotas or obligations can be more complicated to administer than FITs (Mitchell et al., 2006). Moreover, like the UK mechanism, they can do little to minimize the risk of investment if their obligation is only for purchasing rather than including a minimum price or a minimum contract length. But they have the benefit of letting government know the maximum cost per year (Mitchell et al., 2006).

An alternative approach within quotas can involve tendering systems in which both the total share of electricity and a maximum price per kilowatt-hour are set. Developers then submit prices for contracts in a one-off bidding round to compete for funds and contracts (Sawin, 2004).

11.12.3.4 Quality-driven

Quality-driven RE policies aim to ensure energy that says it is renewable actually is RE (and produced sustainably), in the hope that this will encourage greater voluntary RE purchasing. For example, green labeling ensures that the consumer buys RE that is generated and verified as original source. The European Union's requirement for a guarantee of origin on all RE generated within Europe enables trading but also ensures that each unit of energy can only be used once. The US voluntary green power market has similar quality assurance standards and has been growing strongly for many years (Bird et al., 2009).

Voluntary green energy purchasing can include utility pricing programs, retail sales in liberalized markets, and voluntary trading of renewable energy certificates (used in some countries within quota-based systems). Within these schemes, consumers pay a premium price for the green power, which helps to encourage investment in RETs, although the level of premiums may be declining. It is estimated that in 2009 there were over 6 million green power customers in Australia, Canada, Europe, Japan, and the United States (REN21, 2010).

11.12.3.5 Financial Incentives

A range of financial incentives are also in use globally to support RETs, such as policies that use taxes, rebates, grants, payments, and subsidies. (See also section 11.11.) They are used to help "level the playing field" either by lowering the cost of RETs relative to conventional energies or by increasing the value of the RE sold to make it easier for the technologies to compete in the market (Sawin, 2004). They can be linked to a price per kilowatt-hour or to an installed capacity.

Tax incentives are commonly used to provide financial support, through either a production tax credit or an investment tax credit, both of which encourage the investment and build-out of a RET. Production tax credits in the United States provide a financial benefit based on the generated amount of energy from renewable energy sources, which helps reduce the payback period and therefore increase the rate of return, making investment more attractive. As the reward is based in the amount of energy generated, these credits can encourage technologies and installations that are reliable and continuously improving. Other forms of tax relief can reduce the cost of investing in renewables, such as accelerated depreciation, value added tax exemptions, or the removal of import duties (Sawin, 2004).

In 2010, at least 52 countries had some sort of direct capital investment policy in place (REN21, 2011), from national to local levels, offering typically 30–50% of installed cost (mostly for smaller-scale distributed systems such as solar PV). These have been tied to certain technologies in many countries, with PV in particular receiving widespread support that has led to its rapid market growth; in other countries financial support has been offered for a wider range of renewables (REN21, 2010). There is debate about whether a payment should be made upfront on the "capital" outlay or on the output (the energy). Early US experiences shaped global RE policy perceptions that payment on outputs was more efficient (Karnoe, 1993). Yet both instruments, or options among them, may be used. In some cases grants may also be used, either when tax-related policies are deemed ineffective (Bolinger et al., 2009) or when the goal is to encourage small-scale investors (DECC, 2009).

Another means of providing increased revenue (and thus a better rate of return) to investors is net metering, which allows grid-connected generators to sell excess power into the grid, with an obligation for utilities to purchase the excess. (See, for example, US DOE, 2011c). The reimbursement or rebate may be based on retail or wholesale prices and may include a time-of- day value as well. Net metering laws now exist in at least 14 countries and nearly all US states (REN21, 2011).

11.12.4 Other Enabling RE Policies

11.12.4.1 Targets

Targets provide a marker by which all actors involved can assess the situation and act in their own best interests. Establishment of a goal or target may increase investor and developer confidence and may also provide a basis for possible future policy or regulation direction, but it does not set a legal obligation.

Targets have been steadily developing over the last three decades, but the rate of growth and their geographic spread have increased significantly only recently. At the end of 2010, an estimated 96 countries worldwide had policy targets for renewable energy (see Table 11.45), with further targets existing in individual states, provinces, municipalities, and individual cities.

The approach taken for renewable energy targets varies by country and can include a percent share of electricity production, a share of

total primary/final energy supply, an installed capacity target, or total amounts of energy extracted from renewable sources. In addition, the time frame for targets varies from 2010–2012 to 2020–2025 and beyond. Some countries have technology-specific goals, and many also have targets for biofuels or blending requirements.

In the European Union, policies adopted in late 2008 as part of the energy and climate package included agreement on a 20% final energy from renewables target and a 10% target for transport fuels, with sustainability criteria. The legally binding targets are spread across all 27 member states and build on earlier EU-wide targets for 2010 (European Parliament, 2009). China has adopted a national target of 15% of primary energy from renewable by 2020, while India has a range of long-term goals to 2032 that include 15% of power capacity and 10% of transport fuels from renewable energy (REN21, 2010).

11.12.4.2 Economic Regulation

As already highlighted, fossil fuels and nuclear power continue to receive significant subsidies globally, and there can be hidden barriers to RE in economic regulatory approaches. For example, obligations to purchase RE, public investment in distribution networks, and access rules to transmission networks may all favor incumbents and create a market barrier to new entrants (Baker et al., 2009). Exemptions from risks or liabilities and the structure of energy markets may also unfairly penalize intermittent forms of generation (Sawin, 2004; Mitchell, 2008; Morthorst et al., 2007). Removal of these barriers addresses the cost competitiveness of renewables against conventional energies and it may enable the energy system to be more efficient and secure (Gottstein, 2010). For example, the United States has recently developed transmission policies to take account of the difficulties in predicting output for some renewables, giving them a fairer chance in a system designed for conventional generation (REN21, 2008). Allowing electricity markets to include wind forecasts that are nearer market closure is also helpful (Jónsson et al., 2010).

11.12.4.3 Planning and Permitting

Almost all surface areas of the globe are now influenced by ownership, conservation, traditional use, or commercial interests. As a result, the growing deployment of RE technologies may create tensions. Policymakers therefore attempt to balance a planning regime that broadly supports RE use and deployment while at the same time establishing processes that ensure public insight and environmental protection.

Obtaining planning permission for an RE (or any other) project is a social process when different actors and stakeholders are able to become involved and share their views. There is clearly a positive side to this (Ellis et al., 2009). On the other hand, lengthy permitting processes, high application costs, lack of local or regional capacity to deal with RE applications, and (sometimes) local opposition can make the permitting process expensive and time-consuming (Breuker and Wolsink, 2007).

Social acceptance and a commitment to effective planning and permitting help reduce risk and the cost of deployment of RE solutions. Codifying the framework into a set of legal, formal rules and procedures to address the differences and mediate conflicting interests and values is a long-term transition process; the planning and policy process is only one part of that (Agterbosch et al., 2009). Streamlining application processes, adopting benefit-sharing schemes, simplifying legal documents, and so forth are all helpful to permitting for RE (Ellis et al., 2009). However, speeding up the planning process may mean that local participation is inherently reduced.

11.12.5 Heating and Cooling and Transport

11.12.5.1 RE Heating and Cooling

Relative to electricity or liquids for RE fuel, renewable heat has had very little policy support, and RE for cooling has been the subject of even fewer mechanisms. The use of renewable heat is widespread. (See sections 11.2, 11.4, and 11.8.) Examples include solar water heating in China, geothermal heating in Iceland, and biomass CHP in Sweden, although these have resulted from a confluence of factors rather than a specific RE support policy. Policy mechanisms in place are similar to those for electricity, although they have different names: bonus mechanisms (similar to the FIT for electricity) in the United Kingdom; a "use" obligation, where building regulations can compel the adoption of renewable heat technologies (in Germany); standards and building regulations to ensure a minimum quality of hardware and installation alongside the "use" obligations; and fiscal instruments such as tax credits, capital grants, and soft loans (Seyboth et al., 2008).

11.12.5.2 RE Transport

Currently, 95% of the world's transport relies on petroleum, and there is evidence of this increasing annually (IPCC, 2007a; IEA, 2010b). Considerable attention is being given to increasing the share of transport services provided by renewables directly through liquid and gaseous fuels and indirectly via electricity.

Again, policies for renewable transport are similar to those for RE electricity and heat. Policies in Europe and North America that promote the use of RE in transport applications include renewable/low carbon fuel standards, tax incentives, R&D, RFSs, GHG emission standards, preferential government purchasing, and regulation standards and licenses for production and sale of renewable energy carriers (Altenburg et al., 2008; Felix-Saul, 2008).

Care is needed to ensure that the increased use of biofuels (and biomass more generally) does not have negative sustainability impacts and that bio-resource policies account for the wider context of energy policy, as biofuel production may reduce options for other forms of biomass, for food production, and for other uses or destinations. (See also Chapter 20.)

11.12.6 Links with Other Policies

Supporting renewable energy may have other benefits, such as climate change mitigation, poverty eradication, rural development, protection of water resources, energy security, infrastructure development, employment, and demand reduction through energy efficiency.

11.12.6.1 GHG Reduction and Local Environmental Improvements

One of the most obvious and strategic policy links is with climate change, as the supply and use of energy is the main driver of GHG emissions globally (IPCC, 2007b; IPCC, 2011). As a result, there are significant RE policies around the globe to reduce GHG emissions (REN21, 2010). In addition, there are other environmental benefits in relation to air quality and pollution. This includes the reduction of particulates, low-level ozone, sulfur, and nitrogen oxides everywhere (IPCC, 2007a). One exception to this general assumption, however, is the traditional use of biomass, particularly in developing countries, where poor combustion for heat and cooking lowers indoor air quality and has serious health impacts. In these circumstances, access to better technology and cleaner fuels, including fossil fuels, can dramatically improve air quality and health. (See Chapter 4.)

11.12.6.2 Poverty Eradication

The opportunities for renewable energy to help with poverty eradication and the broader Millennium Development Goals are significant, as energy services have been shown to be essential to achieving these. This requires policies to increase both the quality and the quantity of affordable energy services in the world's poorest countries (Modi et al., 2006). The UN has emphasized the close links between energy use and the eight MDGs (UN, 2009). The IEA estimates that 22% of the global population was without access to electricity in 2008 – around 1.5 billion people, 85% of whom live in rural areas. The organization estimated that this figure had fallen by 500 million since 2002. The extent to which this related to the deployment of renewables is less clear. But several programs have focused on this; for example, China has introduced an RE program, including the Riding the Wind Plan and the Brightness Project on solar energy to provide electricity to people in remote areas not been served by small hydropower efforts (World Bank, 2010; see also Chapter 19).

11.12.6.3 Invigorating Agriculture and Rural Areas

Efforts are increasingly being made to replace fossil fuels with biofuels and with biomass from agriculture in order to reduce GHG emissions (IPCC, 2007a) and fossil fuel imports. This can include the use of crops, crop residues, wood, and animal wastes, and additional resources are available from forestry and waste streams. Linking agricultural and renewable policies more closely could help maximize this resource potential while supporting rural development, creating jobs, increasing local energy availability, and yielding other social and environmental benefits (WIREC, 2008). But a range of issues need to be addressed to ensure that these benefits do not have negative impacts on food production, biodiversity, sustainable management of soil and water, and other sustainability criteria. (See Chapter 20.) Increasing the scale of bioenergy deployment globally will also need to take careful account of the socioeconomic-political conditions within a country as well as local resources and assets (WIREC, 2008).

11.12.6.4 Provision and Protection of Water Resources

There are a number of direct links between energy and water policy, including the possible massive reduction of water needs for thermal power plant cooling and the use of RETs to replace expensive diesel for water pumping, desalination, and purification (Bates et al., 2008). These applications, often at small scale, can directly support the MDGs, as they can provide local reliable and clean water while reducing the time it takes to gather water in many developing countries (UN, 2009). Water is also a key global resource for generating power, particularly the large-scale hydro that provides a large amount of electricity in developing and industrial countries. At the same time, biomass-based renewables and concentrated solar power in desert areas may introduce new demands for water. (See Chapter 20.) The substitution of RE for other energy sources may also have a beneficial impact on water usage and quality, such as mining for coal.

11.12.6.5 Energy Security

Energy security policies, while not uniformly framed across countries, have begun to link the development and support of RETs to the reduction in risk of supply and economic volatility of fossil fuels (see, e.g., University of Exeter and University of Sussex, undated). RE can improve the security of energy supply in a variety of ways, including reducing dependence on imported fuels, helping to diversify supply, enhancing the national balance of trade, and reducing vulnerability to price fluctuations (Mitchell et al., 2011).

These various benefits are driving a number of governments to adopt policies to promote RE. In the United States, for example, development and extension of the national Renewable Fuel Standard were framed within the context of reducing imported oil (Arent et al., 2009). In Japan,

with few domestic energy resources, solar energy allows the domestic generation of electricity, with associated policies to support R&D and market deployment. For the last 30 years Brazil has promoted ethanol from sugarcane as an alternative to fossil transport fuels in order to decrease dependency on imported fuels (Solomon et al., 2007). China established its 2005 Renewable Energy Law in part to diversify energy supplies and safeguard energy security. A number of municipalities and local communities are also adopting RE plans to become more energy self-sufficient (St. Denis and Parker, 2009; Mitchell et al., 2011).

11.12.6.6 Infrastructure Development

As discussed in section 11.10, expanded use of renewables will require infrastructure developments that allow distribution of energy for heat, power, and transport applications. Heat tends to be used close to the point of production, often through local heat distribution networks. Changes to transport infrastructure depend on the type of renewable energy that may be exploited, but a significant switch to hydrogen or battery vehicles, for example, may require considerable new up-front planning and infrastructure (Lund and Clark, 2008). An integrated, holistic planning approach may also benefit changes in electricity infrastructure to accommodate more renewables (Baker et al., 2009; Arent, 2010).

The existing infrastructure in many countries was originally designed around large fossil fuel and nuclear generating plants. As such, the operational mindset may be focused on the original intent, so quick change can be difficult. To date, this has not been a major problem in many countries, as grid infrastructure has been designed to meet peak load requirements, meaning most countries have been able to accommodate increasing amounts of renewables while maintaining supply security and reliability. This is likely to become an increasing challenge, however, as the contribution from renewables increases, since some (like wind and solar) are variable resources.

Needed changes can be achieved through planned upgrades and pre-investment in preparation for future renewables or through making the grid infrastructure more active. Linked to the latter approach is the increasing interest in more-intelligent smart or micro grids, demand response, storage, and load shifting. These are based on clusters of connected, distributed generation that are collectively controlled to manage output (Battaglini et al., 2009). Both the European Union and the United States are developing such grids to improve reliability and lower costs (Coll-Mayor et al., 2007). Another approach being considered is "supergrids," which are based on large-scale transmission of renewable electricity over very long distances (Battaglini et al., 2009; FOSG, 2010; DESERTEC Foundation, 2011). This can include connections between existing national grids to balance power, as well as the much more strategic construction of new high-voltage distribution lines to bring in larger areas of supply potential. There are also opportunities to combine approaches to create a "supersmart" grid (Battaglini et al., 2009).

11.12.6.7 Improving Economic Development and Employment

The global financial crisis in 2008 spawned an unprecedented policy response, totaling US_{2005}2.65 trillion in stimulus spending by March 2009 (UNEP, 2009). The UNEP 2010 Sustainable Energy Finance Initiative report stated that 9% of the US_{2005}165 billion in global green stimulus packages had been spent by the end of 2009, with greater shares expected in 2010 and 2011(UNEP and BNEF, 2010). Broadly, these "global green stimulus packages" refer to direct and indirect expenditures on a broad suite of energy solutions, including RETs, energy efficiency, advanced materials, and "smart grids."

There are considerable employment opportunities within the renewable energy sector. UNEP (2009) estimated that approximately 2.3 million people found employment in renewables in recent years; REN21 reports that around 3.5 million direct jobs had been created by 2010 (REN21, 2011). UNEP also stated that projected investments to 2030 – not taking into account the full impacts of the financial and economic crisis – could result in at least 20 million additional jobs globally. These figures mask the complexity involved, as any major international switch to renewables is likely to be accompanied by job losses in the fossil-fuel-based energy sectors.

Frankhauser et al. (2008) provide a useful analysis of employment over time. They highlight the work of Kammen et al. (2006) that compared 13 studies within the European Union and the United States. The more labor-intensive nature of new renewables resulted in net increases in employment over the short term. In the medium term there are economy-wide effects that reinforce overall employment gains. Research in Germany from BMU (2006) showed that just over 50% of 157,000 renewable energy-related jobs were directly related to manufacture and operation, with the rest in related industries. The biggest effects will be felt in the long term, as technical change and innovation create a dynamic impact that results in job creation, productivity improvement, and growth. Although jobs are lost in conventional energy industries, the authors suggest that overall employment may increase on a net level. A more recent EU report (EU, 2009) generally supports this. Additional research is required, however, to better capture the employment and macroeconomic impacts of renewable energy at the local, regional, and global level.

Relative to conventional energy, the renewable market is still small, with a few countries accounting for the bulk of installations. For example, the top five countries for wind power have 72% of global installed capacity. Many of these top countries also have the manufacturing capabilities for RETs and their associated jobs. Some have made specific policy decisions to link renewables to their national economic strategies. Germany's support for renewable energy, for instance, resulted in a competitive export industry (Frankhauser et al., 2008), enabling it to obtain a global share of the market, particularly in wind and PV (UNEP, 2008b). This is true for other countries too: China has become a major global player in many RETs in a short time and is capturing a growing part of the global market for, among other technologies, solar hot water. However, this pattern

also suggests that although competitive advantages can be gained by being an early mover, over time such advantages may balance out as other countries – currently China and India – develop their own manufacturing and export capabilities for RETs (UNEP, 2008b).

11.12.7 Development Cooperation

Technology transfer between countries is a prominent area of discussion in international meetings and summits (Brewer, 2008), but it has been a sticking point at many negotiations between industrial and developed countries (Ockwell et al., 2008). As this topic is discussed in Chapters 22–25, this section is limited to a discussion of cooperation on renewable energy.

11.12.7.1 National Systems of Innovation

National Systems of Innovation play an important role in technology development and its potential for wider distribution within the market. (See Chapter 24.) Foxen et al. (2005) describe the concept of national systems in innovation used by the OECD, which characterizes the innovation system in terms of complex flows of knowledge, influence, and market transactions between a wide range of actors and institutions. These processes vary between countries, but they set the framework for innovation at a national level and help shape the process of technology development.

In the case of renewables, innovation is influenced by national policy intervention, targets, and wider policies relating to R&D and infrastructure development. This should result in a reduction in the cost of RETs and should increase their commercial uptake (Ockwell et al., 2008), assuming that the policies are well designed and implemented. National systems of innovation are therefore important in helping to develop new, commercial renewables for deployment within both industrial and developing countries.

11.12.7.2 Capacity Building

A central part of cooperation between nations involves building capacity within developing countries. (See Chapter 25.) As Ockwell et al. (2008) highlight, the transfer of technology in itself may not have a sustained impact on the uptake and development of low-carbon technologies unless it is accompanied by a transfer of knowledge and expertise, such as information on installing, operating, and repairing the equipment. These broader educational aspects help increase the capacity of companies and therefore the likelihood of effective deployment.

Article 4.5 of the UN Framework Convention on Climate Change (UNFCCC) obliges Annex I countries to ensure the availability of affordable clean technologies to non-Annex I countries. Parties to the convention have agreed on a technology transfer framework (UNFCCC, 2007) that includes five areas for action: technology needs and needs assessments, technology information, enabling environments, capacity building, and mechanisms for technology transfer.

As discussed in Mitchell et al. (2011), perhaps the most important insight in the evolution of technology and innovation in the past 30 years is the recognition that technology transfer is not an end in itself but a means to achieving a greater strategy of technological capacity building (Mytelka, 2007). Technology transfer mostly takes place between firms via the market – through the use of products or services that incorporate a specific technology or through licensing the capability to produce such products, either by an indigenous firm or through a joint venture arrangement or foreign direct investment (Kim, 1991, 1997; UNCTAD, 2010). Its sustainability relies crucially on the successful learning of one party from another and the effective application of that information and knowledge in generating marketable products and services.

11.12.7.3 Impact of the Clean Development Mechanism

The CDM enables Annex I countries to support the development of projects to reduce GHG emissions within developing countries. As of August 2011, a total of 3392 projects were registered, and more than 50% of these were for renewable projects (cdm.unfccc.int). In assessing the contribution of CDM to technology transfer, Schneider et al. (2008) suggest that although the program was not designed for this, it does contribute to the process, as developing countries can gain access to technologies that may not have been available previously. The literature, they suggest, shows that the CDM contributes to the transfer of equipment and capacity building by lowering several existing barriers and by increasing the quality of transfers. They suggest that it is currently the strongest mechanism that the UNFCCC has for technology transfer of RE, although its effectiveness varies considerably with geography, technology, and project size.

11.12.7.4 Role of International Institutions, Arrangements, and Partnerships

Given the nature of development cooperation today and the potential benefits that renewables can offer, a number of initiatives are in place to encourage the transfer of technologies. This includes the work of specific bodies that support countries on climate change, development, and sustainability, including bodies like the UN Development Programme and the UN Industrial Development Organization.

There is an ongoing interest in technology transfer under the mechanisms agreed as part of the UNFCCC:

- Article 4 includes promotion and cooperation on development, application, and diffusion, including the transfer of technologies that

help to mitigate emissions. It also calls for practical steps that promote, facilitate and finance the transfer of environmentally sound technologies.

- The Marrakesh Accords include agreement on the framework of the five themes for technology transfer activities. A summary on the actions being taken under these themes, including the UN bodies involved, shows how many of these can link to energy and renewables (UN, 2008).

- The seventh Conference of the Parties also established the Expert Group on Technology Transfer to analyze and identify ways to facilitate and advance technology transfer.

- The Bali Road Map agreed to at the thirteenth Conference of Parties to the UN-FCCC called for enhanced action on technology development and transfer to support action on climate mitigation and adaptation.

Additional initiatives include the Global Environment Facility (GEF) that supports developing countries. GEF is managed by the World Bank and aims to make the economics of low-impact technologies, such as renewables, more favorable. The 2006–2010 fund amounts to US_{2005}2.67 billion, of which nearly 12% is earmarked for renewable energy (REN21, 2007; 2008; 2010). However, irregular voluntary funding to GEF has created major obstacles to its effective functioning (REN21, 2007). Schneider et al. (2008) suggest that the investment that takes place through the CDM is more significant for technology transfer than the GEF.

The IEA Technology (or Implementing) Agreements encourage cooperation between member and non-member governments and organizations to meet the challenges of energy security, competitiveness, and climate change through technological solutions. They provide a legal contract with standard rules and regulations for a range of technologies that allow the pooling of resources, research, deployment, and development. Currently the renewable-related agreements include bioenergy, geothermal, hydrogen, hydropower, ocean energy systems, PV, solar heating and cooling, concentrating solar power, wind, and RET deployment. Examples of agreements that can support technology transfer include the Networks of Expertise in Energy Technology that works to foster better international cooperation, particularly with non-IEA countries, and the Climate Technology Initiative, which aims to foster international cooperation to accelerate development and diffusion of environmentally sound technologies and practices (IEA, 2009d).

Other examples of international partnerships that include agreements and principles on energy, renewables, and technology transfer, include the following:

- Asia-Pacific Partnership on Clean Development and Climate Change, which includes cooperation on technology transfer and development.

- Johannesburg Renewable Energy Coalition, which focuses on political initiatives to help promote renewable energy at national, regional, and international levels.

- Mediterranean Renewable Energy Program, which includes the objectives to provide modern energy services to rural populations and contribute to climate change mitigation by increasing the share of renewable energy technologies in the region.

- New Partnership for Africa's Development, which includes objectives to tackle poverty and place African countries on a path of sustainable growth and development.

- Small Island Developing States, which aims to support the sustainable development of these counties, including initiatives on renewable energy and climate change.

11.12.7.5 Role of Dedicated Renewable Energy Partnerships

A wide range of renewable energy partnerships also have a role within development cooperation and the wider support of renewable energy. As Suding and Lempp (2007) describe, these include federations, business associations and societies for renewables and specific technologies that include conventional organizations and structures, and numerous much more diverse partnerships and networks. They help to bring like-minded partners together to pool skills and resources to work toward common goals. Examples of these in terms of development cooperation include:

- Global Network on Energy for Sustainable Development

- Global Bioenergy Partnership

- Global Village Energy Partnership

- International Science Panel on Renewable Energies

- International Solar Energy Society

- International Renewable Energy Agency (IRENA)

- Renewable Energy and Energy Efficiency Partnership

- Renewable Energy Policy Network for the 21st Century

- World Council for Renewable Energy.

Of these, IRENA has the most ambitious goals. It was founded in 2009, and as of August 2011, a total of 148 countries and the European Union had signed the agency's statute. IRENA is to provide advice and support to governments on RE policy, capacity building, and technology transfer.

Table 11.46 | Elements in the UN-FCCC/Kyoto Protocol relevant to Renewable Energy.

Element	Current impact on RE	Potential future impact on RE
Long-term goal (UNFCCC, esp. Article 2)	Limited, as not broken down into technology-specific goals	If defined as GHG emissions or concentration, only an indirect signal. If long-term goals were established for global technology shares, then their effect on RE could be significant.
Emission reduction targets (Kyoto Protocol Annex B)	Fair impact, but countries aim to reach the short-term targets with today's low-cost mitigation options, often not RE	Future emission targets will provide an indirect long-term signal. Depends on the stringency of required reductions and the number of countries participating.
Joint Implementation (Kyoto Protocol Article 6)	Limited, as JI volume is small	Limited, as large JI volumes are unlikely.
Clean Development Mechanism (Kyoto Protocol Article 12)	Fair impact, but other reduction options are often more cost-effective	Growing fast, but the number of host countries will decrease. The level is driven by stringency of emission reduction targets of industrial countries. Additionality criterion may be an obstacle to comprehensive national frameworks for RE.
Technology transfer and financial mechanisms (Kyoto Protocol, esp. Article 11; UNFCCC, esp. Article 4	Limited, as the funds are small	Larger only if there is an automatic flow of resources into the funds.

Source: REN21, 2007.

It is to improve the flow of financing and to collaborate with existing RE institutions. Its goal is to increase the share of RE worldwide.

11.12.8 International Policy Initiatives to Stimulate Renewable Energy

11.12.8.1 UN Programs and Initiatives

International policy processes from the UN include programs, summits, and initiatives that link directly and indirectly to renewable energy. By providing an arena for countries and other stakeholders, the UN processes are important for working toward common goals or agreements that translate into national renewable policies (Suding and Lempp, 2007). UN World Summits, such as the 1992 UN Conference on Environment and Development in Rio, initiated many of the processes that continue today. The transition to different energy sources and the promotion of renewable energy were included within Agenda 21 that was approved at that conference. Governments in Rio also adopted the UN-FCCC, approved development of the GEF, and created the Commission on Sustainable Development.

The IPCC was created in 1988 to assess the science, impacts, and possible responses to climate change. To date the IPCC has produced four comprehensive assessments and a number of special and technical reports on climate change; the fifth assessment report is being prepared, and a Special Report on Renewable Energy Sources and Climate Change Mitigation was published in 2011.

The UN-FCCC was the political response to concerns raised by the IPCC. Several of the elements of the UN-FCCC are relevant to renewable energy, including the binding targets agreed under the Kyoto Protocol. (See Table 11.46.)

11.12.8.2 The Group of 8 (G8)

Renewable energy has been featured in several G8 summits:

- The 2005 Gleneagles Summit included a focus on the urgent need for action on climate change. The Gleneagles Plan of Action included a statement to continue development and commercialization of renewable energy, building on the commitments made at a renewables conference in Bonn. The meeting also pledged to work with the IEA on integrating renewables into electricity grids.
- The Russian summit in 2006 agreed to the St. Petersburg Plan of Action on Global Energy Security, which included recognition of the role of renewable energy in creating a secure energy mix.
- The Heiligendamm Summit in Germany in 2007 included a declaration on energy cooperation, in which renewable energy was specified.
- The 2008 G8 Summit in Japan included a reaffirmation of the aim to tackle climate change through the UN-FCCC process. There was a recognition of the important role that renewables have in reducing emissions and improving energy security and commitments to increase investment in R&D.

11.12.8.3 International Renewable Energy Action Plans and Declarations

In addition to the UN world summits, a set of Action Plans and Declarations have been agreed to in order to create additional momentum to advance renewable energy policies and technologies. Following an initial meeting in Bonn, these have been organized and monitored by REN21:

- Bonn 2004 – Numerous Action Plans were developed to maintain momentum developed at the 2002 World Summit on Sustainable Development in Johannesburg; several key outcomes were adopted:
  - an International Action Program that included around 200 actions and commitments from a wide range of stakeholders to develop renewable energy (follow-up on these in 2006 by REN21 suggested 79% were being implemented, resulting in significant annual carbon savings); and
  - a political declaration to create and work within a global policy network, which led to the creation of REN21.
- Beijing 2005 – The Beijing Declaration signed by 78 countries reaffirmed the commitments made under previous UN summits to "substantially increase – with a sense of urgency – the global share of renewable energy in the total energy supply." This included recognition of the need for finance and investment in renewables and a call for greater international cooperation for capacity building in developing countries.
- Washington 2008 – The Washington International Action Program collected pledges on specific and measurable renewable initiatives, including policy commitments, targets, and programs from a wide range of stakeholders. Progress on these pledges will be monitored by REN21 (WIREC, 2008).
- Delhi 2010 – The Delhi International Action Program was announced to encourage governments, international organizations, private companies, industry associations, and civil society organizations to take voluntary action to scale up renewable energy within their jurisdictions or spheres of responsibility.
